RNA-binding proteins are key players in the regulation of gene expression and have been implicated in disease susceptibility, especially in neurological disorders. Here, we present evidence that disruptive mutations of *CSDE1*, which encodes a highly constrained RNA-binding protein involved in neural differentiation, associate with autism spectrum disorders (ASD) and related neurodevelopmental disorders. We observe an excess of *CSDE1* de novo truncating mutations in ASD ( $P < 8 \times 10^{-7}$ ,  $P_{adj} < 0.01$ ) and a significant burden of putative disruptive mutations in a broader neurodevelopmental disorder cohort ( $P = 7 \times 10^{-6}$ ). Patients display consistent phenotypes, including ASD, intellectual disability, and motor and language developmental delay. Using HITS-CLIP, we show that *CSDE1* binding targets are enriched in the targets of two ASD-associated RNA-binding proteins, FMRP and RBFOX. Pathway enrichment analysis reveals that *CSDE1* targets are mainly involved in neuronal development and synaptic plasticity. *CSDE1* knockdown experiments in primary mouse cortical neurons show an increase in neurite length and a decrease in dendritic spine density, while knockout and knockdown experiments in *Drosophila* show defects in synaptic plasticity and development, including an increase in neuromuscular junction bouton number. Our study defines a subtype of autism caused by *CSDE1* putative disruptive mutations and highlights the functional role of *CSDE1* in neuronal development and synaptic plasticity.

**Investigation of novel rare variants in *ASTN2* in Japanese patients with autism spectrum disorders and schizophrenia.** K. Ishizuka, M. Toyama, B. Aleksic, N. Ozaki. Department of Psychiatry, Nagoya University Graduate School of Medicine, Nagoya, Aichi, Japan.

*ASTN2* is a protein that is expressed in the brain and may function in neuronal migration. A deletion at this locus has been associated with schizophrenia. Impairments caused by genetic variants in *ASTN2* might be important for the pathomechanisms in neuropsychiatric disorders including autism spectrum disorders (ASD) and schizophrenia. In the current study, we focused on the investigation of rare coding variants in *ASTN2*, which play major roles in disease causation and might contribute to the missing heritability from genome-wide association studies. First, we conducted exon-targeted resequencing of *ASTN2* with next-generation sequencing technology in 562 Japanese ASD and schizophrenia individuals and detected 13 heterozygous missense variants with allele frequencies of  $\leq 1\%$ . Analyzing the burden of rare coding variants detected in our patients and in Japanese controls reported by iJGVD (Integrative Japanese Genome Variation; a public database), statistically significant association between carriers with allele frequency of  $\leq 0.1\%$  and neuropsychiatric disorders were found. We performed *de novo* analysis when DNA samples from parents were available. All inheritance statuses were either from apparently unaffected parents or of unknown origin, suggesting variable penetrance. While none of the 13 variants scored more than 0.50 based on the *in silico* prediction tool REVEL (rare exome variant ensemble learner; an ensemble method for predicting the pathogenicity of missense variants), 62% of the rare variants (8/13) identified in this study were predicted to be protein-disrupting using SIFT and PolyPhen-2. Taken together, we regarded two missense variants (p.T1067I and p.G539R) as novel ones since each was not registered in either ExAC or iJGVD, the public database; however, we could not distinguish the clinical features of patients with p.T1067I or p.G539R and patients without the variants. At this stage, we could neither confirm nor dismiss the significance of rare *ASTN2* variants in either neuropsychiatric disorder. To assess the impact of the variants discovered here, further investigation by sample size expansion, case-control analysis and biological analysis will be performed. All procedures performed in this study involving human participants were approved by the Ethics Committee of the Nagoya University Graduate School of Medicine. Written informed consent was obtained from the participants and from the parents of the patients under 20 years old.

**Shared rare recurrent copy number variations between autism spectrum disorder and attention deficit hyperactivity disorder.** M.E. Khan<sup>1,2</sup>, J.T. Glessner<sup>1,2</sup>, X. Chang<sup>1,2</sup>, Y. Liu<sup>1,2</sup>, N. Williams<sup>1,2</sup>, F.G. Otiño<sup>1,2</sup>, M. Lemma<sup>1,2</sup>, J. Li<sup>1,2</sup>, C. Kao<sup>1,2</sup>, P.M.A. Sleiman<sup>1,2</sup>, H. Hakonarson<sup>1,2</sup>. 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Neurodevelopmental disorders (NDDs) such as autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD) are representative medical cases often exhibiting elusive phenotypes that require rigorous examination prior to diagnosis. Structural variants have been implicated in NDDs with complex genetic associations exemplified by recurrent copy number variations (CNVs). Diseases broadly associated with similar cell type impairments are biologically hypothesized to share similar etiologies. Investigative platforms aimed to address genetic-based inquiries, such as high-density microarray technologies, have unraveled principles of disease biology. This development has allowed for the application of groundbreaking techniques in fields aimed at NDDs and other psychiatric diseases. Previous studies investigating NDD have uncovered CNVs associated with genes within shared genomic networks. In this study, we investigated 3,082 ASD and 4,243 ADHD cases matched to 11,134 controls with the aim of identifying CNVs conferring disease susceptibility and further elucidating shared disease biology across NDDs. Rigorous quality control through visual inspection of genotype and intensity was undertaken to ensure CNV confidence prior to association studies. To assess the association of metabotropic glutamate receptor (mGluR) network functions underlying NDD pathology, we exhaustively queried patients for CNVs associated with 273 genomic regions of interest defining the mGluR gene network (Elia et al, 2011). Critical CNV boundaries were detected with PennCNV and associated to disease status using ParseCNV software. We observed DPP6 deletions and duplications in 13 cases and no controls. Additionally we saw significant enrichment of CNTN4, GRM5 and GRM8 deletions in cases versus controls. Together, these results suggest disruption of neuronal cell-adhesion and transmission pathways confers substantial risk to multiple NDDs. We identified rare recurrent CNVs enriched in both ASD and ADHD cases showcasing an overrepresentation of these events in NDD cohorts.

**Polygenic risk scores reveal subtypes of autism that differ in coding *de novo* mutational load.** B. Lohman<sup>1,4</sup>, H. Coon<sup>2,3</sup>, G. Marth<sup>1,4</sup>, A. Quinlan<sup>1,4</sup>, A. Docherty<sup>2</sup>, Autism Sequencing Consortium. 1) Department of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT; 2) Department of Psychiatry, University of Utah School of Medicine, Salt Lake City, UT; 3) Department of Biomedical Informatics, University of Utah School of Medicine, Salt Lake City, UT; 4) USTAR Center for Genetic Discovery, University of Utah School of Medicine, Salt Lake City, UT.

The rapid advance of DNA sequencing is poised to revolutionize research and treatment of human disease, both at the population and individual levels. To this end, the Simons Foundation Autism Research Initiative (SFARI) has made a major contribution by generating whole genome sequence for 2076 individuals in 4-member family units; each family containing parents and both a child diagnosed with Autism Spectrum Disorder (ASD; proband) and an unaffected sibling. These data have provided a powerful opportunity to map the genetic basis of ASD and discover genome-wide *de novo* mutations. However, very large GWAS have confirmed a complex and highly polygenic architecture for all major psychiatric disorders. Such complex traits are the product of many common loci of small effect, and few rare variants. Polygenic risk scores (PRS), aggregating the effects of thousands of loci, have been used to successfully subtype individuals into latent genetic classes, and to predict clinical symptoms and prognosis, not only for many cancers but also for psychiatric disorders, including schizophrenia and major depression. Here, using polygenic risk scores for 35 physical and psychological phenotypes (e.g. coronary artery disease, HDL/LDL, schizophrenia and major depression), we trained a decision tree model on Phase 1 of SFARI (n = 519 families) to predict case status and to classify probands into distinct subtypes. Our model identified two distinct subtypes of probands, driven by high- and low-ASD PRS. We then tested for differences in the number of *de novo* mutations between subtypes, identifying significant enrichment for coding mutations in the low-ASD PRS subtype. This result is consistent with the hypothesis that larger effect, more penetrant *de novo* variants may require less burden of polygenic risk to result in expression of the ASD phenotype. Conversely, in cases with higher polygenic risk for ASD, such variants may be more elusive. Our work demonstrates that successful genetic subtyping of individuals, while accounting for critical covariates like sex and ancestry, produces distinct groups with more homogenous genetic backgrounds, simplifying downstream analysis and revealing previously unseen patterns that would be missed by traditional GWAS. We will present our efforts to replicate both our subtyping method and enrichment of *de novo* mutations in the low ASD PRS subtype in SFARI Phases 2, 3, and 4 (n = 1,868 families).

**Cadherins matter to autism spectrum disorders: Which ones?** M.R. Passos-Bueno, C.I.S Costa, E.M. Montenegro, E.S. Moreira, S.S. Costa, N. Lourenço, C. Rosenberg, A. Krepischi, I.M.W. Silva. Centro de Pesquisa sobre o Genoma Humano, Instituto de Biociências, Universidade de Sao Paulo, São Paulo, Sao Paulo, Brazil.

Autism spectrum disorder (ASD) is a neurodevelopmental condition with a known strong genetic component. Genomic analyses have shown that *de novo* and rare loss-of function mutations are important for the etiology of ASD and oligogenic/multifactorial models are expected to explain most of the cases. It has also been shown that disruption of genes functionally important for neuronal cytoskeleton and synaptogenesis contributes to the phenotype, but one currently challenge is to identify which are the critical pathogenic genes. CNV analysis in a Brazilian cohort of 121 patients by chromosomal microarray analysis (CMA) revealed 31 potentially pathogenic CNVs. Of these, 26 contained 27 ASD candidate genes and 15 CNVs contained genes not yet implied in ASD patients. Two out of these 31 CNVs embraces genes of the cadherin family (*CDH11*, *CDH8* and *CDH13*). Screening of a Brazilian cohort composed by 1,029 patients with neurodevelopmental disorders revealed one CNV embracing *CDH13*, *TRIM16* and *PTPNR2* genes, thus reinforcing the association of *CDH13* with neurodevelopmental disruption. *CDH11* and *CDH8* have been pointed out as possible ASD candidate genes and are listed in SFARI database, but with minimum evidence (score 4; <http://sfari.org>), however, *CDH13*, which plays an important role in axonal pathfinding and synaptogenesis is not yet included in this database neither considered as a good ASD candidate gene. Our findings suggest that disruption of these cadherin genes may represent a predisposing hit in ASD and *CDH13* should be included as a novel candidate gene for this condition. FAPESP/CEPID, CNPq.

**De novo duplication on chromosome 19 observed in nuclear family displaying several neurodevelopmental disorders.** C. Sjaarda<sup>1,2</sup>, B. Kaiser<sup>1,2</sup>, A. McNaughton<sup>1,2</sup>, M. Hudson<sup>1,2</sup>, M. Ayub<sup>1</sup>, A. Guerin<sup>3</sup>, X. Liu<sup>1,2</sup>. 1) Psychiatry, Queens University, Kingston, Ontario, Canada; 2) Queen's Genomics Lab at Ongwanada (QGLO), Ongwanada Resource Center, Kingston, Ontario, Canada; 3) Pediatrics, Queen's University, Kingston, Ontario, Canada.

Pleiotropy and variable expressivity have been cited for the occurrence of seemingly distinct neurodevelopmental disorders due to a common genetic etiology within the same family. Here we present a family with a *de novo* 1 Mb duplication involving 18 genes on chromosome 19. Within the family there are multiple cases of neurodevelopmental disorders including Autism Spectrum Disorder, Attention Deficit and Hyperactivity Disorder, Intellectual Disability, and psychiatric disease in individuals carrying this Copy Number Variant (CNV). Quantitative PCR confirmed the CNV was *de novo* in the mother and inherited by both sons. Whole transcriptome analysis demonstrated ~1.5-fold increase in RNA transcript abundance in 14 of the 15 genes that are expressed in the blood of individuals carrying the CNV compared to relatives without the CNV. Examination of transcript abundance across the rest of the transcriptome identified 515 differential expressed genes (p value < 0.05) mapping to ribosome, immune response and cell adhesion pathways. These results suggest the observed CNV may result in varied phenotypic characteristics in family members through altered gene expression, and more broadly that different psychiatric disorders can share genetic variants which lay a framework for later psychiatric dysfunction.

**Characterization of loss of Y chromosome in Autism spectrum disorder.** S.P. Smieszek, Y. Song, W.S. Bush, J.L. Haines. Case Western Reserve University, Cleveland, OH.

Substantial evidence suggests that autism spectrum disorder (ASD) is caused by rare inherited or spontaneous genetic mutations, such as copy number changes and single nucleotide alterations. Nevertheless, the genetic underpinnings detected thus far account for small proportion of ASD. One striking characteristics of ASD is a strong gender bias, with males four times more likely to be on the spectrum than females. Typically, the Y chromosome has not been examined given its relative dearth of coding genes and its complex structure. In addition, the Loss of the Y chromosome (LOY) is the most frequent somatic alteration in men, and its loss and/or duplication could relevant to ASD. LOY already has been associated with shorter lifespan and multiple cancer types. We examined the structure of the Y chromosome (loss and gain) and the role it plays in ASD, focusing on the possibility that it could be a marker of genomic instability in the fathers of ASD cases. We examined full loss of the Y chromosome (LOY) and the mosaic LOY (mLOY) in 2,020 males from the ASD MSSNG whole genome sequencing dataset. We extracted DNA sequence depth information using equally spaced 10kb intervals across the Y chromosome and calculated individual log R Ratio (LRR) for every interval and median LRR for every subject. We detected significant LOY in the affected individuals when compared to controls. We additionally detect familial cases of 100% clonal duplication of the Y chromosome in several affected individuals including one father-son dyad. Furthermore we observe a correlation between *de novo* mutations in the sons and the mLOY in the fathers ( $P < 1 \times 10^{-8}$ ). Moreover we investigated if the LOY phenomena could be a marker of genomic instability in the fathers of ASD individuals. We compared the mLOY distribution of fathers with a control set of fathers and found a significantly higher incidence of mLOY in fathers of ASD (adjusting for age) ( $P < 0.003$ ). We also find greater mLOY incidence when comparing affected and unaffected brothers. We propose that mLOY in fathers is a marker of risk for ASD in their sons. This is the first such attempt to characterize the DNA sequence and structure of the whole Y chromosome, which provides a foundation for further investigation of this poorly characterized genomic region.

**Association of RXFP3 gene polymorphism with co-occurring autism and obesity.** Z. Talebizadeh<sup>1,2</sup>, A. Shah<sup>1</sup>, J. Noel-MacDonnell<sup>1</sup>. 1) Children's Mercy Hosp, Kansas City, MO; 2) University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Concern has been raised over the prevalence of obesity in children with ASD, but this potential co-occurring condition has not been fully studied in this population. The majority of patients with autism take antipsychotic medications, one of the main side effects of which is weight gain (i.e., antipsychotic-induced weight gain-AIWG). A general assumption is that the observed elevated rate of obesity in autism is caused by AIWG. The purpose of this study was to delineate the relationship between autism and obesity. We assessed the prevalence of known AIWG associated alleles in obese and non-obese autistic subjects in order to show that AIWG may not be the only reason for the observed higher rate of obesity. We curated a list of about n=150 SNPs with at least one report of association with AIWG. We assessed phenotypic and genotyping data from Simons Simplex Collection (SSC). We analyzed genotyping data for n=115 AIWG SNPs from probands from SSC. BMI data on probands was used to identify obese and non-obese subjects (> 1000 probands met the applied BMI cut off). Similarly, we evaluated unaffected SSC siblings stratified to obese and non-obese groups. Only one out of 115 AIWG SNPs (rs7702361) achieved an FDR corrected significant p-value, comparing obese versus non-obese autistic subjects. No difference was found for rs7702361, comparing obese versus non-obese unaffected siblings. Comparing obese probands stratified by Mood Stabilizers use did not detect any differences for rs7702361, suggesting that association of this SNP with obesity was independent of drug exposure. Similarly, we evaluated genotyping data for n=74 BMI SNPs. This analysis showed both shared (i.e., familial BMI/obesity risk factors) and distinct BMI associated SNPs in probands and siblings, which may indicate potential differences in the underlying mechanism of obesity in autistic and non-autistic family members. The results from our study shows, for the first time, that obesity in autism may be associated with implications in metabolic pathways including relaxin. rs7702361 is located in the RXFP3 gene, a member of the insulin/relaxin superfamily that regulates appetite and body weight. This gene is selectively activated by a neuropeptide, relaxin-3, modulating emotional-behavioral functions, including response to stress, appetite regulation, and anxiety. Further investigations are warranted on the potential role of the RXFP3 gene in association with co-occurring autism and obesity.

**Insights into the genetic architecture of autism by whole genome sequencing analyses of >3000 families.** T.N. Turner<sup>1</sup>, B.P. Coe<sup>1</sup>, K. Hoekzema<sup>1</sup>, D.E. Dickel<sup>1</sup>, B.J. Nelson<sup>1</sup>, L.A. Pennacchio<sup>2,3</sup>, T. Maniatis<sup>4</sup>, M.C. Zody<sup>4</sup>, E.E. Eichler<sup>1,5</sup>. 1) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA; 2) Functional Genomics Department, Lawrence Berkeley National Laboratory, Berkeley, CA; 3) U.S. Department of Energy Joint Genome Institute, Walnut Creek, CA; 4) New York Genome Center, New York, NY; 5) Howard Hughes Medical Institute, University of Washington, Seattle, WA.

Autism has a high heritability indicating a genetic component. Whole-exome sequencing (WES) and microarray analyses have begun to identify the pathogenic variant in 21% of cases. We have expanded our recent whole-genome sequencing analysis of 516 families to include an additional 1,271 quad (5,084 genomes) and 1,625 trio (4,875 genomes) families from the Simons Simplex Collection and MSSNG projects, respectively. We replicate differential *de novo* mutation (DNM) rates in unique ( $1.3 \times 10^{-8}$ ) versus ancient repeat ( $1.5 \times 10^{-8}$ ) portions of the genome (chi-squared test  $p = 3.7 \times 10^{-189}$ ) irrespective of disease status. We identify a likely gene-disrupting (LGD) DNM false negative rate of ~3.9% in comparison to older exome data, often in the first exon ( $p = 5.0 \times 10^{-10}$ , OR = 6.1), including genes known to be associated with autism (SCN7A, CACNA1A, SYNGAP1, SHANK2, BIRC6, ANKRD11, GIGYF1, ZWILCH, and ADCY5). Combining these data with published WES (<http://denovo-db.gs.washington.edu>) assessed for 12,248 neurodevelopmental disorder trios, we identified eight additional genes enriched for DNM. Restricting our analysis to families that do not have any known LGD or large copy number variants (CNV), we focused on three functional categories of DNM: missense, untranslated region (UTR) and putative, noncoding regulatory regions that are also sites for transcription factor binding in fetal brain (pNCR TFBS). We observe DNM enrichment for severe missense ( $p = 1.6 \times 10^{-3}$ , OR = 1.7) and in genic untranslated regions (UTRs) ( $p = 0.02$ , OR = 1.5). We also observe significant enrichment for *de novo* events in putative regulatory regions of the fetal brain (pNCR TFBS;  $p = 1.5 \times 10^{-3}$ , OR = 1.2). If we restrict this analysis to genes previously implicated in autism (SFARI n = 845 genes), these three functional categories show a combined significance ( $p = 2.9 \times 10^{-3}$ , OR = 1.7). We also observe an excess of patients with multiple DNMs in different genes ( $p = 0.03$ , OR = 1.3) providing further support for a multifactorial model of disease. We are currently integrating these data with a high-resolution CNV map for each genome and working on a second cohort of 8,808 genomes from an additional 2,936 families in order to test for replication of these findings.

Neurodevelopmental disorders (NDDs) are genetically and phenotypically heterogeneous. Ultra-rare and *de novo* gene-disruptive mutations have been shown to play an important role in disease etiology but most of the underlying genes have not yet been discovered. Based on a meta-analysis of *de novo* mutations from 10,927 published exomes of children with developmental delay (DD) and autism spectrum disorder (ASD) in denovo-db (<http://denovo-db.gs.washington.edu/denovo-db/>), we selected 65 candidate genes for targeted sequencing. These candidate genes include 43 with excess *de novo* mutations ( $p < 2.5 \times 10^{-6}$ ), 14 genes with autism sex bias, 6 genes from a network analysis of high-functioning autism, and 2 candidate genes mapping to copy number variant genomic disorders. We designed 2,400 molecular inversion probes and targeted the protein-coding portion of these genes for sequencing in a cohort of 18,836 NDD cases (9,710 with ASD and 9,126 with DD), obtained from 17 centers across the world. After QC, we validated a total of 173 likely gene-disruptive mutations and identified 218 severe missense mutations (CADD score  $> 30$ ) that were not present in a non-psychiatric set of control exomes from ExAC ( $n = 45,376$ ). Controlling for sequence coverage differences, several genes (*CTCF*, *TCF12*, *SPEN*, *ZBTB18*, *HNRNPU*, *KAT6A*, *KIAA2022*, *CHAMP1*, *SATB2*, *AHDC1*, *KCNQ3* and *BRAF*) show evidence of increased mutational burden in cases compared to controls. We are now evaluating transmission of these mutations within the context of families and assessing phenotypic features to determine their association with high-functioning autism, genomic disorders, and gender biases with DD and ASD.

## 2427W

**Exploring polygenic risk scores for depression in a transgender population.** A. Pandit, G.R. Abecasis. University of Michigan, Ann Arbor, MI.

Transgender (trans) individuals are part of a highly stigmatized community for whom prejudice is commonplace. The 2011 National Transgender Discrimination Survey revealed that an estimated 70% of trans individuals have attempted to hide their identity to avoid discrimination in personal and professional settings. To help facilitate medical care for these individuals, the DSM added "gender dysphoria," a controversial term that references the discomfort and stress caused when one's birth gender and perceived gender are incongruent. Studies have found significantly higher rates of depression and anxiety in trans individuals, which is thought to stem from the overwhelming amounts of stigma and prejudice these people experience throughout their lives, oftentimes starting from a very young age. In the same national survey, 41% of transgender respondents answered that they had attempted suicide, compared to 1.6% of U.S. Americans. Known risk factors for depression in the trans community include discrimination, obstacles surrounding hormone therapy and sex-reassignment surgeries, socioeconomic factors, and access to health and social services. However, to date no research has explored genetic risk factors for depression in this population; we sought to examine these patterns using data collected from the Genes for Good study. Using demographics survey responses, we identified 103 presumptive trans subjects and 8,391 cisgender subjects. We then matched trans and cisgender subjects based on age, birth sex, education and income, matching 3 - 6 cisgender controls to each trans participant, resulting in 577 controls. As expected, trans subjects had increased odds of depression compared to cisgender controls: odds of answering "yes" to ever being depressed were significantly higher (95.5% of trans individuals, OR=4.51,  $p=0.005$ ). However, when we calculated polygenic risk scores (PRS) of depression using GWAS results from the Psychiatric GWAS Consortium, we found no significant association between depression PRS and trans status. Our results support the idea that depression in the transgender community is influenced by societal factors and that it is a consequence, rather than a cause, of gender dysphoria and transgender identity. Further, our data illustrates how collecting information on both gender and birth sex separately allowed us to explore the interplay of health and genetics in a marginalized community.

**The interaction between genetic variability and oral microbiome in alcohol use disorder and nicotine dependence.** R. Polimanti<sup>1,2</sup>, J.L. Montalvo-Ortiz<sup>1,2</sup>, Y.Z. Nunez<sup>1,2</sup>, S. Southwick<sup>1,2,3</sup>, J.H. Krystal<sup>1,2,3</sup>, H.R. Kranzler<sup>4</sup>, R.H. Pietrzak<sup>1,2,3</sup>, J. Gelernter<sup>1,2</sup>. 1) Department of Psychiatry, Yale University School of Medicine, West Haven, CT; 2) Veterans Affairs Connecticut Healthcare Center, West Haven, CT; 3) Clinical Neurosciences Division, U.S. Department of Veterans Affairs National Center for PTSD, West Haven, CT; 4) Department of Psychiatry, University of Pennsylvania School of Medicine and VISN 4 MIRECC, Crescenzo VAMC, Philadelphia, PA.

Alcohol drinking and tobacco smoking have substantive effects on the microbiome. To understand whether microbiome variability may be associated not only with drinking and smoking states (i.e., present behaviors) but also with alcohol and tobacco traits (i.e., characteristic behaviors), we investigated the oral microbiome in individuals with alcohol use disorder (AUD) and nicotine dependence (ND) in 739 individuals from the Yale-Penn and NHRV (National Health and Resilience in Veterans) cohorts. Microbiome screening was performed via targeted sequencing of the microbial 16S rRNA gene in DNA samples extracted from saliva. Taxonomic annotation was completed using the SILVA database as reference. We conducted the association analysis using species-level information and applied two analytic approaches. We performed a single-species association analysis of relative quantity considering 14 species that were identified in >90% of the sample. We observed a negative association between AUD and the relative quantity of *Streptococcus sp. 11aTha1* (Beta = -0.26, P = 0.006). The second analytic approach consisted of investigating the overall profile of the microbiome species identified (N = 1,128) using principal component analysis. In this analysis, we considered the top 13 microbiome-based principal components. The association analysis showed a significant positive association between ND and the microbiome-based PC11 (Beta = 0.56, P = 4.08×10<sup>-4</sup>). To investigate further how AUD and ND interact with the inter-individual variability of the oral microbiome, we conducted a gene-by-environment genome-wide interaction study. We observed a genome-wide significant interaction between rs79424066 and ND with respect to microbiome-based PC11 (P = 2.25×10<sup>-6</sup>). Rs79424066 is associated with *NRXN1* expression in brain and non-brain tissues. *NRXN1* gene encodes cell-surface receptors that bind neuroligins to form a calcium-dependent neuroligin/neurexin complex at synapses in the central nervous system. This trans-synaptic complex is required for efficient neurotransmission and is involved in the formation of synaptic contacts. In summary, we report the first evidence of an association of AUD and ND with oral microbiome. Additionally, our genome-wide investigation indicated that ND may interact with variation in brain-relevant genes with respect to the oral microbiome.

**Intersection of impulsive personality traits and drug experimentation: A genome-wide association approach.** S. Sanchez-Roige<sup>1</sup>, P. Fontanillas<sup>2</sup>, S. Elson<sup>2</sup>, The. 23andMe Research Team<sup>2</sup>, J. Gray<sup>3,4,5</sup>, H. deWit<sup>6</sup>, J. MacKillop<sup>7</sup>, A. Palmer<sup>1,8</sup>. 1) University of California San Diego, San Diego, CA; 2) 23andMe, Inc., Mountain View, CA, 94041, USA; 3) Department of Psychology, University of Georgia, USA; 4) Center for Alcohol and Addiction Studies, Brown University School of Public Health, Providence, RI 02903, USA; 5) Center for Deployment Psychology, Uniformed Services University, Bethesda, MD 20814, USA; 6) Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL 60637, USA; 7) Peter Boris Centre for Addictions Research, McMaster University/St. Joseph's Healthcare Hamilton, Hamilton, ON L8N 3K7, Canada; Homewood Research Institute, Guelph, ON N1E 6K9, Canada; 8) Institute for Genomic Medicine, University of California San Diego, La Jolla, CA, USA.

Impulsive personality traits are complex heritable traits associated with numerous neuropsychiatric disorders, particularly substance use disorders. In collaboration with the personal genetics company 23andMe, Inc., we performed several genome-wide association studies (GWAS) on measures of impulsive personality traits (Barratt Impulsiveness Scales, **BIS**; and Impulsive Behavior Scales, **UPPSP**) and drug experimentation (number of different classes of drugs an individual has used) among ~23,000 research participants of European ancestry. The impulsivity and drug experimentation traits showed SNP-heritabilities that ranged from 5 to 11%. Genetic variants of the gene *CADM2* were significantly associated with the UPPSP sensation seeking subscale (P = 8.3 × 10<sup>-9</sup>, rs139528938) and showed a suggestive association with drug experimentation (P = 3.0 × 10<sup>-7</sup>, rs2163971; r<sup>2</sup> = 0.68 with rs139528938). Both are highly correlated (r<sup>2</sup> = 0.69 and 0.57, respectively) with an intronic (rs57401290) SNP in *CADM2* that showed a genome-wide significant association with self-reported risk-taking propensity (rs57401290: p = 5.3 × 10<sup>-9</sup>), and nominal associations with the number of sexual partners (rs57401290: p = 6.0 × 10<sup>-7</sup>) and the number of children (rs57401290: p = 6.2 × 10<sup>-7</sup>) in the UKBiobank cohort. Multiple subscales from both BIS and UPPSP showed strong genetic correlations (>0.5) with substance use traits, including drug experimentation, smoking initiation, and lifetime cannabis use. Several BIS and UPPSP subscales were genetically correlated with attention-deficit/hyperactivity disorder (ADHD), supporting their use as endophenotypes for ADHD. The UPPSP sensation seeking subscale was genetically correlated with the personality trait extraversion. Several impulsivity traits from BIS and UPPSP were moderately correlated but not collinear, suggesting both common etiology and unique genetic variance among the impulsivity traits. Our findings demonstrate a role for common genetic contributions to individual differences in impulsivity. Furthermore, this study is the first to provide a genetic dissection of the relationship between types of impulsivity and various psychiatric disorders.

**Genome-wide association study of posttraumatic stress disorder in female rape victims.** C.M.F. Carvalho<sup>1,2,3</sup>, M.L. Santoro<sup>1,2,3</sup>, F. Talarico<sup>2,3</sup>, B.M. Coimbra<sup>1</sup>, G. Xavier<sup>2,3</sup>, S. Nasser<sup>4</sup>, E.A. Zanardo<sup>4</sup>, L.D. Kulikowski<sup>4</sup>, A.F. Mello<sup>1</sup>, V.K. Ota<sup>2,3</sup>, M.F. Mello<sup>1</sup>, S.I.N. Belangero<sup>1,2,3</sup>. 1) Department of Psychiatry, Universidade Federal de São Paulo, São Paulo, Brazil; 2) Genetics Division of Department of Morphology and Genetics of Universidade Federal de São Paulo (UNIFESP), Brazil; 3) LiNC - Interdisciplinary Laboratory of Clinical Neurosciences of Universidade Federal de São Paulo (UNIFESP), Brazil; 4) Hospital das Clínicas, Faculty of Medicine, Universidade de São Paulo (FMUSP), Citogenomic Laboratory, Brazil.

Posttraumatic stress disorder (PTSD) is a clinical condition that can develop in people who have experienced a traumatic situation, such as sexual assault. Current results of PTSD GWAS (genome wide association study) have suggested that genetic variants may be associated with predisposition to PTSD. However, few studies have been able to identify a consistent genetic marker for PTSD. Therefore, we examined the cross-sectional association of PTSD diagnosis in female rape victim, using the GWA approach. This is the first study assessing GWAS with just rape victim women. The study population consisted of 51 rape victim women with PTSD diagnosis and 45 female healthy controls from Brazil. Assessments included MINI International Neuropsychiatric Interview compatible with Diagnostic and Statistical Manual of Mental Disorder, Clinician-Administered PTSD Scale that evaluate the symptoms of PTSD and Life Events Checklist that appraise the trauma exposure. DNA was extracted from blood and all individuals were genotyped using the Infinium Global Screening Array BeadChip (Illumina) that assesses around 600,000 markers. For association analysis we used logistic regression models adjusted to five principal-component and Bonferroni correction. After quality control of samples, two participants of the study were excluded due to identity-by-descent ( $\text{pihat}=0.145$ ) and none individual was excluded due to missing genotype ( $<0.1$ ). Furthermore 316,320 variants were removed due to missing genotype ( $<0.1$ ), Hardy-Weinberg ( $p>0.00001$ ), minor allele threshold ( $<0.05$ ) Thus, remained for the analysis 50 cases (PTSD group) and 44 controls (no-PTSD group). No single nucleotide variants (SNVs) were associated with PTSD diagnosis, after Bonferroni correction ( $n=324,912$ ) and genomic inflation lambda (based on median chi-square) was of 1.057. We did not find association between SNVs and PTSD. Previous studies found associations between SNV and PTSD but predominantly in military, however, few studies investigated genetic variants in women with PTSD even more victims of sexual abuse. Furthermore, it is difficult to detect genetic variants associated to mental disorders in small samples because of the limited power to detect discrete differences. We found negative results when assessing effects of SNV on the risk to develop PTSD probably due to our limited size sample. Therefore, our next goal is to increase the sample size and consequently the statistical power necessary for genome-wide approaches.

Growing evidence suggests that the glutamatergic modulator ketamine has rapid antidepressant effects in treatment-resistant depressed subjects. The anticholinergic agent scopolamine has also shown promise as a rapid-acting antidepressant. This study applied genome-wide markers to investigate the role of genetic variants in predicting acute antidepressant response to both agents. The ketamine-treated sample included 157 unrelated European subjects with major depressive disorder (MDD) or bipolar disorder (BD). The scopolamine-treated sample comprised 37 unrelated European subjects diagnosed with either MDD or BD who had a current Major Depressive Episode (MDE), and had failed at least two adequate treatment trials for depression. Change in Montgomery-Asberg Depression Rating Scale (MADRS) or the 17-item Hamilton Depression Rating Scale (HAM-D) scale scores at Day 1 (24 hours post-treatment) was considered the primary outcome. Here, we conduct pilot genome-wide association study (GWAS) analyses to identify potential markers of ketamine response and dissociative side effects. Polygenic risk score analysis of SNPs ranked by the strength of their association with ketamine response was then calculated in order to assess whether common genetic markers from the ketamine study could predict response to scopolamine. Findings revealed that genetic variants associated with ketamine response accounted for approximately 6% of the variance in scopolamine response, suggesting modest potential genetic overlap in predictors of response to these agents. These suggestive findings require replication in larger samples in light of low power of analyses of these small samples. Nevertheless, these data provide a promising illustration of our future potential to identify genetic variants underlying rapid treatment response in mood disorders and may ultimately guide individual patient treatment selection in the future.

**Towards an understanding of the genetic architecture of the human cortex: Examining the effects of common variants on cortical thickness and surface area.** S.E. Medland, *The Enhancing Neuro Imaging Genetics through Meta-Analysis (ENIGMA) Consortium*. Psychiatric Genetics, QIMR Berghofer, Herston, Brisbane, Queensland, Australia.

The cerebral cortex underlies our complex cognitive capabilities. Its structure shows variation in surface area and thickness within the population, which can be captured *in vivo* by magnetic resonance imaging. To improve understanding of neurobiological mechanisms underlying adaptive and pathological functioning, we undertook genome-wide association meta-analyses using MRI data from 51,246 individuals from 58 cohorts. To study the genetic architecture of the human cortex we analysed 70 MRI-derived cortical measures: surface area and thickness across the entire brain, and in 34 functionally specific regions averaged across the hemispheres. Across cohorts, structural T1-weighted MRI brain scans were analysed locally using harmonized analysis and quality-control protocols. Cortical parcellations were performed with freely available and validated segmentation software. Corrections for the summary measures were included in the regional measures to account for the omnibus effects of brain size. We identified 250 loci that met nominal genome-wide significance ( $P < 5 \times 10^{-8}$ ; 218 influencing surface area and 32 influencing thickness) within 107 surviving multiple testing correction ( $P < 8.3 \times 10^{-10}$ ). Across loci the strongest evidence of association was seen between variants within 15q14 and the surface area of the pre-central gyri (rs1080066,  $P = 5.3 \times 10^{-122}$ ; variance explained = 0.87%). To localize this finding we examined the association of this loci with sulci depth in the functionally defined sensory-motor regions, finding that the association was strongest with a region of the central sulcus which shows highly variable patterns in MRI data from non-human primate species (analysed using the same protocols). We found significant enrichment for loci influencing total surface area within the germinal zone, present during foetal development. Loci impacting regional surface area clustered near genes involved in Wnt signalling, a pathway influencing progenitor expansion and areal identity. We observed significant positive genetic correlations between global Surface Area and IQ, educational attainment, and Parkinson's disease. Negative genetic correlations were evident between global SA and insomnia, ADHD, depressive symptoms, Major Depressive Disorder and Neuroticism. No significant genetic correlations were observed between global TH and any of the cognitive or neuropsychiatric traits assessed.

**Integration of gene expression and chromatin accessibility data to improve understanding of the genetic architecture of bipolar disorder.**

T. Schwarz<sup>1</sup>, N. Mancuso<sup>2</sup>, R. Ophoff<sup>3,4</sup>, B. Pasaniuc<sup>2,3,5</sup>. 1) Bioinformatics Interdepartmental Program, University of California Los Angeles, Los Angeles, CA USA; 2) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA USA; 3) Department of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA USA; 4) Center for Neurobehavioral Genetics, University of California Los Angeles, Los Angeles, CA, USA; 5) Department of Biomathematics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA USA.

Describing the genetic architecture that contributes to highly polygenic disease traits in the brain such as Bipolar Disorder (BD) presents a major challenge. Because of the complexity of such traits, we have yet to develop a strong understanding of the causal mechanisms behind them. In this work we estimate the genetic basis of gene expression in of 200 cell lines (100 cases, 100 control for BD) and contrast them with risk of BD. We overlap eQTLs with GWAS for BD as well as ATAC sequencing analysis, among other techniques to study the genetic landscape. The combination of data from gene expression along with chromatin accessibility allows us to effectively outline the dynamic interaction between chromatin and transcripts, and gain new insight into the characterization of the disease-specific genetic risk of BD. Additional statistical analysis has helped us identify signature genes with promise to have significant implications in BD. Furthermore, our results provide evidence of potentially crucial pathways in the context of BD.

**GWASs of alcohol consumption and alcohol use disorder in a multi-ancestry U.S. veteran population (N=274,424) yield both overlapping and differing risk loci.** H. Zhou<sup>1,2,11</sup>, H.R. Kranzler<sup>3,4,10</sup>, R.L. Kember<sup>3,4</sup>, R.V. Smith<sup>4,5</sup>, A.C. Justice<sup>1,2,6</sup>, S. Damrauer<sup>3,4</sup>, D.M. Klarin<sup>7,8,9</sup>, R. Polimanti<sup>1,2</sup>, Z. Cheng<sup>1,2</sup>, J. Reid<sup>10</sup>, J. Overton<sup>10</sup>, J.P. Tate<sup>2</sup>, W.C. Becker<sup>1,2</sup>, J. Concato<sup>1,2</sup>, K. Xu<sup>1,2</sup>, H. Zhao<sup>1,6</sup>, J. Gelernter<sup>1,2</sup>, VA Million Veteran Program. 1) Yale School of Medicine, New Haven, CT; 2) Veterans Affairs Connecticut Healthcare System, West Haven, CT; 3) University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 4) Crescenz Veterans Affairs Medical Center, Philadelphia, PA; 5) University of Louisville School of Nursing, Louisville, KY; 6) Yale School of Public Health, New Haven, CT; 7) Boston VA Healthcare System, Boston, MA; 8) Massachusetts General Hospital, Boston, MA; 9) Broad Institute of MIT and Harvard, Boston, MA; 10) Regeneron Pharmaceuticals, Tarrytown, NY; 11) These authors contributed equally.

Although both alcohol consumption and alcohol use disorder (AUD) are heritable, little is known about their polygenic architecture or genetic overlap. We conducted genome-wide association studies (GWASs) of electronic health record (EHR) AUDIT-C scores (measuring consumption) and ICD-9/10 AUD diagnoses in a multi-ancestry Million Veteran Program (MVP) sample of 274,424 individuals. Meta-analysis across the 5 population groups identified 13 independent loci (9 novel) for AUDIT-C and 8 independent loci (5 novel) for AUD. Although 5 loci contributed to both traits (*ADH1B*, *ADH1C*, *SLC39A8*, *GCKR* and *FTO*), there were 8 distinct associations for AUDIT-C (e.g., *IGF2BP1*: insulin like growth factor 2 mRNA binding protein 1) and 3 for AUD (e.g., *DRD2*: D2 dopamine receptor), indicating both genetic overlap and differences between the traits. Partitioning heritability using LD score regression (LDSC) showed significant enrichment in central nervous system and in epigenetic features in brain tissues for both traits, while enrichments for AUDIT-C were also detected in cardiovascular and other cell types. The genetic correlation ( $r_g$ ) between the traits was 0.522 (se=0.0383) in EAs and 0.9304 (se=0.1215) in AAs. Genetic correlations with some other traits were in opposite directions for the two alcohol traits: AUDIT-C was negatively correlated with anthropometric (e.g., BMI,  $r_g=-0.35$ ,  $p=3.25 \times 10^{-19}$ ), cardiometabolic and glycemic traits and major depressive disorder (MDD,  $r_g=-0.22$ ,  $p=7.72 \times 10^{-9}$ ), and positively correlated with reproductive traits and educational attainment ( $r_g=0.25$ ,  $p=1.40 \times 10^{-16}$ ); AUD was negatively correlated with cognitive traits and educational attainment ( $r_g=-0.27$ ,  $p=2.88 \times 10^{-16}$ ), and positively correlated with psychiatric disorders (e.g., MDD,  $r_g=0.41$ ,  $p=2.19 \times 10^{-20}$ ). Phenome-wide association studies of phenotypes using MVP EHR data for the top variants showed many to be highly pleiotropic. The polygenic risk scores (PRSs) for AUDIT-C and AUD were significantly associated with alcoholism (103 cases and 6,132 controls) and alcohol-related disorders (137 cases and 6,132 controls) in an independent sample (Penn Medicine BioBank). Based on a comparison of two alcohol-related phenotypes in a large, relatively homogeneously ascertained cohort, including groups representing 5 different ancestries, we conclude that heavy drinking, while a necessary precondition for developing AUD, is not sufficient to develop the disorder.

Missense *de novo* mutations (DNMs) account for more cases of neurodevelopmental disorders (NDDs) than likely gene-disruptive (LGD) mutations but have been less studied because of their high incidental rate. Missense-specific genes likely account for much of the missing heritability of NDDs and some may be genes with such critical functions that LGD mutations are incompatible with life. Missense mutations also contribute to pathogenicity via gain-of-function effects and are more likely to occur at functionally important locations. To gain statistical power in gene identification, we studied 9,712 missense DNMs in 11,459 individuals with autism spectrum disorder, developmental delay, intellectual disability, or epilepsy, as these NDDs share genotypic and phenotypic components. We identified 220 genes with missense DNMs that are more clustered ( $p < 0.05$ ) in NDD cases than population controls. This set of genes is enriched for roles in the neuronal action potential ( $p = 2.92 \times 10^{-2}$ , FDR corrected). We developed molecular inversion probes targeting clustered regions of these genes and 24 genes with recurrent mutations for sequencing in 18,836 additional NDD cases. We have identified 415 missense events in clustered regions in 8,960 cases, including 17 events at 13 targeted recurrent sites and 60 events at amino acids that bear mutations in other NDD cases. Of the newly identified events, 23 fall in seven voltage-gated ion channels; three of these are in functionally important transmembrane domains. Out of 176 missense DNMs previously seen in 51 of these channels in NDD cases, 85 (48%) occur in these domains or the channel pore, and there is a significant enrichment for mutations in the S4 segment ( $p = 1.85 \times 10^{-13}$ ). Notably, 24/29 (83%) S4 events occur at arginine or lysine residues that provide the molecular mechanism for voltage sensing and channel gating. None of these missense DNMs have been seen in population controls in ExAC (N = 45,376). Eight of the observed substitutions are known to be pathogenic, and while the remaining 16 are novel, homology suggests that they are similarly damaging. The specific effect of these mutations makes them potential targets for therapeutic intervention, and these findings demonstrate the importance of identifying new classes of NDD risk genes by investigating the pattern of missense DNMs.

**Molecular effects of the neuropsychiatric 15q13.3 microdeletion in an induced pluripotent stem cell model of neuronal development.** S. Zhang<sup>1,2</sup>, C. Purmann<sup>1,2</sup>, X. Zhang<sup>1,2</sup>, S. Ma<sup>3</sup>, K. Davis<sup>1,2</sup>, J. Bernstein<sup>4</sup>, W.H. Wong<sup>3</sup>, J. Hallmayer<sup>4</sup>, A.E. Urban<sup>1,2</sup>. 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA; 3) Department of Statistics, Stanford University, Stanford, CA; 4) Department of Pediatrics, Stanford University, Stanford, CA.

The 1.5 Mb microdeletion on chromosome 15q13.3 is strongly associated with several neurodevelopmental and neuropsychiatric disorders, including developmental disability, seizures, schizophrenia and autism spectrum disorder. There are at least eight genes affected by the microdeletion, and quite possibly in a manner specific to tissue and developmental time point. Novel approaches are needed to analyze the deletion's effects on the molecular and cellular level. We created a cohort of induced pluripotent stem cells (iPSCs), from fibroblasts from three patients with the 15q13.3 deletion, and from matching controls. The iPSCs' genomes have been characterized with digital droplet PCR and whole-genome sequencing, and the iPSCs were characterized by staining for the canonical pluripotency markers. Furthermore, we induced the iPSCs into an early neuronal cell type (induced Neurons, iNs). The iNs stained positive for neuronal identity markers and also show neuronal gene expression patterns. RNA-Seq, ATAC-Seq, and genome-wide capture bisulfite sequencing was carried out for the iPSC and iN stages. We saw mostly decreased gene expression levels, for the genes within the deletion boundaries, while the patterns of DNA methylation and chromatin accessibility within the deletion remain mostly unchanged. Outside the CNV locus, transcriptome wide, there are differentially expressed genes (DEGs) on all chromosomes in the 15q13.3 cells. Specifically, there are 178 DEGs in the iPSCs and 369 DEGs in the iNs. Analyses of these DEGs using Ingenuity Pathway Analysis showed alterations in neurodevelopmental pathways, most notably the Wnt pathway. DNA methylation analysis revealed differentially methylated regions (DMRs) spread out genome-wide and also implicated neurodevelopmental genes and gene families, in particular the protocadherins. Analysis of chromatin state showed regions of differential chromatin openness genome-wide as well. In summary, we have created a cohort of iPSCs and iPSC-derived induced neurons from patients with the neuropsychiatric 15q13.3 microdeletion. We can detect gene expression changes for both the genes within the CNV locus as well as transcriptome-wide. Epigenomic marks are generally unchanged within the CNV locus, which correlates with the gene dosage dependent changes in gene expression there, while genome-wide there are marked effects on the levels of epigenomic regulation in the 15q13.3 patient lines.

**Genomics of sleep disordered breathing associated with cognitive behavioral development in the Canadian Healthy Infant Longitudinal Development (CHILD) study.** A. Ambalavanan<sup>1</sup>, J. Choi<sup>1</sup>, A. Lamri<sup>2</sup>, S.K. Tamana<sup>3</sup>, D. Lefebvre<sup>2</sup>, M. Sears<sup>3</sup>, M. Azad<sup>4</sup>, A. Becker<sup>5</sup>, S. Turvey<sup>6</sup>, T. Moraes<sup>6,7</sup>, P. Subbarao<sup>6,7</sup>, P. Mandhane<sup>3</sup>, Q.L. Duan<sup>1,8</sup>. 1) Department of Biomedical and Molecular Sciences, Queens University, Kingston, ON, Canada; 2) Dept of Clinical Epidemiology & Biostatistics, McMaster University, Hamilton, ON, Canada; 3) Department of Pediatrics, University of Alberta, Edmonton, AB, Canada; 4) Department of Pediatrics & Child Health and Community Health Sciences, University of Manitoba, Winnipeg, MB, Canada; 5) Director, Clinical Research, BC Children's Hospital, Vancouver, BC, Canada; 6) Department of Paediatrics, University of Toronto, Toronto, ON, Canada; 7) The Hospital for Sick Children, Toronto, ON, Canada; 8) School of Computing, Queen's University, Kingston, ON, Canada.

Sleep disordered breathing (SDB), a collective term for chronic conditions including habitual snoring and obstructive sleep apnea, affects up to 10% of children between 2 and 8 years old. Studies have shown that SDB in children is associated with neurobehavioral functions related to executive functioning and attention deficit hyperactivity disorder (ADHD). We hypothesize that pre-school SDB may interact with genetic polymorphisms to determine predisposition to cognitive function outcomes during early childhood. In the Canadian Healthy Infant Longitudinal Development (CHILD) study, we selected a total of 513 Caucasian subjects (between 3 months and 5 years) with available parent reported Sleep Related Breathing Disorder (SRBD) subscale preschool SDB in addition to cognitive behavioural externalizing & internalizing checklist (CBCL) scores. In this study, we conducted a genetic analysis using genomics data (Illumina HumanCore Exome BeadChip) of CHILD subjects, which targeted top-ranked 40 autosomal genes previously correlated with Autism Spectrum Disorder (ASD) risk (Krishnan et al 2016, Nat Neurosci). Using a linear regression analysis model, we tested 46,615 SNPs for correlation with CBCL scores of children at age 5 years by including SDB as a covariate in the additive model. Single variant analysis (minor allele frequency over 5%) of CBCL scores resulted in two significant associations with additive effects with SDB: rs62009932 in *RBFOX1* ( $\beta=2.8$ ,  $p=2.47 \times 10^{-5}$ ) and rs2786239 in *GRIK2* ( $\beta=4.06$ ,  $p=2.6 \times 10^{-5}$ ), which are intronic SNPs correlated with externalizing and internalizing CBCL scores, respectively. On-going analysis include a multivariate test of the ASD genes with multiple cognitive behavioural traits to investigate pleiotropic effects. Furthermore, we will further explore gene-environmental interactions using assessments such as parental SDB, sleep duration, apnea-hypopnea index, sleep habits, and physical activity as exposures. Our study has identified that genes correlated with ASD may also contribute to cognitive behavioural outcomes in children during early childhood and that SDB could modulate the genetic predisposition to cognitive behavioural development in children.

Lyall<sup>2</sup>, R. Pearsall<sup>2</sup>, J.P. Pell<sup>2</sup>, D.J. Smith<sup>2</sup>. 1) School of Life Sciences, CMVLS, University of Glasgow, Glasgow, United Kingdom; 2) Institute of Health and Wellbeing, College of Medical, Veterinary and Life Sciences, University of Glasgow, Glasgow, UK; 3) Department of Medicine Solna, Karolinska Institute, Stockholm, Sweden.

Suicidal acts and ideation are a global public health priority, with up to 1 million individuals worldwide dying by suicide each year. Almost all individuals who attempt suicide also have major depressive disorder (MDD), but not all individuals with MDD experience suicidal ideation. Heritability estimates for suicidal behaviour are mostly in the range 30-55%. We investigated the genetic contribution to suicidality by carrying out the largest genome-wide association study (GWAS) to date in 122,822 White British individuals from the UK Biobank (UKB) population cohort ( $n = 39,265$  indivs. with suicidal/self-harming ideation/behaviour). An ordinal phenotype variable was created comprising 5 increasing levels of suicidal and self-harming ideation and behaviour - 0: no self-harm ideation or action; 1: thoughts that life is not worth living; 2: contemplation of self-harm or suicide; 3: actual self-harm; 4: attempted suicide. A model was run using the *clm* function in the 'ordinal' package in R, assuming additive allelic effects at each SNP and adjusting for 8 genetic PCs, age, sex and genotyping chip. LDSR analysis of the resulting summary statistics suggested a significant polygenic contribution and SNP heritability was estimated as 7.6%. Two loci, including a total of 36 SNPs, were associated with the outcome phenotype at genome-wide significance. One locus, on chr.11 (lead SNP: rs598046;  $p = 1.1 \times 10^{-8}$ ), was located within *CNTN5*, a brain-expressed gene encoding an immunoglobulin family protein involved in neuronal cell interactions. Suggestive evidence has been reported for association between *CNTN5* SNPs and both loneliness and response to lithium treatment in bipolar disorder. The other locus, on chr.9 (lead SNP: rs62535711;  $p = 1.3 \times 10^{-6}$ ), was located within the *ZCCHC7* gene. Significant genetic correlations were found with MDD ( $r_g=0.63$ ), neuroticism ( $r_g=0.63$ ), mood instability ( $r_g=0.50$ ) and trait anxiety ( $r_g=0.75$ ). These findings support a biological basis for the known correlation between suicidal behaviour/ideation and neuroticism/MDD, but cannot distinguish shared pleiotropic variants from mediated effects of neuroticism/depression-related variants, nor genes for suicidality *per se* from genes predisposing to other forms of self-harm with effects captured by the UKB questionnaire. Further understanding of the biology of suicidality will inform the development of more effective preventative approaches aimed at reducing these potentially devastating outcomes.

**Significant overlap of genomic regions from extended high-risk autism families with evolutionarily accelerated regions in a species with highly unusual social behavior.** H. Coon<sup>1</sup>, E. Ferris<sup>2</sup>, T.M. Darlington<sup>1</sup>, J. Morgan<sup>1</sup>, R. Sargent<sup>3</sup>, A. Fraser<sup>4</sup>, K.R. Smith<sup>4</sup>, N.J. Camp<sup>3</sup>, C. Gregg<sup>2</sup>. 1) Psychiatry, University of Utah School of Medicine, Salt Lake City, UT; 2) Neurobiology and Anatomy, University of Utah School of Medicine, Salt Lake City, UT; 3) Department of Internal Medicine, University of Utah School of Medicine, Salt Lake City, UT; 4) Population Sciences, Huntsman Cancer Center, Salt Lake City, UT.

**Introduction.** Genetic discoveries for Autism Spectrum Disorder (ASD) have been numerous in the past decade, with evidence for over 100 common and rare variants. However, these discoveries account for only a portion of the genetic risk of ASD. Much of this remaining risk may reside in notoriously elusive variants controlling gene regulation. To address this substantial knowledge gap, we compared genomic results obtained from extended families at high risk for ASD with genomic regions exhibiting accelerated evolution in mammalian species with specific evolved characteristics, including a species with highly unusual social behaviors. **Methods.** Using a novel statistical analysis strategy (Shared Genomic Segments), we discovered 10 genomic regions with significant evidence of familial sharing in large, high-risk ASD families. ASD was diagnosed using gold standard clinical interviews and observation. Genotypes from the Illumina OmniExpress array were used to identify significant genomic segments shared by ASD cases in the high-risk families. Resulting significant shared segments were then interrogated for harboring regions of accelerated evolution in mammalian species that evolved various distinctive traits, including elephant, microbat, orca, dolphin, naked mole rat (NMR), ground squirrel, hamster, orangutan, and prairie vole. Evolved traits can map onto phenotypes of interest for human disease; for example, cancer resistance in elephants. **Results.** Shared genomic segments that segregate in high-risk ASD families were found to harbor significantly more accelerated regions (ARs) in the NMR than expected by chance ( $p=1.84E-14$ ). The NMR is one of two known eusocial mammals. The result was robust to simulations accounting for nonrandom genomic distribution of ARs. **Conclusion.** We show that genomic regions linked to ASD risk are significantly enriched for ARs specifically in NMR, a species that evolved highly unusual social behaviors. Results reveal novel candidate genomic regions for shaping mammalian sociability. Our results establish a combined phylogenomics and human genetics approach to identify new elements of genomic control for an aspect of human behavior strongly associated with autism and other psychiatric disorders.

**Assessment of shared genetic sex-differences across neuropsychiatric and behavioral traits.** E.A. Khrantsova<sup>1,2</sup>, J. Martin<sup>3</sup>, L.K. Davis<sup>4,5,6</sup>, B.E. Stranger<sup>2,7</sup>, *Psychiatric Genomics Consortium Sex-specific cross-disorder analysis group.* 1) Department of Medicine, The University of Chicago, Chicago, IL; 2) Institute for Genomics and Systems Biology, University of Chicago, Chicago, IL; 3) MRC Centre for Neuropsychiatric Genetics and Genomics, Cardiff University, Cardiff, UK; 4) Vanderbilt Genetics Institute; Vanderbilt University Medical Center, Nashville, TN; 5) Division of Medical Genetics, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 6) Department of Psychiatry and Behavioral Sciences, Vanderbilt University Medical Center, Nashville, TN; 7) Center for Data Intensive Science, University of Chicago, Chicago, IL.

Accumulating evidence suggests that widespread phenotypic sex differences in complex traits may include a genetic component beyond sex chromosomes and hormones. Understanding the contribution of sex to complex traits and disorders may have important implications for diagnosis and treatments. Because neuropsychiatric traits moderately share genetic components (Anttila et al., 2016) and are often comorbid, we examined the extent to which males and females share the genetic risk for a range of neuropsychiatric and behavioral traits. Using sex-stratified GWAS summary statistics and the LDSC method, we first assessed genetic correlation between pairs of traits within each sex across several neuropsychiatric and behavioral phenotypes. Next, we assessed whether the genetic correlation of each pair of phenotypes differed significantly between sexes. Overall, the within-sex genetic correlation estimates across each pair of traits were largely similar in males and females. One notable exception is the genetic correlation between educational attainment and alcohol consumption which was significantly higher in females (females:  $R_g(SE)=0.28(0.05)$ ; males:  $R_g(SE)=0.04(0.05)$ , difference z-score=3.55, FDR-corrected  $p=1.1e-2$ ). This finding was replicated in an independent alcohol consumption dataset (difference z-score=2.27, uncorrected  $p=2.3e-2$ ). For traits with moderate genetic correlation, we performed sex-specific cross-trait meta-analyses then identified variants with sex-heterogeneous effects and characterized their biological function. Finally, we investigated the effect of genetic risk for psychiatric disorders in a large hospital population (BioVU) by calculating polygenic risk scores (PRS) for each disorder. We then performed a phenome-wide association study of the PRS separately by sex. We hypothesized that different clinical manifestations of genetic risk for psychiatric disorders may be more easily observed in a hospital population when individuals have not been ascertained into the study for a specific set of behaviors. Consistent with this, preliminary results from BioVU suggest that a cross-disorder PRS was most significantly associated with substance use disorders in males ( $p=5.24e-06$ ) and most significantly associated with mood disorders in females ( $p=5.41e-05$ ). These results elucidate important similarities and differences across sex in the common variant contribution to neuropsychiatric and behavioral phenotypes.

**Genome-wide meta-analyses reveal novel loci for verbal short-term memory and learning and show genetic correlation with schizophrenia, Alzheimer's disease, and type 2 diabetes.** J. Lahti<sup>1</sup>, S. Tuominen<sup>1</sup>, Q. Yang<sup>2</sup>, S. Medland<sup>3</sup>, J. Painter<sup>3</sup>, Z. Gerring<sup>3</sup>, E. Derks<sup>3</sup>, J. Bressler<sup>4</sup>, T. Mosley Jr<sup>5</sup>, C. van Duijn<sup>6</sup>, L.J. Launer<sup>7</sup>, S. Debette<sup>8</sup>, I. Deary<sup>9</sup>, S. Seshadri<sup>3</sup>, K. Räikkönen<sup>1</sup>, *CHARGE Consortium Cognitive Working Group.* 1) Department of Psychology and Logopedics, University of Helsinki, Helsinki, Finland; 2) Boston University, USA; 3) QIMR Berghofer Medical Research Institute, Australia; 4) University of Texas, USA; 5) University of Mississippi Medical Center, The Netherlands; 6) Erasmus Medical Center University Medical Center, The Netherlands; 7) National Institutes of Health, USA; 8) University of Bordeaux, France; 9) University of Edinburgh, UK.

Objectives: Understanding the biological basis of memory functions may help combat neurodegenerative disorders. Despite moderate heritability in twin studies, consistent findings on the molecular genomic basis of memory functions are scarce. This reflects low power in most of the studies. In a large genome-wide association study (GWAS) based on the CHARGE consortium we investigated common genetic variants associated with short-term verbal memory and learning in adults. Methods: We conducted meta-analyses for verbal memory immediate recall test scores and verbal learning scores in a discovery sample across 27 cohorts (N=44,874) and 22 cohorts (N=28,909), respectively. Respective sample sizes of the replication samples were N=8763 and N=3853. All participants were adults of European descent and were free of dementia and stroke. Results: For verbal memory immediate recall test scores, we observed a genome-wide significant signal in an intron of *CDH18* and for verbal learning, we observed a signal peak in the 3p21.1 region with a large LD block in/near *NT5DC2*, *STAB1*, *ITIH1*, *ITIH4*, and *PBRM1*. For both phenotypes, we also observed a signal near *APOC1*. Associations of lead SNPs in all regions replicated ( $p<.05$ ). MAGMA gene-based analyses implicated an additional nine genes for verbal learning (*CALN1*, *TOMM40*, *SMIM4*, *NEK4*, *GNL3*, *AGXT2*, *MUSTN1*, *GLT8D1*, and *ITIH3*). Several SNPs in the 3p21.1 region are eQTLs for *POC1A*, *GNL3*, *GLYCTK*, *DUSP7*, *ITIH4*, *PPM1M*, and *GLT8D1* in brain tissues in the GTEx or Brainiac databases. S-PrediXcan transcriptome-wide analyses showed that *POC1A* expression in the putamen was associated with lower verbal learning scores. Finally, we show with LDscore regression a negative genetic correlation of schizophrenia and Type 2 Diabetes (T2D) to both memory traits; a negative genetic correlation with anxiety and neuroticism for verbal immediate recall; and with Alzheimer's disease (AD) for verbal learning. Conclusions: We showed novel genomic regions in cadherin 18 (*CDH18*) and 3p21.1 that associated with verbal short-term memory and learning, respectively, and we replicated a previously reported finding in *APOC1*. Cadherins are crucial in synaptic plasticity and the 3p21.1 region has been implicated in psychiatric disorders in previous studies. Our results may also partly explain phenotypic links between memory and psychiatric disorders, T2D, and AD.

**Population-scale analysis of copy number variation from whole genome sequencing.** R.E. Handsaker<sup>1,2</sup>, S. Kashin<sup>1,2</sup>, C. Usher<sup>1,2</sup>, C. Whelan<sup>1,2</sup>, M.T. Pato<sup>3</sup>, C.N. Pato<sup>3</sup>, M. Boehnke<sup>4</sup>, S.A. McCarroll<sup>1,2</sup>, WGSPD Consortium. 1) Stanley Center for Psychiatric Research, Broad Institute, Cambridge, MA, 02141 USA; 2) Department of Genetics, Harvard Medical School, Boston, MA, 02115 USA; 3) SUNY Downstate Medical Center, Brooklyn, NY 11203 USA; 4) Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI 48109 USA.

Human genomes exhibit abundant structural variation; this class of variation has been shown to impact many important human phenotypes. However, the full spectrum of structural variation in humans has not been as deeply or as thoroughly ascertained as fine-scale variation (e.g. SNPs and small indels), especially in large populations. We have performed an initial analysis of copy number variation – including deletions, duplications and multi-allelic CNVs – from whole-genome sequencing a cohort of 11,627 individuals from the Whole Genome Sequencing in Psychiatric Disorders (WGSPD) consortium. This cohort is comprised of schizophrenia and bipolar disorder cases, controls and unaffected family members and includes individuals of diverse ancestry including more than 6,500 African Americans and 250 Latinos. Accurate and efficient methods for ascertaining copy number variation at this scale from whole-genome sequencing data have been needed. To address this need, we have enhanced our Genome STRIP research software to efficiently process cohorts of this size in a cloud-computing environment. To date, we have ascertained more than 60,000 copy number variants of length greater than one kilobase, including variants in many repetitive regions of the genome. We have performed uniform genotyping of these variants across the cohort to allow accurate characterization of allele frequencies and to place the structural alleles on SNP haplotypes. Most of this variation appears to be segregating in human populations at allele frequencies below 1%. We estimate that 58% of all protein-coding genes are impacted by at least one copy number variant ascertained in this cohort. This set of broadly genotyped CNVs will make it possible to begin to understand the patterns of rare, segregating copy number variation in large populations and across different ancestry groups. To facilitate access to this resource, we have developed an interactive web interface to allow researchers to search and explore this data set and view the evidence for each variant.

**3q29 deletion syndrome: Neuropsychiatric and behavioral phenotypes.** R.M. Pollak<sup>1</sup>, M.M. Murphy<sup>2</sup>, M.P. Epstein<sup>2</sup>, M.E. Zwick<sup>2</sup>, C.E. Saulnier<sup>3</sup>, J.G. Mulle<sup>2</sup>. 1) Genetics and Molecular Biology Program, Laney Graduate School, Emory University, Atlanta, GA; 2) Department of Human Genetics, Department of Medicine, Emory University, Atlanta, GA; 3) Department of Pediatrics, Department of Medicine, Emory University, Atlanta, GA.

3q29 deletion syndrome (3q29DS) is a rare (~1:30,000) genomic disorder characterized by a 1.6 Mb heterozygous deletion on chromosome 3 and is associated with a wide range of phenotypes, including neurodevelopmental and neuropsychiatric disorders, growth deficits, feeding problems, and congenital heart defects. Notably, the 3q29 deletion confers a 40-fold increased risk for schizophrenia, a 30-fold increased risk for Autism Spectrum Disorder (ASD), and a significantly increased risk for intellectual disability and generalized anxiety disorder. In order to develop a more comprehensive picture of ASD in 3q29DS, we used Emory University's 3q29DS registry (3q29deletion.org) to collect self-report data on 3q29DS patients and typically developing controls, including a custom medical and demographic questionnaire (n=94 3q29DS, 64 control); Achenbach Behavior Checklists (CBCL/ABCL, n=48 3q29DS, 57 control); Social Responsiveness Scale (SRS, n=48 3q29DS, 59 control); and the Social Communication Questionnaire (SCQ, n=33 3q29DS, 46 control). Statistical testing and data visualization were performed in R. Self-report data from 3q29DS registry participants shows increased prevalence of ASD diagnosis versus the general population (30.7% vs. 1.47%,  $p < 2.2 \times 10^{-16}$ ). The male:female ratio of self-reported ASD diagnosis in 3q29DS is 1.8:1, strikingly different from the 4:1 ratio in the general population. Additionally, some participants that do not report an ASD diagnosis scored in the clinical range on all self-report scales, indicating substantial impairment in the absence of a clinical diagnosis. Finally, 3q29DS individuals show a novel constellation of ASD features, including less compromised social motivation compared to other domains, which is dramatically different from the profile observed in idiopathic ASD. These results show that the 3q29DS population is significantly enriched for ASD diagnosis and ASD features measured via standardized ASD symptomology surveys. Our findings suggest ASD evaluation should be the standard of care for individuals newly diagnosed with 3q29DS. Our findings also suggest that cognitive behavioral therapy strategies may be successfully deployed in 3q29DS, by leveraging the relatively intact social motivation of 3q29DS individuals.

**In silico evidence for the contribution of expression dysregulation of 16p11.2 genes to schizophrenia.** M. Vysotskiy, L.A. Weiss. Department of Psychiatry, Weill Institute for Neurosciences, Institute for Human Genetics, University of California San Francisco, San Francisco, California.

A copy number variant at 16p11.2 is strongly associated with behavioral disorders. Schizophrenia, for example, is observed more frequently in duplication, but not deletion, carriers. Not every gene in the 30-gene region may influence schizophrenia; however, finding a set of primary driver genes for behavioral phenotypes remains unsolved. Duplications are likely to increase transcription levels, a potential mechanism for their pathogenicity. We hypothesize that in the general population (individuals carrying two copies of each CNV gene), psychiatric disease risk will also be affected by expression variation in these genes, but in more modest ways. The effect of transcription on phenotype can be studied *in silico* by using SNP (eQTL) predictive models (PredictDB) to "impute" gene expression into genetic datasets and associating this genetically-predicted expression with phenotype; this can also be done with summary statistics. Here, we use a brain-specific model trained on data from the CommonMind Consortium, with genes not in the model imputed as the median of all other tissues. Using schizophrenia summary statistics from the Psychiatric Genomics Consortium (PGC), we have observed that expression variation at 16p11.2 has a greater contribution to schizophrenia compared to matched permuted sets of adjacent genes ( $P < 0.01$ ). Six genes at or near the region showed significant positive association with schizophrenia: *INO80E* ( $P = 2 \times 10^{-9}$ ), *TMEM219* ( $P = 1 \times 10^{-6}$ ), *DOC2A* ( $P = 6 \times 10^{-7}$ ), *PPP4C* ( $P = 2 \times 10^{-6}$ ), *MAPK3* ( $P = 4 \times 10^{-6}$ ), *MAZ* ( $P = 6 \times 10^{-6}$ ). Because there are 16p11.2 genes that are expected to influence downstream genes, which may have additional impact on schizophrenia, we explored the effects of transcriptional variation in genes downstream of CNV genes. We generated downstream regulatory networks by identifying genes in the Genotype-Tissue Expression Consortium (GTEx) data whose expression was correlated with the genetically-predicted expression of 16p11.2 genes. 91% of 16p11.2 genes tested had at least one downstream gene, and on average, each gene had 28 unique targets; this compares with XX% of genes and YY targets in control regions. Six genes at or near 16p11.2 had networks positively associated with schizophrenia: *BOLA2*, *DOC2A*, *CD2BP2*, *PRRT2*, *SULT1A4*, *MAPK3* (permuted  $P < 0.05$ ). Our results suggest multiple 16p11.2 genes contribute to schizophrenia, directly or by affecting genes downstream, and that this CNV region is unusually influential on additional genes in *trans*.

**2445W**

**Polygenic risk score improves prediction of alcohol-related morbidities.** T.T.J. Kiiskinen<sup>1</sup>, N. Mars<sup>1</sup>, J. Koskela<sup>1</sup>, J.T. Rämö<sup>1</sup>, J. Kaprio<sup>1</sup>, V. Salomaa<sup>2</sup>, P. Mäkelä<sup>2</sup>, A.S. Havulinna<sup>1,2</sup>, S. Ripatti<sup>1,3,4</sup>, GSCAN. 1) Institute for Molecular Medicine Finland (FIMM), HiLIFE, University of Helsinki, Helsinki, Helsinki, Finland; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) Program in Medical and Population Genetics and The Stanley Center for Psychiatric Research, The Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 4) Department of Public Health, Clinicum, Faculty of Medicine, University of Helsinki, Helsinki, Finland.

Alcohol drinking is a major dose-dependent contributor to global morbidity and mortality. Alcohol drinking behavior is strongly affected by genetic factors: estimated heritability of alcohol consumption is 43% and its genomic heritability-estimate is 13%. A growing number of large scale GWASes have identified multiple loci associated with alcohol consumption. Measures of this polygenic burden may provide more objective prognostic information independent of individual reporting bias. Here, we aim to study if a polygenic risk score (PRS) for alcohol consumption is associated with alcohol-related morbidities and mortality in the Finnish FINRISK population survey cohorts ( $n = 27,344$ ) spanning 1992 to 2012. We used summary statistics from the largest existing GWAS meta-analysis of alcohol consumption (GSCAN consortium,  $n = 527,282$  after exclusion of all Finnish samples) and applied a Bayesian PRS method (LDpred) to create a genome-wide PRS for alcohol consumption. To identify individuals with major alcohol-induced health events, we constructed 21 somatic and psychiatric alcohol-related disease endpoints using nationwide hospital discharge, causes-of-death and prescription drug purchase registries that were electronically linked to the cohort baseline data. One SD increase in the PRS of alcohol consumption was associated with a 9.5 g increase in weekly pure alcohol intake ( $\beta = 9.47 [8.06-10.90]$  g,  $p = 6.3 \times 10^{-39}$ ). The PRS was associated with lifelong alcohol-related morbidities status ( $n = 1,430$ ) with a 32 % increase in the risk per 1 SD increase in the PRS when alcohol consumption was not in the model (OR = 1.32 [1.25-1.40],  $p = 6.0 \times 10^{-23}$ ), and with a 24 % increase when alcohol consumption was included in the model (OR = 1.24 [1.17-1.31],  $p = 5.6 \times 10^{-13}$ ). Using Cox regression, the PRS was associated with a 20% increase in the risk of combined alcohol-related major health events, hospitalization or death ( $n = 715$  cases) (HR = 1.20 [1.11-1.29],  $p = 2.0 \times 10^{-6}$ ). We observed a similar increase in the risk of alcohol-related mortality alone ( $n = 273$  deaths) (HR = 1.22 [1.09-1.39],  $p = 1.0 \times 10^{-3}$ ). In conclusion, increased polygenic risk for alcohol consumption is associated with alcohol-related health events. The PRS was associated with alcohol-related morbidities even when self-reported baseline alcohol consumption was in the model. These preliminary findings show promise for utilizing genetic information to improve risk estimation for alcohol-related disorders.

**Mutation screening in *SHANK2* and *SHANK3* genes in Brazilian individuals with autism spectrum disorder.** D.B.A. Rosan<sup>1</sup>, A.L. Bossolani-Martins<sup>2</sup>, S. Ezquina<sup>3</sup>, L.A. Britto<sup>3</sup>, M.R. Passos-Bueno<sup>3</sup>, A.C. Fett-Conte<sup>4</sup>. 1) Universidade Estadual Paulista Julio de Mesquita Filho (UNESP/IBILCE), Sao Jose do Rio Preto, Sao Paulo, Brazil; 2) Universidade Federal do Mato Grosso do Sul (UFMS), Paranaiba, Mato Grosso do Sul, Brazil; 3) Universidade de Sao Paulo (USP), Sao Paulo, Sao Paulo, Brazil; 4) Faculdade de Medicina de Sao Jose do Rio Preto (FAMERP), Sao Jose do Rio Preto, Sao Paulo, Brazil.

Autism spectrum disorder (ASD) is a severe neuropsychiatric disorder characterized by impairment of social communication, with repetitive patterns of behavior, interests or activities. With a complex and heterogeneous etiology, numerous genetics, epigenetics and environmental factors can explain this changes that affect 1-68 individuals. Several genes are linked to the ASD etiology, many of them are responsible for encoding proteins involved in the formation and function of synapses, acting with a probable additive effect, resulting in the behavioral phenotype. Among those genes are the *SHANK* family, composed by *SHANK1*, *SHANK2* and *SHANK3* genes that are expressed in different regions of the brain encoding scaffolding proteins that function as molecular scaffolds in the postsynaptic density of excitatory synapses. This study aimed to investigate the presence of mutations in the exons 11, 13 and 22 of *SHANK2* and exons 2, 6 and 21 of *SHANK3* genes to evaluate a possible association with the behavioral phenotype and the heritability of some variations with the broad autism phenotype (BAP) in the parents. We sequenced 200 Brazilian individuals with idiopathic ASD and the results were compared with those of a control group composed of 566 Brazilian individuals without psychiatric disorders. In *SHANK3*, we found three novel variants, one missense (NM\_033517.1:c.206A>G) not present in the parents and two synonymous (NM\_033517.1:c.4176C>G and NM\_033517.1:c.4152C>T), the first one was also found in the patient's father with BAP. We also found two previously described variation, one synonymous (NM\_033517.1:c.3813C>T) and a missense (NM\_033517.1:c.4216C>G) that was not found in the parents, but in the patient's sister with BAP, we found another variation in this exon (NM\_033517.1:c.4108A>G). Those variants were not found in the control group. In *SHANK2*, we found a previously described synonymous variation (NM\_012309.4:c.1716C>T) in an individual with ASD and his mother with BAP, but not in controls. Five missense variations were found in the patients and in controls, but not in the parents (NM\_012309.4:g.70666765C>T; NM\_012309.4:c.1289C>T; NM\_012309.4:c.1706G>A; NM\_012309.4:c.1759C>T and NM\_012309.4:c.2453G>A). Genetic studies have demonstrated the strong association of variants in those genes with susceptibility to ASD and BAP, even synonymous variants may play a role in the etiology. Further investigations should be carried out to clarify the effect of those variants.

**2447F**

**Whole exome sequencing and linkage analysis in an extended pedigree segregating dyslexia.** A.K. Adams<sup>1</sup>, D.T. Truong<sup>2</sup>, S.D. Smith<sup>3</sup>, E.G. Willcutt<sup>4,5</sup>, R.K. Olson<sup>4,5</sup>, J.C. DeFries<sup>4,5</sup>, B.F. Pennington<sup>6</sup>, J.R. Gruen<sup>1,2,7</sup>. 1) Department of Genetics, Yale University, New Haven, CT; 2) Department of Pediatrics, Yale University, New Haven, CT; 3) Munroe Meyer Institute, University of Nebraska Medical Center, Omaha, NE; 4) Institute for Behavioral Genetics, University of Colorado, Boulder, CO; 5) Department of Psychology and Neuroscience, University of Colorado, Boulder, CO; 6) Department of Psychology, University of Denver, Denver, CO; 7) Investigative Medicine Program, Yale University, New Haven, CT.

With the cost of sequencing continuing to fall, and the remaining difficulty of ascertaining large collections of unrelated subjects for genome wide association studies, recent approaches have returned to sequencing and linkage analysis of large extended families to discover new genes associated with complex disorders. One such family with a long history of use in dyslexia research is family 6432. While 6432 has previously been used in linkage studies to identify *DYX1* in 1983, the variant or variants that contributed to the observed linkage results remain unknown. In the present study, whole exome sequencing (WES) was performed on 27 members of family 6432, a forty-three member, four generation pedigree segregating dyslexia in a Mendelian dominant manner with no apparent evidence of sex-biased inheritance. Resulting sequence was aligned, processed, and variants were identified according to the Broad Institute's GATK best practices for sequencing using an in-house pipeline. Variants were annotated using a combination of ANNOVAR and VEP to maximize number of *in silico* tools for variant information. Because of the significant number of variants observed across all members of the family, and the peculiar structure of WES data relative to SNP marker array data, the Pedigree based analysis pipeline (PBAP) was used to select non-overlapping marker subpanels and sample inheritance vectors (in MORGAN) for later linkage analysis. File conversions were handled by either PLINK or MEGA2 as appropriate. Both twopoint and multipoint linkage analysis was performed using SOLAR at 1cM resolution. Variants under corresponding linkage peaks with LOD > 1 were checked for variant segregation and *in silico* prediction of damage to corresponding proteins. Linkage results, and corresponding variants under peaks are forthcoming. Taken together, this study represents the first attempt to sequence and reanalyze a previously collected dyslexia family to discover potentially causal variants underlying an identified dyslexia associated locus.

**2448W**

**Potential role of rare variants in the genetics of tardive dyskinesia.** A. Alkelai<sup>1</sup>, L. Greenbaum<sup>2,3</sup>, E.L. Heinzen<sup>1</sup>, D. Goldstein<sup>1</sup>, B. Lerer<sup>1</sup>. 1) Institute for Genomic Medicine, Columbia University, New York, NY, USA; 2) The Danek Gertner institute of Human Genetics, Chaim Sheba medical center, Tel Hashomer, Ramat Gan, Israel; 3) The Joseph Sagol Neuroscience Center, Chaim Sheba medical center, Tel Hashomer, Ramat Gan, Israel; 4) Biological Psychiatry Laboratory, Department of Psychiatry, Hadassah-Hebrew University Medical Center, Jerusalem, Israel.

Tardive dyskinesia (TD) is a chronic, irreversible side effect of antipsychotic treatment. TD occurrence is influenced by both clinical and demographic variables, as well as genetic factors. Contribution of common variants to TD susceptibility has been investigated in recent years, including by the genome-wide association study approach, but results are inconsistent. In order to discover the involvement of rare variants in this phenotype, we implemented the whole exome sequencing (WES) method. We performed whole exome sequencing in 20 Ashkenazi and 17 Non-Ashkenazi Jewish schizophrenia patients with severe TD, and 18 Ashkenazi and 25 Non-Ashkenazi patients without any manifestation of TD (total AIMS score of zero) despite more than 10 years of exposure to antipsychotics. We performed a case-control, exome-wide collapsing analysis including 37 patients with severe TD and 43 patients without any manifestation of TD. We also performed an additional analysis including 37 patients with severe TD and 965 unrelated healthy Jewish controls. Comparing genetic variation across 18,668 protein-coding genes we found a significant case-enrichment of rare loss of function variant in gene that seem to be relevant to this disorder (a presynaptic protein that is involved in synaptic membrane exocytosis). Follow-up case-control study in a different TD sample is currently ongoing to confirm these initial results.

**2449T**

**A variant affecting levels of succinylcarnitine is associated with HLA-DQB1\*06:02-negative essential hypersomnia.** T. Miyagawa<sup>1,2</sup>, S.S. Khor<sup>2</sup>, H. Toyoda<sup>2</sup>, M. Shimada<sup>1,2</sup>, K. Mishima<sup>3</sup>, M. Honda<sup>1,4</sup>, K. Tokunaga<sup>2</sup>. 1) Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Department of Sleep-Wake Disorders, National Institute of Mental Health, National Center of Neurology and Psychiatry, Tokyo, Japan; 4) Seiwa Hospital, Neuropsychiatric Research Institute, Tokyo, Japan.

Essential hypersomnia (EHS) is a lifelong sleep disorder characterized by excessive daytime sleepiness. Cataplexy, which is typical in narcolepsy, is not present in EHS. EHS is associated with human leukocyte antigen (HLA)-DQB1\*06:02, similar to narcolepsy. DQB1\*06:02-positive and -negative EHS are different in terms of their clinical features and follow different pathological pathways. DQB1\*06:02-positive EHS and narcolepsy are associated with the same susceptibility genes. However, there are fewer studies of DQB1\*06:02-negative EHS. Therefore, we performed a genome-wide association study with replication for DQB1\*06:02-negative EHS in 408 Japanese patients and 2,247 Japanese healthy controls. As a result, a SNP (rs10988217), which is located 15 kb upstream of carnitine O-acetyltransferase (CRAT), showed a significant association with DQB1\*06:02-negative EHS ( $P = 7.5 \times 10^{-9}$ , odds ratio = 2.63). Meanwhile, no significant association was observed between rs10988217 and narcolepsy or DQB1\*06:02-positive EHS. The risk allele of rs10988217 was correlated with higher expression levels of CRAT in various tissues and cell types. In human blood, the risk allele was also associated with levels of succinylcarnitine, which is a short-chain acylcarnitine ( $P = 1.4 \times 10^{-18}$ ). The leading SNP in the CRAT region was the same in associations with both DQB1\*06:02-negative EHS and succinylcarnitine. Next, to assess the relationship between DQB1\*06:02-negative EHS and succinylcarnitine, levels of succinylcarnitine were measured in 48 patients with DQB1\*06:02-negative EHS and 20 control subjects using a LC-MS/MS method. We found that succinylcarnitine levels were lower in the patients, compared with the control subjects ( $P = 0.031$ ). CRAT catalyzes the reversible transfer of short-chain acyl groups from a short-chain acyl-CoA thioester to carnitine, thus forming the corresponding short-chain acylcarnitine. These results suggest that DQB1\*06:02-negative EHS may be associated with an underlying dysfunction in energy metabolic pathways.

**Schizophrenia-associated functional study of a POU3F2 regulated-TRIM8 signaling pathway in neural progenitor cells.** C. Ding<sup>1</sup>, C. Chen<sup>1</sup>, Q. Meng<sup>1</sup>, R. Dai<sup>1</sup>, Y. Jiang<sup>1</sup>, C. Liu<sup>1,2</sup>. 1) Center for Medical Genetics, Central South University, Changsha, Hunan, China; 2) Department of Psychiatry, SUNY Upstate Medical University, Syracuse, USA.

**Background:** Schizophrenia (SCZ) is a highly heritable psychiatric disorder, and is associated with high morbidity and recurrence rate. This is because SCZ is a complex brain illness with unknown pathogenic mechanisms. Genome-Wide Association Studies have identified hundreds of SCZ associated loci, which contain many genes and SNPs. However, their underlying connections and biological effects are not clear. Recently, we identified *POU3F2* as one of the core regulators of gene co-expression network through transcriptome data from patients with schizophrenia and healthy controls. *POU3F2* regulates *TRIM8* through SCZ associated SNPs, which is located in the *TRIM8* promoter region and disrupt *POU3F2* binding sites. However, these bioinformatic results based on transcriptome data require further validation. The function of *POU3F2* and *TRIM8* in the pathogenesis of SCZ remain unknown. Accumulating evidence suggests that SCZ is likely a neurodevelopmental disorder. Several SCZ risk genes contribute to brain development through regulating proliferation and differentiation of neural progenitor cells (NPCs). In this study, we validated the regulatory relationship between transcriptome factor *POU3F2* and its target *TRIM8* via experiments and studied the potential effects on brain development. **Methods:** 1) We changed *POU3F2* expression and performed RT-qPCR and western blot to detect consequent expression changes of *TRIM8*. 2) The predicted regulatory elements disrupted by SNPs were verified by dual-luciferase reporter assay. We also studied the direct interaction between *POU3F2* and corresponding regions through EMAS. 3) To assess the proliferation ability of NPCs, we performed CCK-8 and Edu incorporation assays. To evaluate differentiation changes caused by expression changes of *POU3F2* and *TRIM8*, we performed neurons and astrocytes differentiation assays. **Results:** 1) Experimental results confirmed *POU3F2* positively regulates *TRIM8* expression at mRNA and protein levels. 2) *POU3F2* regulates *TRIM8* through a regulatory region that harbors the SCZ associated SNP (rs5011218), which affects *POU3F2* binding efficiency. 3) *POU3F2* and *TRIM8* inhibited the proliferation of NPCs through regulating the cell cycle. The neurons differentiation of NPCs was promoted by *POU3F2* and *TRIM8*, but they do not impact astrocytes differentiation. **Conclusion:** *POU3F2* regulates *TRIM8* expression via SCZ associated SNP (rs5011218). This pathway contributes to the risk of SCZ through affecting brain development.

**Whole genome sequencing in specific language impairment (SLI) exposes a shared genetic basis for language ability in autism spectrum disorders.** J. Michaelson, T. Koomar, J.B. Tomblin. University of Iowa, Iowa City, IA.

Specific language impairment (SLI) is a developmental language disorder that affects an estimated 7% of school-aged children, and has a lifelong impact on social, educational, vocational, and mental health outcomes. Although SLI shares some similarity with autism spectrum disorder (ASD) in terms of deficits in social communication, ASD is an exclusionary criterion in the diagnosis of SLI. Nevertheless, there is some evidence that there may be elements of shared genetic risk between the conditions. SLI has an estimated heritability of > 0.5, and most genetic studies to date have focused on common variation. Genetic risk for SLI likely resembles that of other neurodevelopmental conditions: a large degree of heterogeneity, with a mix of rare alleles of large effect and common polygenic risk. Here we report the first whole genome sequencing study of SLI (N=400), providing the first glimpse of the full spectrum of genetic variation underlying language ability: from rare to common, single nucleotide variants (SNVs) to structural variants (SVs). Early results show that, as expected, overall burden of SVs is predictive of IQ, and furthermore that SV burden in ASD risk genes is specifically predictive of language ability (even after correcting for IQ). Spatiotemporal expression patterns of ASD risk genes with the strongest associations with language ability converge on regions of the brain well-supported for critical roles in language. Models trained on the SLI sample that used pathway burden as predictors of language generalized successfully in predicting language ability in ASD cohorts, while identifying molecular mechanisms that contribute positively and negatively to language ability, and suggesting that these mechanisms are relevant to language across diagnostic boundaries. We found that genes and pathways that show positive contributions to language with increasing genetic burden demonstrate signatures of human-specific accelerated substitution, while genes and pathways that show a negative effect on language with increasing burden indicated evidence of stricter conservation. Furthermore, putative language-associated genes were enriched for lateralized brain expression, consistent with language as a highly lateralized function in the brain. By overlaying these language-specific findings on larger studies of ASD, we are taking the first steps in illuminating the molecular pathways that support language ability.

**A genome-wide association study of completed suicide in Utah.** J.S. Anderson<sup>1</sup>, A.A. Shabalin<sup>1</sup>, J. Shade<sup>1</sup>, A.V. Bakian<sup>1</sup>, D.E. Adkins<sup>1</sup>, B. Callor<sup>2</sup>, E.D. Christensen<sup>2</sup>, E. DiBlasi<sup>1</sup>, D. Gray<sup>1</sup>, C. Hayward<sup>2</sup>, D.J. Porteous<sup>4</sup>, A.C. Edwards<sup>3</sup>, Q. Li<sup>5</sup>, H. Coon<sup>1</sup>, A.R. Docherty<sup>1</sup>. 1) Psychiatry, University of Utah School of Medicine, Salt Lake City, UT; 2) Utah State Office of the Medical Examiner, Utah Department of Health, Salt Lake City, UT; 3) MRC Human Genetics Unit, University of Edinburgh, Edinburgh, UK; 4) Centre for Genomic and Experimental Medicine, University of Edinburgh, Edinburgh, UK; 5) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University School of Medicine, Richmond, VA; 6) Johnson and Johnson, New York, NY.

**Background:** Suicide is the tenth leading cause of death in the United States, with more than 40,000 suicide deaths per year. Importantly, of the approximately 3,600 per 100,000 individuals in the US who exhibit suicidal behavior or ideation, fewer than 1% actually go on to complete suicide. Heritability of *completed* suicide is estimated at 43%, indicating that genetic factors almost certainly play an important role. Because of difficulties in data collection, genetic studies examining completed suicide are rare and underpowered. Here we present results from the largest genome-wide association study (GWAS) of completed suicide to date. **Methods:** Through collaboration with the Utah Office of the Medical Examiner, we collected blood samples from 1321 individuals who died by suicide. Samples were genotyped using the Illumina Infinium PsychArray platform and cases of European ancestry were carefully matched to a large cohort of control samples from Generation Scotland, resulting in 1070 suicide cases and 3532 controls (total  $N = 4602$ ). A mixed-model GWAS of 7 358 674 variants was conducted using GEMMA, and comparison analyses were conducted with the Utah population of the 1000 Genomes Project. Gene set and pathway enrichment analyses were employed to characterize function in the implicated variants. **Results:** A total of 126 variants mapping to 4 genes (*TLR 1*, *TLR 6*, *TLR 10*, *FAM114A1*) met genome-wide significance ( $p < 5 \times 10^{-8}$ ). An additional 63 variants were nominally significant at  $q < 0.05$  and mapped to 11 genes, including *HLA-C* and *HLA-V*. *HLA* imputation and pathway analysis further implicated major histocompatibility complex and immune-related genes in risk of suicide completion. **Discussion:** In the context of other recent findings relating major histocompatibility complex variations to psychosis and general inflammatory markers to major depression, these results help suggest that immune-related genes are indicated not only in broad psychopathology, but in extreme, rare outcomes. We discuss potential targets for future research, as well as propose that polygenic risk scores for suicide completion, calculated from these summary statistics, may help address the current gap of genetic research on completed suicide.

## 2453F

**Sex matters: Genome-wide association study reveals sex differences in nicotine metabolism biomarker genetics among African American but not European American smokers.** M.J. Cigarette smoking behavior and cessation rates differ between men and women. Nicotine, the major psychoactive compound in cigarettes, is metabolically inactivated by CYP2A6 to cotinine and then to 3'hydroxycotinine. The Nicotine Metabolite Ratio (NMR; 3'hydroxycotinine/cotinine) is a heritable (~60-80%) biomarker of CYP2A6 activity and nicotine metabolism that prospectively predicts smoking cessation. In genome-wide association studies (GWASs) of the NMR controlling for sex, ~99% of hits in African (AA) and European ancestry (EA) smokers were in chromosome 19 (contains *CYP2A6*). Here we conducted sex-stratified GWASs of the NMR in AA and EA smokers from two smoking cessation clinical trials (NCT01314001 and NCT00666978). Additive genetic models adjusted for population substructure and NMR covariates (e.g. age and BMI). Overall, marked sex differences were observed in AA but not in EA smokers. In AA males ( $n=352$ ), only  $n=37/80$  genome-wide significant (GWS) hits were found on chromosome 19; the top overall hit was rs12459249, located 9.5kb 3' of *CYP2A6* (for C vs. T:  $\beta=0.61$ ,  $P=4.5e-18$ ). Other GWS regions with  $>1$  hit included chromosomes 3, 6, 11, and 22; none of these regions were significant in AA females ( $n=503$ ). The chromosome 3 signal comprised 14 hits located ~150-200kb 5' of *CBLB*, involved in proteosome-mediated protein degradation. The chromosome 6 signal represented two independent loci, with one region containing 6 hits located ~6-15kb 3' of a gene putatively involved in drug transport (i.e. *SLC17A2*). In AA females,  $n=66/71$  GWS hits were found on chromosome 19; the top overall hit differed from AA males and was rs11878604, located 16kb 3' of *CYP2A6* (for C vs. T:  $\beta=-0.67$ ,  $P=3.0e-24$ ). Other GWS regions in AA females were intergenic, including a locus with 3 hits located ~1MB 5' of *TMEM132C* on chromosome 12, and were not significant in AA males. In EA males ( $n=541$ ) and females ( $n=389$ ), all GWS hits ( $P<5e-8$ ) were found in chromosome 19 ( $n=73$  and  $n=43$  hits in males and females, respectively). In each sex, the top hit was the intronic *CYP2A6* SNP rs56113850 (for C vs. T:  $\beta=0.72$ ,  $P=4.3e-37$  in males;  $\beta=0.63$ ,  $P=2.9e-21$  in females). Our findings in AA show sex differences in genetic influences on a nicotine metabolism biomarker predictive of success on smoking cessation treatments, demonstrating intersections between genetic variation, race, sex, and metabolism which may lead to improved smoking treatment strategies for men and women.

**2454W**

**A genome-wide study for interactions of Cytomegalovirus infection with genetic variation affecting age-of-onset of bipolar disorder.** *B.J. Coombes<sup>1</sup>, B. Larrabee<sup>1</sup>, H. Sicotte<sup>1</sup>, S.L. McElroy<sup>2</sup>, M.A. Frye<sup>3</sup>, R. Yolken<sup>4</sup>, J.M. Biermacka<sup>1,3</sup>.* 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Lindnor Center of HOPE, University of Cincinnati, Cincinnati, OH; 3) Department of Psychiatry and Psychology, Mayo Clinic, Rochester, MN; 4) Department of Pediatrics, John Hopkins University School of Medicine, Baltimore, MD.

Bipolar disorder (BD) is a highly heritable disease, but most of the heritability remains unexplained. Identifying genetic risk factors is likely hampered by the extensive heterogeneity in BD and inadequate investigation of gene-environment (GE) interactions. Here, we aim to study GE interactions with Cytomegalovirus (CMV) exposure that are associated with age-of-onset of BD. CMV IgG and IgM antibody levels were measured in 173 patients with early onset BD (age 19 or younger) and 664 patients with late onset BD (age 20 or older). Early onset BD patients had lower seropositive rates of CMV IgG but higher titer levels of CMV IgM than patients with late onset BD. To find GE interactions associated with age-of-onset, we performed a SNP-level and gene-level gene-environment wide interaction scan (GEWIS). At the SNP-level, we used a two-step strategy to reduce the multiple testing burden and found a significant interaction of CMV IgM titer levels with rs138548272 ( $p = 1.6 \times 10^{-6}$ ), which is 150kb upstream of a gene that encodes the glutamate metabotropic receptor (*GRM3*). *GRM3* is involved in brain function and has been found to be perturbed in individuals with schizophrenia. At the gene-level, we performed a biologically-informed GEWIS by testing for association of interactions between antibody titer and estimated gene-expression in a given tissue. Gene expression was estimated from SNP data using PrediXcan, which incorporates tissue-specific expression quantitative trait loci information to predict gene expression for each individual. In a scan of 7866 genes with predicted expression in four candidate brain tissues, one gene, DNA polymerase epsilon (*POLE*), had significant interaction with CMV IgM ( $p = 4.4 \times 10^{-9}$ ). The results suggest that DNA damages caused by CMV infection combined with mutations leading to low expression of *POLE*, which is involved in DNA repair, may increase the likelihood of developing BD at an earlier age. No significant SNP or gene-level interactions were found with CMV IgG. This work reveals that certain exposures may explain some of the clinical and genetic heterogeneity in BD. Further investigation into the role of specific genes in modifying the effect of CMV infection on BD and its sub-phenotypes is warranted.

**Genome-wide association study in an Australian population identifies *FZD1* and ionotropic glutamate receptor pathway associated with schizophrenia.** *X. Liu<sup>1</sup>, J.R. Atkins<sup>2,3</sup>, W.R. Reay<sup>2,3</sup>, H.M. Cairns<sup>2,3</sup>, C. Fitzsimmons<sup>2,3</sup>, M.J. Green<sup>4,5,7</sup>, R.J. Scott<sup>2</sup>, V.J. Carr<sup>6,7</sup>, A.V. Boddy<sup>1</sup>, S. Low<sup>1,6</sup>, M.J. Cairns<sup>2,3,7</sup>.* 1) Faculty of Pharmacy, University of Sydney, Sydney, NSW, Australia; 2) School of Biomedical Sciences and Pharmacy, University of Newcastle, Newcastle, Australia; 3) Hunter Medical Research Institute, Centre for Brain and Mental Health Research, Newcastle, Australia; 4) School of Psychiatry, University of New South Wales, Sydney, Australia; 5) Neuroscience Research Australia, Sydney, Australia; 6) Cancer Precision Medicine Center, Japanese Foundation for Cancer Research, Tokyo, Japan; 7) Schizophrenia Research Institute, Sydney, Australia.

Schizophrenia is a genetically complex psychotic disorder with a high heritable component and a substantial health burden. To investigate genetic loci associated with schizophrenia in an Australian population, we conducted a genome-wide association study (GWAS) for schizophrenia (466 schizophrenia cases and 280 controls). Gene-based analysis identified *FZD1* (Frizzled Class Receptor 1) ( $P=4.79 \times 10^{-9}$ ) as being involved in the pathogenesis of schizophrenia and pathway enrichment analysis also implicated genes regulating the ionotropic glutamate receptor pathway ( $P=4.92 \times 10^{-2}$ ). These findings could contribute to a better understanding of schizophrenia susceptibility, pathogenesis and shed light on targets for new therapeutics.

**2456F**

**Treatment remission in late-life depression: Post-GWAS *in silico* biological characterization of variants associated venlafaxine treatment.** V.S. Marshe<sup>1,2</sup>, M. Maciukiewicz<sup>2</sup>, A.K. Tiwari<sup>2,3</sup>, E. Sibille<sup>2,4</sup>, D. Blumberger<sup>2</sup>, J.F. Karp<sup>5,6</sup>, E.J. Lenze<sup>7</sup>, C.F. Reynolds, III<sup>6</sup>, J.L. Kennedy<sup>1,2,3</sup>, B.H. Mulsant<sup>1,2,3</sup>, D.J. Mueller<sup>1,2,4</sup>. 1) Institute of Medical Science, University of Toronto, Toronto, ON, Canada; 2) Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada; 3) Department of Psychiatry, University of Toronto, Toronto, ON, Canada; 4) Department of Pharmacology, University of Toronto, Toronto, ON, Canada; 5) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA; 6) VA Pittsburgh Health System, Geriatric Research Education and Clinical Center, Pittsburgh, PA, USA; 7) Healthy Mind Lab, Department of Psychiatry, Washington University, St. Louis, MO, USA.

**Background.** In geriatric depression, antidepressant treatment response is often slow and incomplete. Therefore, biomarkers are needed to personalized treatment approaches. We conducted a GWAS for late-life depression remission after antidepressant treatment and leveraged post-hoc, gene-based/network approaches to understand the genetic architecture of antidepressant response. **Methods.** We included 307 older adults (>60 years) with MDD and treated with venlafaxine XR for 12 weeks. A standard GWAS was conducted for post-treatment remission status, followed by *in silico* biological characterization of associated genes. We conducted gene-based association using MAGMA for 17,651 genes. Subsequently, we explored tissue specificity for differentially expressed genes using RNA-seq expression data from 53 specific tissues from GTEx. For biological pathway enrichment, we explored gene sets from KEGG, GO, Reactome, and BioCarta. To further understand venlafaxine remission in the context of protein interactions, we conducted protein-protein interaction (PPI) network analysis using experimentally validated data for PPIs from the STRING Interactome. **Results.** We extracted 886 genes found to be associated with remission prior to correction for multiple testing ( $p < 0.05$ ). At the gene level, there was a significant over-representation of genes expressed in whole blood (FDR adjusted,  $p = 0.04$ ). Although there was no significant enrichment of differentially expressed genes, we observed down-regulation in the anterior cingulate cortex, frontal cortex and the spinal cord (unadjusted  $p < 0.05$ ). We observed a nominal association (unadjusted  $p < 0.05$ ) of intracellular signaling networks including (1) Biocarta ErbB2, TNFR2, and  $\beta$ -arrestin; (2) KEGG ErbB and neurotrophin; and (3) Reactome EGFR. Our PPI network analysis found 1 core network, consisting of 312 seeds, 711 interacting proteins, and 1730 overall interactions. The ten central 'hub' proteins included UBC, EGFR, GRB2, PIK3CA, CDK5, APP, RPA1, IKBKB, RAF1 and NCOR1 which have previously associated with AD and MDD. This subnetwork showed significant enrichment for signaling pathways including neurotrophins, ErbB, MAPK, and Wnt ( $p < 5.0e-07$ ). **Conclusions.** Overall, our post-GWAS analyses support the involvement of known processes in synaptic plasticity, as well as, intracellular signaling pathways including MAPK and neurotrophins (e.g., BDNF) as being potentially involved in venlafaxine treatment remission in older adults.

**GRM8 association with response to antipsychotic iloperidone treatment.** M. Polymeropoulos, S. Smieszek, C. Polymeropoulos. Vanda Pharmaceuticals, DC, DC.

In order to understand the pharmacogenomic basis of response to iloperidone treatment administered to schizophrenia patients, we conducted a genome-wide association study. Genotypes of 205 patients were utilized to evaluate the treatment with antipsychotic iloperidone. Using linear regression, we have directly tested the association between SNPs and PANSS-T (day 28), correcting for essential covariates including principal components. We identified SNPs associated with iloperidone efficacy in the Glutamate Metabotropic Receptor 8 (GRM8), top variant: rs13222700 ( $P < 1 \times 10^{-6}$ ). Metabotropic glutamate receptor type 7 (GRM7) and type 8 (GRM8) are involved in the neurotransmission of glutamate which is supposed to play an important role in the development of schizophrenia and major depressive disorders. Minor allele associates with lower PANSS-T, effect observed in treated and not the placebo MAF in pop (Include). Furthermore there is a significant association (pval 0.0008) of the rs13222700 with MR (ilo+88)/95, where the minor allele seems to be a marker for slow metabolizers. Furthermore, Haploreg v4.1 was used to investigate the regulatory potential. In accordance the identified locus maps to an enhancer region. It shows evidence of changed motifs for STAT and Sox. Furthermore, analysis of a library of transcription factor binding site position weight matrices predicts that the SNP alters the binding site via 6 transcription factors sites. The locus has been shown to be a significant (0.00008) eQTL for GRM8 and there are 2 other strong loci. In addition, we confirmed variants previously reported in NPAS3. To investigate further we conducted a logistic regression based on binary cutoffs at PANSS 30 and on the top ends of the distribution logistic model, splitting dataset into two groups, robust responders ( $\geq 30$  PANSS-Tchange) vs weak ( $< 20$  PANSS-Tchange). GRM8 signal was present. Other top loci directed us NRXN3, GRIP1, NPAS3, SHANK2, NTRK2. To leverage the top results we conducted enrichment analysis which showed enrichment in categories such as regulation of neurotransmitter levels (GO:0001505), regulation of glutamate secretion GO:1903294, impaired synaptic plasticity (P-value: 0.00001), hyperactivity: NTRK2 (0.0002), decreased prepulse inhibition (0.0009). The study provides greater understanding of the variability in treatment response and may lead to further optimization of the benefit to risk ratio for the affected patients. .

**2458T****A genome-wide association study of emotion recognition and theory of mind.**

*M.R. Woodbury-Smith<sup>1,2</sup>, P. Szatmari<sup>2,3</sup>, S.W. Scherer<sup>2,4</sup>, A.D. Paterson<sup>2,5</sup>.*

1) Newcastle University, Newcastle upon Tyne, United Kingdom; 2) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, ON, Canada; 3) Division of Child and Youth Mental Health, University of Toronto, Toronto, ON, Canada; 4) McLaughlin Centre for Molecular Medicine, University of Toronto, Toronto, ON, Canada; 5) Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada;.

Our capacity to negotiate the complex social world is mediated by numerous brain mechanisms working together. At a neuropsychological level, there is evidence for genetic contributions for several of these mechanisms. The Avon Longitudinal Study of Parents and Children (ALSPAC) has collected data on two such neuropsychological domains, emotion recognition and theory of mind (ToM), in more than 5,000 typically developing children (M:F ~ 1:1), who have also been genotyped with imputation to the 1000 genomes project. We have undertaken a genome-wide association study (GWAS) of both of these traits. Previously, genome-wide significant signals for ToM have been published from 23andMe data (N ~80,000). Using non-imputed SNPs, genome-wide estimation of heritability was ~5-7% for both traits, with very little shared heritability. Three loci with suggestive evidence of association for emotion recognition were identified; these did not overlap the published 23andMe results for ToM. GWAS of ToM in ALSPAC identified five signals at the suggestive level of significance; these also did not overlap with the published ToM results, or with the ALSPAC emotion recognition signals. Our results suggest unique rather than shared genetic mechanisms for these two traits, and a number of loci that may harbour genes underlying social cognition have been identified. Our study therefore has important implications for the understanding of the genetic underpinning of everyday social interaction.

**2459F****Causal network relationships of multiple brain structure and behavior phenotypes based on BSNIP genetic association data.**

*Y. Xia<sup>1,2</sup>, N. Alliey-Rodriguez<sup>3</sup>, M. Keshavan<sup>4</sup>, G. Pearson<sup>5</sup>, B. Clementz<sup>6</sup>, J. Bishop<sup>7</sup>, C. Tamminga<sup>8</sup>, P. Buckley<sup>9</sup>, J. Sweeney<sup>10</sup>, C. Chen<sup>2</sup>, E. Gershon<sup>3</sup>, C. Liu<sup>1</sup>, BSNIP consortium.* 1) Department of Psychiatry, SUNY Upstate Medical University, Syracuse, NY; 2) Center for Medical Genetics, School of Life Sciences, Central South University, Changsha, Hunan, China; 3) Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL; 4) Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA; 5) Olin Neuropsychiatry Research Center, Institute of Living, Hartford Hospital, Hartford, CT; 6) Psychology Department, Psychology Building University of Georgia Athens, Georgia; 7) PHARM Experimental&Clin Pharm, College of Pharmacy, University of Minnesota, Minneapolis, MN; 8) Paul M. Bass Administrative and Clinical Center, Dallas, Texas; 9) VCU School of Medicine, Richmond, VA; 10) Department of Psychiatry, UT Southwestern Medical Center in Dallas, Texas.

Developing quantifiable intermediate neurobiological and behavioral phenotypes (Phenos) for reclassification of psychiatric disorders has attracted much attention. However, the genetic contribution to these Phenos and the causal relationship among them remain unknown. Illustrating the genetic contribution and causal relationship among the Phenos will present an opportunity for understanding the etiology of the disease. The Bipolar and Schizophrenia Network for Intermediate Phenotypes (B-SNIP) consortium collected 1,115 unrelated individuals along with genetic analysis on 463 extensive Phenos from clinical and behavioral interview data, brain structural magnetic resonance imaging, diffusion tensor imaging data. To estimate the heritability of the Phenos and the causal relationship among them, MR-base platform was used. We found 121 Phenos with the estimated heritability larger than 0.2 while 78 Phenos with at least one genome-wide significant SNP, involving 231 SNPs. Among the 231 SNPs, 42 SNPs are in hub genetic factors which are defined as SNPs achieve significance in more than two Phenos. Combining with brain QTL data from multiple resources, we found 27 out of the 42 SNPs are also eQTL SNPs. Genetic similarity results showed that 17 out of the 78 Phenos were highly correlated ( $r > 0.6$ ,  $p < e-5$ , corrected for 3,003 tests). We found 61 Phenos pairs with significant causal effect ( $p < e-4$ , corrected for 272 tests). We built up a directional Phenos network based on the causal results. Two Phenos (white matter cortical volumes from the left frontal pole and right entorhinal C.) were the root Phenos, which only have a causal effect on the others. Four Phenos (grey matter thickness of right insula, cortical gyrification indices of superior parietal and fusiform, grey matter of left postcentral) are top Phes with no causal effect to other Phenos. Meanwhile, the cortical gyrification indices of left paracentral, precentral, postcentral, frontal pole, superior frontal, and rostral middle frontal are middle Phenos, which means they are both products and contributors of the causal effect to each other. This is an investigation for genetic contribution and causal effect of the brain and behavior related Phenos. We identified brain and behavioral quantitative traits that are genetically influenced. We further illustrated the causal relationships among Phenos, which suggests the basis for genetic dissection and developmental biology of psychiatric disorders. .

**Predicting the genetic regulation of schizophrenia in African American populations.** *P.N. Fiorica<sup>1,2</sup>, H.E. Wheeler<sup>2,3</sup>*. 1) Department of Chemistry and Biochemistry, Loyola University Chicago, Chicago, IL; 2) Department of Biology, Loyola University Chicago, Chicago, IL; 3) Department of Computer Science, Loyola University Chicago, Chicago, IL.

Due to the dearth of genomic studies in people of recent African ancestry, determining the transferability of genetic association study results across populations has been challenging. Recent African ancestry populations have more genetic variation than European and Asian populations. Adding to the complexity of analysis, African American genetic ancestry is usually admixed, including chromosome blocks of both West African and European ancestry. This genetic variation, combined with environmental variation, may lead to differences in the way people in these populations express complex traits. Specifically, neuropsychological disorders, such as schizophrenia have been determined to be heritable diseases regulated by many loci. In a cohort of 2,220 African American (1241 Cases-979 Controls) individuals acquired from the Genetic Association Information Network, we performed genotype quality control, principal component analysis, imputation, and a case-control GWAS for schizophrenia. No SNPs significantly associated with schizophrenia susceptibility in this cohort. In addition to using SNP-level association tests, we performed PrediXcan, a gene-based association method for trait mapping using transcriptome prediction models from all 44 tissues of the GTEx Project. PrediXcan measures association between genetically regulated levels of expression and the targeted phenotype. Additionally, by associating a phenotype with the predicted level of expression, we can use PrediXcan to identify the direction of effect of each gene. In doing so, we identified significantly associated levels of predicted expression for three genes: increased expression of *SMPD3* (Bonferroni adjusted  $P=0.043$ ) and decreased expression of *ZBTB1* ( $P=0.040$ ) and *DHH* ( $P=0.022$ ) associated with schizophrenia susceptibility. None of these genes have been reported in the NHGRI-EBI GWAS Catalog to be associated with schizophrenia, but they were associated with schizophrenia in a meta-analysis of the Psychiatric Genomics Consortium data in gene2phenotype.org, thus highlighting the advantages of PrediXcan application to smaller cohorts in comparison to GWAS. Furthermore, due to a lower multiple tests burden, PrediXcan was able to identify significant associations, where a traditional GWAS could not. These results augment previous data identifying the potential for PrediXcan to be used as a superior method for identifying genetic susceptibility compared to other genetic association tests.

## 2461T

**Study of alcohol metabolizing genes (ADH1C and ALDH2) polymorphism in alcohol dependence. A case control study from India.** *B. Shankarappa<sup>1,2</sup>, S. Byrappa<sup>2</sup>, R. Chandra<sup>2</sup>, M. Purushottam<sup>2</sup>, S. Jain<sup>2</sup>, P. Murthy<sup>2</sup>*. 1) Department of Psychiatry, St Johns Medical College Hospital, Bangalore, 560034, India; 2) Molecular Genetics Lab, Department of Psychiatry, National Institute of Mental Health and Neurosciences, Bangalore, 560029, India.

**Aim:** □ To study the association of ADH1C(rs698) and ALDH2 (rs671) polymorphism in alcohol dependent subjects compared to controls. **Background:** Alcohol dependence (AD) is a major public health problem affecting many people and families. It is a risk factor for many health problems and several neuro-psychiatric syndromes. The symptoms of alcohol withdrawal can vary from being relatively mild, to being severe, such as Delirium tremens (DT) and seizures (SZ). Alcohol dehydrogenase (ADH) and Aldehyde dehydrogenase (ALDH) are enzymes involved in alcohol metabolism. Alcohol is converted to acetaldehyde by ADH then to acetic acid by ALDH. Km of the ADH1C is very high; In-vitro, in presence of hydrophobic substance its activity increases, which is useful for the first pass metabolism. Polymorphisms of these enzymes are known to play a role in alcohol dependence. ADH1C\*1 allele is more active (2.5 fold) than ADH1C\*2. **Method:** Male participants were selected from patients seen at the Centre for Addiction Medicine, NIMHANS. Individuals who met the criteria for alcohol dependence (ICD 10) were recruited into the study after obtaining informed consent. The clinical instruments applied included SAGA-IV, SADQ, MINI, FHAM and RCCL1 for alcoholic liver disease. In the present study ALDH2 SNP was studied in AD (N=223) and controls (N=150) and ADH1C polymorphism among AD subjects (N=335) and age matched controls (N=150). Of these AD subjects there were some who had experienced DT (N=154) and others who had not (N=178). DNA isolated from the peripheral blood was used for genotyping. Taqman assay and PCR-RFLP method was used for genotyping. **Results:** Genotype and allele frequencies did not differ between AD subjects and controls. The ADH1C\*2 allele frequency ( $*2=0.48$ ;  $P=0.03$ ) was significantly higher in AD with DT compared to AD without DT. The less active allele, ADH1C\*2, was more prevalent in the those who experienced DT. ALDH2 polymorphism was monoallelic in both the groups. **Discussion:** ADH1C activity is known to be dynamically regulated through induction or kinetic activation. The ADH1C\*2 allele has a higher Km for alcohol (6.5) with lower activity. Occurrence of ADH1C\*2 could be associated with a deleterious change in acetaldehyde concentration during withdrawal. It is interesting that we have found higher frequency of ADH1C\*2 allele in AD subjects with DT. Studying other SNPs of ADH1C & ALDH2 might further help to understand the phenomenon better. .

**Identification of risk genes in sub-threshold genome-wide association study loci in schizophrenia.** R. Chen, Q. Wang, Y. Ji, Q. Wei, H. Yang, X. Zhong, B. Li. Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN.

Genome-wide association studies (GWAS) have identified numerous genetic variants associated with human complex traits/diseases, however translating the findings into understanding is a big challenge. A reason is that genetic architecture of complex traits/disease is far to be comprehensive due to the discovery power. Most complex traits/diseases involve in a large number of genetic risk contributors and each accounts for a modest effect, which require a large sample size to achieve an adequate power in GWAS. Although consortium-level collaboration has greatly overcome the issue, the discovered variants only explain a modest proportion of heritability. Many plausible associations almost reach whole genome significance are neglected. Another reason is that most associating variants are located in non-coding regions and exert effects in regulatory ways. Identifying genes that variants manifest on is still challenging. Emerging evidence shows that genetic association can be validated by biology evidence, so integration of multiple lines of evidence should help identifying high confidence risk genes from a set of GWAS loci. In this study we applied a network-based framework by the integration of multiple dimension data to identify risk genes from sub-threshold GWAS loci (subGWAS) leveraging the information from significant GWAS loci (sigGWAS) and then use the extended gene list to gain new insights about the etiology of schizophrenia. Our results show that subGWAS loci are enriched for signals: 1) subGWAS loci from PGC enrich heritability in an independent cohort; 2) Many subGWAS loci reach the whole genome significance in the following larger sample size study. We also found that the high confidence genes (HRG) identified from subGWAS were enriched in risk signals: HRG explained more heritability than a local background and enriched in previously schizophrenia-associating gene sets, like miR137 target genes; shows tissue specificity in brain and higher expression in prenatal brain; defects of HRG showed central nervous system phenotypes in mouse. Studies have established that psychiatric disorders share genetics at variant level but not at gene level because it's hard to identified risk genes from other disorders like bipolar and major depression given their GWAS is behind schizophrenia. Using more candidate genes from subGWAS loci, we aimed to explore the sharing of these disorders at gene level to advance our knowledge of psychiatric disorders.

Recent studies have reported cases of partial chromosomal deletions or duplications in children with language impairment and dyslexia [1, 2]. These copy-number variations (CNVs) involved genes with relevance for neurodevelopmental traits. The purpose of the present study was to validate these findings and to investigate possible gene-brain-phenotype associations. In a sample of 21 children with carefully phenotyped language impairment and/or dyslexia and 54 typical controls, DNA was genotyped with the Illumina Human PsychArray-24 v1.1. CNVs were detected by consensus of at least two of three hidden-Markov model algorithms using the online service CNV-Webstore. Results were filtered against a list of 107 candidate genes and regions compiled from previous reports of CNVs as well as single nucleotide variants thought to influence language functions. Gene expression levels in brain tissue across the lifespan were obtained from the Genotype-Tissue Expression and the Human Brain Transcriptome databases. CNVs overlapping with four previously reported CNVs were found. Heterozygous deletions overlapping with *DNAH14*, *CNTNAP2*, and *CTNNA3* were found in five children with language impairment and/or dyslexia. A heterozygous duplication overlapping with parts of *OTUD7A* and *CHRNA7* was found in one child with dyslexia. Most severe phenotypes involved the *CTNNA3* deletion. Only one typical control child had a CNV of interest, in this case a deletion involving *DNAH14*. These findings thus validate previously published CNV results. A look at gene expression levels in the brain across the lifespan shows that four of the five genes of interest in this study (the exception is *CHRNA7*) are highly expressed in the cerebellum during early prenatal development. Most striking prenatal cerebellar expression patterns were found for *CTNNA3*. These findings are consistent with the recent literature on cerebellar involvement in linguistic functions including spoken and written language processes [3]. References 1. **2464T****A new phenotyping algorithm for identifying cases of developmental language disorder in large-scale electronic health record systems.**

*C.E. Walters*<sup>1,5</sup>, *K. Margulis*<sup>2,5</sup>, *J.E. Below*<sup>3</sup>, *N.J. Cox*<sup>3</sup>, *S.M. Camarata*<sup>2</sup>, *R.L. Gordon*<sup>4,3,5</sup>. 1) Neuroscience Program, Vanderbilt University, Nashville, TN; 2) Dept. of Hearing & Speech Sciences, Vanderbilt University Medical Center, Nashville, TN; 3) Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville, TN; 4) Dept. of Otolaryngology, Vanderbilt University Medical Center, Nashville, TN; 5) Program for Music, Mind & Society at Vanderbilt, Nashville, TN.

Developmental language disorder (DLD), also known as specific language impairment, is a heritable communication disorder characterized by language acquisition delay and difficulties with grammar and vocabulary. Despite its high prevalence in the population (7% of children) and heritability, prior GWAS of DLD have been characterized by small sample sizes. The aim of this study is to utilize an electronic health record (EHR) phenotyping approach as a first step towards large-scale GWAS of DLD. We developed a phenotyping rubric to identify cases of DLD in EHRs in a major biobank based in an academic medical center. Our initial search retrieved a set of 983 EHRs containing the following ICDs: 315.32/F80.2 (mixed-expressive receptive language disorder), 315.31/F80.1 (expressive language disorder), and 315.39/F80.89 (other developmental language disorders) and that have genetic data on file; cases were excluded from the initial search where hearing loss, intellectual disability, or chromosomal anomalies were indicated. Manual review was then performed on the EHRs to sort them into one of four categories: Category 1 consists of cases of DLD when no other medical condition that could be related to the DLD is present (normal childhood illnesses such as asthma might be present). Category 2 includes cases of DLD co-occurring with a major medical problem that is not thought to cause the DLD (e.g. diabetes, but not neurodevelopmental disorders). Therefore, cases in Categories 1 and 2 (marked for inclusion) had no other medical condition is thought to share a biological basis with DLD is indicated. Category 3 (neurological) and Category 4 (trauma) consisted of co-morbid or already present conditions that could have caused the DLD, and were marked for exclusion. Results of manual review showed that N=481 (49%) of the records met inclusion criteria (Categories 1 and 2). Automation of the algorithm, solely using ICD codes, to sort the EHRs into the four categories is underway using the KNIME programming tool. The preliminary analysis shows 75% positive predictive value of the automated algorithm for determining inclusion vs. exclusion when compared to the manual coding. Ongoing work is focused on improving the performance of the automated algorithm. This groundwork will facilitate the future direction of the study, in which we plan to validate the algorithm in biobank data (>2000 records) from multiple sites and conduct a full GWAS on associated genetic data.

**2465F****Assessment of associations between mitochondrial DNA haplogroups and attention deficit and hyperactivity disorder in Korean children.**

*I.W. Hwang*<sup>1</sup>, *S.H. Han*<sup>1</sup>, *B.N. Kwon*<sup>1</sup>, *H.J. Kim*<sup>1</sup>, *N.R. Lee*<sup>1</sup>, *M.H. Lim*<sup>2</sup>, *H.J. Kwon*<sup>3</sup>, *H.J. Jin*<sup>1</sup>. 1) Biological sciences Dept, Dankook University, Cheonan, South Korea; 2) Psychology and Psychotherapy Dept, Dankook University, Cheonan, South Korea; 3) Preventive Medicine Dept, Dankook University, Cheonan, South Korea.

Attention deficit hyperactivity disorder (ADHD) is a multifactorial disorder with multiple environmental and genetic factors. Until now, many genetic variants have been reported to be associated with ADHD, but there are no reports pertaining to the genetic association between mtDNA haplogroups and ADHD. Therefore, we performed an mtDNA haplogroup analysis of a total of 472 Korean children. The 20 East Asian specific mtDNA haplogroups were determined using the SNaPshot assay. We also sequenced the displacement loop (D-loop) region, position 15,971–613. Our results showed that haplogroup B4 was significantly associated with ADHD (OR, 1.90; 95% CI, 1.055 – 3.429;  $p = 0.031$ ). Marginally significant association with ADHD was found in haplogroup B5 (OR, 0.26; 95% CI, 0.059 – 1.139;  $p = 0.041$ ), and a similar result was also observed in boys diagnosed with ADHD (OR, 0.17; 95% CI, 0.022 – 1.340;  $p = 0.048$ ). Compared with the girls, those with ADHD carried an excess of the haplogroup D4b (OR, 4.83; 95% CI, 1.352 – 17.272;  $p = 0.014$ ). Stratified analysis of subtypes also showed significant results (combined: haplogroup B4,  $p = 0.007$ ; inattentive: haplogroup F,  $p = 0.022$ ). In the BASC-2 analysis, haplogroup D4 was significantly associated with adaptive scales ( $p < 0.05$ ). Our results showed a possible role of mtDNA haplogroups in the genetic etiology of ADHD and ADHD symptoms in Korean children.

**2466W**

**Comparative prevalence of copy number variation in common childhood neurodevelopmental disorders.** *J.N. Kapalanga<sup>1,2</sup>, S. Vanderstell<sup>1</sup>, H. Ahmad<sup>2</sup>.* 1) Paediatrics, Western University, Owen Sound, Ontario, Canada; 2) Paediatrics, McMaster University, Hamilton, Ontario, Canada.

CNV have been observed in neurodevelopmental disorders (NDD) in past studies and many pathogenic variants are shared among certain NDD. In pediatric practice, patients with a certain constellation of behavioral, emotional, cognitive and social difficulties are investigated by microarray as a first-tier test to determine a diagnosis. In the majority of cases the clinical constellation is consistent with a pre-test differential diagnosis that includes four NDD, viz; ADHD, FASD, ASD, and FXS. While prenatal alcohol exposure is the known cause of FASD and mutations in the FMR gene are the known causes of FXS, a single cause has not been identified in ADHD and ASD. And yet a large number of patients with a diagnosis of any of the four NDD share a common phenotype. Studies have suggested that many pathogenic CNVs are shared among NDD. This suggests that certain CNVs play an important role in an etiopathogenetic mechanism resulting in a shared phenotype. The purpose of this study is to: 1) determine the prevalence of CNV in ADHD, FASD, ASD and FXS patients with a shared constellation of behavioral, emotional, cognitive and social relatedness clinical features, 2) to determine whether any specific CNVs are shared across diagnoses 3) to determine whether any shared CNVs are pathogenic, and to compare the findings with data from other studies. As described previously a multicenter and multiclinic patient sample, of 89 FASD, 98 ADHD, 79 FXS and 82 ASD patients aged 6 to 18 and 50 controls were studied. We performed genomic arrays using the Illumina BeadChip platform employing Infinium cytoSNP-850K v1.1 array type. The data was analyzed by the BlueFuse Multi 4.3 software. We compared the prevalence of CNV between the patients with NDD, and controls. We report that the prevalence of CNV was 9, 13, 11, 7.8 % in ADHD, FASD, ASD and FXS patients, respectively, compared to 5% in controls ( $P < 0.05\%$ ). For FXS the full mutation and premutation CNV were excluded in the count. The CNV were found throughout the genome with no hot spots at any one region. We compared our findings with data from large sample studies. We identified known disease loci and loci not previously reported. Although CNVs are commonly found in normal individuals, the finding of significantly higher CNV prevalence across NDD with a shared phenotype suggests that the CNVs identified in the patient group, play some role in disease etiopathogenesis. This is in agreement with previous studies.

**2467T**

**ABCC1 genetic variation and antiepileptic mood stabilizer pharmacoresistance in bipolar disorder.** *J.M. Biernacka<sup>1,2</sup>, B. Coombes<sup>1</sup>, A.M.-C. Ho<sup>3</sup>, B. Larrabee<sup>1</sup>, M. Nassan<sup>2</sup>, B. Singh<sup>2</sup>, C. Colby<sup>1</sup>, S. McElroy<sup>4</sup>, M. Frye<sup>2</sup>.* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Department of Psychiatry & Psychology, Mayo Clinic, Rochester, MN; 3) Department of Molecular Pharmacology & Experimental Therapeutics, Mayo Clinic, Rochester, MN; 4) Lindner Center of HOPE/University of Cincinnati, Cincinnati, Ohio.

Bipolar disorder (BD) is a highly heritable psychiatric disorder characterized by recurrent episodes of mania/hypomania and depression. BD is treated with various medications including certain anti-epileptic drugs (AEDs), such as valproate and lamotrigine, which have mood stabilizing effects. However, AED mood stabilizers (AED-MSs) do not lead to symptom improvement in all BD patients. We investigated the pharmacogenomics of AED-MSs by performing a genome-wide search for genetic variants associated with response to AED-MSs in BD. We used clinical and genetic data from 199 participants in the Mayo Clinic Bipolar Disorder Biobank with retrospectively defined clinical response to AED-MSs. Response to AED-MSs was quantified using the total Alda score, a semi-quantitative metric of clinical improvement. Of the 199 patients with AED-MS Alda scores, most had an Alda score for divalproex/valproate ( $N=110$ ) or for lamotrigine ( $N=99$ ), with a small proportion representing other AED-MSs including carbamazepine and oxcarbazepine. Gene-level tests of association were performed using MAGMA. These gene-level analyses identified two genes significantly associated with AED-MS response: *DISP1* ( $p=7.8E-07$ ) and *ABCC1* ( $2.0E-06$ ). *ABCC1* is a member of the ATP-binding cassette (ABC) gene family, which encode a set of ABC transporters that play a significant role in drug disposition and response. Various studies have implicated these transporters in epilepsy pharmacoresistance, but little is known about their contribution to AED-MS response in BD. Further analyses of our data showed that the gene-level finding was driven largely by two SNPs: rs875740 ( $p\text{-value} = 3.3 \times 10^{-6}$ ) and rs35590 ( $p\text{-value} = 3.8 \times 10^{-6}$ ). Application of PrediXcan to test the association of clinical phenotype with tissue-specific gene expression estimated from SNP data also demonstrated association of *ABCC1* with AED-MS response and indicated that higher gene expression is associated with worse treatment outcomes (whole blood:  $\beta = -2.2$ ,  $p = 0.009$ ). These findings are highly consistent with the drug transporter hypothesis in AED research, which proposes that overexpression of ABC transporters contributes to non-responsiveness. While our results warrant replication and follow-up in independent samples, the observed association of *ABCC1* genetic variation with AED-MS response suggests a pharmacokinetic role of *ABCC1* in response to these medications in the treatment of BD.

**2468F**

**Common variants derived from PGC GWAS on schizophrenia have limited power to contribute to the treatment response or resistance to antipsychotic drugs.** J. Li. Department of Psychiatry, Northwestern University, Chicago, IL.

**Background:** Drug targeted gene-set enrichment analysis support polygenic overlap between pathogenesis of schizophrenia and mechanism of action of antipsychotic drugs (Ruderfer DM et al. 2016). However, whether this accumulated genetic burden for SCZ confers increased risk for treatment response or resistant has not been determined. Many of genetic markers identified from pharmacogenomics studies of ours (Li, J et al 2018) or others (e.g. Stevenson J, et al. 2016) have been linked to schizophrenia or other psychiatric disorders. **Method:** The purpose of this study is 1) to determine whether SCZ risk loci identified by the PGC GWAS, individually and collectively by creating polygenic risk scores (PRS), had a significant effect on predicting treatment response to antipsychotic drugs in a combined dataset of three double-blind registration trial of lurasidone; 2) to test the association between PRS and treatment-resistant schizophrenia (TRS) in an independent cohort of TRS and Non-TRS (Li J et al. 2014), the phenotype of which was determined by is operationally defined as persistence of moderate to severe positive symptoms despite two or more trials of 4–6 week duration with typical or atypical APDs other than clozapine. **Result/Conclusion:** Some SNPs showed a nominal association with  $\Delta$ PANSS-TOT<sub>LOC<sub>FBWK</sub></sub> ( $p < 0.05$ ), but none survived Bonferroni correction. The alleles, from those SNPs annotated for *CACNA1C*, *TCF4*, *SNAP91*, '12q24', '17p11' which showed increased risk for SCZ, were associated with a poor response to lurasidone. Alleles from those loci at *SNX19*, '3p21', '1q21', which showed increased risk for SCZ, were associated with a better response to lurasidone. Although we observed a trend for an association between PRS and treatment response with increased overall SCZ risk having poor response to lurasidone ( $\beta > 0$ ), particularly in  $\Delta$ PANSS-POS ( $p < 0.05$ ), this association did not consistently show a statistical significance throughout all levels of partitions of genetic loci, suggesting that the common variants for SCZ risk identified by PGC GWAS, collectively, have limited power to predict response to lurasidone. No significant association between the PRS and Treatment-Resistant Schizophrenia in an independent cohort of TRS vs NTRS. This was consistent with the result from others (Wimberley T et al. 2017), suggesting that the polygenic risk score has limited power to predict the treatment response or resistant to antipsychotic drugs at the individual patient level.

**2469W**

**MR-PheWAS: Causal association between depression and multiple diseases outcome using depression genetic variants as instrument.** A. Mu-lugeta<sup>1,2</sup>, A. Zhou<sup>1</sup>, E. Hypponen<sup>1,3,4</sup>. 1) Australian Centre for Precision Health, University of South Australia Cancer Research Institute, Adelaide, Australia; 2) Department of Pharmacology, School of Medicine, College of Health Science, Addis Ababa University, Addis Ababa, Ethiopia; 3) Population, Policy and Practice, UCL Great Ormond Street Institute of Child Health, London, UK; 4) South Australian Health and Medical Research Institute, Adelaide, Australia.

**Background:** Depression has profound effects on an individual's life but evidence relating to the causal effects on health is limited. Previous studies on causal prediction challenging due to confounding and reverse causation. The aim of this study is to explore the causal association between depression and a range of disease outcomes using linked data on hospitalisations and mortality in the UK Biobank. **Methods:** We performed hypothesis-free phenome-wide association analyses using depression genetic risk score (GRS) on 925 disease outcomes using data from 337,536 participants in the UK Biobank. GRS – disease outcome associations passing the multiple-test corrected significance threshold ( $P < 0.0019$ ) were followed by Mendelian randomization (MR) analyses. MR analyses were conducted using inverse-variance weighted MR (MR IVW), weighted median MR and MR-Egger. We conducted multiple sensitivity analyses, including identification of potential pleiotropic variants through running phenome-wide association analysis of each depression variants. **Results:** Depression GRS was associated with 42 distinct disease outcomes in the phenome-wide association analysis, with MR IVW analyses supporting a possible causal link between depression and 36 of these disease outcomes. As expected, GRS was strongly associated with depression diagnosis and mood disorders ( $P < 8.5 \times 10^{-14}$ ), with signals also seen for related co-morbidities including anxiety (OR 1.89, 95%CI 1.50 to 2.38,  $P = 6.5 \times 10^{-8}$ ), and sleep disorders (OR 1.59, 95%CI 1.27 to 1.98,  $P = 4.9 \times 10^{-6}$ ). There was evidence for a causal effects on cardiovascular diseases including IHD (OR 1.30, 95%CI 1.15 to 1.47,  $P = 4.0 \times 10^{-3}$ ) and atherosclerosis (OR 1.28, 95%CI 1.10 to 1.48,  $P = 1.4 \times 10^{-3}$ ), and disorders of lipid metabolism like hypercholesterolemia (OR 1.22, 95%CI 1.12 to 1.34,  $P = 1.6 \times 10^{-6}$ ). GRS also suggested associations with several disorders of the digestive system (including diseases of oesophagus (OR 1.30, 95%CI 1.17 to 1.46,  $P = 3.3 \times 10^{-6}$ , and gastrointestinal haemorrhage (OR 1.26, 95%CI 1.11 to 1.43,  $P = 3.5 \times 10^{-4}$ ) and asthma (OR 1.23, 95%CI 1.06 to 1.44,  $P = 6.2 \times 10^{-3}$ , as well as associating with symptoms/disorders of urinary system (OR 1.36, 95%CI 1.19 to 1.56,  $P = 9.2 \times 10^{-6}$ ). **Conclusion:** This finding may help policymakers implement early detection and management strategies of depression for preventing other diseases occurrence.

**Whole genome sequencing analysis identifies multiple candidate variants in a family with autism spectrum disorder.** K. Calli<sup>1</sup>, Y. Qiao<sup>1</sup>, R.K.C. Yuen<sup>2</sup>, R.M. Stowe<sup>3</sup>, S. Martell<sup>1</sup>, C. Chijiwa<sup>1</sup>, E. Rajcan-Separovic<sup>1</sup>, S.W. Scherer<sup>2</sup>, M.E.S. Lewis<sup>1</sup>. 1) Medical Genetics, University of British Columbia (UBC), Vancouver, British Columbia, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Psychiatry and Medicine (Neurology), UBC, Vancouver, British Columbia, Canada; 4) Pathology and Laboratory Medicine, UBC, Vancouver, British Columbia, Canada.

Whole genome sequencing (WGS) has been more widely used as a tool in the clinical diagnosis and it helps increase the diagnosis rate up to 20% in autism spectrum disorders (ASDs). Thus far, more than 100 genes and CNV loci have been reported to be associated with ASD susceptibility. However, none are found in >1% of cases with ASDs, suggesting a diverse genetic heterogeneity of the disorders. We have recruited >700 families with simplex and multiplex ASD and are performing chromosome microarray and whole genome sequencing studies as part of the iTARGET Autism project (<http://www.itargetautism.ca/>) and the MSSNG project (<https://www.mss.ng/>). Using WGS in a trio ASD family in combination with internal bioinformatics pipelines and a commercial software VarSeq, we identified 4 inherited rare damaging missense single nucleotide variants (SNVs) in 4 genes (DNMT3A, PHF2, NRXN2, and SNRPN), and one rare copy number variant (CNV). The CNV is a paternally inherited 14 Kb microdeletion in ZNF517, which is also confirmed by DNA microarray. The variants in DNMT3A and SNRPN were also confirmed by Sanger sequencing. Clinically, the male proband has ASD, moderate intellectual disability, developmental delay, verbal apraxia, post-natal macrocephaly, large stature, adult-onset epilepsy (age 22 years), and mild facial dysmorphism (round facies, bitemporal narrowing, narrow palpebral fissures, low-set and protuberant ears, hypotonia, high arched palate). Neither parent has intellectual disability or ASD, though the father has macrocephaly and over-growth. All of the genes involved in these rare variants and CNV are reported to be ASD-related and involved in brain/neuron development. De novo mutations in the above SNV genes and a recurrent deletion in ZNF517 gene have been identified in cases with ASDs. In our proband, mutations in DNMT3A, PHF2, and SNRPN are paternally inherited while NRXN2 is maternal. DNMT3A is a newly identified ASD candidate gene and its mutation is associated with Tatton-Brown-Rahman Syndrome. Some of the phenotypes are shared in our proband. Functional analysis is in progress including whole transcriptome analyses. Conclusion: DNMT3A is likely the most relevant gene accounting for both ASD and features concordant with Tattan-Brown-Rahman syndrome. Alternatively, our subject's ASD phenotype reflects a collection of quantitative phenotypic traits associated with each of the multiple ASD risk genes identified and its complex genetic origins.

**Targeted sequencing of postsynaptic protein genes associated with schizophrenia: A role for multiple rare risk mutations in schizophrenia susceptibility.** M. Cheng, T. Hu, S. Hsu, H. Tsai, S. Tsai. Yuli Branch, Taipei Veterans General Hospital, Hualien County, Taiwan.

Schizophrenia is a chronic debilitating mental disorder with a high genetic component in its etiology. It is a neurobiological disorder with aberrant synaptic connectivity and synaptogenesis. Postsynaptic scaffolding proteins in the NMDA receptor-postsynaptic signaling complexes play a crucial role in regulating the synaptic transmission and the functions of various synaptic receptors. Genes involved in the formation and functional integrity of synapses can be considered as the candidate genes for schizophrenia. This study aims to identify the rare and pathogenic mutations of postsynaptic protein genes in patients with schizophrenia. We sequenced the exon regions of 18 genes encoding the synaptic proteins that belong to DLGAP, NRXN, NLGN, SHANK, and HOMER family in 98 schizophrenia patients on the Ion PGM system. We identified 50 missense heterozygous mutations, and *in silico* analysis showed some of these mutations were damaging or pathological to the protein function. Ten missense mutations, *DLGAP3*:p.H22N; *DLGAP3*:p.G352E; *DLGAP3*:p.S455R; *NRXN2*:p.642T; *SHANK2*:p.L158F; *NLGN2*:p.R309Q; *DLGAP1*:p.F70L; *SHANK3*:p.P209A; *NLGN3*:p.V346M; *NLGN3*:p.Q691R, were absent in 1517 healthy controls from Taiwan BioBank, and ExAC data set. We conducted genotyping assay in an independent sample set of 500 cases and 500 healthy controls, and none of these mutations were detected, suggesting these ten missense mutations are schizophrenia-specific variants. Immunoblot analysis revealed the protein expressions of three mutants, *SHANK2*:p.L158F; *SHANK3*:p.P209A; *NLGN3*:p.V346M, were increased in HEK293 cells compared with wild-type, while that of four mutants, *DLGAP3*:p.H22N; *DLGAP3*:p.G352E; *DLGAP3*:p.S455R; *NLGN2*:p.R309Q, were decreased. The study suggests that postsynaptic density genes harbor rare functional mutations that affect proteins expressions in some schizophrenia patients, support rare coding variants may contribute to the genetic architecture of schizophrenia. The identified postsynaptic density gene mutations, especially, the NLGN gene family, the SHANK gene family, and the DLGAP family shed light on future functional genomic investigations of the genes and related biological pathways of schizophrenia.

**BrainSeq phase II: Schizophrenia-associated expression differences between the hippocampus and the dorsolateral prefrontal cortex.** L. Collado Torres<sup>1,2</sup>, E.E. Burke<sup>1</sup>, J.H. Shin<sup>1</sup>, A. Rajpurohit<sup>1</sup>, S.A. Semick<sup>1</sup>, A. Peterson<sup>1</sup>, C. Valencia<sup>1,3</sup>, R. Tao<sup>1</sup>, A. Deep-Soboslay<sup>1</sup>, T.M. Hyde<sup>1,4,5</sup>, J.E. Kleinman<sup>1,5</sup>, D.R. Weinberger<sup>1,4,5,6,7</sup>, A.E. Jaffe<sup>1,2,4,6,8,9</sup>, *BrainSeq Consortium*. 1) Lieber Institute for Brain Development, Baltimore, MD; 2) Center for Computational Biology, Johns Hopkins University, Baltimore, MD; 3) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) Department of Psychiatry, Johns Hopkins School of Medicine, Baltimore, MD; 5) Department of Neurology, Johns Hopkins School of Medicine, Baltimore, MD; 6) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 7) Department of Neuroscience, Johns Hopkins School of Medicine, Baltimore, MD; 8) Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 9) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

**Background:** We previously identified widespread genetic, developmental, and schizophrenia-associated changes in polyadenylated RNAs in the dorsolateral prefrontal cortex (DLPFC), but the landscape of hippocampal (HIPPO) expression using RNA sequencing is less well-explored. **Methods:** We performed RNA-seq using RiboZero on 900 tissue samples across 551 individuals (286 with schizophrenia) in DLPFC (N=453) and HIPPO (N=447). We quantified expression of multiple feature summarizations of the Gencode v25 reference transcriptome, including genes, exons and splice junctions. Within and across brain regions, we modeled age-related changes in controls using linear splines, integrated genetic data to perform expression quantitative trait loci (eQTL) analyses, and performed differential expression analyses controlling for observed and latent confounders. **Results:** We identified widespread transcriptional regulation in the DLPFC and the hippocampus over development, with 10,839 genes differentially expressed across age and brain regions (Bonferroni < 0.01) that are nominally replicated in BrainSpan (n = 79 tissue samples, 40 DLPFC and 39 HIPPO). Of these genes, 5,982 (~55%) contain differentially expressed exons and splice junctions that replicated in BrainSpan. We found 48 genes differentially expressed (at FDR < 5%) in hippocampus and 243 in DLPFC between schizophrenia patients and non-psychiatric controls. 36 of the 332 (10.8%) differentially expressed genes in HIPPO at FDR<20% are also differentially expressed in DLPFC, suggesting regional heterogeneity of the molecular correlates of schizophrenia diagnosis. We characterized extensive genetic regulation of gene expression with significantly different effects across the two brain regions: we identified 115,787 region-dependent eQTLs (at FDR < 1%), corresponding to 1,484 genes, at the gene, exon, or splice junction level (99 across all three). These region-dependent eQTLs included clinically relevant risk variants – five schizophrenia risk loci showed significant differential regional regulation. The eQTL results are available via <http://eqtl.brainseq.org/>. **Discussion:** We show extensive regional specificity of developmental and genetic regulation, and schizophrenia-associated expression differences between the hippocampus and DLPFC. These findings suggest that some components of the transcriptional correlates of developmental and genetic risk for schizophrenia may be brain region-specific.

## 2473T

**Genomic prediction of depression risk and resilience under stress.** Y. Fang<sup>1</sup>, L. Scott<sup>2</sup>, P.X.K. Song<sup>2</sup>, S. Sen<sup>1</sup>. 1) Molecular & Behavioral Neuroscience Institute, University of Michigan, Ann Arbor, MI; 2) Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI.

**Background:** Stress is a key trigger for major depression but there is substantial variation in response to stress between individuals. Advancing our ability to predict depression under stress holds great potential in reducing the burden of the disorder. Large-scale depression genome-wide association studies has, for the first time, provided basis for meaningful depression genomic risk scores, which have not yet been utilized for prediction of depression under stress. **Study Design:** A prospective longitudinal study utilizing physician training as a model stressor. **Participants:** 5227 interns starting residency training at 412 institutions in 14 specialties. **Measures:** Training interns were assessed for depressive symptoms with the Patient Health Questionnaire-9 (PHQ-9) and a series of demographic, psychological and historical measures before the start of the high-stress intern year (baseline). Subsequently, subjects were assessed for depressive symptoms using PHQ-9 quarterly through intern year. Depression polygenic risk score (MDD-PRS) was derived from the PGC2/23andMe dataset and assessed as a predictor of baseline and internship PHQ-9. Further, to identify whether genetic risk was acting through known risk factors, we incorporated previously identified risk factors into the model. **Results:** We found that MDD-PRS significantly predicted PHQ-9 both at baseline and under internship stress, while MDD-PRS was better predictive of depression under stress (beta=0.083, p=5.11e-13) than of baseline depression (beta=0.052, p=4.99e-5). 86.5% of the association between MDD-PRS and depression at baseline was explained by previously identified risk factors (gender, neuroticism, depression history, childhood stress). In contrast, these factors only explained 57.0% of the association under internship stress. Further, MDD-PRS better differentiated interns at low risk of depression from the rest of interns (bottom 2.5% vs. remaining 97.5%: t=3.9, p=1.4e-4) than those at high risk from the rest of interns (top 2.5% vs. remaining 97.5%: t=1.6, p=0.12). **Comment:** Genomic polygenic risk score has meaningful value in predicting future depression under stress. The PRS prediction is only partially overlapping with known psychological, demographic and historical predictors of depression, suggesting that MDD-PRS could add unique predictive power to existing models. Further, MDD-PRS may have particular utility in identifying individuals with high resilience to depression under stress.

**2474F****Metabotropic glutamate receptor association in attention deficit**

**hyperactivity disorder.** J.T. Glessner<sup>1,2</sup>, M.E. Khan<sup>1,2</sup>, X. Chang<sup>1,2</sup>, Y. Liu<sup>1,2</sup>, N. Williams<sup>1,2</sup>, J. Li<sup>1,2</sup>, H. Hain<sup>1,2</sup>, F. Mentch<sup>1,2</sup>, C. Kao<sup>1,2</sup>, P.M.A. Sleiman<sup>1,2</sup>, H. Hakonarson<sup>1,2</sup>. 1) Children's Hospital of Philadelphia, Philadelphia, PA., USA; 2) Perelman School of Medicine, University of Pennsylvania, PA., USA.

A polygenic disease model for most psychiatric conditions is undeniable. However, the era of agnostic genome wide scans evaluating increasing sample sizes cannot continue indefinitely. After a decade of detecting CNVs and associating them to disease phenotypes through large case-control cohorts and families, we have elucidated the pathophysiology of neuropsychiatric conditions and circumscribed relevant gene networks. Whether the singular base, <50bp, or larger span variant, we have detected it using array, whole exome sequencing or whole genome sequencing. The complex disease paradigm and spectrum of phenotypes is explicitly modeled in the nature of disease gene association. Metabotropic glutamate receptor (mGluR) genes have been especially pivotal hubs of psychiatric gene association networks. Here we explore the phenotypic and genotypic spectrum of psychiatric disorders in regards to targeted drug therapies. Using modern high-density SNP arrays allows for cost-effective large-scale evaluation of the mGluR network in neuropsychiatric conditions. We evaluated 1,500 samples with ADHD and called their mGluR network CNVs. The mGluR network constitutes 273 genes from first and second degree protein-protein interactors of the 8 GRM genes, 4 of which achieved individual statistical significance in our previous studies (Elia et al, 2011). An 8 member abbreviated mGluR gene network was introduced to model the most prevalent CNVs in the ADHD population demonstrating the greatest treatment response in neuropsychiatric symptoms to the mGluR modulator fasoracetam. A total of 154 positive individuals were found for the 8 gene set from the 1500 samples analyzed. A script was developed to allow highly efficient turn-around time for genotyping and analysis. Follow-up visual validation was performed on CNVs meeting minimum confidence score requirements. CNV detection on high-density SNP arrays, annotation, visual review, and reporting reached >98% accuracy based on Taqman validation. We first discovered significant mGluR CNV associations in ADHD and autism. Subsequent analysis found associations to phenotypes including anxiety, mood disorder, Tourette's, anorexia, conduct disorder, oppositional defiant disorder, and schizophrenia were also associated with an increased burden of mGluR CNVs compared to control subjects.

**2475W****A burden of rare damaging coding variants in obsessive compulsive**

**disorder.** M. Halvorsen<sup>1</sup>, J. Samuels<sup>2</sup>, B. Maher<sup>2</sup>, Y. Wang<sup>2</sup>, F. Goes<sup>2</sup>, G. Nestadt<sup>2</sup>, D. Goldstein<sup>3</sup>. 1) UNC Chapel Hill, Chapel Hill, NC; 2) Johns Hopkins University, Baltimore, MD; 3) Columbia University, New York, NY.

Obsessive Compulsive Disorder (OCD) is a complex neuropsychiatric disorder characterized by persistent intrusive thoughts and repetitive behavior. Like many other neuropsychiatric disorders, heritability studies offer support for genetics explaining some portion of OCD risk. Most genetic work on OCD has focused on common variation, leaving the rare variant contribution to OCD risk comparatively unexplored. To assess the burden of rare variants in OCD, we have generated what to our knowledge is currently the largest single collection of exome sequence data for OCD 'trios' and singleton cases. We have called *de novo* mutations in nearly 600 OCD trios, and report an excess of damaging coding mutations in line with what has been observed in other neuropsychiatric disorder cohorts. Combining the cohort with an OCD patient *de novo* mutation callset recently made available by a separate group (Cappi et al. 2017) we observe that *CHD8* is hit 3 times across 776 samples (2x loss of function, 1x damaging missense,  $p = 2.5 \times 10^{-5}$ ). This gene is the only one in the combined cohort with recurrent loss of function mutation. Furthermore, we have conducted gene-based 'collapsing' analyses of rare damaging coding variants in over 1,200 OCD cases relative to a cohort of controls without neuropsychiatric disorders. While we have not identified a single gene in collapsing analysis results that passes the exome-wide significance threshold, we note that *SLITRK5*, whose knockout in mice has previously been reported to generate an OCD phenotype, is the top-ranking single result (odds ratio = 8;  $p = 1 \times 10^{-5}$ ). Results from both *de novo* and case/control analyses are the strongest evidence to date for the presence of rare variants of large effect in OCD genetic architecture.

**Visual masking deficits in schizophrenia: A view into the genetics of the disease through an endophenotype.** F.A. Hodel<sup>1,2</sup>, A. Shaqiri<sup>3</sup>, M. Roinishvili<sup>4,5</sup>, E. Chkonia<sup>5,6</sup>, A. Brand<sup>7</sup>, J. Fellay<sup>1,2</sup>, M. Herzog<sup>3</sup>. 1) Global Health Institute, School of Life Sciences, EPFL, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) Laboratory of Psychophysics, Brain Mind Institute, EPFL, Lausanne, Switzerland; 4) Laboratory of Vision Physiology, Ivane Beritashvili Center of Experimental Biomedicine, Tbilisi, Georgia; 5) Institute of Cognitive Neurosciences, Free University of Tbilisi, Tbilisi, Georgia; 6) Department of Psychiatry, Tbilisi State Medical University, Tbilisi, Georgia; 7) Institute of Psychology and Cognition Research, University of Bremen, Bremen, Germany.

Schizophrenia is a chronic disorder determined by a complex mix of genetic and environmental factors. To better understand the contributions of human genetic variation to schizophrenia, we performed a genome-wide association study of a validated endophenotype: a backward masking task, in which two vertical bars, slightly offset in the horizontal direction, are shortly presented to participants, who are asked to indicate the offset direction (left vs. right). The bars are followed by a mask, which makes the task difficult. The time between the bars and mask was determined in 214 schizophrenia patients, 113 first-order relatives, and 148 controls. In comparison to the response times observed in controls ( $42.1 \pm 30.6$  ms), performance was significantly reduced in healthy relatives ( $61.3 \pm 57.3$  ms), and more strongly deteriorated in schizophrenia patients ( $129.4 \pm 113.2$  ms), supporting the notion that masking is an endophenotype of schizophrenia. We genotyped all participants on the Infinium Global Screening Array with Multi-Disease drop in. To search for associations between human polymorphisms and our endophenotype, we performed a single-marker genome-wide association study using linear mixed model on log-transformed data, implemented in GCTA software. We did not identify any genome-wide significant association ( $p < 5 \times 10^{-8}$ ), indicating that common variants with strong effects are unlikely to contribute to the large inter-individual differences observed in schizophrenia-related visual masking deficits.

**Whole genome sequencing of 1,748 veteran twins to detect risk and measure rare variation associated with major depressive disorder.** D. Hupalov<sup>1</sup>, C. Forsberg<sup>2</sup>, J. Goldberg<sup>2,3</sup>, W. Kremen<sup>4,5</sup>, M. Lyons<sup>6</sup>, A. Soltis<sup>1</sup>, C. Viollet<sup>1</sup>, R. Ursano<sup>7</sup>, M. Stein<sup>4</sup>, C. Franz<sup>4</sup>, V. Vaccarino<sup>8</sup>, Y. Sun<sup>8</sup>, N. Smith<sup>2,3</sup>, C. Dalgard<sup>1</sup>, M. Wilkerson<sup>1</sup>, H. Pollard<sup>1</sup>. 1) The American Genome Center, Collaborative Health Initiative Research Program, Uniformed Services University, Bethesda, MD; 2) Seattle Epidemiologic Research and Information Center, Office of Research and Development, U.S. Department of Veteran Affairs, Seattle, WA; 3) Department of Epidemiology, University of Washington, Seattle, WA; 4) Department of Psychiatry, University of California, San Diego, San Diego, CA; 5) VA San Diego Center of Excellence for Stress and Mental Health, San Diego, CA; 6) Department of Psychological & Brain Sciences, Boston University, Boston, MA; 7) Department of Psychiatry, Uniformed Services University, Bethesda, MD; 8) Department of Epidemiology, Emory University, Atlanta, GA.

Major Depressive Disorder (MDD) is a complex neuropsychiatric disease with known genetic associations but without known links to rare variation in the human genome. Initial studies, based on SNP-arrays of common alleles, have identified 47 regions associated with MDD among individuals of European ancestry. Here, we report the sequencing of 1,711 whole genomes at 30X mean depth, including 988 monozygotic twins, 632 dizygotic twins, and 91 singletons sequenced in an effort to identify rare genetic variation associated with MDD. Sequencing results were hierarchically clustered using 54 quality metrics to identify and remove bias, resulting in 33 samples being excluded. Population structure was characterized via principle component analysis. Specimen organization within the cohort was also used to observe other potential biases, concluding no batch effect was present as a result of collection date, sequencing date, or sample processing. Kinship among twins was quantified and its impact on statistical significance of associations measured via association trials, finding a moderate inflation of test statistics when including twins. Veterans were classified as having MDD based on psychiatric interview diagnostic criteria. Using previously published genome-wide association summary statistics from one independent study, we calculated a polygenic risk score (PRS) using 13 loci. In preliminary, unadjusted analyses, we found a modestly higher PRS among Veterans with a history of MDD than among those without a history:  $-0.101$  versus  $-0.112$  ( $p$ -value 0.17). An initial look at average rare variant burden across loci was found to be 9,320 rare variants per 0.5Mb window, including an average of 174 exonic rare variants per 0.5Mb window within our patient cohort. A deeper exploration of the 47 loci is underway. These preliminary results may represent a replication of the MDD associations in a new independent cohort and provide support for undertaking a deeper investigation of MDD rare variation. These initial investigations together set the stage for discovering new rare variants in this complex and chronic disease and potentially expanding the genetic risk landscape for MDD.

Young<sup>13</sup>, W. Zhao<sup>18</sup>, S. Vrieze<sup>1</sup>, *Trans-Omics for Precision Medicine Whole Genome Sequencing Program (TOPMed)*. 1) University of Minnesota, Twin Cities, Minneapolis, MN; 2) University of Washington, Seattle, WA; 3) Johns Hopkins University, Baltimore, MD; 4) Brigham & Women's Hospital, Boston, MA; 5) Stanford University, Stanford, CA; 6) Morehouse School of Medicine, Atlanta, GA; 7) University of Mississippi, University, MS; 8) Yale University, New Haven, CT; 9) Tulane University, New Orleans, LA; 10) University of Colorado at Denver, Denver, CO; 11) NIH National Heart, Lung and Blood Institute, Bethesda, MD; 12) George Washington University, Washington, DC; 13) University of North Carolina, Chapel Hill, NC; 14) University of Maryland, College Park, MD; 15) University of California, San Diego, La Jolla, CA; 16) Albert Einstein College of Medicine, Bronx, NY; 17) Tougaloo College, Tougaloo, MS; 18) University of Michigan, Ann Arbor, MI.

Smoking is a major preventable cause of morbidity and mortality in the United States and is moderately heritable. Genome wide association studies (GWAS) has allowed the discovery of hundreds of common variants associated with smoking. Although low frequency variants are expected to influence tobacco use, these rare variants are yet to be identified possibly due in part to the high statistical power required to test rare variants. Most of the GWAS for smoking have been conducted in individuals with European ancestry and similar associations have not been studied in non-European populations. As a part of the Trans-Omics for Precision Medicine Whole Genome Sequencing Program (TOPMed), we seek to identify rare variants associated with four measures of smoking behaviors in a multi-ethnic sample. Among the four phenotypes, two relate to the initiation of smoking, capturing the age at which they started smoking regularly and whether an individual has ever become a regular smoker in their life. Another relates to smoking cessation which contrasts current and former smokers. Finally, the number of cigarettes smoked per day reflects the heaviness of tobacco use among smokers. At the time of writing, the TOPMed project has called genotypes from 65,000 individuals with 30x whole genome sequences. A subset of 45,000 individuals from this data freeze have one or more smoking phenotypes. We are conducting single variant association tests for age of initiation, smoking initiation, smoking cessation, and cigarettes smoked per day with 154,176,919 variants with minor allele count  $\geq 1$  using whole genome sequences from 7,067 individuals. The preliminary results for age of initiation showed no significant associations, suggesting that additional samples will be required to raise the statistical power to detect significant associations. We will present updated results from single variant tests and gene based tests on larger samples, up to the full sample of 45,000 for one or more phenotypes. Stronger power to detect effects will be achieved as the remainder of our sample is analyzed and as the data available to us continues to grow with the release of new data freezes through TOPMed. .

**2479T**

**Association of HLA locus alleles with posttraumatic stress disorder.** S. Katrinli<sup>1</sup>, A. Lori<sup>2</sup>, K.J. Ressler<sup>2,4</sup>, A.K. Smith<sup>1,4</sup>. 1) Department of Gynecology & Obstetrics, Emory University, Atlanta, GA; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 3) Department of Psychiatry, Harvard Medical School and McLean Hospital, Belmont, MA; 4) Department of Psychiatry and Behavioral Sciences, Emory University, Atlanta, GA.

**Background:** Immune dysfunction is commonly reported among those with posttraumatic stress disorder (PTSD). An individual's immune response is shaped, in part, by the highly polymorphic Human Leukocyte Antigen (HLA) locus, which has been implicated widely in major psychiatric disorders. The goal of this study was to test for association between common HLA genotypes and PTSD. **Methods:** Genome-wide data (HumanOmni1-Quad) was used to impute classical HLA alleles in 403 lifetime PTSD cases and 399 controls of African ancestry. HLA imputation was performed using HIBAG and multi-ethnic parameter estimates. Posterior probabilities for HLA alleles in each locus was  $\geq 0.8$ . Validation of the model with HAPMAP ASW and LWK data also yielded  $\geq 0.92$  overall accuracy. Association with lifetime PTSD was evaluated using logistic regression, controlling for the first two principal components (ancestry) and gender. A Bonferroni correction was used to adjust for multiple testing in each HLA gene. The effect of HLA alleles on gene expression was assessed by weighted correlation network analysis (WGCNA), using 312 subjects with available expression data (HT12). For associated modules, enrichment analysis was performed using anRichtm (Internal Collection). **Results:** Among the 7 HLA genes tested, HLA-C\*07:01 (OR=1.8,  $p=1.7 \times 10^{-3}$ ), DQA1\*01:01 (OR=1.8,  $p=7.9 \times 10^{-3}$ ) and DQB1\*05:01 (OR=1.7,  $p=2.1 \times 10^{-3}$ ) were more common in those with PTSD. WGCNA was used to explore expression patterns in those with each of the PTSD risk alleles. HLA-C\*07:01 associated with 7 expression modules enriched (FDR < .05) for multiple biological pathways including general transcriptional processes and B cell receptor signaling. Interestingly, there was also enrichment in brain-specific expression highly relevant to PTSD (nucleus accumbens and amygdala). HLA-DQA1\*01:01 associated with 2 expression modules, one enriched in NOD-like receptor signaling. HLA-DQB1\*05:01 correlated with 2 expression modules one of which was enriched for cytokine signaling. These PTSD alleles have also been associated with other major psychiatric disorders. **Conclusions:** These results support an effect of HLA alleles on immune system and neural mechanisms to PTSD.

**2480F****Genome-wide association study of heritable psychological distress symptoms.**

S. Kim<sup>1,8</sup>, H.J. Jang<sup>1,2,8</sup>, W. Myung<sup>3,9</sup>, S. Cha<sup>1</sup>, H. Lee<sup>3,4</sup>, S.K. Cho<sup>1,5</sup>, B. Kim<sup>1</sup>, J.W. Kim<sup>2</sup>, D.K. Kim<sup>6</sup>, E.A. Stahl<sup>7</sup>, H.H. Won<sup>1,9</sup>. 1) Samsung Advanced Institute for Health Sciences and Technology (SAIHST), Sungkyunkwan University, Samsung Medical Center, Seoul, South Korea; 2) Department of Laboratory Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, South Korea; 3) Department of Neuropsychiatry, Seoul National University Bundang Hospital, Seongnam, South Korea; 4) Institute of Health and Environment, Seoul National University, Seoul, South Korea; 5) Molecular Genetic Epidemiology Section, National Cancer Institute (NCI), Frederick, MD 21701, USA; 6) Department of Psychiatry, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, South Korea; 7) Department of Genetics and Genomic Sciences, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 8) Co-first authors; 9) Co-corresponding authors.

**Background** Psychological distress symptoms are known to affect psychiatric disorder and medical illness. In addition to environmental factors, substantial interindividual variation also influences psychological distress, suggesting that genetic variation may be an underlying factor. In this study, we aim to examine heritability and genetic determinants of individual symptoms of psychological distress. **Methods** Psychological distress symptoms of 12,680 individuals in the Korean Genome and Epidemiology Study were assessed using a validated 18-item scale of psychological well-being index short form. We genotyped these individuals and estimated the heritability of individual psychological distress symptoms using the GCTA-REML method. We performed a genome-wide association analysis of individual psychological distress symptoms that showed significant heritability. Cell-type group analysis was conducted to investigate enrichment of heritability in particular cell types using linkage disequilibrium (LD) score regression. We used the GTEx expression quantitative trait locus (eQTL) database to investigate association of detected variants and their LD proxies ( $r^2 > 0.8$  in East Asians) with expression levels of genes. **Results** Three psychological distress items showed significant heritability: subjective well-being (9%), fatigue and appetite (11%), and enjoying daily life (8%). Partitioned heritability analysis showed that heritability of subjective well-being was enriched in the central nervous system (CNS) including brain ( $P < 0.05$ ). Two genome-wide significant associations were observed: rs6735649 with subjective well-being ( $P = 1.32 \times 10^{-8}$ , odds ratio [OR] = 1.18, 95% confidence interval [CI]: 1.12–1.25), and rs35543418 with enjoying daily life ( $P = 1.33 \times 10^{-8}$ , OR = 1.59, 95% CI: 1.35–1.86). Variants in high LD with rs6735649 were associated with expression levels of *STEAP3* and *C1QL2* in brain tissues. **Conclusions** Our findings demonstrate that psychological distress symptoms are partly heritable and two genetic loci are associated with subjective well-being or enjoying daily life. Further analysis in larger cohorts and different populations is required to replicate our findings and to identify additional genetic variants.

**2481W**

**Dopamine perturbation of gene co-expression networks reveals differential response among schizophrenia subjects for translational machinery.** M.Z. Kos<sup>1</sup>, J. Duan<sup>2,3</sup>, A.R. Sanders<sup>2,3</sup>, L. Blondell<sup>1</sup>, E.I. Drigalenko<sup>4</sup>, M.A. Carless<sup>1</sup>, P.V. Gejman<sup>2,3</sup>, H.H.H. Goring<sup>1</sup>, *Molecular Genetics of Schizophrenia (MGS) Collaboration*. 1) South Texas Diabetes and Obesity Institute, Department of Human Genetics, University of Texas Rio Grande Valley School of Medicine, San Antonio, TX; 2) Center for Psychiatric Genetics, NorthShore University HealthSystem, Evanston, IL; 3) Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL; 4) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX.

The dopaminergic hypothesis of schizophrenia (SZ) postulates that positive symptoms of SZ, in particular psychosis, are due to disturbed dopaminergic neurotransmission via the dopamine (DA) receptor D2 (DRD2), for which most antipsychotic drugs antagonize. However, dopaminergic abnormalities in SZ tend to be pre-synaptic and likely non-receptor-mediated, with the oxidative effects of DA linked to cellular toxicity and neurodegeneration. To investigate the non-receptor-mediated effects of DA on gene expression patterns in SZ, we used a cell perturbation approach *ex vivo*, generating transcriptomic profiles in B-cell transformed lymphoblastoid cell lines from 514 SZ cases and 690 controls, both before and after DA exposure (100  $\mu$ M). Weighted Gene Co-expression Network Analysis (WGCNA) of RNA-seq data identified seven co-expression modules under baseline conditions, of which six were preserved in DA-stimulated data. One of these modules shows significantly increased association with SZ after DA perturbation (baseline:  $P = 0.023$ ; DA-stimulated:  $P = 7.8 \times 10^{-8}$ ;  $\Delta$ AIC = -10.5). This module is highly enriched for ribosomal proteins (FDR =  $2 \times 10^{-110}$ ) and genes involved in co-translational targeting (FDR =  $4 \times 10^{-141}$ ), as well as mitochondrial oxidative phosphorylation and neurodegeneration. Genome-wide SNP association testing revealed tentative QTLs underlying the module co-expression, most notably at *FASTKD2* (top  $P = 2.8 \times 10^{-6}$ ), a gene involved in mitochondrial translation. These results provide key insights into the long-standing dopaminergic hypothesis of SZ by substantiating the role of translational machinery in SZ pathogenesis, with a potential dopaminergic mechanism disrupting mitochondrial function, and demonstrates the utility of disease-relevant functional perturbation to the study of complex genetic etiologies.

**Whole blood transcriptome analysis in bipolar disorder reveals strong lithium effect.** C.E. Krebs<sup>1</sup>, A.P.S. Ori<sup>2</sup>, A. Vreeker<sup>2</sup>, T. Wu<sup>2</sup>, R.M. Cantor<sup>1</sup>, M.P. Boks<sup>3</sup>, R.S. Kahn<sup>3</sup>, L.M. Olde Loohuis<sup>3</sup>, R.A. Ophoff<sup>1,2,4</sup>. 1) Human Genetics, UCLA, Los Angeles, CA; 2) Center for Neurobehavioral Genetics, UCLA, Los Angeles, CA; 3) Department of Psychiatry, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, The Netherlands; 4) Department of Psychiatry and Biobehavioral Sciences, UCLA, CA.

Bipolar disorder (BP) is a highly heritable mood disorder with a complex genetic architecture. It is commonly treated prophylactically with the mood stabilizer lithium (Li), although treatment responses vary widely across patients. Both how bipolar disorder genetic variants confer risk and the molecular mechanisms underlying Li's therapeutic effects remain poorly understood. We performed a whole blood transcriptome analysis in a BP case-control sample ( $N_{\text{subjects}} = 480$ ) by RNA sequencing. After correcting for technical and biological covariates including medication use with limma, very few genes showed significant case-control differential expression (DE;  $FDR < 0.05$ ,  $N_{\text{genes}} = 6$ ). Further analysis, however, revealed widespread changes in gene expression linked to Li treatment at the time of blood draw ( $FDR < 0.05$ ,  $N_{\text{genes}} = 976$ ). These genes were enriched for immune response and calcium signaling functional annotations, among others. In a gene co-expression network constructed from all RNA-sequencing samples, 27 modules of co-expressed genes were discovered, five of which were significantly associated with Li use. To determine if any of the DE profiles could be explained by differences in blood cell-type composition, we applied CIBERSORT to deconvolute cellular heterogeneity based on an external panel of 22 blood cell type gene expression signatures. After accounting for cell-type composition, the number of Li-induced differentially expressed genes decreased ( $FDR < 0.05$ ,  $N_{\text{genes}} = 233$ ), but still showed enrichment for immune response and calcium signaling functional annotations. One of the five Li-associated co-expression modules was also associated with a cell type proportion estimate ( $P_{\text{lithium}} = 9.40E-04$ ,  $P_{\text{neutrophils}} = 3.19E-4$ ) and was enriched for immunity functional annotations. We performed gene set analysis with MAGMA to examine whether the DE genes were enriched for BP or Li-response genetic risk, but found no such evidence. Overall, these results suggest that Li acts on immune response and calcium signaling pathways. While we observe elevated levels of neutrophils in Li users, changes in cell-type composition do not fully account for these patterns of DE. Our findings add to mounting evidence of Li's immune-related and calcium regulatory mechanisms, providing novel molecular validation with the largest Li-treated transcriptome dataset to date.

**Genetic associations with suicide attempt severity.** D.F. Levey<sup>1,2</sup>, R. Polimanti<sup>1,2</sup>, Z. Cheng<sup>1,2</sup>, H. Zhou<sup>1,2</sup>, Y. Nunez<sup>1,2</sup>, S. Jain<sup>5</sup>, F. He<sup>5</sup>, R. Ursano<sup>6</sup>, R. Kessler<sup>9</sup>, J. Smoller<sup>9,10,11</sup>, M. Stein<sup>3,4,5</sup>, H. Kranzler<sup>6,7</sup>, J. Gelernter<sup>1,2</sup>. 1) Yale University, New Haven, CT; 2) Veteran Affairs Connecticut Healthcare Center, West Haven, CT; 3) University of California San Diego, CA; 4) VA San Diego Healthcare System, San Diego, CA; 5) University of California San Diego, La Jolla, CA; 6) University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 7) Veterans Integrated Service Network 4 Mental Illness Research, Education and Clinical Center, Crescenz Veterans Affairs Medical Center, Philadelphia, PA; 8) Uniformed Services University of the Health Sciences, Bethesda, MD; 9) Harvard Medical School, Boston, MA; 10) Massachusetts General Hospital, Boston, MA; 11) Broad Institute of MIT and Harvard, Cambridge, MA.

**Objective:** In 2015, ~800,000 people died by suicide worldwide. For every death by suicide there are as many as 25 suicide attempts, which can result in serious injury even when not fatal. Despite this large impact on morbidity and mortality, the genetic influences on suicide attempt are poorly understood. **Method:** We performed a genome-wide association study (GWAS) of severity of suicide attempts to investigate genetic influences. A discovery GWAS was performed in Yale-Penn sample cohorts of European Americans (EAs,  $n=2,439$ ) and African Americans (AAs,  $n=3,881$ ). Replication was attempted in the completely independent Army-STARRS cohorts consisting of EAs ( $n=9,382$ ), AAs ( $n=1,488$ ), and Latinos ( $n=2,963$ ). When combined for a trans-population meta-analysis, the final sample size included  $n=20,153$  individuals. **Results:** In the Yale-Penn discovery sample, we found one genome-wide significant (GWS) signal in EAs near the gene *LDHB* ( $rs1677091$ ,  $p=1.07 \times 10^{-8}$ ) and three GWS associations in AAs: *ARNTL2* on chromosome 12 ( $rs683813$ ,  $p=2.07 \times 10^{-8}$ ), *FAH* on chromosome 15 ( $rs72740082$ ,  $p=2.36 \times 10^{-8}$ ), and on chromosome 18 ( $rs11876255$ ,  $p=4.61 \times 10^{-8}$ ). We conducted a limited replication analysis in the Army-STARRS cohorts.  $rs1677091$  replicated in Latinos ( $p=6.52 \times 10^{-3}$ ). A variant in LD with *FAH*  $rs72740082$  ( $rs72740088$ ;  $r^2=0.68$ ) was replicated in AAs (STARRS AA  $p=5.23 \times 10^{-3}$ ; AA meta,  $1.51 \times 10^{-9}$ ). **Conclusions:** To our knowledge, this is the first GWAS of suicide attempt severity. We identified GWS associations near genes involved in anaerobic energy production (*LDHB*), circadian clock regulation (*ARNTL2*), and the catabolism of tyrosine (*FAH*). These findings provide evidence of genetic risk factors for suicide attempt severity, providing new information regarding the molecular mechanisms involved.

**Severity of nausea and vomiting during pregnancy predicted by psychiatric and psychological traits.** P.A. Lind<sup>1</sup>, L. Colodro-Conde<sup>1</sup>, B. Couvy-Duchesne<sup>1,2</sup>, J. Painter<sup>1</sup>, M. Wright<sup>2</sup>, G. Montgomery<sup>2</sup>, D. Nyholt<sup>1,3</sup>, S.E. Medland<sup>1</sup>. 1) QIMR Berghofer Medical Research Institute, Brisbane, Australia; 2) University of Queensland, Brisbane, Australia; 3) Queensland University of Technology, Brisbane, Australia.

Nausea and vomiting in pregnancy (NVP) affects ~70% of pregnant women to different degrees. Around 14% of pregnant women experience severe NVP and this progresses to hyperemesis gravidarum (HG) in around 1-3% which, without treatment, can be life threatening. Women who experience severe NVP and HG have higher rates of major depressive disorder (MDD) prior to and after the index pregnancy, as well as post-traumatic stress disorder PTSD as a consequence of severe NVP or HG. Herein we examined the extent to which individual differences in the severity of NVP can be predicted by a polygenic risk score (PRS) derived from the latest Psychiatry Genomics Consortium MDD (leave out QIMR; Wray et al 2018) and PTSD analyses (Bolton et al, 2014). We also tested to what extent the genetic risk for related traits (neuroticism and cortisol levels) could explain such differences. Our preliminary analysis using data on NVP were obtained from two studies undertaken at the QIMR (Australia), which are part of the NVP Genetics Consortium. The sample comprised 1,440 unrelated women with mean age at the time of the survey of 48 (range: 26-78). The severity of NVP was measured with a 5-point scale. Polygenic risk scores were calculated using the PLINK profile score method for clumped SNPs (thresholds of  $p \leq 5 \times 10^{-8}$ ,  $1 \times 10^{-5}$ , 0.001, 0.01, 0.05, 0.1, 0.5 or 1). Linear regressions on the profile scores were performed, controlling for ancestry (using four principal components), age and age squared at survey time, cohort, and if it was a twin pregnancy. Around 19% women had severe NVP symptoms. Only the genetic risk for MDD predicted the severity of NVP (all PRS calculated from  $p < 0.001$  to  $p < 1$ ). The genetic risk for MDD as assessed by PGC2, which is independent of the time at which any depressive symptoms manifest, could predict NVP features. There is no evidence that the genetic risk for the other traits studies predict NVP.

**Multi-omics analysis identifies mitochondrial pathways associated with anxiety-related behavior in mice and panic disorder patients.** Z. Misiewicz<sup>1,2,3</sup>, S. Iurato<sup>2</sup>, N. Kuleskaya<sup>1,3</sup>, L. Salminen<sup>1,3</sup>, L. Rodrigues<sup>2</sup>, G. Maccarrone<sup>2</sup>, J. Martins<sup>2</sup>, D. Czamara<sup>2</sup>, M. Laine<sup>1,3</sup>, E. Sokolowska<sup>1,3</sup>, K. Trontti<sup>1,3</sup>, I. Balcells<sup>1,3</sup>, C. Rewerts<sup>2</sup>, S. Saarnio<sup>1,3</sup>, B. Novak<sup>2</sup>, D. Park<sup>2</sup>, A. Erhardt<sup>2</sup>, C.W. Turck<sup>2</sup>, I. Hovatta<sup>1,3</sup>. 1) Molecular and Integrative Biosciences Research Program, University of Helsinki, Helsinki, Finland; 2) Max Planck Institute of Psychiatry, Munich, Germany; 3) Department of Psychology and Logopedics, University of Helsinki, Finland.

Anxiety disorders are common mental disorders. They are influenced by genetic and environmental factors and an interaction between them, which is largely undefined. Our aim was to identify biological pathways associated with anxiety through integrative analyses of omics data from a mouse model of chronic psychosocial stress and exposure-induced panic attacks in panic disorder (PD) patients. To induce an anxiety-like response, we subjected two inbred mouse strains, innately non-anxious C57BL/6NCRl (B6) and anxious DBA/2NCRl (D2), to psychosocial stress (chronic social defeat stress, CSDS). Following CSDS, we carried out the social avoidance (SA) behavioral test, to divide the mice into those susceptible and resilient to the behavioral effects of stress. The strains had distinct response to stress as 87% of D2, but only 30% of B6, showed social avoidance behavior. We then analyzed the bed nucleus of the stria terminalis (BNST), a part of the extended amygdala involved in stress response, for differences in gene (RNA sequencing) and protein (liquid chromatography-tandem mass spectrometry) expression between the stress-resilient, susceptible and control mice. The analyses showed downregulation of mitochondria-related pathways in the D2 (both on mRNA and protein levels) and upregulation in the B6 strain (on mRNA level). We also observed upregulation of cytochrome c (CYCS), a key element of the mitochondrial electron transport chain, in the B6 resilient and susceptible mice versus controls, which was validated by western blot ( $P = 0.015$  and  $P = 0.027$ , respectively). We next conducted gene set enrichment analyses of the transcriptomic mouse CSDS and PD patients' blood data, collected directly and 24 h after exposure-induced panic attack. We found upregulation of mitochondria-related gene sets in the stressed B6 mice ( $FDR < 0.05$ ), downregulation in the stressed D2 mice, and upregulation in the PD patients after exposure-induced panic attack ( $FDR < 0.05$ ). To see if CSDS leads to changes in mitochondrial number, we carried out electron microscopy and observed that susceptible B6 mice had a larger number of pre-synaptic mitochondrial cross-sections than B6 resilient mice ( $P < 0.05$ ). In conclusion, we found a global evolutionarily conserved response of mitochondrial pathways in anxiety-related behaviors. Identification of the underlying mechanisms will provide much needed insight into the molecular basis of anxiety, a critical step in developing targeted therapy.

**Profile of the GCOP Study: A genome cohort on psychosocial traits in a dimensional perspective.** T. Nishiyama<sup>1</sup>, C. Wang<sup>2</sup>, A. Hishida<sup>3</sup>, M. Watanabe<sup>4</sup>, H. Nakagawa<sup>1</sup>, S. Nakamura<sup>1</sup>, K. Katayama<sup>1</sup>, H. Narimatsu<sup>1</sup>, S. Suzuki<sup>1</sup>. 1) Nagoya City University Graduate School of Medicine, Nagoya, Japan; 2) Department of Public Health, Aichi Medical Univ. School of Medicine, Aichi, Japan; 3) Department of Preventive Medicine, Nagoya Univ. Graduate School of Medicine, Nagoya, Japan; 4) Cancer Prevention and Control Division, Kanagawa Cancer Center Research Institute, Yokohama, Japan.

Mental disorders are the leading cause of years lived with disability, worldwide [Whiteford HA. 2013], and lead to higher morbidity and mortality rates. Conversely, many health conditions increase the risk for mental disorders. But, mechanisms for interactions between mental health conditions and other health conditions remain poorly understood [Prince M. 2007]. Therefore, we undertook a Genome Cohort on Psychosocial traits (GCOP) Study to clarify the mechanism, taking into account genetic vulnerability since every mental condition has a genetic contribution [Burmeister M. 2008]. The GCOP Study relies on a dimensional perspective that bridges between the healthy and the pathological mental traits [Kruger RF. 2014]. According to this perspective, we sampled individuals along these spectra in order to maximize precision of measurement and statistical power, as opposed to case-control designs. Recruitment of the GCOP Study was started in July, 2015 and would be continued until March, 2020. The Study collects blood, health checkup records and questionnaires for measuring psychosocial traits including personality, distress, autistic traits, attention-deficit/hyperactivity traits, obsessive-compulsive traits, psychoticism, nicotine/alcohol dependence, gambling addiction, sleep disturbance, morningness, social support, and social capital, as well as demographic and socioeconomic data, physical activity, and diet. This baseline survey was conducted in Gifu and Aichi prefectures, central Japan. 4,369 adult participants have been sampled to date and our target sample size is 40,000. After the baseline survey, GWAS will be conducted for the sample. Ethics committees of all participating centers approved the study, and all participants gave written informed consent. The GCOP Study has a dual structure. A small portion of the sample will be followed up annually by questionnaires for measuring psychosocial traits and health checkup records, while this follow-up is not conducted for the other sample. Furthermore, all the sample will be followed up for death, emigration, and cancer registration in Japan for 15 years. This unique large population-based cohort study enables us to elucidate mechanisms for interactions between mental health conditions and other health conditions. .

**Genetic variations in ghrelin (*GHRL*) and its receptor (*GHSR*) genes associated with alcohol use disorder.** N. Ramoz<sup>1,3</sup>, P. Gorwood<sup>2,3</sup>. 1) Center of Psychiatry and Neuroscience, INSERM U894, Paris, France; 2) Sainte-Anne Hospital, CMME, Paris, France; 3) University Paris Descartes, Paris, France.

It is clear that an addiction to a substance is the consequence of the combination of genetic factors (heritability of 0.5 for alcohol dependence) and environmental factors, such as exposure to alcohol, the level of school education or family and social situation. There is not a gene of alcoholism but there are vulnerability genes that increase the risk of developing alcohol dependence. Now, for addiction, we use the concept of "use disorder", and therefore for alcoholism or alcohol-dependence, we use the term of alcohol use disorder (AUD). The physio-pathobiology of AUD is likely involving the brain reward system and neurotransmitters, as well as, neuro-endocrine hormones and peptides acting in the physiology and regulation of brain and body homeostasis. Thus, the ghrelin system is implicated in the regulation of growth hormone (GH) secretion, food intake, energy expenditure and glucose homeostasis. There are several evidence confirming that the ghrelin system is involved in excessive alcohol consumption and AUD, from animal models to human evaluations. Thus, peripheral blood ghrelin concentrations are lower in AUD patients compared to healthy controls. In contrast, high ghrelin concentrations are observed in AUD patients who are abstinent. Furthermore, ghrelin levels may predict relapse to alcohol drinking in human. Finally, intravenous ghrelin administration compared to placebo in AUD patients induces the desire/craving to drink alcohol in response to alcohol cues, and increases alcohol self-administration. In our study, we search for identify mutations and polymorphisms (Single Nucleotide Variants SNVs or polymorphisms SNPs) specifically associated with alcohol dependence in candidate genes by sequencing. Our methodology was to perform high-throughput sequencing, in both directions with x70 reading depth, of the exons characterized by the ghrelin (*GHRL*) and its receptor genes (*GHSR*) and the ghrelin precursor, in 700 subjects of the COGA cohort, constituting 146 families, including 406 alcohol-dependent patients. Our sequencing results allowed us to identify several SNPs and SNVs. The specificity and the pathogenic impact in the alcohol dependence of each variant must be confirm and validate. Thus, the screening of de novo mutations in these families must be studied in other AUD cohorts and in the general population.

## 2488T

**Genetic associations between psychiatric disorder risk and phenotypic factors in UK Biobank.** R. Shafee<sup>1,2</sup>, C.E. Carey<sup>2,3,4</sup>, R.K. Walters<sup>2,3,4</sup>, D. Palmer<sup>2,3,4</sup>, L.E. Abbott<sup>2,3,4</sup>, D.P. Howrigan<sup>2,3,4</sup>, C. Churchhouse<sup>2,3,4</sup>, B.M. Neale<sup>2,3,4</sup>, E.B. Robinson<sup>2,3,4,5</sup>. 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA; 4) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 5) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA.

Common polygenic variation strongly contributes to risk for psychiatric disorders including attention deficit/hyperactivity disorder (ADHD), autism spectrum disorder (ASD), and schizophrenia (SCZ). Every individual possesses some degree of polygenic risk for each of these conditions. Biobanks with large-scale phenotypic and genomic data, such as the UK Biobank (UKBB), can thus be leveraged to better understand the full spectrum of outcomes associated with that risk. Such analyses can clarify how genetic risk for psychiatric disorders varies in phenotypic presentation and highlight clinically useful associations. Beginning with more than 2500 traits measured in UKBB, we identified 350 traits with significant common-variant heritability in the white British UKBB subsample (N=333,554) using LD Score Regression (LDSR). To improve interpretability we next conducted factor analysis on these 350 traits and identified a 40-factor solution yielding cohesive and interpretable factors. The factors included a range of physical (e.g. pain, asthma), behavioral (e.g. neuroticism, sleep), and cognitive outcomes (e.g. intelligence/education). We performed a GWAS of each factor controlling for age, sex, and ancestry-informative principal components. Using disorder-specific GWAS results from recent consortium-level meta-analyses, we estimated the genetic correlation between each factor and ADHD, ASD, and SCZ via LDSR. All three psychiatric disorders were moderately genetically associated with poorer overall mental (e.g., life dissatisfaction factor:  $r_g = .30$  to  $.39$ ) and physical (e.g., general health factor:  $r_g = -.18$  to  $-.53$ ) health, as well as with certain behavioral factors (e.g., sleep issues:  $r_g = .22$  to  $.56$ ). In contrast, divergent profiles of genetic correlation across disorders were observed for factors such as alcohol use (ADHD only  $r_g = .57$ ), weight (ADHD  $r_g = .37$ , vs. SCZ  $r_g = -.12$ ), and wearing glasses (ADHD  $r_g = -.27$ , vs. ASD  $r_g = .28$ ; all  $p < 1e-9$ ). It has been clearly established that the common polygenic influences on risk for neuropsychiatric disorders partially overlap. While polygenic risk for each disorder is defined by association to its clinical features (e.g. behavioral problems), we highlight how this polygenic risk can also differ substantially in its biomedical and cognitive correlates. These results suggest that the shared and unshared polygenic influences on risk for psychiatric disorders can be used to distinguish elements of the disorders' underlying biology.

Current evidence from case/control studies indicates that genetic risk for psychiatric disorders derives primarily from numerous common variants, each with a small phenotypic impact. The literature describing apparent segregation of bipolar disorder (BP) in numerous multigenerational pedigrees suggests that, in such families, large-effect inherited variants might play a greater role. To evaluate this hypothesis, we conducted genetic analyses in 26 Colombian and Costa Rican pedigrees ascertained for BP1, the most severe and heritable form of BP. In these pedigrees, we performed microarray SNP genotyping of 856 individuals and high-coverage whole-genome sequencing (WGS) of 454 individuals, the largest BP pedigree sample sequenced to date to the best of our knowledge. In addition, we performed family-aware genotype imputation to nearly double the sample size of individuals with WGS data to 785 individuals. We analyzed these data to obtain high-quality genotypes for several categories of genetic variants, including single nucleotide variants (SNVs), copy number variants (CNVs), short tandem repeats (STRs), and *de novo* mutations. With this rich genetic information, we have investigated the roles of common and rare variants in risk of severe BP (BP1). We identified that the BP1 individuals, compared to their unaffected relatives, had higher polygenic risk scores estimated from SNPs associated with BP discovered in independent genome-wide association studies, and displayed a higher burden of rare deleterious SNVs and rare CNVs in a set of genes hypothesized previously to be relevant to BP1. Parametric and non-parametric linkage analyses using SNPs in microarray data and STRs detected from WGS identified 15 BP1 linkage peaks, encompassing about 100 genes. There was one locus (16q23) with the linkage evidence observed with both parametric and non-parametric analysis, but none of common coding SNVs in the locus had significant association p-values after multiple testing correction. We also developed a new statistical approach to test the segregation of rare variants, but we observed no significant segregation pattern for any particular rare coding SNVs and CNVs suggesting that the variants contributing to our linkage findings may lie outside of coding regions. These results suggest that even in extended pedigrees, genetic risk for BP appears to derive mainly from small to moderate effect rare and common variants.

**Genetic markers of human evolution are enriched in schizophrenia.** *B. Xiang, K.Z. Liu, M.L. Yu, X.M. Liang, C.H. Huang, W. Lei, J. Chen, J. Zhang, W.Y. He, T. Zhang.* Affiliated of Southwest Medical University, Luzhou, Sichuan, China.

**Aim:** The human brain is the outcome of innumerable evolutionary processes. The systems genetics of schizophrenia could bear their signatures, which may be associated with the etiology of schizophrenia. **Methods:** On this basis, we analyzed schizophrenia (SCZ) using the GWAS summary statistics from the Psychiatric Genomics Consortium. Machine learning derived scores were used to investigate two natural-selection scenarios: complete selection (loci where a selected allele reached fixation) and incomplete selection (loci where a selected allele has not yet reached fixation). We chose these SNPs with the top-5% for incomplete and complete selection score, and based on the *p* value of these SNPs to obtain five subgroups:  $p < 0.0001$ , 0.001, 0.01, 0.05 or 0.1. **Results:** In the complete selection, we obtained 48 genes ( $p < 0.0001$ ), 118 genes ( $p < 0.001$ ), 289 genes ( $p < 0.01$ ), 569 genes ( $p < 0.05$ ), 775 genes ( $p < 0.1$ ). In the incomplete selection, we detected 29 genes ( $p < 0.0001$ ), 69 genes ( $p < 0.001$ ), 213 genes ( $p < 0.01$ ), 512 genes ( $p < 0.05$ ), 776 genes ( $p < 0.1$ ). The brain transcriptome data was obtained from BrainSpan, we found that 48 and 29 genes were enriched for the transcriptional co-expression profile in the prenatal dorsolateral prefrontal cortex (DFC), inferior parietal cortex (IPC), and ventrolateral prefrontal cortex (VFC), and three core genes (*GNA13*, *TBC1D19*, and *RNF111*) were identified to be involved in regulating early brain development. Functional enrichment also revealed that calcium ion binding, internalization of ErbB1, and IGF1 pathway. **Conclusions:** This study showed a marker of human evolution, which is in line with the hypothesis that the persistence of schizophrenia is related to the evolutionary process of becoming human, and demonstrated that the DFC, VFC and IPC may play a central role in neurodevelopment and SCZ risk.

**2491T**

**Increased burden of rare protein-disrupting variants within neuron synaptic genes among 483 patients with bipolar 1 disorder.** *J. Xiaoming<sup>1,2</sup>, M. Kvale<sup>2</sup>, L. Shen<sup>2</sup>, K.K. Thai<sup>2</sup>, P.Y. Kwok<sup>2</sup>, C. Schaefer<sup>3</sup>, N. Risch<sup>2,3,4</sup>.* 1) Department of Neurology, University of California San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California San Francisco, San Francisco, CA; 3) Kaiser Permanente Northern California Division of Research, Oakland, CA; 4) Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA.

Bipolar disorder (BD) is a severe and common mental disorder characterized by episodes of mania and depression, and affects approximately 5.7 million Americans. Genome-wide association studies have identified up to 30 loci that contribute to BD susceptibility, implicating genes that encode ion channels, neurotransmitter transporters, and synaptic components. However, whether rare variation contributes to BD pathogenesis remains unknown. We performed whole-exome sequencing (WES) in a multi-ethnic cohort of 483 unrelated individuals with bipolar 1 disorder (B1D) and 483 ancestry-matched controls. Populations examined include European (40%), African American (20%), Latino (20%), and East Asian (20%). Analysis of 966 exomes revealed 149,632 rare (gnomAD maximum population-specific minor allele frequency  $< 1\%$ ) single nucleotide variants (SNVs) that disrupt a protein coding sequence or splice-site. We assigned variant pathogenicity according to ACMG criteria using the software InterVar, and identified 508 pathogenic (predominantly splice site and stop gain) and 819 likely pathogenic (predominantly missense) variants. We observed no exome-wide enrichment of rare synonymous or protein-altering SNVs in individuals with B1D compared to healthy controls. We then examined 3,230 genes categorized as loss-of-function (LOF) intolerant, which include genes disrupted in neurodevelopmental and psychiatric disorders, and found an increased burden of rare pathogenic SNVs within these genes in B1D patients (0.29 per individual) compared to controls (0.22) ( $OR = 1.5$ ,  $P = 0.03$ ). Given the episodic nature of BD, we then hypothesized that disease pathogenesis might be driven in part by dysregulated neuronal synaptic function. We examined 2,788 synaptic genes (whose RNAs undergo alternative splicing by RBFOX proteins), and observed a significant enrichment of rare pathogenic SNVs in B1D patients (0.24 per individual) compared to controls (0.16) ( $OR = 1.54$ ,  $P = 0.005$ ). The risk for B1D increased with the number of such variants, which ranged from 0 to 3 per individual. Importantly, this enrichment was exclusive to 1,222 synaptic genes that are considered LOF-intolerant ( $OR = 1.8$ ,  $P = 0.0002$  for all pathogenic and likely pathogenic SNVs), and was not present in 1,587 synaptic genes that are LOF-tolerant ( $P = 0.89$ ). Our results suggest that rare protein-disruptive variants, especially in genes that influence neuronal synaptic function, might contribute to susceptibility in bipolar 1 disorder.

**Meta-analysis of GWAS summary data identifies novel pathways associated with alcohol use disorder.** *H. Zhang, S.P. Chou.* National Institute on Alcohol Abuse and Alcoholism, Rockville, MD.

Alcohol use disorder is one of the most prevalent psychiatric disorders globally. Genetic component attributes to about half of the risk for alcoholism. Most genome-wide association studies (GWAS) mainly focus on single genetic variant or individual gene analysis, which may not have enough power to detect the multiple small independent association signals underlying the susceptibility loci. We conducted the meta-analysis of genetic pathways on alcohol dependence by using publicly available GWAS summary data from the Study of Addiction: Genetics and Environment (SAGE; dbGaP study Accession: phs000092; Illumina 1M beadchip array), which included 1,235 alcohol dependent cases and 1,433 unrelated, alcohol-exposed, non-alcohol dependent controls in the European ancestry (EA) population and 662 alcohol dependent cases and 499 controls in the African American (AA) population. The GCTA-fastBAT (a fast and flexible set-Based Association Test) software was used to perform association analysis of genetic pathways in either ethnic population separately, followed by meta-analysis of pathway association analysis in both these two ethnic groups using Fisher's method. A total of 33 genetic pathways yielded  $P < 10^{-2}$  in the EA population, while 9 genetic pathways passed the same significant threshold ( $P < 10^{-2}$ ) in the AA population. Notably, three biological pathways show genetic association ( $P < 0.05$ ) in both discovery EA population and replication AA population: Reactome SHC mediated signaling pathway (discovery  $P = 7.4 \times 10^{-3}$ , replication  $P = 0.04$ , meta-analysis  $P = 2.7 \times 10^{-3}$ ), KEGG PPAR Signaling pathway (discovery  $P = 1.1 \times 10^{-2}$ , replication  $P = 0.02$ , meta-analysis  $P = 1.7 \times 10^{-3}$ ) and Biocarta CDC42RAC pathway (discovery  $P = 4.3 \times 10^{-2}$ , replication  $P = 0.02$ , meta-analysis  $P = 8.1 \times 10^{-3}$ ). Our meta-analysis of genetic pathway on GWAS summary data uncovered several novel pathways involving in susceptibility to alcohol dependence. Our results indicated that pathway-level GWAS models is useful to identify and further validate small independent genetic signals for complex traits and diseases in human.

**Depression state-related biomarkers detected by whole-blood RNA sequencing.** *H. Lee<sup>1</sup>, Y. Lee<sup>1</sup>, C. Wu<sup>1</sup>, I. Chen<sup>1</sup>, Y. Lin<sup>1</sup>, S. Liao<sup>1</sup>, H. Chen<sup>2</sup>, P. Kuo<sup>1,2</sup>.* 1) Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 2) Research Center for Genes, Environment and Human Health, National Taiwan University, Taipei, Taiwan; 3) Department of Psychiatry & Center of Sleep Disorders, National Taiwan University Hospital, Taipei, Taiwan; 4) Department of Psychiatry, National Taiwan University Hospital, Taipei, Taiwan.

Recurrent depressive episode is characterized in patients with major depressive disorder (MDD) or bipolar disorder (BPD). To better understand the underlying biological mechanisms of depressive episode, we aimed to investigate transcriptome changes between acute episode versus remission status for depressive episode among patients with MDD or BPD using RNA sequencing. At the discovery phase, we recruited five clinically diagnosed patients with BPD or MDD, who were repeatedly measured for their severity of depressive symptoms using Hamilton Depression Rating Scale (HAMD) during episode (HAMD score  $\geq 16$ ), and follow-up for at least two-months till remission (HAMD score  $\leq 7$ ). Blood samples were drawn at the time of depression severity assessment. We applied RNA sequencing with appropriate quality control, normalization, and differential expression analyses to examine differentially expressed genes (DEGs) between the two statuses. Several DEGs were identified, including Small Integral Membrane Protein 10 Like 1 (*SMIM10L1*;  $\log_2FC = 1.38$ ,  $P = 3.80 \times 10^{-5}$ ), Maestro Heat Like Repeat Family Member 6 (*MROH6*;  $\log_2FC = 1.18$ ,  $P = 4.89 \times 10^{-4}$ ), and scribbled planar cell polarity protein (*SCRIB*;  $\log_2FC = 1.11$ ,  $P = 6.18 \times 10^{-4}$ ), though these genes were insignificant after FDR correction. Preliminary results were validated using quantitative real-time PCR and the replication study using an independent sample of additional five pairs of the patients are underway. Pathway analysis was performed to identify enriched pathways for DEGs, and we found that immune-related pathways stood out for their associations with depressive episode. Further studies with a bigger sample size are needed to examine the targets identified in our study in order to identifying reliable biomarkers for depression state.

Schizophrenia (SCZ) patients are 1.5-2 times more likely to develop type 2 diabetes (T2D) compared to the general population. Several explanations for this epidemiologic link have been proposed, including environmental factors, the use of antipsychotic medication, and/or shared genetic aetiology; however, the aetiology underlying this observed comorbidity remains poorly understood. Here, we investigate the presence and extent of a shared genetic background between SCZ and T2D using genome-wide approaches. We used summary statistics from two large-scale GWAS of SCZ and T2D from the PGC ( $n_{\text{cases}}=34,241$ ;  $n_{\text{controls}}=45,604$ ) and DIAGRAM ( $n_{\text{cases}}=12,171$ ;  $n_{\text{controls}}=56,862$ ) consortia, respectively, to perform genetic overlap analyses, including pathway analysis and a regional colocalisation test. We identify five genomic regions with evidence of colocalising SCZ and T2D signals, three of which contain known loci for both diseases. We also observe a significant excess of shared association signals between SCZ and T2D at nine out of ten investigated p-value thresholds. Finally, we identify 29 genes associated with both T2D and SCZ, several of which have been implicated in biological processes relevant to these disorders. Additionally, we performed a genome-wide association study (GWAS) and polygenic risk score analysis in a Greek sample collection (GOMAP) comprising three patient groups: SCZ only ( $n=924$ ), T2D only ( $n=822$ ), comorbid SCZ and T2D ( $n=505$ ); samples from two separate Greek cohorts were used as population-based controls ( $n=1,125$ ). We used the DIAGRAM and PGC data to construct risk scores in GOMAP. Risk scores for both disorders were significantly associated with comorbidity of SCZ and T2D compared to controls. Together our results show for the first time that patients with comorbid SCZ and T2D have a higher genetic predisposition to both disorders compared to controls, demonstrating that the observed comorbidity between SCZ and T2D is at least in part due to shared genetic mechanisms.

**BACKGROUND** Studies of familial schizophrenia in the Finnish population have previously identified replicable associations for haplotypes and SNPs at the genomic loci of the phosphodiesterase 4D gene (*PDE4D*). However, causal variants have yet to be identified. We used a three-stage sequencing and genotyping study design in order to identify and replicate any potential functional variants at the *PDE4D* locus. **METHODS** The *PDE4D* genomic region was sequenced in 96 individuals from 20 families and identified 4,570 variants, of which 380 associated ( $p<0.05$ ) with schizophrenia in these families. Based on bioinformatic functional prediction from location of the variant in exonic or regulatory regions, 14 variants were genotyped in 1,122 individuals from 301 families alongside 323 population controls (Stage 1). Three SNPs remained significant in their association to schizophrenia ( $p<0.05$ ), and were thus further genotyped in an identically ascertained family cohort consisting of 1,696 individuals from 369 families, alongside an additional 794 unrelated population controls, and 2,733 individuals from other Finnish cohorts ascertained for major mental illnesses (Stage 2). **RESULTS** Two SNPs located in regions of predicted transcription factor binding sites were identified to significantly replicate in their association to schizophrenia: Stage 1, rs35278 OR=1.36, 95% CI 1.08-1.71; and rs165940 OR=1.40, 95% CI 1.11-1.77; Stage 2, rs35278 OR=1.18, 95% CI 1.04-1.34; and rs165940 OR=1.25, 95% CI 1.09-1.42. Further analysis revealed that rs165940 associates with a broad diagnosis of psychotic disorders ( $p=0.025$ , OR=1.18, 95% CI 1.07-1.30), and with an endophenotype of verbal learning and memory ( $p=0.0078$ ,  $\beta=-0.19$ ). Since both SNPs have potential regulatory functions, through their locations, we utilised the GTEx portal to establish their status as potential eQTLs. Only rs165940 (MAF=0.319) showed significant association with expression changes of *PDE4D* within the brain (cerebellum:  $p\text{-value} = 0.04$ ,  $\text{post-prob} = 0.9$  and  $m\text{-value} = 1.4$ ). **CONCLUSIONS** Our findings support the role of *PDE4D* in psychiatric disorders, with replicable association in familial schizophrenia in Finland. Further characterisation suggests it plays a role in the psychotic and cognitive domains of these disorders. SNP rs165940, through its association and status as an eQTL, is the most likely principal variant of interest for being the functional mutation at this locus.

**Non-Alzheimer's aging brain, behavior and biomarkers in down syndrome and mouse.** L. Dai<sup>1</sup>, J. Schieving<sup>2</sup>, J. Tippetts<sup>4</sup>, O. Abdullah<sup>3</sup>, M.C. Burbach<sup>5</sup>, A. VanHoek<sup>3</sup>, A. Ramirez<sup>3</sup>, J.O. Edgin<sup>6</sup>, M. Prigge<sup>5</sup>, J. Anderson<sup>7</sup>, J.R. Korenberg<sup>1</sup>. 1) Pediatrics, Medical Genetics, University of Utah, Salt Lake City, UT; 2) Korenberg Research, University of Utah, Salt Lake City, UT; 3) Neurology/Korenberg Research, University of Utah, Salt Lake City, UT; 4) Bioengineering, University of Utah, Salt Lake City, UT; 5) Pediatrics, University of Utah, Salt Lake City, UT; 6) Psychology, University of Arizona, Tucson, AZ; 7) Radiology, University of Utah, Salt Lake City, UT.

A major challenge for therapeutics of aging is determining the mechanisms of normal aging and accelerated aging versus Alzheimer's disease (AD). Down syndrome (DS) is a major cause of genetic imbalance causing brain disease throughout the lifespan and provides an important genetic model to study aging and AD. Le Becker 1985 and Mann 1988 show basal ganglia calcification in both DS and AD patients, more severely with increased age in DS. The genetics, neurobiology and cognitive consequences of the pathology are unknown. To fill the gap, we used MRI in a young DS cohort ( $n=22$ ;  $21.5 \pm 6.4$  years), and showed lesions in the globus pallidus (GP) in 23% of full trisomy 21 subjects, showing early onset in DS. With respect to cognitive effects we found a significant correlation between the Intra-Extra Dimensional Set Shift test (IED) in young DS with lesions in the GP, suggesting a non-AD deficit related to the lesions. Further, the presence of a GP lesion in a 22yo individual, 22 yo with partial trisomy, suggested gene candidates between APP and MX1, whose overexpression determines the lesions. We noted no significant correlation between the lesions and the APOE genotyping results, suggesting that APOE does not contribute to the lesion in DS. Finally, we performed MRI and CT on the Ts65Dn mouse model of DS, aged (12-27 months) and found mild to severe lesions in the thalamus of all Ts65Dn mice, with minor lesions present only in aged litter mate wild type controls. Histologic calcium staining using the Von Kossa method defined the lesions as calcium bearing. This is the first report of calcification in the anterior nucleus of the thalamus of the Ts65Dn mouse, of interest because it is the target of the GPI, a region of the MRI holes in DS. Taken together, our results establish new genetic mechanisms for the cognitive deficits in DS at young ages, that could also affect the non-AD accelerated aging seen in DS. The prominent thalamic calcification in the Ts65Dn mouse provides an opportunity to study the genetic and neural mechanisms of accelerated aging and possibly its interaction with AD.

**Calculating the effects of autism risk gene variants on dysfunction of five major biological processes identifies clinically-meaningful information.** O.J. Veatch<sup>1</sup>, D.R. Mazzotti<sup>1</sup>, J.S. Sutcliffe<sup>2</sup>, R.T. Schultz<sup>3</sup>, T. Abel<sup>4</sup>, B. Tunc<sup>3</sup>, S.G. Assouline<sup>5</sup>, E.S. Brodtkin<sup>6</sup>, J.J. Michaelson<sup>7</sup>, T.K. Nickl-Jockschat<sup>8</sup>, Z.E. Warren<sup>9</sup>, B.A. Malow<sup>9</sup>, A.I. Pack<sup>1</sup>. 1) Center for Sleep and Circadian Neurobiology, Department of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Vanderbilt Genetics Institute, Department of Molecular Biology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 3) Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA; 4) Iowa Neuroscience Institute, University of Iowa, Iowa City, IA; 5) Belin-Blank Center for Gifted Education and Talent Development, University of Iowa, Iowa City, IA; 6) Department of Psychiatry, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 7) Department of Psychiatry, University of Iowa, Iowa City, IA; 8) Department of Pediatrics, Vanderbilt University Medical Center, Nashville, TN; 9) Department of Neurology, Vanderbilt University Medical Center, Nashville, TN.

Autism spectrum disorders (ASD) are neurodevelopmental conditions that encompass a wide-range and severity of symptoms. Quantitative ASD phenotypes are influenced by inherited common, rare, and *de novo* genetic variation. However, the details of how genetic variation contributes to variable symptomatology are still unclear. This creates a major challenge for the field in order to translate vast amounts of genetic data into clinically-useful information. To determine if current evidence could be useful to informing treatment of symptoms in ASD, we identified variants in known ASD risk genes that were predicted damaging to the encoded protein products using whole-exome sequencing available for 2,392 individuals with ASD whose data were included in the Simons Simplex Collection. We then developed an approach to calculate the likelihood of genetic dysfunction in five Gene Ontology-defined biological processes that were significantly enriched for ASD candidate genes. These processes included nervous system development, synaptic signaling, cognition, regulation of membrane potential, and chromosome organization. Unsupervised clustering was used to subgroup individuals based on scores reflecting the likelihood of genetic dysfunction in each enriched process. Dysfunction in genes related to cognition distinguished a distinct subgroup of individuals ( $n=885$ ) with lower IQs ( $pFDR=4.3 \times 10^{-3}$ ), reduced adaptive behavior ( $pFDR=7.0 \times 10^{-3}$ ), and increased social deficits ( $pFDR=4.3 \times 10^{-2}$ ) when compared to individuals with no evidence of dysfunction in these genes ( $n=1,488$ ). Variation in the *PTGS2*, *ABCA7* and *SHANK3* genes was strongly associated with assignment to the subgroup defined by cognition gene dysfunction ( $p < 1.0 \times 10^{-3}$ ). In particular, an inherited stop-gain variant in the pharmacogene, *PTGS2*, which encodes Cyclooxygenase-2 (COX2), was associated with having intellectual disability defined as an IQ < 70 (OR=1.43, 95%CI=1.04, 1.97,  $p=4.0 \times 10^{-2}$ ) and increased risk for irritable bowel syndrome (OR=5.38, 95%CI=1.85, 15.58,  $p=2.0 \times 10^{-3}$ ). We expect that screening for deleterious variants in the subset of ASD candidate genes involved in cognition may be useful for identifying genetic factors that are clinically informative and should be prioritized for functional follow-up. This has implications in designing more comprehensive genetic testing panels and may provide the basis for more informed treatment in ASD.

**Deep phenotyping revealed differential global developmental milestone deficits in siblings with 15q11.2 microdeletion.** *K.M.F Uddin<sup>1,2</sup>, M.M Rahman<sup>3</sup>, B. Mohammed<sup>3</sup>, H. Akter<sup>3</sup>, N.J Dity<sup>3</sup>, M.A Rahaman<sup>2</sup>, M.R Islam<sup>2</sup>, M.A Rahaman<sup>2</sup>, M.A Baqui<sup>1,2</sup>, K.A Islam<sup>3</sup>, M. Nasir<sup>1</sup>, M. Uddin<sup>4,5</sup>.* 1) Biochemistry, Holy Family Red Crescent Medical College, Dhaka, Bangladesh; 2) NeuroGen Technologies Ltd., Dhaka, Bangladesh; 3) Bangabandhu Sheikh Mujib Medical University, Dhaka, Bangladesh; 4) Mohammed Bin Rashid University of Medicine and Health Sciences, College of Medicine, Dubai, United Arab Emirates; 5) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada.

Global developmental delay (DD) is a highly heterogeneous and complex condition that impacts at least ~3% of general population. Genetics contributes as a significant risk factor into the etiology of DD. Copy number variants (CNVs) are a genetic variant that has been shown to be major source of risk factor. We have analyzed a quartet family in Bangladesh where two siblings were impacted by DD. We have applied a custom array comparative hybridization (aCGH) designed to target the genomic regions that are outside of the common CNVs. The array comprised of 32,696 probes targeting regions impacted by rare deletions or duplications with a resolution of >100kb. Circular binary segmentation algorithm was used on the normalized  $-\log_2$  values to detect CNVs. Here we describe the two cases of a non-consanguineous family, one is eleven years old boy and another is two years old boy with a confirmed diagnosis of DD with intellectual disability. aCGH analysis revealed a 0.460 Mb-microdeletion in both cases at chromosome 15q11.2. There was a history of maternal epilepsy that was reported at early age (eight years old) and had been treated on Tegretol drug. We have conducted deep phenotyping and clinical observation shows delay in speech, cognitive and physical developmental milestones, low IQ = 56, in the elder sibling. In contrast, the younger sibling's clinical presentations are significantly different that includes facial dysmorphism, microcephaly, delay in speech, cognitive and physical developmental milestones and low IQ. Our finding show, 15q11.2 microdeletion alone might not contribute to the entire phenotypic spectrum and the differential clinical presentation can be due to the differences in genetic background or a second penetrant variant. .

**Mutation identified for of ADHD families in the US Hispanic population by whole exome sequencing.** *P. Acevedo<sup>1</sup>, F. Trevino<sup>1</sup>, J. Peralta<sup>1</sup>, K. Wang<sup>2</sup>, J. Blangero<sup>1</sup>, R. Crutchfield<sup>1</sup>, B. Sur<sup>1</sup>, C. Xu<sup>1</sup>.* 1) University of Texas Rio Grande Valley, Brownsville, TX; 2) East Tennessee State University.

Introduction: Attention deficit hyperactivity disorder (ADHD) is a common psychiatric disorder that has a worldwide prevalence of 4%. The disabilities, morbidities, and economic burden inherent to ADHD represent a major public health problem and, consequently, an important area of focus in health research. Evidence from family, twin, and adoption studies on ADHD indicates a high degree of heritability. The recent advancement of molecular techniques has facilitated identification of several genetic variants associated with ADHD in predominately Caucasian populations. There has been limited research in the U.S Hispanics/Latino populations. Whole exome sequencing (WES), as a rapid and reliable means, has identified causative mutations for a number of diseases. Therefore, we applied WES to identify pathogenic mutations for ADHD from the US Latino population. Material and Methods: 29 subjects (16 affected with ADHD) from 9 families recruited from the U.S. Hispanic/Latino population from the Departments of Psychiatry/Neurology and Pediatrics at the Texas Tech University Health Sciences Center. WES was performed by the Illumina Nextera Rapid Capture Exome Enrichment kits, then bioinformatics predictions were conducted. Results: A total of 555,801 variants were observed in all 29 subjects. After filter, a number of pathogenic genes/mutations were identified in affected family members with ADHD, particularly one mutation (NM\_000152.3:c.858+8G>A) in glucosidase alpha, acid (GAA) gene on 17q25.3 was discovered in seven affected subjects from three families with ADHD from the U.S. Hispanic population. Defects in this gene have been identified as the underlying cause of glycogen storage disease II, also known as Pompe's disease, autism and ADHD-like phenotypes. The consequence of this mutation may be involved in gene splicing. To identify high impact genes and biological pathways, further bioinformatics analysis, "hotspot" analysis, and literature-based searches are ongoing currently. Conclusion: This WES led to the discovery of additional ADHD genes in the U.S. Latino population; however, future validation and segregation analyses using a large sample are needed to confirm the current findings.

**Genome-wide association of word reading: Overlap with risk genes for neurodevelopmental disorders.** K. Price<sup>1,2,3</sup>, K.G. Wigg<sup>2</sup>, Y. Feng<sup>2</sup>, K. Blokland<sup>3</sup>, M. Wilkinson<sup>3</sup>, G. He<sup>4</sup>, E. Kerr<sup>5,6</sup>, S. Guger<sup>6</sup>, M. Lovett<sup>6</sup>, L. Strug<sup>4,7</sup>, C.L. Barr<sup>1,2,3</sup>. 1) Department of Physiology, University of Toronto, Toronto, Ontario, Canada; 2) Krembil Research Institute, University Health Network, Toronto, Ontario, Canada; 3) The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Genetics & Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 5) Department of Paediatrics, University of Toronto, Toronto, Ontario, Canada; 6) Department of Psychology, The Hospital for Sick Children, Toronto, Ontario, Canada; 7) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Canada.

Specific reading disabilities (RD) represent a major health, social, and educational handicap. RD can cause significant academic impairment in children and subsequent occupational underachievement in adults. Comorbid psychiatric disorders are common in children with RD (e.g., mood disorders, anxiety, and attention-deficit/hyperactivity disorder), further impacting academic achievement and social development. RD is a neurobiological learning disability characterized by difficulties with accurate/fluent word recognition, poor spelling, and decoding abilities. Despite high heritability, there have been few published GWAS studies. We performed a GWAS for a measure of word reading on two samples, one a family based sample selected for reading difficulties from Toronto and the other a population based sample called the Philadelphia Neurodevelopmental Cohort (PNC). The final analysis was performed with >5 million single nucleotide polymorphisms (SNPs) on 624 children from the Toronto sample and 4629 individuals from the PNC. The results from the SNP based analyses did not identify genome-wide significant results, however results near significance, indicate overlap for genes previously identified in GWAS for educational attainment and risk factors for neurodevelopmental disorders, particularly autism spectrum disorder (ASD). Known or suspected ASD was an exclusion criteria for the Toronto sample, thus the overlap with autism suggests shared genetic risk for ASD, possibly for shared genetic contributions to language difficulties. Notable among the identified genes were *FOXP1* and *RBFOX1*. *FOXP1* is a transcription factor that forms heterodimers with *FOXP2*, the first gene shown to contribute to speech and language. *FOXP1* has been identified as contributing to speech delay, language, and cognitive impairment in addition to ASD. The *RBFOX* family of RNA splicing proteins have been previously implicated in ASD, language and Rolandic epilepsy, a benign epilepsy syndrome associated with a spectrum of learning, language, and reading problems. The findings implicating *FOXP1* and *RBFOX1* are particularly interesting because deregulation would predict global change in transcription and splicing in neural cells. Further, pathway analysis identified the panther pathway "axon guidance mediated by Netrin". The findings from pathway analysis support previous evidence from neuroanatomical studies for altered neuronal migration/axon guidance as a contributor to RD.

**2501F**

**Comparison of two phenotypes to identify SNPs associated with poor reading skills.** H. Lancaster<sup>1</sup>, V. Dinu<sup>2</sup>, J. Li<sup>3</sup>. 1) Speech and Hearing Science, Arizona State University, Tempe, AZ; 2) Biomedical Informatics, Arizona State University, Tempe, AZ; 3) School of Computing, Informatics, and Decision Systems Engineering, Arizona State University, Tempe.

Reading difficulties account for 85% of children receiving special education services. While the genetic basis of reading disorders is largely unknown, there is substantial evidence for an underlying genetic mechanism. Understanding the genetic mechanism of reading difficulties is crucial to developing earliest identification methods. The objective of this study was to compare two phenotypes for reading difficulties, a case-control and a continuous phenotype, to determine if there was convergence between the phenotypes and which SNPs were associated with reading difficulties. We used behavioral and genetic data provided by Avon Longitudinal Study of Parents and Children. There were ten measures of reading skills, including measures of single word reading, non-word reading, phonological awareness, spelling, reading fluency, and reading comprehension. A binary case-control phenotype was assigned if a child had three out of ten reading measures one standard deviation below average. There were 1,215 cases (58.76% male) and 6,856 controls (49.62% male). We derived a continuous reading skill score using confirmatory factor analysis. We had data for 3,933 children (51% male) for the reading skill score. Plink was used to perform logistic (case-control) and linear (continuous) regressions for genome wide association by chromosome. Results were compared between phenotypes. Preliminary results revealed that there 52 SNPs identified by both phenotypes before multiple correction. After multiple test correction, there were no SNPs in common between the two phenotypes and there were no significant SNPs for the binary case-control phenotype; however, there were ten SNPs that remained significant for the reading skill phenotype, six on chromosome 14 (rs74491386, rs45547933, rs77940109, rs78487170, rs78277203, rs192227868) and four on chromosome X (rs181384543, rs191271648, rs185462130, rs185003220). Five of the SNPs on chromosome 14 are intronic variants for *PPP2R5C* and the SNPs on chromosome X are intronic variants for *PTCHD1-AS*. Both of these genes are highly expressed in the brain, anterior cingulate cortex and cerebellum respectively. These preliminary analyses suggest that viewing reading ability as a continuous skill, similar to education attainment, is a fruitful line of investigation. Preliminary results suggest a complex biological mechanism plays a part in the genetics of poor reading.

Intellectual disability (ID) is a genetically and clinically heterogeneous disorder, making diagnosis and treatment of ID patients difficult. The Northern Finnish Intellectual Disability (NFID) study aims to identify inherited variation contributing to ID. Finland is known to have a small founder population that has undergone several bottlenecks and genetic drift, which is particularly accentuated in the late-settlement area in northern Finland. Simulation studies show that in such populations, variants which are acted on by negative selection can exist at higher frequencies than in older populations, and indeed we see an increase in the frequency of some loss-of-function (LoF) mutations in Finland compared to other European populations. Within Finland, ID is reported to have higher prevalence in the northern late-settlement areas, suggesting inherited genetic factors contribute to the risk of ID. These inherited genetic factors are also likely to be more important in the etiology of mild ID, enriched in our cohort, rather than in severe ID. Previous work by Kurki *et al.* (bioRxiv 332023) have found in the NFID cohort an enrichment of protein-truncating variants in LoF intolerant genes, and identified a homozygote variant in the *CRADD* gene associated with a specific syndrome with ID and pachygyria. This variant is 50 times higher in the Finnish population compared to non-Finnish European populations, demonstrating the benefits of utilizing population isolates in rare variant analysis of diseases under negative selection. We have also found that common variant load contributes to ID in the NFID cohort, and that the educational attainment (EDU), intelligence quotient (IQ) and schizophrenia polygenic risk scores (PRS) were associated with ID, explaining 0.9%, 0.5%, and 0.6% of the heritability on the liability scale, respectively. The EDU PRS also appears to explain more heritability in mild (2.2%) than severe ID (0.6%) subsets of patients. We present the extended analysis of the NFID cohort with genotype and exome sequence data from 742 ID patients and 653 family members. We will expand this analysis to the exome sequence of 938 total ID patients.

**Polygenic risk scores distinguish speech and language subgroups in the Cleveland Family Study Cohort.** P. Bencheq<sup>1</sup>, R. Igo<sup>1</sup>, H. Voss-Hoyne<sup>1</sup>, B. Truitt<sup>1</sup>, L. Freebairn<sup>2</sup>, J. Tag<sup>2</sup>, B. Lewis<sup>2</sup>, C. Stein<sup>1</sup>, S. Iyengar<sup>1</sup>. 1) Department of Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 2) Department of Psychological Sciences, Case Western Reserve University, Cleveland, OH.

Speech and language are evolved human attributes whose neural basis resides in the Broca (speech and language output) and Wernicke (language comprehension) areas in the brain's left hemisphere along the Sylvian fissure. Genetic analysis of neurodevelopmental disorders (e.g., dyslexia, autism, schizophrenia, and various syndromes), and evolutionary comparisons with multiple species have contributed to our understanding of how children acquire speech and language naturally from infancy to adolescence. A distinctive insight into the neural basis of speech and language comes from the 4-10% of children without other diagnoses, predominantly affected with speech and language disorders; little of this is explained by FOXP2. Speech sound disorders (SSD) refer to difficulty in producing sounds or syllables, while language impairment (LI) represents an inability to comprehend or utilize language appropriately; SSD and LI are frequently comorbid. We and others have shown that children with SSD+LI, and children with childhood apraxia of speech (CAS), a severe form of SSD, have poorer performance on several endophenotypes than children with only SSD, arguing for a continuum of risk. We hypothesized that risk variants associated with particular endophenotypes accrue with increasing severity of speech and language deficits. We generated polygenic risk scores (~950 variants (range=[890,1024]) at  $P \leq 0.001$ ) using effect estimates from genome-wide association studies (GWAS) of articulation, expressive and receptive language, vocabulary, reading, and spelling (range of N per GWAS=[298,432]). Risk scores were constructed with index variants showing the strongest association in a region, removing other variants in linkage disequilibrium ( $r^2 > 0.5$ ). We used a linear mixed model to model the relationship between polygenic risk score and clinical group (no disorder, LI only, SSD only, SSD+LI, CAS in increasing order of severity), controlling for familial relationship (total N=686). Clinical subgroup was strongly associated with polygenic risk score for all endophenotypes ( $P < 1 \times 10^{-6}$ ). Furthermore, we observed the greatest risk load in the most severely affected group, CAS, and the second greatest load was usually in children with SSD+LI. These results demonstrate that increasing genetic burden is associated with greater severity of SSD and LI, suggesting that children seen in clinical practice have significant heterogeneity and may need personalized treatment paradigms.

**Whole exome sequencing and functional validation in zebrafish identify novel genes for mitochondrial disorders.** *P. Arumugam<sup>1</sup>, A.K. Meena<sup>2</sup>, S.U. Megha<sup>3</sup>, C. Venkatapathi<sup>4</sup>, G. Sandeep<sup>4</sup>, K. Thangaraj<sup>1</sup>.* 1) CSIR-Centre for Cellular and Molecular Biology, Hyderabad, India; 2) Department of Neurology, Nizam's Institute of Medical Sciences, Hyderabad, India; 3) Department of Pathology, Nizam's Institute of Medical Sciences, Hyderabad, India; 4) Department of Neurology, Bhimavaram Hospitals, Bhimavaram, India.

Mitochondrial disorders have emerged as a common cause of inherited disease. They are caused by mutations which reside in either nuclear or mitochondrial DNA (mtDNA). Their diagnosis and treatment remains challenging. The prevalence of mitochondrial disorders in India is more than the projected data available in the literature. In India, with a huge number of endogamous ethnic groups, the transmission rate of mitochondrial disorder is more. We used Sanger sequencing in 325 patients with mitochondrial disorders to identify pathogenic mutations in complete mtDNA and common nuclear genes. We have identified pathogenic mutations in mtDNA and common nuclear genes in 27% of the cases. However, the majority of cases (>70%) remain genetically undetermined. Therefore, we performed whole exome sequencing of 30 patients with mitochondrial disorders who do not have mutations in both mtDNA and common nuclear genes with phenotype of mitochondrial disorders, identified several novel genes involved in mitochondrial functions including *ALKBH1*, Cystathionine-Beta-Synthase (*CBS*) and Androgen Receptor (*AR*) cause severe autosomal recessive mitochondrial disorders, furthermore we have sequenced complete *ALKBH1*, *CBS* and *AR* genes in 275 patients with mitochondrial disorders, found biallelic *ALKBH1*, *CBS* and *AR* mutations in 14 patients cause severe recessive mitochondrial disorders. These mutations disrupted the function of the gene, showed complete co-segregation with the disease phenotype and absent in 650 ethnically matched control chromosomes. *ALKBH1* was recently discovered as a demethylase for mitochondrial tRNA, a new epigenetic modification. We found mutations in *ALKBH1* cause combined oxidative phosphorylation deficiency and severe multisystemic mitochondrial disorders. Knock-down of *alkbh1* in zebrafish using morpholino oligonucleotides (MOs) showed severe developmental abnormalities. RT-PCR analysis of zebrafish *alkbh1* expression in adult organs and during development showed that the *alkbh1* mRNA is highly enriched in brain, testis, intestine, muscle, heart and it is highly enriched in the early stage of zebrafish embryos. Interestingly, the knockdown of zebrafish *alkbh1* also causes developmental abnormalities via p53-dependent apoptosis. Our study shows the usefulness of exome sequencing and functional validation in zebrafish for identification of novel genetic causes of inherited mitochondrial disease.

**Improved methods for molecular genetic understanding of mitochondrial diseases to facilitate clinical diagnostics.** *I. Barbosa<sup>1</sup>, K. Thompson<sup>2</sup>, O.V. Poole<sup>3</sup>, M. Champion<sup>4</sup>, R.D.S. Pitceathly<sup>5</sup>, C. Fratter<sup>6</sup>, J. Poulton<sup>6</sup>, R. McFarland<sup>7</sup>, R.W. Taylor<sup>8</sup>, C. Deshpande<sup>9</sup>, M.A. Simpson<sup>1</sup>.* 1) Faculty of Life Sciences and Medicine, School of Basic and Medical Biosciences, King's College London School of Medicine, London, UK; 2) Wellcome Centre for Mitochondrial Research, Newcastle University, Newcastle upon Tyne, UK; 3) MRC Centre for Neuromuscular Diseases, University College London Institute of Neurology and National Hospital for Neurology and Neurosurgery, London, UK; 4) Evelina London Children's Hospital, Guys and St Thomas' NHS Foundation Trust, London, UK; 5) Oxford Medical Genetics Laboratories, Oxford University Hospitals NHS Trust, Oxford, UK; 6) Nuffield Department of Women's and Reproductive Health, University of Oxford, The Women's Centre, Oxford; 7) Clinical Genetics Department, Guys and St Thomas' NHS Foundation Trust, London, UK.

Approximately 1300 genes in the nuclear genome are known to encode components of the mitochondrial proteome. To date pathogenic variants in only a quarter of these genes have been reported to be associated with clinical mitochondrial disease. This genetic heterogeneity and the extensive clinical variability, pose challenges to establish the molecular genetic basis of mitochondrial disease. To establish best practice protocols for detecting pathogenic variations in patients with mitochondrial disease, we have undertaken whole exome sequencing of patients with clinical and biochemical evidence of mitochondrial disease in whom previous genetic investigations excluded mitochondrial DNA rearrangements and mutations. We established an analytical protocol to efficiently assist the interpretation of the patients' exome variant profiles in the context of nuclear encoded mitochondrial genes. Overall, our strategy yielded a diagnosis in more than half of the patients studied. About 30% of patients were found to harbour pathogenic mutations in established nuclear encoded mitochondrial disease genes. In approximately 25% of patients, pathogenic variants were identified in genes with no previous reports of association with mitochondrial disease. In the latter group, functional studies and the identification of causative mutations in the same gene in unrelated individuals led to the confirmation of novel genetic causes of mitochondrial disease. These include mutations in three genes (*HTRA2*, *GFM2*, *RTN4IP1*) with known mitochondrial function for which there was no previous association with a clinical mitochondrial disorder. As a result of this study, families have been able to benefit from prenatal genetic testing. Here we present the newly identified mitochondrial disease genes from our study with evidence supporting causality, as well as novel mutations in previously reported genes. We also present the bioinformatics strategies employed to improve diagnosis, including phenotype driven ranking as the basis of our approach to success, and finally highlight limitations of some approaches.

**Gene expression profiling of dorsal root ganglion in the mouse whole-body inducible *Clec16a* knockout model.** M. Bakay, R. Pandey, H. Hain, B. Strenkowski, H. Hakonarson. Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

*CLEC16A* is genetically linked with twelve distinct autoimmune disorders including multiple sclerosis. We and others reported that *Clec16a* knockout (KO) and *Clec16a* mutant mice display a neurologic disease. Specifically, our whole-body inducible *Clec16a* KO mice exhibit a neuronal phenotype including tremors, impaired gait and dystonic postures with an increase in severity over time. However, despite strong evidence implicating CLEC16A in the nervous system its functional role in it is not determine. We hypothesized that an RNA-based expression signature might provide us clues to the mechanism of CLEC16A action in the nervous system. Towards this end, we have expression profiled the dorsal root ganglia (DRG) from four control and six *Clec16a* KO mice with Affymetrix Clariom D Assay. The Transcriptome Analysis Console (TAC 4.0) Software was used to analyze data and visualize results. We also used both, Ingenuity Pathway Analysis and iPathwayGuide solutions to perform functional analysis. Among the total 65,956 genes on the Mouse Clariom D Assay expression of 29,402 (45%) genes was detected in the DRGs. The array data distribution indicated that expression of most genes was not strongly changed. We used a 2-fold change in signal intensity in combination with  $p$ -value $<0.05$  as a cut-off to consider the differential expression of a gene as significant. We identified 403 differentially expressed genes DEG (258 up- and 145 down-regulated) in DRG from *Clec16a* KO mice when compared to control. Among the down-regulated genes, 60% of the known genes were mitochondrial and metabolic genes. The majority of up-regulated genes are genes involved in signaling, including PI3K-mTOR, TGF-beta, MAPK and cytokine signaling. Diseases and conditions that are overrepresented in the set of differentially expressed genes were preferentially represented by metabolic, mitochondrial and neurodegenerative or nervous system diseases. Our results revealed that lack of *Clec16a* expression is resulting in downregulation of metabolic pathways, proteasome and oxidative phosphorylation; and in upregulation of several signaling pathways leading to altered immune response and increased apoptosis. This could suggest that drugs modulating cytokine-mediated proinflammatory responses may be effective in treating or preventing neurological autoimmune disorders such as multiple sclerosis in individuals with risk associated CLEC16A variants.

Hereditary retinal degenerations (HRDs) are rare diseases leading to progressive visual impairment and blindness. They are generally transmitted as monogenic traits, obeying Mendel's laws of inheritance, and affect indiscriminately individuals from all ethnic groups. However, compared to other populations, Japanese display a unique landscape of HRD mutations. Following the genomic screening of 331 unrelated Japanese patients, we identified two alleles in the ciliary gene *RP1* that were enriched in patients but were also relatively prevalent in the general population. The first was determined by the insertion of an *Alu* element in the last exon of the gene (allele frequency in the Japanese population = 0.1%), while the other was a nonsense variant (p.Arg1933\*) in the same exon. The *Alu* insertion which is causing a frameshift and a truncated protein (p.Tyr1352Alafs\*9) was found homozygously in six patients and co-segregated with the disease in the families as a classical Mendelian recessive allele. However, this insertion was also found heterozygously in 10 patients. Six of them were in fact compound heterozygous for either of two other changes in *RP1*: a novel frameshift mutation (p.Cys1399Leufs\*5, two individuals) and a nonsense variant (p.Arg1933\*, four individuals). Both variants segregated within their respective families. This latter nonsense was found to be almost polymorphic in Japan (allele frequency = 0.6%), did not cause disease in homozygosis or heterozygosis, but was considerably enriched in HRD patients (allele frequency = 2.1%, i.e. a 3.5-fold enrichment;  $p$ -value =  $1.29 \times 10^{-6}$ ) and could rarely act as a Mendelian mutation, *in trans* with other pathogenic variants like the *Alu* insertion. This variant is therefore acting as a quasi-Mendelian allele. After having identified 10 patients carrying the nonsense variant heterozygously without any second hit, we looked at enrichment of rare functional or disruptive alleles affecting retinal ciliary proteins elsewhere in the genome. We found indeed an enrichment of these alleles in patients vs controls supporting the hypothesis of a ciliary mutational load previously proposed in ciliopathies. Our results suggest that rare conditions such as HRDs can be paradoxically determined by relatively common variants, following a quasi-Mendelian model that could fill the gap that currently exists between monogenic and complex diseases.

**Genome-wide association analyses identify 139 loci associated with macular thickness in the UK Biobank cohort.** X. Gao, H. Huang, H. Kim. Department of Ophthalmology and Visual Sciences, University of Illinois at Chicago, Chicago, IL.

The macula, located near the center of the retina in the human eye, is responsible for providing critical functions, such as central, sharp vision. Structural changes in the macula are associated with many ocular diseases, including macular degeneration and glaucoma. Although macular thickness is a highly heritable trait, no genome-wide association study (GWAS) has been performed. Here, we describe the first GWAS of macular thickness, which was measured by spectral-domain optical coherence tomography using close to 68,000 participants from the UK Biobank cohort. We identified 139 unique genetic regions associated with macular thickness at genome-wide significance ( $P < 5 \times 10^{-8}$ ). The most significant loci were *LINC00461* ( $P = 5.1 \times 10^{-120}$ ), *TSPAN10* ( $P = 1.2 \times 10^{-118}$ ), *RDH5* ( $P = 9.2 \times 10^{-105}$ ), and *SLC6A20* ( $P = 1.4 \times 10^{-71}$ ). Results from gene expression demonstrated that these genes are highly expressed in the retina, further providing functional support. Other hits included previously reported age-related macular degeneration genes (*NPLOC4*,  $P = 1.7 \times 10^{-103}$ ; *RAD51B*,  $P = 9.1 \times 10^{-14}$ ) and known primary open-angle glaucoma genes (*SIX6*,  $P = 4.4 \times 10^{-11}$ ; *CDKN2B-AS1*,  $P = 4.6 \times 10^{-10}$ ). Through cross-phenotype analysis, these genetic loci also exhibited pleiotropic effects with myopia, neurodegenerative diseases (e.g. Parkinson's disease, schizophrenia, and Alzheimer's disease), cancer (e.g. breast, ovarian, and lung cancers), and metabolic traits (e.g. body mass index, waist circumference, and type 2 diabetes). Our findings provide the first insight into the genetic architecture of macular thickness and may further elucidate the pathogenesis of macular degeneration and glaucoma.

**Combining information across multiple traits dramatically improves polygenic risk profiling for glaucoma.** S. MacGregor<sup>1</sup>, X. Han<sup>1</sup>, J. An<sup>1</sup>, J.S. Ong<sup>1</sup>, M.H. Law<sup>1</sup>, E. Souzeau<sup>2</sup>, A. Qassim<sup>2</sup>, D.A. Mackey<sup>3,4</sup>, P. Gharahkhani<sup>1</sup>, A.W. Hewitt<sup>3,5</sup>, J.E. Craig<sup>2</sup>. 1) QIMR Berghofer Medical Research Institute, Brisbane, Queensland, Australia; 2) Department of Ophthalmology, Flinders University, Flinders Medical Centre, Bedford Park, Australia; 3) Menzies Institute for Medical Research, University of Tasmania, Australia; 4) Lions Eye Institute, Centre for Vision Sciences, University of Western Australia, Australia; 5) Centre for Eye Research Australia, University of Melbourne, Australia.

Primary open-angle glaucoma (POAG), one of the most heritable human diseases, is a leading cause of blindness worldwide. Whilst current treatments are generally effective in preventing disease progression, many patients present when irreversible damage has already occurred. Given the large genetic component to risk, gene based risk prediction may improve outcomes by identifying early those at highest risk, whilst reducing monitoring costs for those at low risk. It is now clear that glaucoma has a polygenic genetic architecture and hence very large sample sizes are required for accurate prediction. Current sample sizes in glaucoma genome-wide association studies are limited. Two key endophenotypes for glaucoma are intraocular pressure (IOP) and vertical cup disc ratio (VCDR) - both show significant genetic correlation with POAG. We built a genetic risk prediction model using 7,947 glaucoma cases and 119,318 controls from UK Biobank. To improve prediction accuracy, we combined glaucoma with data from the correlated endophenotypes using a multivariate approach (MTAG). Endophenotype data comprised 133,492 individuals with IOP from UK biobank and a previously published International Glaucoma Genetic Consortium data set, with a subset also measured for VCDR. We tested our genetic risk score in 1,734 advanced glaucoma and 2,938 controls from the Australia and New Zealand Registry of Advanced Glaucoma. Prediction accuracy increased dramatically when the endophenotype data were included. Based on the multivariate prediction approach, individuals in the top decile for the genetic risk score were at 15 fold increased risk of glaucoma relative to the bottom decile. Amongst the cases, individuals in the top decile were diagnosed 7 years earlier than those in the bottom decile.

**Unique spectra of deafness-associated mutations in Mongolians provide insights into the genetic relationships between among Eurasian populations.** Y.H. Lin<sup>1,2</sup>, J. Erdenechuluun<sup>3,4</sup>, Y.H. Lin<sup>2,5</sup>, K. Ganbat<sup>4,6</sup>, Z. Makhbal<sup>6</sup>, C.Y. Tsai<sup>2,5</sup>, W.C. Hsu<sup>2</sup>, C.C. Wu<sup>2,7</sup>, P.L. Chen<sup>2,7</sup>. 1) Graduate Institute of Molecular Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 2) Dept of Otolaryngology, National Taiwan University Hospital, Taipei, Taiwan; 3) Dept of Otolaryngology, Mongolian National University of Medical Sciences, Ulaanbaatar, Mongolia; 4) The EMJJ Otolaryngology Hospital, Ulaanbaatar, Mongolia; 5) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan; 6) Dept of Otolaryngology, National Center for Maternal and Child Health, Ulaanbaatar, Mongolia; 7) Dept of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan.

More than 50% of idiopathic sensorineural hearing impairment (SNHI) cases have a genetic etiology. From the epidemiological perspective, mutations of three deafness genes: *GJB2*, *SLC26A4*, and *MT-RNR1*, are much more prevalent than those of other genes worldwide. However, mutation spectra of common deafness genes differ significantly across different populations. Here, we performed comprehensive genetic examination and haplotype analyses in 188 unrelated Mongolian families with idiopathic SNHI, and compared their mutation spectra and haplotypes to those of other European and Asian cohorts. We achieved genetic diagnoses in 18 (9.6%) of the 188 families, including 13 with bi-allelic *GJB2* mutations, three with bi-allelic *SLC26A4* mutations, and two with homoplasmic *MT-RNR1* m.1555A>G mutation. Interestingly, three *GJB2* mutations prevalent in other populations, including c.35delG in Caucasians, c.235delC in East Asians, and c.-23+1G>A in Southwest and South Asians, were simultaneously detected in Mongolian patients. Haplotype analyses further confirmed founder effects for each of the three mutations, indicating that each mutation derived from its ancestral origin independently. By demonstrating the unique spectra of deafness-associated mutations, our findings may have important clinical and scientific implications for refining the molecular diagnostics of SNHI in Mongolian patients, and for elucidating the genetic relationships among Eurasian populations.

**Ocular disease mechanisms elucidated by genetic regulation of gene expression in human retinal pigment epithelium.** B. Liu<sup>1</sup>, M. Calton<sup>2</sup>, N. Abell<sup>2</sup>, B. Balliu<sup>2</sup>, G. Benchorin<sup>2</sup>, M. Gloudemans<sup>3</sup>, J. Hu<sup>4</sup>, D. Bok<sup>4</sup>, S. Montgomery<sup>5</sup>, D. Vollrath<sup>2</sup>. 1) Department of Biology, Stanford University, Palo Alto, CA; 2) Department of Genetics, Stanford University, Palo Alto, CA; 3) Program in Biomedical Informatics, Stanford University, Palo Alto, CA; 4) Department of Ophthalmology, Jules Stein Eye Institute, UCLA, Los Angeles, CA; 5) Department of Pathology, Stanford University, Palo Alto, CA.

The importance of vision to humans has motivated the identification of hundreds of GWAS loci for complex ocular disorders such as age-related macular degeneration (AMD) and myopia, but the molecular mechanisms are unknown for most loci. The retinal pigment epithelium serves important roles in ocular development and retinal homeostasis. To identify candidate causal genes for complex eye phenotypes, we genotyped 23 unrelated human fetal retinal pigment epithelium (fRPE) samples, and profiled their transcriptomes under culture conditions that modulated cellular energy metabolism (glucose or galactose). Comparison with GTEx revealed 130 fRPE-enriched genes (>4 standard deviations), including known fRPE markers such as *RPE65* and *RGR*. Gene set enrichment analysis revealed *pigment granule* and *sensory perception of light stimulus* (FDR < 1x10<sup>-3</sup>) to be the top two pathways over-represented among fRPE-enriched genes. Comparison of transcriptomic profiles across glucose and galactose treatments identified 1924 differentially expressed genes (FDR < 1x10<sup>-2</sup>) primarily enriched in *cholesterol metabolism* (FDR < 1x10<sup>-4</sup>), a key pathway in AMD development. Genes associated with inherited retinal disorders and glaucoma had elevated expression in fRPE (P < 1.6x10<sup>-10</sup>), and such elevation was more pronounced in fRPE than in GTEx samples. Using stratified LD score regression, we found that variants near fRPE-enriched genes explain a larger fraction of risk than variants near GTEx tissue-enriched genes for both myopia and AMD. Together, these results suggest that fRPE can model both monogenic and polygenic ocular disorders better than cell types and tissues in public datasets. We next characterized the genetic regulation of gene expression and splicing. By combining total and allele-specific expression, we found 759 shared, 288 glucose-specific, and 201 galactose-specific eQTLs (FDR < 0.05), including known ocular disease genes such as *ABCA1* (glucose-specific) and *PRPF8* (galactose-specific). Comparison with GTEx identified three RPE-specific eQTLs (*TYR*, *CRX*, and *MFRP*). Fine-mapping of myopia and AMD GWAS loci with e/sQTL identified 8 candidate causal genes, 5 of which have not previously been linked to ocular diseases. Our study highlights the unique transcriptomic characteristics of fRPE compared to publicly available cell types and tissues and provides a novel resource to map the genetic regulation of expression and splicing in fRPE to monogenic and complex ocular disorders.

**2512T**

**Multiple new genetic regulatory effects in blood discovered for age-related macular degeneration.** A. V. Segre<sup>1,2,3</sup>. 1) Ocular Genomics Institute, Massachusetts Eye and Ear, Boston, MA; 2) Department of Ophthalmology, Harvard Medical School, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA.

The majority of common variant associations found to date for Age-related Macular Degeneration (AMD), lie in noncoding regions, making it hard to decipher the causal mechanisms and genes in these regions. Furthermore, about half of the heritability of AMD has yet to be detected. Given the implication of the innate immune system in AMD pathogenesis, we tested whether variants associated with gene expression changes (expression quantitative trait loci or eQTLs) in whole blood or monocytes could help identify a proportion of the missing heritability of AMD and prioritize causal genes in known and new loci. We applied an extension of our eQTLEnrich method, that tests whether eQTLs in a given tissue are enriched for multiple modest (GWAS  $p < 0.05$ ) to strong ( $p < 5 \times 10^{-8}$ ) complex trait associations, correcting for various confounding factors, including eQTL tissue-specificity, to the largest publicly available GWAS meta-analysis of intermediate and advanced AMD (~23,000 cases, ~18,000 controls) and whole blood eQTLs (FDR < 5%) from the Genotype-Tissue Expression (GTEx) Project. We found significant enrichment of AMD associations amongst blood eQTLs ( $P = 1 \times 10^{-5}$ , Fold enrichment = 1.7), suggesting 140 new genetic associations with regulatory effects on AMD. To identify the true associations over noise, we applied our eGeneEnrich method to the target genes of eQTLs with AMD GWAS  $p < 0.05$ , and found multiple genes enriched in immune system processes, e.g., interferon signaling, the complement cascade, and MHC class I-mediated antigen presentation, as well as other biological processes, such as cell adhesion and lipid metabolism. Our analysis proposes new genes in the complement system with regulatory effects on AMD risk, whose genetic effects are smaller than previously reported associations for AMD in complement genes that harbor protein altering variants. Colocalization analysis helped prioritize high confidence causal genes for co-occurring AMD loci with eQTLs. By estimating the tissue-specificity of top ranked AMD-associated blood eQTLs compared to 47 non-blood GTEx tissues, and testing their effect on gene expression in normal and interferon-induced monocytes, we highlight regulatory effects that are likely to influence AMD risk via the immune system and inflammatory response. This work demonstrates that variation in transcriptional regulation substantially contributes to AMD risk, and proposes new target genes whose dysregulation in the blood may lead to AMD development.

**Pervasive evidence of gene-environment interactions in genetic variants associated with refractive error.** A. Pozarickij<sup>1</sup>, J. Guggenheim<sup>1</sup>, C. Williams<sup>2</sup>. 1) Cardiff University, Cardiff, UK; 2) University of Bristol, Bristol, UK.

Refractive error is a complex trait that is estimated to affect 49.8% of the world population by 2050. It leads to an increased risk of developing myopic maculopathy, glaucoma and other ocular health problems. Susceptibility is determined both by genetic and environmental factors, but the evidence for their interplay is lacking. Here, we aimed to find out whether SNPs associated with refractive error are involved in gene-environment interaction (GxE). Our analysis included 72,985 individuals from UK Biobank cohort. To assess the pervasiveness of interactions, 149 genetic variants were selected. Conditional quantile regression models were fitted to detect changes in genetic variant effects across quantiles of the phenotype distribution. An unweighted polygenic risk score (PRS) was constructed and used to identify GxE with University attendance. We found that the majority (90%) of SNPs for refractive error showed evidence of non-constant effects. Typically, these variants had inverse-U shaped effect size profiles, with the strongest effects observed at the phenotype extremes, and effects closer to zero in emmetropes. Individuals who had a University degree had a more negative refractive error, on average, irrespective of their genetic susceptibility to myopia and their location in the refractive error distribution. The PRS x University attendance interaction also varied across percentiles, but with a different profile. This interaction effect was largest at the 30<sup>th</sup> percentile ( $b_{GxE} = -0.38$  diopters, 95% CI -0.32 to -0.43,  $p = 4.8 \times 10^{-41}$ ) and smallest at the 75<sup>th</sup> percentile ( $b_{GxE} = +0.01$  diopters, 95% CI -0.02 to +0.03,  $p = 0.68$ ). Thus, the PRS x University attendance interaction appeared to have negligible influence on the refractive error in some individuals (for example, those at the 75<sup>th</sup> percentile), and yet was associated with a difference in refractive error of more than 1.50 diopters for those with a -2 SD vs. +2 SD PRS located at the 30<sup>th</sup> percentile of the refractive error distribution. In contrast to current findings, our results indicate that GxE are common in refractive error development. The interaction effects typically have major impacts, such that effect sizes are often 2-fold greater for individuals in the phenotype extremes compared to those in the centre. Thus, the complex interplay between genetic and environmental factors uncovered in this work explains some of the missing heritability for refractive error.

**2514W****Persistent developmental stuttering: Genetic factors and therapy**

**outcomes.** C. Frigerio Domingues<sup>1</sup>, Z. Gkalitsiou<sup>2</sup>, A. Zezinka<sup>1</sup>, E. Sainz<sup>1</sup>, J. Gutierrez<sup>1</sup>, C. Byrd<sup>2</sup>, R. Webster<sup>2</sup>, D. Drayna<sup>1</sup>. 1) National Institute on Deafness and Other Communication Disorders, National Institutes of Health, Bethesda, MD - USA; 2) Lang Stuttering Institute and Moody College of Communication, University of Texas, Austin, TX - USA; 3) Hollins Communications Research Institute, Roanoke, VA - USA.

Stuttering is a common, genetically complex disorder characterized by involuntary disruptions in the flow of speech. The disorder has thus far been associated with variants in the *GNPTAB*, *GNPTG*, *NAGPA*, and *AP4E1* genes. These four genes are related to intracellular trafficking that is responsible for delivering endosomal cargoes to their correct location within the cell. We studied a set of patients with persistent developmental stuttering (50 mutation carriers and 47 non-mutation carriers) that all underwent a standardized intensive fluency shaping therapy program (IFSTP). Subjects' pre-therapy and post-therapy speech fluency records were analyzed to test whether therapy outcomes differed in those who carried a mutation in any of these known stuttering genes compared to individuals without such mutations. Speech fluency pre- and post-therapy was evaluated with observer-based quantitative stuttering dysfluency measures (percent words stuttered, PWS), and by subjects' self-reported measures of fluency, anxiety, and struggle behavior (perceptions of stuttering inventory, PSI). Both the subjects and speech pathologists who performed fluency ratings were blind to mutation status. The differences between pre-therapy and post-therapy fluency scores were taken as the measure of near-term therapy efficacy, and differences between groups were evaluated by t-tests. The IFSTP was effective for both groups, however, PSI scores showed significantly less improvement in individuals who carry a mutation (relative risk=1.75, odds ratio=2.92,  $p=0.0058$ ). In addition, there was a trend toward poorer therapy outcomes in mutation carriers using PWS as scored by independent raters. We conclude that this fluency shaping therapy program produced significant improvements in speech fluency, however, mutation carriers achieved significantly less resolution of self-reported dysfluency, anxiety and struggle behavior following therapy, and that independent professional ratings of speech fluency displayed a trend toward poorer therapy outcomes in mutation carriers as well. Taken together, these results suggest that stuttering mutation carriers are more resistant to therapy compared to those without such mutations.

**Three loci associated with risk of advanced age-related macular degeneration (AMD) also influence anti-VEGF treatment response.** O. Garcia Rodriguez<sup>1</sup>, S.S. Pan<sup>1</sup>, P. Whitehead<sup>1</sup>, L.D. Adams<sup>1</sup>, R.A. Laux<sup>2</sup>, J.K. Welch<sup>1</sup>, J.L. Kovach<sup>3</sup>, S.G. Schwartz<sup>2</sup>, A. Agarwal<sup>1,5</sup>, J.L. Haines<sup>2</sup>, M.A. Pericak-Vance<sup>1</sup>, W.K. Scott<sup>1</sup>. 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 3) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL; 4) Ophthalmology and Visual Sciences, Vanderbilt University Medical Center, Nashville, TN; 5) West Coast Retina, San Francisco, CA.

Response to anti-vascular endothelial growth factor(anti-VEGF) treatment for choroidal neovascularization(CNV) is variable. Identifying genetic factors that modulate treatment response could allow targeting of therapies to individuals most likely to respond positively. Fritsche et al. (2016) demonstrated that 52 common/rare single nucleotide polymorphisms(SNPs) in 34 loci account for 50% of the variation in the risk of developing AMD. Most genetic studies of treatment response have examined the association of these known genetic risk factors on treatment response, with few replicated results. We examined the association between 15,161 SNPs in these 34 loci and one-year change in visual acuity(VA) in 90 non-Hispanic white individuals with CNV(107 eyes) treated monthly for the first three months and as needed afterward. Samples were genotyped using the Illumina HumanCoreExome-24 v1.3 array and imputed against the 1000 Genomes Project Phase I reference panel. Association of one-year change in VA(measured as the change in logMAR) with SNP dosage was analyzed using linear mixed models, adjusting for age, sex, treatment, correlation of paired eyes, and population substructure (the top 3 principal components from EIGENSTRAT analysis). There were six variants in three AMD risk loci significantly associated with treatment response when correcting for the 34 loci tested( $\alpha=1.5 \times 10^{-3}$ ). Each C allele at rs1951409( $p=9.62 \times 10^{-4}$ ) and each A allele at rs199555630( $p=6.73 \times 10^{-4}$ ) in *RAD51B* ( $R^2=0.28$ ) were associated with worse VA one year after anti-VEGF treatment. Each T allele at rs117086110( $p=5.21 \times 10^{-5}$ ) and each A allele at rs76904544( $p=6.00 \times 10^{-5}$ ) in *RAD51B*( $R^2=0.94$ ) were associated with improved VA. There was no correlation between the SNPs in *RAD51B* positively and negatively associated with VA. Two other variants: rs2233739( $p=3.51 \times 10^{-4}$ ) in *LIPC* and rs12519450 in *RAD51B* with VA. *PRLR/SPEF2*( $p=1.28 \times 10^{-3}$ ) were associated with improved VA. Previous studies have not associated these six variants with anti-VEGF treatment response in CNV. *RAD51B* is involved in DNA repair and is associated with several cancers which may also be treated with anti-VEGF therapy. These results suggest that some biological mechanisms governing risk of AMD may also govern response to anti-VEGF treatment. These findings could allow anti-VEGF therapeutic regimens to be tailored to particular genetic profiles associated with positive or negative responses, improving outcomes and saving costs.

**Identifying genes that underlie primary open-angle glaucoma using genetically determined gene expression.** *J. Hirbo<sup>1</sup>, J. Bailey<sup>1</sup>, P. Pawar<sup>2</sup>, P. Evans<sup>1</sup>, E. Gamazon<sup>1</sup>, R. Tao<sup>1</sup>, K. Joos<sup>1</sup>, J. Wiggs<sup>2</sup>, M. Brantley<sup>1</sup>, N. Cox<sup>1</sup>.* 1) Vanderbilt University School of Medicine, Nashville, TN; 2) Harvard Medical School, Boston, MA, United States; 3) Case Western Reserve University School of Medicine, Cleveland, OH, United States.

Glaucoma is an eye disease characterized by progressive loss of the nerve connecting to the brain that leads to visual field loss, which if untreated will ultimately cause irreversible blindness. Glaucoma poses a large public health and economic burden that is estimated at nearly 5.8 billion annually. Increased intraocular pressure (IOP) is the most common risk factor for glaucoma, especially in Primary Open Angle Glaucoma (POAG). However, IOP-independent risk factors, such as vascular dysregulation, play an important part in the pathogenesis of glaucoma in some individuals who usually have a "normal" IOP termed normal-tension glaucoma. The only proven therapeutic approaches to treat POAG are for lowering IOP. One of the main limiting factors in developing effective therapies for POAG is lack of a clear understanding of the molecular mechanisms in disease etiology. There have been over twenty genome wide association studies (GWAS) on POAG, POAG risk factors and related endophenotypes that have cumulatively identified >200 potentially causal variants, but the biological mechanisms underlying these associations are not clear. All except one of these GWAS variants are noncoding, and might play a regulatory role. We hypothesized that the correlation of genetically determined component of gene expression with POAG can provide a powerful method to identify genes involved in the etiology of the POAG. We used two gene-based methods, PrediXcan and MetaXcan, that provide a framework for directly correlating imputed genetically determined gene expression with disease risk. We applied PrediXcan using models trained on 48 GTEx tissues to estimate individual level gene expression in a total of 5020 POAG cases and 36,330 controls of European descent. We applied MetaXcan on summary statistics from GWAS meta-analysis of IOP by Springelkamp et al., 2017. We determined the joint effects of gene expression variation imputed across the tissues using Multi-Tissue PrediXcan. We identified two novel genes, PGM5P2 and RAB38, that fall in regions with sub-genome wide significant SNPs in GWAS results. We also confirmed four genes, GAS7, TMCO1, SIX6 and CDKN2B that were previously suggested to underlie IOP and causal in Glaucoma because of being in vicinity to loci identified in GWAS. Our results points to novel pathophysiology that underlie POAG. If confirmed by experiment in model animals, these findings would offer novel gene targets for POAG therapies.

**Gene-based study of ocular quantitative traits in 14,346 patients from Geisinger.** *N.A. Restrepo, C.R. Bauer, N.S. Josyula, E.D.K Cha, S.A. Pendergrass.* Biomedical and Translational Informatics, Geisinger, Rockville, MD.

Studies of vision impairment and blindness are rapidly accruing, elucidating how vision loss and blindness will burden economies and limit quality of life for affected patients. Genetics plays an integral role in ocular diseases such as age-related macular degeneration (AMD) and glaucoma which have been extensively validated, however the biological underpinnings are still vague and poorly characterized in certain conditions. Determining shared genetic risks is the first step towards investigating the genetic architecture of vision health. Gene- and pathway-based association analyses were performed to test the effects of rare variants in 1,385 autosomal genes extracted from the NHGRI-EBI GWAS catalog with 11 quantitative ocular traits. Targeted genes were selected to contain all genes associated ( $p < 1 \times 10^{-5}$ ) with an ocular trait, ocular disease, or traits correlated with ocular health (i.e., HDL). Whole exome sequencing data was used from 44,020 European samples in Geisinger MyCode Community Health Initiative. The associations were performed on a subset of 14,346 patients who underwent an eye exam at Geisinger. A SKAT-based linear regression algorithm was implemented adjusting for age and sex. Biofilter and Biobin software packages were utilized to retrieve genomic locations and to perform association testing, respectively. Pathway analyses were conducted using GO Pathway and Reactome. We identified fifty-two significant gene associations ( $p < 1 \times 10^{-5}$ ) all correlated to phenotypic traits related to corneal topography (K1, K2, and central corneal thickness). A number of these risk loci were previously found to contribute to the risk of genetically-correlated eye diseases including myopia, age-related nuclear cataracts, and corneal astigmatism. Of interest is the association of genes related to eye diseases not typically correlated with corneal topography traits, such as, AMD (i.e., *TXNB* and *COL4A1*) and glaucoma (i.e., *LMO7*). Pathway analysis (FDR  $p < 0.05$ ) highlights an enrichment of top genes relevant to the structural complex of collagen trimers, collagen biosynthesis, assembly, and degradation. This study highlights the potential of gene discovery to elucidate shared genetic etiologies of eye diseases, previously not assumed to be related. This approach may identify cellular mechanisms involved in AMD and glaucoma risk. Future studies will explore interactions between genes and biological functions of ocular traits and their impact on ocular health. .

**PMEL missense variants are associated with pigment dispersion syndrome and pigmentary glaucoma.** M.A. Walter<sup>1</sup>, A.A. Lahola-Chomiak<sup>1</sup>, T. Footz<sup>1</sup>, K. Nguyen-Phuoc<sup>1</sup>, G.J. Neil<sup>2</sup>, B.J. Fan<sup>3</sup>, K.F. Allen<sup>3</sup>, D.S. Greenfield<sup>4</sup>, R.K. Parrish<sup>5</sup>, K. Linkroum<sup>3</sup>, L.R. Pasquale<sup>3</sup>, R.M. Leonhardt<sup>6</sup>, R. Ritch<sup>7</sup>, J.E. Craig<sup>8</sup>, W.T. Allsion<sup>1,2</sup>, O.J. Lehmann<sup>1,9</sup>, J.L. Wiggs<sup>3</sup>. 1) Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) Department of Biological Sciences, University of Alberta, Edmonton AB, Canada; 3) Ocular Genomics Institute and Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA; 4) Department of Ophthalmology, Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Palm Beach Gardens, FL; 5) Anne Bates Leach Eye Hospital, Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL; 6) Department of Immunobiology, Yale University School of Medicine, New Haven, CT; 7) Einhorn Clinical Research Center, New York Eye and Ear Infirmary of Mount Sinai, New York, NY; 8) Department of Ophthalmology, Flinders Medical Centre, Adelaide, South Australia; 9) Department of Ophthalmology, University of Alberta, Edmonton AB, Canada.

Pigmentary Glaucoma (PG) is a common glaucoma subtype that results from release of pigment from the iris, called Pigment Dispersion Syndrome (PDS), and its deposition throughout the anterior chamber of the eye. Although PG has a substantial heritable component, no causative genes have yet been identified. We used Whole Exome Sequencing (WES) of two independent pedigrees to identify 2 *PMEL* variants associated with heritable PDG/PG. *PMEL* (premelanosome protein) encodes a key component of the organelle essential for melanin synthesis, storage, and transport (melanosome). Targeted screening of *PMEL* in three independent cohorts (n= 394) identified seven additional PDS/PG-associated non-synonymous variants. Five of nine variants exhibited defective processing of the *PMEL* protein. In addition, analysis of PDS/PG-associated *PMEL* variants expressed in HeLa cells revealed structural changes to the melanosome indicating altered amyloidfibril formation in 5 of 9 variants. Knockdown of the homologous *pmelain* zebrafish caused profound pigmentation defects in the eye further supporting *PMEL*'s role in ocular pigmentation and function. Taken together, these data support a model in which missense *PMEL* variants represent dominant negative mutations that impair the ability of *PMEL* to form functional amyloid fibrils. While *PMEL* mutations have previously been shown to cause pigmentation and ocular defects in animals, this research is the first report of mutations in *PMEL* causing human eye disease.

**Do carriers of "high penetrance" myocilin variants always get glaucoma?** P. Gharahkhani<sup>1</sup>, X. Han<sup>1</sup>, E. Souzeau<sup>2</sup>, JS. Ong<sup>1</sup>, J. An<sup>1</sup>, OM. Siggs<sup>3</sup>, KP. Burdon<sup>2,3</sup>, DA. Mackey<sup>3,4</sup>, AW. Hewitt<sup>5,6</sup>, JE. Craig<sup>2</sup>, S. MacGregor<sup>1</sup>. 1) QIMR Berghofer Medical Research Institute, Brisbane, Australia; 2) Department of Ophthalmology, Flinders University, Flinders Medical Centre, Adelaide, Australia; 3) Menzies Institute for Medical Research, University of Tasmania, Hobart, Australia; 4) Centre for Ophthalmology and Visual Sciences, University of Western Australia, Lions Eye Institute, Perth, Australia; 5) Centre for Eye Research Australia, Royal Victorian Eye and Ear Hospital, University of Melbourne, Melbourne, Australia.

Glaucoma is the leading cause of irreversible blindness worldwide. Current treatments for glaucoma are generally effective in preventing disease progression if applied early. Given glaucoma has a strong genetic basis, gene-based prediction of risk is likely to assist with early diagnosis. The p.Gln368Ter variant in *MYOC* is a well-established variant for glaucoma with carriers reported to have a high risk of glaucoma. However, the clinical utility of screening this variant remains controversial because although the variant was initially reported to have a very high penetrance (70-100%) in family-based studies, recent population-based studies found much lower estimates (10-20%). We used 411337 white-British ancestry participants including 7997 glaucoma cases within UK Biobank (UKB) to examine penetrance and effect size of *MYOC* p.Gln368Ter for glaucoma and ocular hypertension (OHT). We used OHT as a proxy for glaucoma since a proportion of glaucoma cases remain undiagnosed due to the lack of comprehensive eye examination. We then compared these results with those from two Australian registry-based studies comprising 3071 glaucoma cases and 6750 historic controls. In UKB, the ORs (95% confidence interval, CI) of p.Gln368Ter for primary open angle glaucoma (POAG), glaucoma (including POAG, self-report, and unspecified glaucoma), OHT, and OHT or glaucoma were 6.60 (3.86, 10.48), 4.43 (3.49, 5.55), 3.65 (2.62, 4.99), and 4.28 (3.15, 5.75), respectively. The penetrance of p.Gln368Ter in glaucoma, OHT, and OHT or glaucoma was 7.55%, 24.3% and 30.84%, respectively. In registry-based studies, the OR (95% CI) of p.Gln368Ter for advanced glaucoma was 12.16 (6.34, 24.97) while the risk was lower for non-advanced glaucoma: OR=3.97 (1.55, 9.75). The penetrance was 56.10% and 69.51% for glaucoma and glaucoma/suspects, respectively. For age 65 and above, ~50% of *MYOC* p.Gln368Ter carriers had glaucoma or OHT in UKB and ~83% in registry-based studies. These results show that although the penetrance of p.Gln368Ter in general population is not as high as it has been reported in registry-based studies, it is much higher than those reported in previous population-based studies, probably due to ascertainment bias towards healthy individuals in those studies. Overall, our results supports clinical utility of genetic testing for p.Gln368Ter to help identify individuals who are at greater risk of developing glaucoma and direct them to early screening and appropriate management.

## 2520W

**Dissecting corneal layers from keratoconus cornea towards differential gene expression analysis.** M. Gajecka<sup>1,2</sup>, M. Udziela<sup>3</sup>, R. Malinowski<sup>4</sup>, M. Olszak<sup>4</sup>, J.P. Szaflik<sup>3</sup>, K. Jaskiewicz<sup>1,2</sup>. 1) Poznan University of Medical Sciences, Poznan, Poland; 2) Institute of Human Genetics Polish Academy of Sciences, Poznan, Poland; 3) Department of Ophthalmology, Medical University of Warsaw, Warsaw, Poland; 4) Institute of Plant Genetics, Polish Academy of Sciences, Poznan, Poland.

**Background:** Keratoconus (KTCN) is a multifactorial eye disorder leading to a loss of vision acuity. The human cornea comprises of 5 layers, including three cellular: epithelium, stroma and endothelium. Precise pathogenesis of the disease, including significance of the individual corneal layers, remains unclear. Analyses conducted on the full-thickness corneas provide results from the heterogeneous mixture of cells, masking differential gene expression and phenotype correlations. **Aim:** The protocol selection and optimization for obtaining homogeneous cell populations from specific corneal layers, towards differential gene expression analysis. **Material and Methods:** The fresh-frozen cornea from a KTCN-patient, after a penetrating keratoplasty procedure, is cut on a cryotome. During a laser microdissection (LM) procedure the corneal epithelium, stroma and endothelium are dissected. After RNA extraction (Single Cell RNA Purification Kit, Norgen Biotek, Canada) assessment of RNA quality (RIN) and quantity is performed using Agilent RNA 6000 Pico Kit. RT-qPCR reactions with multiple primers are executed. **Results:** We examined the LM method for our purposes. Other considered technics (fluorescence activated cell sorting, FACS, microfluidics) require a dissociation step, during which the tissue architecture (extracellular matrix, cell-cell junctions) is disrupted. Collagenase treatment would be necessary for the connective tissue such as cornea, what significantly changes the gene expression. We successfully optimised the LM protocol, embracing tissue fixation, staining and setting of laser's parameters, visually documenting all steps. RNA quality and quantity was satisfactory towards RT-qPCR reactions. Surprisingly, the *Actinβ* (as a reference gene), chosen in the first place, was not evenly expressed in all analysed layers. Future research plans include differential expression analyses based on RNA-seq experiments. **Conclusions:** We assume that it is crucial to assess differential expression in the separate corneal layers. We consider that both, downstream and high-throughput studies using dissected corneal layers will contribute to the increase of knowledge about the KTCN pathogenesis.

## 2521T

**Association between additive effects of genetic variants associated with primary open-angle glaucoma and age at diagnosis of glaucoma.** F. Mabuchi<sup>1</sup>, N. Mabuchi<sup>1</sup>, Y. Sakurada<sup>1</sup>, S. Yoneyama<sup>1</sup>, K. Kashiwagi<sup>1</sup>, H. Iijima<sup>1</sup>, Z. Yamagata<sup>2</sup>, M. Takamoto<sup>3</sup>, M. Aihara<sup>4</sup>, T. Iwata<sup>5</sup>, K. Kawase<sup>6</sup>, Y. Shiga<sup>7</sup>, K. Nishiguchi<sup>8</sup>, T. Nakazawa<sup>9,10</sup>, M. Ozaki<sup>10</sup>, M. Araie<sup>11</sup> for the Japan Glaucoma Society Omics Group (JGS-OG). 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Yamanashi, Japan; 3) Dept Ophthalmology, Saitama Red Cross Hospital, Saitama, Saitama, Japan; 4) Dept Ophthalmology, Graduate School of Medicine, Univ Tokyo, Bunkyo-ku, Tokyo, Japan; 5) Division of Molecular and Cellular Biology, National Institute of Sensory Organs, National Hospital Organization Tokyo Medical Center, Meguro-ku, Tokyo, Japan; 6) Gifu University Hospital, Gifu, Gifu, Japan; 7) Dept Ophthalmology, Tohoku Univ Graduate School of Medicine, Sendai, Miyagi, Japan; 8) Dept Advanced Ophthalmic Medicine, Tohoku Univ Graduate School of Medicine, Sendai, Miyagi, Japan; 9) Dept of Retinal Disease Control, Tohoku Univ Graduate School of Medicine, Sendai, Miyagi, Japan; 10) Ozaki Eye Hospital, Hyuga, Miyazaki, Japan; 11) Kanto Central Hospital of the Mutual Aid Association of Public School Teachers, Setagaya-ku, Tokyo, Japan.

**Purpose:** Genetic variants associated with primary open-angle glaucoma (POAG) can be classified into two types. One is a genetic variant associated with intraocular pressure (IOP) elevation (IOP-related genetic variant), while the other is a genetic variant associated with a vulnerability of optic nerve independent of IOP (non-IOP-related genetic variant). This study was conducted to investigate the association between the additive effects of IOP-related or non-IOP-related genetic variants and age at diagnosis of glaucoma as an indicator of POAG progression. **Methods:** Eleven variants identified as IOP-related genetic variants, including rs1052990 (near gene: *CAV2*), rs11656696 (*GAS7*), rs59072263 (*GLCCI1/ICA1*), rs2472493 (*ABCA1*), rs58073046 (*ARHGEF12*), rs2286885 (*FAM125B*), rs6445055 (*FNDC3B*), rs8176743 (*ABO*), rs747782 (*PTPRJ*), rs4619890 (*AFAP1*), and rs2745572 (*FOXC1*), and 9 variants considered as non-IOP-related genetic variants, including rs3213787 (*SRBD1*), rs735860 (*ELOVL5*), rs1063192 (*CDKN2B*), rs1900004 (*ATOH7*), rs10483727 (*SIX6*), rs11969985 (*GMD5*), rs3785176 (*PMM2*), rs1192415 (*TGFBR3*), and rs35934224 (*TXNRD2*), were genotyped for 505 patients with POAG and 246 control subjects. The total number of risk alleles of the 11 IOP-related or 9 non-IOP-related genetic variants was calculated for each participant as genetic risk scores (GRSs). A logistic regression model was used to estimate the risk (odds ratio) of glaucoma for each risk allele of genetic variants, and the sum of the logarithmically converted odds ratios of 11 IOP-related or 9 non-IOP-related genetic variants was used as weighted GRSs (WGRSs). The association between these GRSs or WGRSs and age at diagnosis of glaucoma was evaluated. **Results:** There were significant relationships between the GRS (Beta = -0.16, P = 0.0005) or WGRS (Beta = -0.13, P = 0.0039) of 11 IOP-related genetic variants and the age at diagnosis of glaucoma by multiple linear regression analysis adjusted for gender. As the GRS or WGRS of IOP-related genetic variants increased, the age at diagnosis of glaucoma became younger. **Conclusions:** Additive effect of IOP-related, not non-IOP-related, genetic variants was associated with age at diagnosis of glaucoma in POAG, which indicates that IOP-related genetic variants (IOP elevation) rather than non-IOP-related genetic variants (vulnerability of optic nerve) may play an important role for POAG progression.

**2522F**

**Opsin gene probes accurately predict red-green color vision deficiencies derived from a web-based Ishihara plate color perception test.** *M.L. Multhaup, M.N. Johnson, J.F. Shelton, M.J. Strand, B.L. Koelsch, B. Alipanahi.* 23andMe, Mountain View, CA.

Red-green colorblindness is an umbrella term for several X-chromosome-linked color vision deficiencies highly prevalent among men. These conditions encompass a spectrum of severity, and many men with less severe disorders are unaware that they have color vision deficiencies at all. The vast majority of red-green colorblindness in humans is due to variation in the X-chromosome medium and long wave opsin genes, *OPN1MW* and *OPN1LW*. These genes are derived from a relatively recent gene duplication and share 98% similarity by nucleotide sequence. The nucleotides that are divergent between these genes are disrupted in red-green colorblindness, making the creation of colorblindness-informative gene-specific probes difficult and rendering this region uncovered by most standard genotyping arrays. 23andMe has created custom genotyping probes to detect variants in these two genes. In parallel, we have also collected self-reported colorblindness status from over 350,000 male research participants and developed a custom 8-plate Ishihara color perception test completed by more than 40,000 male research participants. We developed a scoring system for our Ishihara test that indicates both full and partial colorblindness and is highly correlated with self-reported colorblindness. We used raw probe intensity data to fit gradient tree boosting models predicting full and partial colorblindness. These models had area under receiver-operator curves of greater than 0.95 and 0.87, respectively, positive predictive values of 60% and negative predictive values of 99% in out-of-sample testing cohorts. Using raw probe intensity for prediction resulted in substantially higher prediction accuracy than either default genotype calls or a custom-calling scheme designed individually for each probe. We hope to use these models to identify 23andMe customers who may not know that they are partially red-green colorblind and should undergo further testing in order to facilitate positive quality of life interventions..

**The role of regulatory variants in FZD6-related gene network in nonsyndromic cleft lip and palate.** *L. Malli<sup>1</sup>, Q. Yuan<sup>2</sup>, B.T. Chiquet<sup>2,3</sup>, A. Letra<sup>3</sup>, G.T. Eisenhoffer<sup>4</sup>, J.T. Hecht<sup>1,2,3</sup>.* 1) MDAnderson UTHealth Graduate School of Biomedical Sciences, Houston, TX; 2) McGovern Medical School, Houston, TX; 3) University of Texas School of Dentistry, Houston, TX; 4) University of Texas MD Anderson Cancer Center, Houston, TX.

Nonsyndromic cleft lip with or without cleft palate (NSCLP) is a common birth defect with a prevalence of 1 in 700 that annually affects approximately 4000 newborns in the United States. Despite improvement in treatments, NSCLP continues to pose major medical, psychosocial, and financial burdens. We, and others, have shown that perturbation of *FZD6* and related genes causes severe craniofacial anomalies: 1) knockdown or overexpression of *fzd6* causes craniofacial abnormalities in zebrafish, 2) loss of *lrp6* significantly reduces Wnt signaling in mutant mouse embryos causing orofacial clefts, 3) knockdown or mutant forms of *lrp5* cause abnormal craniofacial cartilage phenotypes and cleft palate in zebrafish, and 4) the facial region completely fails to form in mice deficient for *dkk1*. These genes act at the receptor level of the  $\beta$ -catenin mediated Wnt pathway. The goal of this study was to identify variation in regulatory elements upstream of *FZD6*, *LRP5*, *LRP6* and *DKK1* and their contributions to NSCLP. Twenty-one variants in these genes were assessed for allele-specific binding and 10 variants, 1 in *FZD6*, 3 in *LRP6*, 3 in *LRP5* and 3 in *DKK1*, showed differential DNA-protein binding patterns. To assess their effect on gene expression, these variants and their flanking regions were cloned upstream of luciferase promoter constructs. Five variants, rs115369160, rs7139600 and rs7136380 in *LRP6* and rs7069912 and rs114205486 in *DKK1*, had significant allele-specific effects on luciferase assays in 293T cells and are being assessed in other cell types to evaluate tissue specificity. Utilizing a stable zebrafish reporter line,  $\beta$ -catenin was evaluated in craniofacial development from 1-7 days post fertilization (dpf) and was highly active in the oral cavity and other facial regions between 3-5 dpf. Morpholino knockdown of *fzd6* in these reporter fish resulted in a reduction in  $\beta$ -catenin activity in the oral cavity at 3 dpf. *Lrp5*, *lpr6* and *dkk1b* are now being similarly assessed. The results of this study provide important information about the effects of regulatory variants in *FZD6* and related  $\beta$ -catenin/Wnt pathway genes and their role in craniofacial development. This sets the stage for subsequent evaluation of these noncoding variants in NSCLP families.

**Minimizing facial dysmorphologies associated with Down syndrome by inhibition of DYRK1A related pathways.** N. Martínez-Abadías<sup>1</sup>, J.M. Starbuck<sup>2</sup>, R. González<sup>3</sup>, X. Seviliano<sup>3</sup>, A. González<sup>3</sup>, J. Sharpe<sup>1</sup>, R. De La Torre<sup>4</sup>, M. Dierssen<sup>5,6</sup>. 1) Multicellular Systems Biology, European Molecular Biology Lab (EMBL), Barcelona, Spain; 2) Department of Anthropology, University of Central Florida, Orlando, FL, USA; 3) Grup de Recerca en Tecnologies Mèdia (GTM), La Salle - Universitat Ramon Llull, Barcelona, Spain; 4) Integrative Pharmacology and Systems Neuroscience, IMIM–Hospital del Mar Medical Research Institute, Barcelona, Spain; 5) Cellular & Systems Neurobiology, Center for Genomic Regulation (CRG), The Barcelona Institute of Science and Technology, Barcelona, Spain; 6) Universitat Pompeu Fabra (UPF), Barcelona, Spain.

Down syndrome affects 1 out of 700 live born individuals and is the most prevalent genetic cause of intellectual disability. It is caused by trisomy of chromosome 21, which leads to a complex pleiotropic phenotype that involves a recognizable set of facial traits. Recent studies have shown that the overall genetic imbalance caused by the 1.5-fold gene dosage increase associated with trisomy 21 can be modulated through inhibition of kinase activity by the green tea flavanol epigallocatechin-3-gallate (EGCG). Although all genes and signaling pathways are yet to be discovered, available evidence indicates that EGCG inhibits several DYRK1A related pathways, such as the *NFAT* (Nuclear factor of activated T-cells) signaling pathway and transcription factors *DCAF741* and *GLI142*, which are overexpressed in Down syndrome and play a critical role as regulators of brain, skeletal and facial development. Here we provide for the first time clinical evidence of the potential benefits of EGCG treatment to facial morphology in Down syndrome. We analyzed a cross-sectional sample of 287 children from 0 to 18 years old including euploid children, children with either non-disjunction or mosaic Down syndrome, as well as children with Down syndrome who had taken EGCG as dietary supplements. We assessed global and local facial shape differences between children with Down syndrome and euploid controls analyzing the 3D coordinates of 21 anatomical landmarks identified on 3D facial reconstructions using Geometric Morphometric methods. Our observational study revealed that EGCG treatment since early in development is associated with intermediate facial phenotypes and significant facial improvement scores. If taken during the three first years of life, EGCG supplementation reduced by 47% the number of facial differences of trisomic and euploid individuals, by normalizing length, width, and depth dimensions of the midface, with strongest effects on the philtrum and nasal regions. Our findings thus suggest a potential beneficial effect of EGCG on facial development in Down syndrome. In a broader context, our phenomic approach could be applied to other disorders associated with facial dysmorphologies to correlate facial phenotypes with different levels of genetic expression and to test the efficacy of potential therapeutic treatments.

**Insights into the etiology of nonsyndromic orofacial clefting by WGS of Colombian trios.** E.J. Leslie<sup>1</sup>, L. Moreno-Urbe<sup>2</sup>, P. Chopra<sup>1</sup>, D.J. Cutler<sup>1</sup>, E. Feingold<sup>3</sup>, C. Valencia-Ramirez<sup>4</sup>, C. Restrepo<sup>4</sup>, A.C. Lidral<sup>5</sup>, M. Arcos-Burgos<sup>6</sup>, E. Liao<sup>7</sup>, R.A. Cornell<sup>2</sup>, M.L. Marazita<sup>1</sup>. 1) Emory University, Atlanta, GA; 2) University of Iowa, Iowa City, IA; 3) University of Pittsburgh, Pittsburgh, PA; 4) Fundación Clínica Noel, Medellín, Colombia; 5) Private Practice, MI; 6) Australian National University, Canberra, Australia; 7) Massachusetts General Hospital; Harvard Medical School, Boston, MA.

Orofacial clefts (OFCs) represent the largest group of craniofacial malformations in humans with a worldwide prevalence of 1 in 1000 live births. OFCs, including cleft lip and palate (CLP), are regarded as complex traits with a strong genetic component influencing risk. Genetic studies including linkage, GWAS, and sequencing have identified a number of genetic risk factors, but have not been able to define a single genetic mechanism underlying this disorder. Because all types of variants (common, rare, de novo, etc.) appear to confer risk, the genetic etiology of OFCs remains difficult to fully elucidate. To comprehensively examine genetic risk factors for OFCs, we performed whole genome sequencing (WGS) on 276 case-parent trios with CLP from Colombia as part of the Gabriella Miller Kids First Pediatric Research Program. Genomic DNA was extracted from peripheral blood cells; paired end sequencing was performed at >30X coverage on the Illumina HiSeq X instrument and variant calling was performed using GATK. Our first analyses focused on de novo mutations (DNMs) which, despite multiple lines of evidence supporting them as causes of OFCs, have been poorly represented in sequencing studies. We identified 251 exonic DNMs across all genes; four genes (*CTNND1*, *KLB*, *HLA-DRB5*, and *MUC2*) had multiple DNMs, resulting a genome-wide statistical significance. To further explore the genes with only one DNM, we focused on genes belonging to the IRF6 regulatory network because the IRF6 transcription factor has been demonstrated to be a chief determinant of both syndromic and nonsyndromic forms of OFCs. We identified 238 putative IRF6 target genes by performing ChIP-seq for Irf6 in zebrafish embryos and cross-referencing with RNA-seq in wildtype and *irf6*<sup>-/-</sup> zebrafish and mouse craniofacial gene expression databases. In the WGS data, we identified one de novo mutation in *IRF6* (p.Asn88Asp) and 7 additional nonsynonymous or loss-of-function mutations in IRF6 target genes (representing 3% of all DNMs). These included mutations in *CDH2* (p.Arg656Trp), *GRHL3* (p.Pro480Ser), and *TFAP2A* (p.Glu104\*). Together, these analyses support growing evidence for de novo mutations in the etiology of OFCs. Further, it demonstrates the important role of IRF6 and provides rationale for further explorations of rare inherited variants and noncoding regulatory variants in and around these genes, and expansion of this approach to other OFC risk loci.

**2526W****Structural variation in neural tube defects: Adding another layer to a complex genetic architecture.** *P. Wolujewicz<sup>1,2</sup>, V. Aguiar-Pulido<sup>1</sup>, R.H. Finnell<sup>3</sup>, C.E. Mason<sup>1,2,4</sup>, O. Elemento<sup>1,2,4,5</sup>, M.E. Ross<sup>1</sup>.*

Neural tube defects (NTDs), especially spina bifida (SB), are common debilitating birth defects that involve multiple genes and environmental factors. While genetic heritability estimates for NTDs range from 60-70%, the genetic architecture has proven to be complex and mutations in more than 400 genes can produce NTDs in mice. Attempts to identify human mutations that confer risk for NTDs remains a challenge. While several studies have investigated the inherent genomic variation in NTDs (e.g. exploring SNVs from exomes as well as CNVs from array data), the interrogation of all types of structural variants remains largely unexplored and no study to date has analyzed structural variation in NTD patients via whole genome sequencing (WGS) approaches. Here, we conducted WGS on over 150 SB patients and over 150 population-matched controls to elucidate the contribution of structural variants in order to better understand the complex genetic nature of this malformation. To this end, we have developed an integrative approach for germline structural variant detection and annotation as well as a visualization framework to aid in variant validation and interpretation. Using our approach, we report on the burden of structural variants in NTD cases and genes that are enriched with this form of variation that are likely to be associated with the condition.

**2527T****Utility of early tongue reduction surgery in patients with Beckwith-Wiedemann syndrome.** *J.L. Cohen<sup>1,2</sup>, B. Sajorda<sup>1</sup>, E. Traxler<sup>1</sup>, W. Frederic<sup>1</sup>, K. Duffy<sup>1,2</sup>, E. Hathaway<sup>1,2</sup>, J.A. Taylor<sup>1,2</sup>, C. Cielo<sup>1,2</sup>, J.M. Kalish<sup>1,2</sup>.*

1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) The Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA.

Macroglossia is a cardinal feature of Beckwith-Wiedemann syndrome (BWS) and has been associated with obstructive sleep apnea (OSA), speech and/or feeding difficulties, and may be treated with tongue reduction (TR). There are no guidelines advising standard technique or timing for surgery. Some experts recommend waiting until age 6-12 months to avoid possible tongue tissue regrowth. We sought to determine who would benefit from early tongue reduction (ETR), defined as less than 12 months old, or very early tongue reduction (VETR), defined as less than 6 months old. We hypothesized that ETR and VETR would benefit BWS patients who presented early in life with clinical indications for surgery. We conducted a retrospective review of the BWS registry and determined 28 patients underwent TR at any age during the past 4 years at our institution. We determined the BWS clinical scores and reviewed molecular testing on available tongue tissue. We examined polysomnography reports and clinical feeding, pulmonary, and surgery evaluations. Of the 28 TR subjects, 8 had VETR, 7 had ETR. Tongue methylation analysis showed concordance with the patients' blood analysis. The average BWS clinical score of subjects with VETR (11.3+/- 0.7) was greater than those who had ETR (8.6+/- 0.6) ( $p < 0.05$ ). Indications for performing VETR included OSA (8/8), often accompanied by other respiratory support needs (5/8), or feeding difficulties (5/8). Of the 15 patients within the VETR and ETR groups, at least 3 were prenatally diagnosed with macroglossia. In subjects for whom polysomnography was performed, median obstructive apnea hypopnea index was 30.8 (VETR) and 16.8 (ETR) preoperatively. Six of the eight subjects that underwent VETR experienced resolution of OSA based on post-operative polysomnography or clinical assessment. The earliest TR case, at 7 days old, was diagnosed prenatally and demonstrated improved speech, feeding, and sleep outcomes prior to NICU discharge and at long-term 2-year follow-up. Based on this data, if a patient with BWS is prenatally diagnosed with macroglossia, or requires respiratory support in the neonatal period, we recommend evaluation for OSA followed by consideration of VETR. The data supports that VETR and ETR are safe and effective in treating the indications for surgery.

## 2528F

**A population-based study of gene-alcohol interactions and orofacial cleft risk.** A.L. Petrin<sup>1</sup>, W. Lyu<sup>2</sup>, L. DeRoo<sup>3</sup>, P.A. Romitti<sup>4</sup>, M.M. Jenkins<sup>5</sup>, R.G. Mungers<sup>6</sup>, J.C. Murray<sup>7</sup>, A.J. Wilcox<sup>8</sup>, R.T. Lie<sup>9</sup>, G.L. Wehby<sup>10</sup>, L.M. Moreno Uribe<sup>1,9</sup>, *National Birth Defects Prevention Study*. 1) Dows Institute, College of Dentistry, the University of Iowa, Iowa City, IA, USA; 2) Department of Health Management and Policy, University of Iowa, Iowa City, Iowa, USA; 3) Department of Global Public Health and Primary Care, University of Bergen, Bergen, Norway; 4) Department of Epidemiology, College of Public Health, The University of Iowa, Iowa City, Iowa, USA; 5) Centers for Disease Control and Prevention, National Center on Birth Defects and Developmental Disabilities, Atlanta, Georgia, USA; 6) Department of Nutrition and Food Sciences, Utah State University, Logan, Utah, USA; 7) Department of Pediatrics, Carver College of Medicine, University of Iowa, Iowa City, Iowa, USA; 8) Epidemiology Branch, National Institute of Environmental Health Sciences/National Institutes of Health, Durham, North Carolina, USA; 9) Department of Orthodontics, College of Dentistry, the University of Iowa, Iowa City, IA, USA.

Prior studies have shown conflicting results for maternal prenatal alcohol consumption and the risk for orofacial clefts (OFCs), possibly hiding significant heterogeneity in risk by maternal and fetal alcohol metabolism genes. We examined interaction effects on isolated OFC risk between first-trimester maternal alcohol use (any alcohol and average drinks/sitting) and 7 alcohol metabolism genes/loci (ADH1B/ADH1C, ADH1C, ALDH1A1, CTBP2, MLLT3, OPRL1, SMC2) in both mothers and children. We combined individual-level data from 5 population-based studies—Iowa Case–Control Study, National Birth Defects Prevention Study, Norway Facial Clefts Study, Norwegian Mother and Child Cohort, and Utah Child and Family Health Study—to create the largest population-based case-control sample to date, consisting of 1,330 (1,743) case children (mothers) and 2,549 (3,417) control children (mothers). We evaluated interactions between each alcohol consumption measure and gene/locus using multivariable logistic regression, including fixed effects for study site, maternal age and education at delivery, pre-pregnancy body mass index, and first-trimester smoking and folic acid/multivitamin use. We observed significant interaction effects between any maternal first-trimester alcohol consumption and maternal ADH1B/ADH1C ( $p < 0.05$ ) and ALDH1A1 ( $p < 0.01$ ) genotypes. Cleft lip only (CLO) risk doubled for mothers homozygous for the minor allele of ADH1B/ADH1C rs1789891 (adjusted odds ratio (aOR)=2.36, 95% confidence interval (CI)=1.16–4.81), while cleft palate only (CPO) risk increased (aOR=1.54, 95% CI=1.06–2.23) for mothers homozygous for the major allele of ALDH1A1 rs2303317. Similar interactions were observed when mothers reported <5 drinks per sitting. CLO risk was significantly higher when mothers reported repeated  $\geq 5$  drinks per sitting with the minor allele of maternal MLLT3 rs4621895 (aOR=3.86, 95% CI=1.65–9.12) and fetal OPRL1 rs6010718 (aOR=24.05, 95% CI=1.95–298.87); CPO risk also increased with the same fetal variant (aOR=11.47, 95% CI=1.16–112.17). These findings suggest meaningful heterogeneity in the risk of OFC subtypes associated with maternal alcohol consumption by variants in certain alcohol metabolism genes.

## 2529W

Non-syndromic cleft lip with or without cleft palate (nsCL/P) is a common congenital malformation and has a multifactorial etiology. The common risk variants, mostly identified by GWAS, explain about 25% of the genetic heritability. We hypothesize that a fraction of the remaining genetic liability is explained by rare dominant *de novo* mutations. In order to identify such rare *de novo* mutations, we performed whole exome sequencing (WES) in 50 trios, consisting of nsCL/P patients and their unaffected parents. This resulted in identification of 33 *de novo* mutations in 33 genes. Among these were *de novo* mutations in *CDH1* and *TRMO*, both already known to be associated with nsCL/P. To find further support for a contribution of these candidate genes to nsCL/P, and to strengthen our hypothesis of dominant *de novo* events adding to nsCL/P etiology, the candidate genes were subjected to a large-scale resequencing study with single-molecule molecular inversion probes (smMIPs). The independent resequencing cohort comprised nsCL/P patients and population-matched controls of Arabian, Mexican and European ancestry ( $n_{\text{cases}}=1,013$ ,  $n_{\text{controls}}=1,591$ ). The assay was designed using the MIPGEN pipeline. smMIPs for 32 genes were successfully designed. Libraries were sequenced on HiSeq2500 with 2x125bp read length. Raw reads were aligned with BWA and variants were called with UnifiedGenotyper. Downstream analysis included filtering for CADD  $\geq 15$  and MAF  $\leq 0.1\%$ . Only those variants not present in any of the controls were used for further analysis which included manual inspection of reads and segregation analysis. As a first step of our data analysis, we checked the genes *CDH1* and *TRMO* for deleterious variants. We identified 1 rare stop gain and 8 rare missense variants in *CDH1*, and 1 rare stop gain and 3 rare missense variants in *TRMO*. Notably, the average CADD score of these variants was  $>25$ . Of particular interest is the stop gain in *CDH1* (NM\_004360:p.R598X) which leads to a loss of the cytosolic binding domains of the CDH1 binding partners CTNND1 and CTNNB1. This protein complex is part of the epithelial adhesion complex which was recently shown to lead to nsCL/P when disrupted in a mouse model. First results of our resequencing approach found further indications for a contribution of rare variants in *CDH1* and *TRMO* to nsCL/P development. Further analyses of our data are on the way, aiming at identification of rare *de novo*/co-segregating variants in novel candidate genes for nsCL/P.

Holoprosencephaly (HPE) is a pathology of forebrain development characterized by high phenotypic and locus heterogeneity. The disease presents with various clinical manifestations at the cerebral or facial levels. Several genes have been implicated in HPE but its genetic basis remains unclear: different transmission patterns have been described including autosomal dominant, recessive and digenic inheritance. Conventional molecular testing approaches result in a very low diagnostic yield and most cases remain unsolved. In our study, we address the possibility that genetically unsolved cases of HPE present an oligogenic origin and result from combined inherited mutations in several genes. All patients initially underwent a routine diagnostic procedure (Whole Exome Sequencing and CGH-array analyses) following the American College of Medical Genetics and Genomics-Association (ACMG) guidelines. 26 unrelated families with no established diagnosis were considered eligible for the hypothesis of oligogenic inheritance and included in the study. Their exome data was reanalyzed using more permissive settings. To identify variants of clinical interest, we used an integrative approach combining variant- and gene-based prioritization involving clinical ontologies and analysis of gene co-expression networks. Clinical phenotyping and exploration of cross-species similarities with known mouse mutants were further performed on a family-by-family basis. Statistical validation was performed on 744 ancestrally matched healthy controls provided by the Genome of the Netherlands (GoNL) project. Variants of clinical interest were identified in 180 genes significantly associated with key pathways of forebrain development including Sonic Hedgehog (SHH) and Primary Cilia. Oligogenic events were observed in 10 families and involved both known and novel HPE genes including recurrently mutated *FAT1*, *NDST1*, *COL2A1* and *SCUBE2*. The incidence of oligogenic combinations was significantly higher in HPE patients compared to the GoNL control population (Fisher's exact test  $p$ -value =  $3.237e-14$ ). We also show that depending on the affected genes and pathways, patients present with particular secondary clinical phenotypes. This study reports novel HPE and HPE-related phenotype genes and supports oligogenicity as clinically relevant model in this disease. It also underlines that integrating clinical phenotyping in genetic studies will improve the identification of causal variants in rare disorders.

**Screening for 22q11.2 deletions and duplications in a large biobank data-set at a tertiary medical center uncovers new and undiagnosed cases.** J.J. Connolly<sup>1</sup>, M.H. Harr<sup>1</sup>, J.T. Gleesner<sup>1</sup>, F.D. Mentch<sup>1</sup>, F. Mafra<sup>1</sup>, T.B. Crowley<sup>1,2</sup>, P.M.A. Sleiman<sup>1,2</sup>, D.M. McDonald-McGinn<sup>1,2</sup>, H. Hakonarson<sup>1,2,3</sup>, *Electronic Medical Records and Genomics (eMERGE) Outcomes Group*. 1) Childrens Hospital of Philadelphia, Philadelphia, PA; 2) The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA; 3) Divisions of Human Genetics, Childrens Hospital of Philadelphia, Philadelphia, PA, USA.

**Background:** The biorepository at the Center for Applied Genomics (CAG) at the CHOP contains samples from over 100,000 CHOP patients and over 20,000 parents. In addition to biosamples, the majority of patients have consented to electronic health record (EHR) review with regular updates and re-contact, facilitating longitudinal collection of health information. It has been recognized that there is variability in the deletion breakpoints across the 22q11.2 critical region leading to variable inclusion of critical genes, and consequently, some phenotype-genotype correlations have been established. The phenotype of 22q11.2 duplications is reported to be more variable than the reciprocal deletion, and therefore more difficult to diagnose clinically.

**Methods:** To further investigate the prevalence and variability of these syndromes we screened a dataset of over 30,000 genotyped subjects who had been randomly recruited to the CAG biorepository and approximately 10,500 genotyped subjects from the Electronic Medical Records and Genomics (eMERGE) consortium in search of copy number variation (CNV) across the 22q11.2 region. CNVs were classified according to breakpoints and size consistent with the regions of segmental duplications LCR22A through LCR22H. EHR review was completed for all CHOP patients to determine whether the diagnosis was previously known by the patient's healthcare providers. Participants with previously unknown CNV(s) underwent review of clinical features to identify findings consistent with 22q11.2 deletion or duplication syndrome.

**Results:** We identified 48 deletions and 34 duplications in 81 CHOP patients and 10 duplications in eMERGE participants. Of 81 patients, 37 patients did not have EHR documentation indicating the diagnosis was previously known. The undiagnosed cases were duplications (34) or atypical deletions (3). EHR review revealed fewer hospital encounters and fewer items on the problem list for those with duplications than those with deletions. **Conclusions:** These data suggest that even at tertiary medical centers with expertise in 22q copy number variation, a proportion of patients with 22q CNVs remain undiagnosed, in particular those patients who do not have a standard LCR22A-LCR22D deletion or those who carry a duplication. EHR review adds to the knowledge of the phenotypic spectrum of patients with 22q11.2 duplications. Data lend support to national efforts of newborn screening for this relatively common syndrome.

**Development of CNV analysis method for newborn screening using Global Screening Array (GSA).** *M.-J. Kim<sup>1</sup>, J. Joo<sup>2</sup>, K.C. Lee<sup>2</sup>, H.J. Kwon<sup>2</sup>, A. Goyal<sup>2</sup>, A. Kurkciyan<sup>1</sup>, A. Espiritu<sup>1</sup>, M.-F. Wu<sup>1</sup>, J.-S. Bae<sup>2</sup>, S. Lee<sup>2</sup>, M.S. Lee<sup>1,2</sup>.* 1) Diagnostics, Inc. 5795 Kearny Villa Rd, San Diego, CA 92123 USA; 2) Eone-Diagnomics Genome Center (EDGC), Inc. #291 Harmony-ro, Yeon-su-gu, Incheon, 22014, South Korea.

Structural variation is the structural alteration in the genome including duplications, deletions, translocations, and inversions. Some copy number variations (CNVs) are clearly related to diseases such as Angelman, Cri-Du-Chat, Digeorge and Jacobsen syndromes. It is critical to detect these variations as early as possible to prevent the onset of symptoms or minimize/reduce disease impact. Genome-wide genotyping microarrays have been used to detect those CNVs, which is reliable and efficient method for large-scale analysis. Newborn screening test using genome-wide CNV analysis can detect chromosomal abnormalities of a variety of genetic disorders. With a high resolution, microarray-based CNV analysis is a useful method to identify microdeletions and microduplications as well as novel CNVs. The microarray has provided a genomic tool for research applications including disease risk profiling studies, pharmacogenomics research, wellness characterization, and complex disease discovery. The Infinium Global Screening Array (GSA, Illumina, USA) contains multi-ethnic genome-wide content, curated clinical research variants, and quality control (QC) markers for precision medicine research. In addition to the consortium-developed 646,824 SNP markers, we designed 34,136 additional markers including pharmacogenomics and Korean-specific contents, resulted in 680,960 markers in total. In this present work, we performed analytical validation of the GSA for CNV detection using Coriell control human genomic DNAs for the newborn screening.

**Co-occurrence of recurrent copy number variations in a child with complex clinical phenotype.** *B. Melegh<sup>1,2,3</sup>, A. Till<sup>1,2,3</sup>, M. Czako<sup>1,2,3</sup>, A. Szabo<sup>1,2,3</sup>, K. Hadzsiev<sup>1,2,3</sup>.* 1) Department of Medical Genetics, University of Pecs, Pecs, Hungary; 2) Szentagotai Research Center, University of Pecs, Pecs, Hungary; 3) Clinical Center, Medical School, University of Pecs, Pecs, Hungary.

Two copy number variations observed on the same chromosome in a patient is quite rare. Here we report a patient, who beside of the 17p11.2 microduplication had an additional deletion of 17q12 region. The routine cytogenetic investigation, which was indicated at 8 months of age of the baby because of neonatal hypotonia, developmental delay, renal cysts, hearing loss and minor anomalies, resulted in normal karyotype. Because of the complex clinical symptoms array CGH analysis using Agilent Sureprint 8x60K oligo-array (ISCA v.2) was performed. The array CGH detected a 3,573 Mb recurrent microduplication of 17p11.2 and additionally a 1,638 Mb deletion affecting 17q12.; and the unexpected results provided explanation of the complex clinical features allowing for a more detailed genotype-phenotype analysis. Our patient has been diagnosed as having Potocki-Lupski syndrome, renal cysts, and diabetes syndrome at the same time, which is a novel phenotypic variant of this disease group.

**Chromosome 22q11 microdeletion: Potential modifiers of the cardiovascular phenotype found in heart development genes.** *B. Rebolledo-Jaramillo<sup>1</sup>, G. Repetto<sup>1</sup>, F. Benavides<sup>1</sup>, H. Poggi<sup>1</sup>, A. Cuiza<sup>1</sup>, P. Alvarez<sup>2</sup>.* 1) Center for Genetics and Genomics, Clin Alemana - Univ Desarrollo, Santiago, Chile; 2) Hospital Dr Roberto del Rio, Santiago, Chile.

**Chromosome 22q11.2 microdeletion syndrome (22q11DS) is the most common microdeletion syndrome in humans, with an estimated frequency of 1/4000. The syndrome shows marked variable expressivity not associated with deletion size or parental origin, suggesting the presence of modifiers elsewhere in the genome. Approximately 50-60% of patients have congenital heart disease (CHD), so the aim of this study was to search for genetic modifiers of the cardiovascular phenotype through whole exome sequencing (WES). We included 60 patients with 22q11DS: 25 cases with conotruncal severe CHD and 35 controls. WES was performed at the Northwest Genome Center (NWGC), using Roche Nimblegen V2 Exome capture and 75 bp paired-end sequencing. Variant calling was done with BWA+GATK best practices, and 22 cases and 33 control remained after quality control. We conducted a weighted combination of burden and SKAT tests, on loss of function (LOF) and rare (MAF <0.001) predicted deleterious single-nucleotide variants (rdSNVs), defined as missense variants where at least two of six predictors SIFT, PolyPhen-2, MutationTaster, MutationAssessor, FATHMM and CADD predicted damaging impact (6,560 variants in total), and found 58 genes with p-value<0.05. Among them, a single gene, *NES*, matched gene pathways related to CHD. The *NES* gene has been described as a putative target of *WNT1* during heart development, and experiments in rodents have shown its role in heart and brain development. We then relaxed the rare variant criteria and analysed all predicted deleterious LOF and missense variants (23,363 variants in total). We found 304 genes with p-value<0.05, nine of which matched CHD related pathways: *MBP*, *HDAC10* and *NOTCH2* (neural crest differentiation), *SPHK1*, *HNF4A* and *S1PR3* (human stem cell pluripotency), *ADAM19* (mesodermal commitment), *BMP1* (cardiac progenitor differentiation), and *DOCK8* (factors involved in megakaryocytes development and platelet production). Neural crest cells are critical for the outflow tract septation, and histone modifier genes, such as *HDAC10*, has been previously associated with CHD. However, there not seem to be a single gene responsible for the cardiovascular phenotype observed in our cohort. In fact, the variants within the genes were rare, 1 to 4 alleles among the 22 cases. So, for the other cases, variants in genes in the remaining 22q11 region or elsewhere in the genome may be associated with the presence of CHD. **Novel candidate genes to nonsyndromic orofacial clefts revealed by exome and target gene sequencing.** *L.A. Brito, S. Ezquina, G. Yamamoto, G. Hsia, S.G. Ferreira, M.R. Passos-Bueno.* Department of Genetics, University of Sao Paulo, Sao Paulo, Sao Paulo, Brazil.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is a prevalent developmental disorder affecting ~1:1000 live-born children. Despite presenting a high heritability, which reaches 85% in Brazil, common variant can only explain a small fraction of, according to recent meta-analyses. On the other hand, the role played by rare, high-effect genetic variants in NSCL/P complex etiology has increasingly been focus of attention. Here, we used exome sequencing in familial cases of NSCL/P to unravel the relevance of rare variants to the disease, as well as the role of new candidate genes. We sequenced, in total, 32 affected individuals from 10 familial cases, segregating NSCL/P under autosomal dominant-like inheritance. After filtering for shared variants within families (assuming a major causal variant) and prioritizing rare (<.005) variants in functionally relevant genes, we identified, for two families, a pathogenic variant in the epithelial-cadherin gene (*CDH1*). For the remaining families, a list of 11 candidate variants in novel candidate genes was raised. Pathway analysis including all genes harboring rare variants in these families indicated an enrichment of Wnt signaling pathway genes (both canonical and non-canonical / Planar Cell Polarity pathway). To investigate the ethiological role of these pathways, sequencing of a panel containing 31 genes with known expression during lip and palate development, in 500 NSCL/P patients from familial cases, have also been performed.

**Somatic mosaicism in the MAPK-ERK signaling pathway in sporadic cerebral arteriovenous malformations.** S. Gao, D. Guo, M. Lawton, L. Pawlikowska, H. Kim. Center for Cerebrovascular Research, University of California San Francisco, 1001 Potrero Avenue, San Francisco, CA 94110.

Cerebral arteriovenous malformations (AVMs), with an estimated 0.01% frequency in the population, are a leading cause of hemorrhagic stroke in young adults. Most cerebral AVMs are sporadic, suggesting that somatic mutations might underlie these lesions. A recent study reported two recurrent somatic mutations in *KRAS*, a member of the MAPK-ERK signaling pathway, in cerebral AVM lesions at low allelic frequencies (0.9% to 4%) in 74% of patients studied. Given that somatic mutations in several genes of the MAPK-ERK pathway are associated with other vascular anomalies, we hypothesized that somatic mosaicism in other genes of the MAPK-ERK signaling pathway might contribute to the development of cerebral AVMs. **Methods:** We analyzed whole-exome sequencing data generated from paired AVM tissue and peripheral blood of 17 unrelated patients with sporadic cerebral AVMs. Somatic mutations were called using GATK Mutect2, intersected with a list of 267 genes belonging to the MAPK-ERK signaling pathway (KEGG database), and filtered to identify genes harboring somatic mutations in more than one patient and recurrent somatic mutations. We applied three filters: 1) at least three reads containing somatic mutations in AVM tissue; 2) no reads containing somatic mutations in blood; 3) allelic frequency of candidate somatic mutations greater than 3%. Two patients were excluded due to poor sequencing quality, as indicated by a greater number of variants identified compared to other patients. **Results:** Average sequencing read depth was 91X across the exome. We found 29 genes in the MAPK-ERK signaling pathway bearing candidate somatic mutations in at least two patients. Among these, we identified three recurrent somatic mutations in three genes (*CACNA2D4*, *RASGRF1*, and *KRAS*), including the previously reported *KRAS*<sup>p.G12V</sup> mutation. *KRAS* mutations were validated using droplet digital PCR, with a high concordance of allelic frequency of the mutant allele (p.G12V) between whole-exome sequencing (4.80%) and droplet digital PCR (4.88%). **Conclusions:** We have replicated the finding of somatic, recurrent *KRAS* mutations in sporadic cerebral AVM. Potential somatic mosaicism was also observed in a subset of genes of the MAPK-ERK signaling pathway in patients with sporadic cerebral AVM.

**Understanding the genetic contribution to heterotaxy syndrome.** A. Sridhar, SM. Ware. Wells Center for Pediatric Research, Indiana University School of Medicine, Indianapolis, IN.

Heterotaxy (HTX) is a rare congenital anomaly syndrome accompanied by thoracic and/or abdominal situs abnormalities resulting from abnormal left-right patterning during embryonic development. HTX can occur as an autosomal dominant, recessive, or X-linked condition, but is most commonly multifactorial. Individuals with primary ciliary dyskinesia (PCD) or syndromic ciliopathies can exhibit a HTX phenotype, but the prevalence of these conditions amongst individuals with HTX is unknown. We aimed to identify the incidence of Mendelian disease amongst prospectively recruited individuals with HTX and further delineate genetic associations by defining variant burden. In order to investigate known Mendelian genetic cause we interrogated 285 whole exomes and evaluated 172 genes compiled from HTX, PCD and ciliopathy clinical panels. Forty-three subjects (15%) revealed likely pathogenic variants that were X-linked (2.1%, including multiple participants with Oculo-Facio-Cardio-Dental syndrome), autosomal recessive (8.8%, including 5.6% with PCD, 2.1% with syndromic ciliopathies and 1.1% with other genetic syndromes) or autosomal dominant (4.2%, including multiple individuals with variants in *CHD7*). Eight individuals (2.8%) had multigenic inheritance patterns. In this cohort, 37 individuals (13%) had a family history of HTX, of which only 6 (16%) had an identifiable genetic cause. In order to further define genetic associations, a variant burden analysis was performed using an expanded candidate list of 2293 genes associated with HTX, cilia, or congenital heart defects. Using a Wilcoxon Rank-Sum test we show an increased burden of likely pathogenic variants in European cases compared to controls from the 1000 genomes study (p-value = 0.03). A parallel analysis with 2293 autism genes revealed no difference in variant burden (p-value = 0.8) between cases and controls. In summary, this study demonstrates that in a prospectively recruited cohort, 15% have identifiable genetic causes, including critically ill infants with unsuspected PCD or syndromic ciliopathies. However, even in individuals with a known family history of HTX, the molecular basis was identified in a minority of participants, indicating an opportunity for novel gene discovery. Variant burden analyses indicate increased pathogenic variant burden in European cases compared to controls, suggesting that HTX may result from combinatorial interactions of multiple susceptibility alleles in many individuals.

Dysregulation of PI3K/AKT signaling pathway has been implicated in a number of human cancers and overgrowth syndromes, including PROS. In contrast to cancer, characterized by multiple genetic aberrations, in PROS a single activating mutation has been identified and shown to be associated with overgrowth. ARQ 092 is an oral, allosteric, selective pan-AKT inhibitor that potently inhibits AKT1, 2 and 3 isoforms. Both biochemical and cellular studies showed that ARQ 092 inhibited AKT activity through binding to its active and inactive forms. In PROS-patient derived cells, ARQ 092 demonstrated higher antiproliferative activity with lower cytotoxicity as compared to other PI3K inhibitors. In the dose escalation cohort, pts received ARQ 092 QD at up to three dose levels (15-25-35 mg/m<sup>2</sup>). Based on the preliminary PK and safety data assessment, the highest biologically active and safe dose level was determined to be 25 mg/m<sup>2</sup>. Patients enrolled in the expansion cohort receive ARQ 092 QD at up to two dose levels (15-25 mg/m<sup>2</sup>). To date, 11 pts (5 males, 6 females, median age 5.8 years [range 2.6-12.1]) with different phenotypes with confirmed PIK3CA mutations who satisfied all eligibility criteria were enrolled. All pts received ARQ 092 at the dose of 15 mg/m<sup>2</sup>; dose has been increased to 25 mg/m<sup>2</sup> in 2 pts and to 35 mg/m<sup>2</sup> in 1pt. All enrolled pts are ongoing and have been on treatment between 1 and 51 weeks. The primary objective is safety. Treatment-emergent adverse events (AE) were reported in 4 pts (36%) and were predominantly graded 1 or 2. Only one AE (skin mass) was assessed as drug-related. The most common AEs were fever (40%), rash and abdominal pain (each 20%). No pts were discontinued due to toxicity, intolerance or non-compliance. Preliminary efficacy is one of the secondary objectives. Some patients revealed clinical improvement of mobility and pain. In 5 pts who have been on treatment for at least 3 cycles, an improvement in Karnofsky/Lansky scale was noted. ARQ 092 has demonstrated preliminary activity and manageable toxicity in PROS pts. Further evaluation of ARQ 092 in this patient population is ongoing. Additional efficacy data, including volumetric imaging analyses; PK; pharmacodynamic; changes in Quality of Life, functional tests and performance status; and safety will be presented (NCT03094832).

**Introduction** Congenital Obstructive Uropathy (COU) represents a common cause of kidney failure in children and adolescents. Monogenic forms of disease account for a small portion of cases, highlighting high genetic heterogeneity. Rare variants burden association tests represent promising approaches to identify novel disease genes. **Methods** We conducted whole exome sequencing (WES) in 292 unrelated patients with COU and 8,541 population controls. Following diagnostic variant annotation in genes associated with congenital anomalies of the kidney and urinary tract (CAKUT) using ACMG criteria, we searched for novel susceptibility genes using case-control exome-wide collapsing analyses. We tested gene-level dominant and recessive models using a fisher-exact association test for ultra-rare functional variants. Qualifying variants for association were selected using computational algorithmic scores based on conservation and location in intolerant domains. We analyzed gene-set enrichment using 299 OMIM genes implicated in Mendelian and complex forms of CAKUT and compared to a control Olfactory gene set. Finally, we cross-annotated suggestive signals with results from a genome-wide association study (GWAS) for common variants composed of 398 cases and 8,197 controls. **Results** ACMG-based diagnostic variant prioritization revealed pathogenic mutations in 11 (3.7%) COU cases. Gene-level collapsing showed 20 genes with a  $P < 5 \times 10^{-4}$  for dominant models ( $MAF \leq 0.0005$ ) and 2 genes for recessive model ( $MAF \leq 0.01$ ). Among these candidates, two were of particular interest. 1. *MAZ* (dominant missense model;  $P = 3.58 \times 10^{-5}$ ) was recently showed to regulate urogenital development in a mouse model. 2. *FLNA* (recessive model;  $P = 4.25 \times 10^{-5}$ ), a gene implicated in Otopalatodigital Spectrum Disorders, where hydronephrosis and megaureter have been reported. Cross-annotation with GWAS results showed supportive evidence for association of common variants to *MAZ* ( $P = 7.06 \times 10^{-3} - 6.96 \times 10^{-4}$ ; joint  $P$ -value for common and rare variants =  $4.6 \times 10^{-7}$ ), thus reinforcing candidacy for this gene in human COU. Gene set analysis showed enrichment for rare functional CAKUT variants ( $\chi^2 = 9.12$ ;  $P = 2.5 \times 10^{-3}$ ) compared to Olfactory control genes ( $\chi^2 = 0.15$ ;  $P = 0.70$ ) in cases versus controls. **Conclusions** This study presents an integrated approach to collectively address the contribution of rare and common variants in the etiology of COU. Preliminary results suggest rare and common variants in *MAZ* as novel risk factors for COU.

**Rare inherited disorders that arise as a result of abrogating multiple systemic pathways.** S. Mian, M. Samman, E. Faqeih, W. AlTuraif, M. Mudish, A. AlNawfal. King Fahad Medical City, Riyadh, Saudi Arabia.

**Introduction** The ability to introduce effective clinical management protocols for patients presenting with rare inherited disorders is predicated upon accurate delineation of loci with abrogated function. Exome sequencing facilitates rapid screening of variants that are pathogenic in nature. Non-random population dynamics can alter the frequency of inherited disorders and consanguinity is one such mechanism by which enrichment/selection can produce a bias in pathogenic allelic frequency. Evidence is presented of dual molecular diagnosis in a single patient from consanguineous parents. **Materials and Methods** IRB approval was obtained from KFMC ethics committee to undertake a retrospective analyses of clinical exome sequence data. DNA libraries were constructed using Agilent SureSelect v5. Sequencing was carried out to an average depth of coverage of 150x. Quality metrics were assessed using FASTQC v.0.11.5. Alignment, quality filtering and variant identification were undertaken using Lasergene v15.0 (DNASTAR, USA) and reference assemblies aligned against GRCh37.p13. QIAGEN Clinical Insight (Qiagen, USA) interpret software was used in variant analysis and interpretation. **Results** One patient from consanguineous parents presented with a neurodegenerative disorder including: failure to thrive, developmental regression, hypotonia and lactic acidosis. Clinical exome sequencing identified two known pathogenic homozygous variants in distinct genetic loci. The first variant impacted mitochondrial gene function while the second abrogated pathways linked to glycosylation. **Conclusions** In regions with high consanguinity, dual (and higher order) pathologies are likely. Molecular laboratories need to be vigilant that patients may present with more than one genetic disorder and consequently guide physicians on the management of these patients.

**Ascertainment of APOE  $\epsilon$ 4 homozygotes without Alzheimer disease for investigation of protective factors: The ASPREE Healthy Ageing Biobank.** A.J. Huq<sup>1,2</sup>, M. Riaz<sup>2</sup>, J. Ryan<sup>2</sup>, I. Winship<sup>1</sup>, E. Storey<sup>1,2</sup>, R. Woods<sup>2</sup>, J. McNeil<sup>2</sup>, P. Lacaze<sup>1,2</sup>, ASPREE Investigator Group. 1) Clinical Genomics, Royal Melbourne Hospital, Parkville, Victoria, Australia; 2) Department of Epidemiology and Preventive Medicine, School of Public Health and Preventive Medicine, Monash University, Melbourne, Australia.

Alzheimer disease and related dementias are a significant public health concern globally, with an estimated 50 million individuals affected. Late onset Alzheimer disease (LOAD) is the predominant cause of dementia, yet characterization of the genetic causes of LOAD remain incomplete. The APOE  $\epsilon$ 4 allele is the strongest known genetic risk factor for LOAD, which in the homozygous state (estimated 2% of the population), confers an odds ratio of up to 15 for developing dementia, compared to the common APOE  $\epsilon$ 3 allele. Despite this elevated risk, some APOE  $\epsilon$ 4 homozygotes remain unaffected by Alzheimer disease to an advanced age, seeming to outlive their genetic risk. However, these individuals are difficult to ascertain and make the focus of research, due to their advanced age, rarity of genotype in the population and requirement of cognitive assessments to confirm the absence of cognitive decline. Here we describe the identification, and focused investigation, of 46 healthy elderly APOE  $\epsilon$ 4 homozygotes aged 75 years or older, with no diagnosis of dementia, cognitively screened to pass the Modified Mini-Mental State Examination (3MS) with a score  $>77$ . A further 123 APOE  $\epsilon$ 4/ $\epsilon$ 4 cognitively normal participants aged between 70 and 75 are being followed up longitudinally. These individuals are currently enrolled in the ASPirin in Reducing Events in the Elderly (ASPREE) study and Healthy Ageing Biobank. Consented DNA samples are currently being sequenced, to accompany the battery of cognitive testing data conducted over the past five years. Some individuals in this group are aged  $>90$  years, and score above average in all cognitive domains. We will compare this cohort with a group of early-onset Alzheimer disease cases (also  $\epsilon$ 4 homozygotes,  $>20$  currently recruited) in an extreme-phenotyping study design. We conducted a systematic review of comparable studies, and found almost all were limited by sample size, and/or merged  $\epsilon$ 4 heterozygotes with  $\epsilon$ 4 homozygotes in study groups, lacking the adequate controls. Here, we describe the genomic screening of over 10,000 biobanked elderly individuals required to identify these 169 APOE  $\epsilon$ 4 homozygotes. We are generating polygenic risk scores in these individuals, to compare with those who develop dementia at a younger age, as well as other approaches to identify modifying factors. This cohort has the unique potential to identify possible protective factors in LOAD that may off-set APOE  $\epsilon$ 4 risk.

**Serum metabolites associate with cognition phenotypes among Bogalusa Heart Study participants.** M. Shi<sup>1</sup>, J. He<sup>1</sup>, C. Li<sup>2</sup>, K. Yaffe<sup>3</sup>, S. Li<sup>1</sup>, L.A. Bazzano<sup>1</sup>, J. Kinchen<sup>4</sup>, P. Stuchlik<sup>1</sup>, X. Mi<sup>1</sup>, J.L. Nierenberg<sup>1</sup>, X. Gu<sup>1,5</sup>, T.N. Kelly<sup>1</sup>.

1) Tulane University, New Orleans, LA; 2) University of Georgia, Athens, GA; 3) University of California, San Francisco, CA; 4) Metabolon, Inc., Durham, NC; 5) Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing, China.

**Background** Few studies have explored the relationship between the human metabolome and cognition using untargeted metabolomic profiling. Using this agnostic approach, we aimed to identify novel metabolites and metabolite modules associated with cognition in a cross-sectional analysis of Bogalusa Heart Study (BHS) participants. **Methods** Untargeted ultrahigh performance liquid chromatography-tandem mass spectroscopy was used to detect and quantify serum metabolites of 1,177 BHS participants (773 whites and 404 African-Americans). Phenotypes were collected by trained technicians using a battery of 8 cognitive tests and a global cognition score was calculated based on the crude scores from these tests. The association of single metabolites with cognition was assessed using multiple linear regression models to adjust for important covariables. Weighted correlation network analysis (WGCNA) was utilized to identify modules of co-abundant metabolites and examine their covariable adjusted correlations with cognition. All analyses were conducted according to race and in the entire population, using Bonferroni-corrected alpha-thresholds to determine statistical significance. **Results** Nine metabolites, including two with unknown biochemical identities, achieved Bonferroni-corrected significance,  $P < 4.16 \times 10^{-5}$ , in at least one of the three population groups. Among the seven named metabolites, four were from lipid sub-pathways that included fatty acid metabolism (9-hydroxystearate and 12, 13-DiHOME), plasmalogen [1-(1-enyl-palmitoyl)-2-palmitoleoyl-GPC (P-16:0/16:1)] and primary bile acid metabolism (glyco-alpha-muricholate). The maltose, N-acetyl-isoptreanine and 7-methylguanine metabolites from the glycogen metabolism, polyamine metabolism and purine metabolism sub-pathways respectively were also discovered. In addition, there were three metabolite modules which achieved Bonferroni-corrected significance,  $P < 5.56 \times 10^{-3}$ , in whites and one module was also significant in the whole population. These three modules were largely comprised of metabolites from the lipids pathway. **Conclusion** The current study identified novel associations of 7 metabolites with known biochemical structures and 3 metabolite modules with cognition, providing new insights into the physiological mechanisms regulating cognitive function. Prospective studies are warranted to articulate their etiologic relevance in the development of cognitive impairment.

With an increasingly aging global human population, the number of people with dementia is rapidly increasing. Alzheimer's disease (AD) is the most common subtype of dementia, followed by Vascular Dementia (VaD), and Dementia with Lewy Bodies (DLB). Although detection of these dementia, especially in the early stages, remains a substantial challenge due to the lack of specific biomarkers, microRNAs (miRNAs) have recently received a lot of attention as the novel biomarkers. Here, by means of serum miRNA expression of 2,181 Japanese individuals, we comprehensively investigated potential miRNA biomarkers. On a basis of a supervised PCA logistic regression method, we detected optimal biomarkers and constructed risk prediction models according to subtype of dementia. The final risk prediction model achieved a high accuracy of 0.873 on a validation cohort in AD, when using 78 miRNAs: Accuracy=0.836 with 86 miRNAs in VaD; Accuracy=0.825 with 110 miRNAs in DLB. We further predicted candidate target genes, of interest of pharmaceutical investigation, from the miRNAs using miRDB. Co-expression network analysis of the target genes revealed key functional modules/genes in dementia. This is also the first report applying miRNA-based risk prediction models to a dementia prospective cohort. Our study demonstrates our models to be effective in prospective disease risk prediction, and with further improvement, such as integrative analyses of genomic and/or transcriptomic data, may contribute to practical clinical use in dementia.

**Understanding relationships among APOE4, BMI, Alzheimer's disease, and longevity, using Mendelian Randomization approach.** *S. Ukrainitseva, H. Duan, K. Arbeeve, I. Zhbannikov, O. Bagley, A. Yashkin, E. Stallard, A. Kulminski, I. Akushevich, A. Yashin.* Duke University, Durham, 27708 NC, USA.

The APOE e4 allele is a major genetic risk factor for Alzheimer's disease (AD), and it has also been linked to BMI/weight loss in AD and to reduced longevity. However, the mechanism connecting the APOE e4 and AD (or longevity) through the aging-changes in BMI is unclear. In this study, we investigated the effects of carrying the APOE e4 on the behavior of individual age-trajectories of BMI, and the impact of an earlier and faster decline in BMI on AD risk and total survival in Framingham Study participants. We also employed Mendelian Randomization (MR) approach to help clarify causal connections between the earlier/faster decline in BMI and AD, as well as longevity, using the APOE e4 as an instrumental variable. We found that the APOE e4 significantly affected individual age-trajectories of BMI, so that it was associated with both earlier and faster declines in BMI in females, regardless of AD history. We also found that the probability of survival and staying free of AD at ages 75+ and 80+ depends on the age at which BMI starts to decline. Females with an early decline in BMI (in their 60s) had an increased risk of AD and all-cause mortality later in life. Next, in MR study, we found that the age at maximum BMI (after which it starts to decline) was a significant mediator of the APOE e4 effects on both AD and longevity in females. The rate of the decline in BMI was also causally linked to female longevity. These results suggest that APOE e4 may influence onset of AD in females through the earlier decline in BMI, and it may influence female longevity through both the earlier and faster declines in the BMI. One potential mechanism connecting the earlier decline in BMI and AD might involve female hormonal changes around menopause. This research was supported by the NIH grants P01AG043352 and R01AG046860.

**Exploiting population cohorts to interrogate genomic and transcriptomic factors associated with exceptional blood aging.** *E. Bader<sup>1,2</sup>, M.J. Favé<sup>1</sup>, V. Bruat<sup>1</sup>, E. Gbeha<sup>1</sup>, P. Awadalla<sup>1,2</sup>.* 1) Computational Biology, Ontario Institute for Cancer Research Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

Hematopoiesis is a tightly controlled, dynamic process that continuously replenishes the cellular populations that circulate in peripheral blood. While the negative effects of the aging process on hematopoiesis are well documented, the underlying factors that maintain healthy hematopoiesis in old age remain unknown. To investigate mechanisms that modulate the effects of the aging process on blood we exploit Canada's largest population cohort, the Canadian Partnership for Tomorrow Project (CPTP). Over 320 000 Canadians are enrolled in the CPTP and data available for these participants include RNA-seq from PBMCs (n=997), cytokine profiles (n=8975), genotypes (n=11 230), complete blood counts (CBC; n=43 128), and detailed health and lifestyle questionnaires. First, we characterize the transcriptional landscape of individuals relative to their age and CBCs. Differential gene expression analyses reveal that individuals with similar CBCs have few differentially expressed genes (DEGs), irrespective of age, while individuals similar in age with extremely different CBCs have many DEGs. We classify DEGs into genes that are involved in the normal aging process, genes that prevent blood aging, and genes that advance blood aging; GO biological processes enriched in these gene groups include cell adhesion (e.g FOXP3), erythrocyte development (e.g SOX6), and protein ubiquitination (e.g SPRTN), respectively. Notably, SPRTN mutations are associated with genomic instability and have been observed in individuals with progeroid syndrome who present with advanced aging phenotypes. We also observe that the regulatory effects of some SNPs (e.g rs992472166 in VT11B) are dependent on an individual's age and CBCs by mapping expression quantitative trait loci (eQTLs). Interestingly, VT11B has a role in autophagy, a process that, when induced, has been shown to increase longevity. Finally, to investigate the phenotypic effects of the DEGs and eQTL SNPs we test for associations with blood biochemistry variables, physical measures, and disease outcomes. Collectively, these results uncover genomic and transcriptomic factors associated with the blood aging process, which provide insight into the molecular mechanisms that regulate this process, and can be used to assess the extent of blood aging in an individual and potential health risks.

**The Canadian longitudinal study on aging: Genome-wide genetic data on 9,900 participants available for your research!** V. Forgetta<sup>1</sup>, C. Darmond-Zwaig<sup>2</sup>, A. Belisle<sup>2</sup>, R. Li<sup>2</sup>, C. Balion<sup>3</sup>, C. Wolfson<sup>4</sup>, G. Lettre<sup>5</sup>, G. Pare<sup>3</sup>, A. Paterson<sup>6</sup>, C. Verschuur<sup>7</sup>, M. Lathrop<sup>2</sup>, P. Raina<sup>7</sup>, J.B. Richards<sup>1,8,9</sup>, J. Ragousis<sup>2,10</sup>, *Canadian Longitudinal Study on Aging/Étude longitudinale canadienne sur le vieillissement*. 1) Centre for Clinical Epidemiology, Lady Davis Institute, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Department of Human Genetics, McGill University, Montreal, QC, Canada; 3) Hamilton Regional Laboratory Medicine Program, McMaster University, St. Joseph's Hospital St. Luke's Wing, Hamilton, ON, Canada; 4) Department of Epidemiology and Biostatistics and Occupational Health, McGill University, Montreal, QC, Canada; 5) Montreal Heart Institute and Université de Montréal, Montreal, Quebec, Canada; 6) The Hospital for Sick Children Research Institute, The Hospital for Sick Children, Toronto, ON, Canada; 7) Department of Health Research Methods, Evidence and Impact, McMaster University, Hamilton, ON, Canada; 8) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 9) Department of Human Genetics, McGill University, Montréal, Québec, Canada; 10) Department of Bioengineering, McGill University, Montreal, QC, Canada.

Genetic and environmental factors contribute to maintaining health and in the development of disease and disability as people age. The Canadian Longitudinal Study on Aging (CLSA) is a national long-term study that will follow 51,338 men and women with the aim to provide information on the changing biological, medical, psychological, social, lifestyle and economic aspects of participants' lives. Here we present the availability and quality assessment of genetic data for 9,900 participants. CLSA participants provided information through in-home interviews and additional in-depth information gathered through physical examinations and biological specimen collection (blood and urine) at one of 11 data collection sites across Canada. We have collected physical measures including cognition, vision (acuity, retinal camera, tonometry), audiometry, anthropometrics, blood pressure, electrocardiogram, carotid ultrasound, spirometry, performance tests, and bone mineral density and body composition by DXA on 30,097 participants. Whole genome genotyping was conducted on 9,900 participants using the Affymetrix Axiom array followed by imputation to the Haplotype Reference Consortium. Quality assessment of the genetic data included both marker- and sample-based tests, as well as analysis of sex-chromosome abnormalities, population structure, and familial relatedness. The genetic data release comprises both directly genotyped data for 794,409 genetic markers and whole-genome imputed data for >39.2 million genetic variants. Approximately 90% of the cohort is of Northern and Western European ancestry. The genotype imputation is of similar quality to UK Biobank, with 83% of the variants having an information quality score of >0.3. We detected 33 subjects with discordance between genetic vs self-reported sex and used copy number profiling to identify or confirm 19 participants with sex chromosome abnormalities, as well as 2 cases of Charcot-Marie-Tooth disease. We demonstrate the utility of this resource through genome-wide association studies on height, lipid traits, and bone mineral density. A future release will provide genetic data for an additional 20,000 participants. First follow-up of participants is due to end in mid-2018 with data release in Spring 2019. Qualified researchers from any country can easily access this genomic and phenotypic data release via the CLSA Data Access Portal at <https://www.clsa-elcv.ca/data-access>.

**10-year follow-up of the super-seniors study: Compression of morbidity and genetic factors in survivors.** L. Tindale<sup>1,2</sup>, D. Salema<sup>1</sup>, A. Brooks-Wilson<sup>1,2</sup>. 1) Canada's Michael Smith Genome Sciences Centre, BC Cancer Research Centre, Vancouver, BC, Canada; 2) Biomedical Physiology and Kinesiology, Simon Fraser University, Burnaby, BC, Canada.

**Background:** Super-Seniors are healthy, long-lived individuals who were recruited at age 85 years or older with no history of cancer, cardiovascular disease, diabetes, dementia, or major pulmonary disease. In a 10-year follow-up, we aimed to determine whether surviving Super-Seniors showed compression of morbidity; and to test whether the allele frequencies of longevity-associated variants in *APOE* and *FOXO3* were more extreme in such long-term survivors. **Methods:** Super-Seniors who survived and were contactable were re-interviewed 10 years after initial characterization. Health and lifestyle were characterized via questionnaire. Geriatric tests including the Timed Up and Go, Geriatric Depression Scale, Instrumental Activities of Daily Living and the Mini-Mental State Exam were administered, and data were compared to results from on average 10 years earlier. As well, genotype and allele frequencies for SNPs rs7412 and rs429358 in *APOE*, and rs2802292 in *FOXO3* were compared to the frequencies in the original collection of Super-Seniors and mid-life controls. **Results:** Of the 480 Super-Seniors recruited from 2004-2007, 13 were alive, contactable, and consented to re-interview (mean age = 100.1 ± 3.3). Eight of these 13 participants (62%) still met Super-Senior health criteria. Diseases that occurred in late life were cardiovascular (5 of 13; 38%) and lung disease (1 of 13; 8%). The surviving group of centenarians had a higher frequency of *APOE* and *FOXO3* longevity-associated variants even when compared to the original long-lived Super-Senior cohort. **Conclusion:** Although physical and mental decline occurred in the decade between interviews, the majority of Super-Seniors re-interviewed still met the original health criteria. These observations are consistent with reports of compression of morbidity at extreme ages, particularly in centenarians. The increased frequency of longevity-associated variants in this small group of survivors is consistent with studies that reported a larger role for genetics at older ages.

**Longitudinal study of gene expression and regulation during a critical period of human aging.** B. Balliu<sup>1</sup>, M. Durrant<sup>1</sup>, O. de Goede<sup>1</sup>, N. Abell<sup>1</sup>, X. Li<sup>1</sup>, B. Liu<sup>1</sup>, M.J. Gloudemans<sup>1</sup>, N. Cook<sup>2</sup>, K.S. Smith<sup>1</sup>, S. Jaiswal<sup>1</sup>, C. Sabatti<sup>1</sup>, L. Lind<sup>2</sup>, E. Ingelsson<sup>1</sup>, S.B. Montgomery<sup>1</sup>. 1) Stanford University School of Medicine, Stanford, CA; 2) Uppsala University, Uppsala, Sweden.

Molecular and cellular changes are intrinsic to aging and age-related diseases. Several studies have investigated the combined effects of age and genetics on gene expression; however, there has been no large long-term, longitudinal characterization of these molecular changes within individuals. We performed RNA sequencing in whole-blood from the same 65 individuals at age 70 and 80 (130 samples), for which SNP array data was also available. Then, we examined how gene expression and genetic regulation were altered over this critical 10-year aging period. We discovered 1,291 genes whose expression level was significantly associated with age (FDR<5%). Enrichment analysis of the differentially expressed genes showed significant enrichment in age-related pathways, e.g. metabolism of proteins, adaptive immune system, and regulation of DNA replication and apoptosis. Moreover, we observed a depletion in the number of genetically-regulated genes at age 80, relative to age 70 (Binomial proportion test;  $p$ -value =  $3.3 \times 10^{-3}$ ). Genes with the largest loss of genetic regulation with age are involved in DNA repair and genome stability, e.g. *POLD3*; as well as in signal transduction pathways, e.g. *GNAS*. In addition, we observed that overall allelic imbalance increased slightly within individuals with age (Wilcoxon signed rank test;  $p$ -value =  $1.5 \times 10^{-3}$ ). We found four genes with individual-level differences in allele-specific expression (ASE) with age, e.g. *GNAS*; a known marker of clonal hematopoiesis that also showed a large loss of genetic regulation with age. Further, we found seven genes with population-level differences in ASE, e.g. *NEAT1*, which plays an important role in the innate immune response. Lastly, we identified 580 genes with significant patterns of age-specific alternative splicing, e.g. *SFPQ*, implicated in stress responses and double-strand break repair, and *SETX*, which has been associated with amyotrophic lateral sclerosis, an age-related disease with aberrant splicing patterns. In summary, we have performed the first long-term longitudinal study of human gene expression and genetic regulation of expression that highlights transcriptome dynamics late in life. Together, our findings highlight that age is associated with both population- and individual-level changes in gene expression, ASE, and alternative splicing and that the genetic architecture of a subset of genes is unstable and is characterized by a loss of genetic control at the population level.

**Whole-genome sequence variants associated dyspnea among current and former smokers from the COPDGene study.** M.N. McDonald<sup>1</sup>, H. Tiwari<sup>2</sup>, M. Flickinger<sup>3</sup>, V. Srinivasainagendra<sup>4</sup>, P. Lakshman Kumar<sup>5</sup>, R. Casaburi<sup>6</sup>, E. Regan<sup>7</sup>, R.G. Barr<sup>8</sup>, A.W. Manichaikul<sup>9</sup>, M.E. Hall<sup>1</sup>, E. Oelsner<sup>1</sup>, M.H. Cho<sup>9</sup>, C.A. Vaz Fragoso<sup>9</sup> for the COPDGene and NHLBI TOPMed Investigators. 1) University of Alabama at Birmingham, Birmingham, AL; 2) University of Michigan, Ann Arbor, MI; 3) Harbor-UCLA Medical Center, Torrance, CA; 4) National Jewish Hospital, Denver, CO; 5) Columbia University, New York, NY; 6) University of Virginia School of Medicine, Charlottesville, VA; 7) University of Mississippi Medical Center, Jackson, MS; 8) Harvard Medical School, Brigham and Women's Hospital, Boston, MA; 9) Yale University School of Medicine, New Haven, CT.

Dyspnea, also known as shortness of breath, is associated with poor health related quality of life and is a strong predictor of mortality. It is reported commonly in older individuals including those suffering from chronic obstructive pulmonary disease (COPD) and congestive heart failure (CHF) among other conditions. We hypothesize the identification of genomic regions associated with dyspnea may enable new diagnostic and treatment strategies for managing dyspnea across a wide range of disorders. Dyspnea was dichotomized based on whether a participant reported a modified Medical Research Council (mMRC) dyspnea score greater or equal to 2. We assessed whether both single nucleotide variants (SNVs) and gene-based regions were associated with dyspnea in 8321 current or former smokers aged 40 years or older from the COPDGene Study using whole-genome sequencing (WGS) as part of the Trans-Omics for Precision Medicine (TOPMed) program. SNVs, with minor allele frequencies (MAF) > 1%, were tested for association with dyspnea using EPACTS adjusting for age, sex, pack-years of smoking, lung function and principal components to control for population substructure. Gene-based tests were performed using SNVs with MAF < 5% using SKAT-O adjusting for the same covariates. Analysis of WGS data was performed using the University of Michigan's Encore pipeline. No SNV or gene-based region was associated at a level that achieved statistical significance. The top SNV associated with dyspnea was rs73882506 (MAF=4.4%, OR: 1.1, P= 1.5e-07) intergenic between the genes *SPATA16* and *ECT2*. The top region associated in the gene-based testing was *PLCXD1* on the X chromosome (P=6.8E-6). Future efforts will be directed at expanding the analysis of dyspnea to additional TOPMed studies including the Framingham Heart Study, Jackson Heart Study, Multi-Ethnic Study of Atherosclerosis and ECLIPSE among others in addition to performing COPD and CHF stratified analyses.

**Quantifying biological age using multiple modalities.** *H. Tang*<sup>1,2</sup>, *A. Bernal*<sup>1,2</sup>, *E.T. Cirulli*<sup>1,2</sup>, *C. Leon Swisher*<sup>1,2</sup>. 1) Human Longevity, Inc., San Diego, CA; 2) These authors contributed equally to this work.

Chronologically, we all age at the same rate, but the rates at which our bodies appear to age vary greatly from person to person. Multiple modalities can be used to measure changes that occur in our bodies, corresponding to different aspects of aging. For example, genomic DNA in cells gradually acquires damage over time via side effects of normal metabolic and molecular processes such as oxidative stress and cell division. Damage can accumulate at specific genomic locations and affect all cells, effectively acting as a genomic clock. Damage can also randomly spread throughout the genome of each cell, resulting in a state of somatic mosaicism that is thought to be an important cause for aging as well as other diseases. Here, we use whole-genome sequence data, untargeted metabolomics, and whole body and brain MRI scans to quantify individuals' biological ages. We find strong correlations between predicted biological age and actual chronological age, validating our models. Furthermore, we identify differences in the health characteristics of individuals whose chronological and biological ages are discordant. Our results indicate that measurements from multiple modalities can be harnessed to more precisely quantify the health and biological age of an individual.

**2551T**

**No evidence of an association between mitochondrial DNA and accidental falls.** *E. Ryu*, *G.D. Jenkins*, *P.Y. Takahashi*. Mayo Clinic, Rochester, MN.

**Background** Accidental falls are a major public health concern in the aging population. Mitochondrial dysfunction is potentially linked with accelerated aging and other factors associated with accidental falls like comorbidities. In this study, we assessed whether mitochondrial DNA (mtDNA) is associated with risk of accidental falls. **Methods** We used existing whole genome sequencing data from 953 Mayo Clinic Biobank participants. Accidental falls were defined as having at least one ICD-9 code for fall-related injuries treated at the emergency department (ED) between the time of blood collection and September 2017. We considered mtDNA copy number, single nucleotide variants (SNVs), and degree of heteroplasmy as factors related to mtDNA. MtDNA copy number was defined as the relative quantity of mtDNA compared to nuclear DNA, and the degree of heteroplasmy was defined as the proportion of non-reference alleles for a given SNV. Cox models were used to assess whether mtDNA-related variables were associated with risk of accidental falls during the follow-up period. The models were adjusted for age, sex, and comorbidities defined by the number of chronic conditions recommended by the US-DHHS. **Results** In the study cohort, 112 subjects (12%) experienced accidental falls requiring ED visits, with the median follow-up of 6.7 years (25th- 75th percentiles: 5.5 to 7.4 years). The study subjects had the median age of 61 year, 50% of females, and had the median of 3 chronic conditions at blood collection. Adjusting for age, sex, and the number of chronic conditions, mtDNA copy number was not associated with the risk of accidental falls (HR=0.67; 95% CI=0.29 – 1.56). Neither SNVs nor the degree of heteroplasmy was significantly associated with accidental falls after correcting for multiple testing. **Conclusions** Although the link between mitochondrial dysfunction and a wide range of age-related health outcomes has been widely supported in the literature, our study suggests that mtDNA may not play an important role in accidental falls that occur in the relatively short period of follow-up. However, a follow-up study with a larger sample size is required because the current study may lack statistical power.

**The PhenX Toolkit: An update on a resource for geriatric research.** L.A. Kilpatrick<sup>1</sup>, M. Sano<sup>2</sup>, S. Cummings<sup>3</sup>, P.L. De Jager<sup>4</sup>, C. Depp<sup>5</sup>, J. Guralnik<sup>6</sup>, T. Harris<sup>7</sup>, D. Houston<sup>8</sup>, C. Kwas<sup>9</sup>, D.P. Kiel<sup>10</sup>, R. Mayeux<sup>4</sup>, L. Farrer<sup>11</sup>, M. Phillips<sup>12</sup>, E.M. Ramos<sup>12</sup>, W. Rossi<sup>12</sup>, T. Hendershot<sup>1</sup>, S. Hwang<sup>1</sup>, D. Maiese<sup>1</sup>, A. Riley<sup>1</sup>, H. Pan<sup>1</sup>, W. Huggins<sup>1</sup>, C.M. Hamilton<sup>1</sup>. 1) RTI International, Research Triangle Park, NC; 2) Icahn School of Medicine at Mount Sinai, New York, NY; 3) California Pacific Medical Center, San Francisco, CA; 4) Columbia University, New York, NY; 5) University of California, San Diego, San Diego, CA; 6) University of Maryland School of Medicine, Baltimore, MD; 7) National Institute on Aging, Bethesda, MD; 8) Wake Forest School of Medicine, Winston-Salem, NC; 9) University of California, Irvine, Irvine, CA; 10) Institute for Aging Research, Hebrew SeniorLife and Harvard Medical School, Boston, MA; 11) Boston University, Boston, MA; 12) National Human Genome Research Institute, Bethesda, MD.

In 2017, a Working Group (WG) of geriatrics experts convened to identify standard measures of phenotypes and exposures recommended for human genome, biomedical, and epidemiological research in older adults. As the Geriatrics WG finishes, we have started a Pediatric Development domain that also builds on existing Toolkit (TK) content. The Geriatrics WG followed a consensus-based process identifying 18 new measures and the information that supports their use (i.e., protocol [method used to collect data], how to administer the protocol) to the PhenX Toolkit. These measures, specifically for use in older populations, utilize protocols from the Health and Retirement Study (HRS), the Health Aging and Body Composition (ABC) Study, and other well-established sources. Along with presenting details of Geriatrics measures in the TK, we will share some gaps identified in available research instruments. The measures and protocols selected by the Geriatrics WG are available on the web-based PhenX Toolkit website (<https://www.phenxtoolkit.org/>). These new measures complement other measures for older adults available in the PhenX Toolkit. The PhenX Toolkit has been funded by the National Human Genome Research Institute (NHGRI) since 2007 and is a catalog of well-established measures covering 25 research domains with over 500 standard measures. This resource makes broadly validated, well-established measures available for biomedical researchers to improve statistical power and effects via cross-study analyses and helps facilitate study replication. Additionally, measures are valuable for researchers who are not experts in working with the older adults who may want to include the population in their study design. We will also present the new design and navigation of the PhenX Toolkit, updates on new content for Hemophilia and Health Equities, and collaborative efforts with the National Institutes of Health (NIH) Common Data Element (CDE) Initiative and the database of Genotypes and Phenotypes (dbGaP). The breadth of measures available in the TK is helpful when designing or expanding a study. The Geriatrics domain and measures in the PhenX Toolkit are another set of tools for the research community to use in its work to support research with older adult participants. *Funding provided by a Genomic Resource Grant (U41HG007050) from NHGRI, with co-funding from the National Institute on Drug Abuse (NIDA) and the Office of the Director, National Institutes of Health (OD).*

**Varying effect of APOE alleles on extreme longevity in European ethnicities.** A. Gurinovich<sup>1</sup>, H. Bae<sup>2</sup>, S.L. Andersen<sup>3</sup>, A. Puca<sup>4,5</sup>, G. Atzmon<sup>6</sup>, N. Barzila<sup>6</sup>, T.T. Perls<sup>3</sup>, P. Sebastiani<sup>7</sup>. 1) Bioinformatics Program, Boston University, Boston, MA; 2) College of Public Health and Human Sciences, Oregon State University, Corvallis, OR; 3) Boston University School of Medicine, Boston, MA; 4) Department of Medicine and Surgery, University of Salerno, Fisciano, SA, Italy; 5) Cardiovascular Research Unit, IRCCS MultiMedica, Sesto San Giovanni, MI, Italy; 6) Albert Einstein College of Medicine, Bronx, NY; 7) Department of Biostatistics, Boston University School of Public Health, Boston, MA.

Apolipoprotein E (*APOE*) is a well-studied gene with multiple effects on aging and longevity. The gene has three common polymorphisms, E2, E3 and E4, whose frequencies vary by ethnicity and are associated with different levels of blood cholesterol. *APOE* E4 is a known risk factor for Alzheimer's and has a deleterious effect on extreme longevity, while E2 is associated with healthy aging and longevity. We analyzed ethnic specific effects of *APOE* alleles on extreme human longevity using genetic data of about 9,000 individuals from four studies of extreme longevity: the New England Centenarian Study, the Southern Italian Centenarian Study, the Longevity Gene Project, and the Long Life Family Study. The aggregated data comprised several European ethnicities and included 2144 cases of extreme longevity defined as individuals who lived past the 1 percentile survival age from the 1900 birth year cohort (i.e. age > 96 for males, and >100 years for females). For the analysis we used our new method PopCluster that combines logistic regression modeling, principal component analysis of genome-wide genetic data, hierarchical clustering, and a novel recursive bottom-up tree parsing procedure to automatically discover subsets of individuals in which the effects of a variant are statistically different. This analysis identified ethnically different clusters in which the effect of *APOE* E2 and E4 alleles on extreme longevity changed substantially. For example, PopCluster discovered a large group of 1089 subjects enriched of Southern Italians with weaker protective effect of *APOE* E2 and weaker damaging effect of *APOE* E4 on extreme longevity compared to other European ethnicities. Another example is a large cluster (977 subjects) enriched of subjects of Ashkenazi Jewish descent with strong protective effect of *APOE* E2 and significant detrimental effect of *APOE* E4 on extreme longevity. These results suggest possible interaction of this gene with nutrition habits or other environmental factors.

**2554T**

**Comparison of multiple omics aging clocks.** *E. Macdonald-Dunlop<sup>1</sup>, P.K. Joshi<sup>1</sup>, J.F. Wilson<sup>1,2</sup>*. 1) Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, Scotland, United Kingdom; 2) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, United Kingdom.

**Background:** Biological age, a measure of deterioration and aging that is distinct from chronological age has been found to predict disease and mortality (Fischer et al., 2014). Since the first published measure of biological age: Hannum's epigenetic clock, closely followed by Horvath's epigenetic clock, aging clocks have been built using telomere length (Zhang et al., 2014), facial morphology (Chen et al., 2015), metabolomics (Fischer et al., 2014), glycomics (Kristic et al., 2014) and proteomics (Enroth et al., 2015). However, comparison between clocks has so far been limited. Fortunately, the ORCADES study is a deeply annotated cross-sectional cohort with approximately 1,000 individuals, where multiple omics assays such as circulating plasma proteins, lipids, glycans and metabolomics are available, enabling consistent comparisons in a common dataset. **Aims:** (i) To replicate and potentially improve published aging clocks, and partition proteomic aging across protein panels (ii) for the first time to compare their accuracy in measuring age in a single dataset (iii) for the first time to analyse the effect of giving up smoking on the evolution of biological clock age. **Methods:** Elastic net regression were used to create multiple omics clocks in a training set and their accuracy assessed in a testing set and an additional independent cohort, in univariate and bivariate analyses. **Results:** We replicate existing clocks, (with some improvement of our proteomics clock over Enroth et al's,  $r^2=0.83$ ) in predicting chronological age. We find our cardiovascular protein clock ( $r^2=0.89$ ) outperforms our inflammation protein clock ( $r^2=0.67$ ). We also find that our protein clock ( $r^2=0.89$ ) outperforms our glycan clock ( $r^2=0.45$ ). In bivariate analysis we find large but not complete overlap between the two clocks. Finally, we expand on Enroth et al's finding by showing that there is also a significant difference of average biological age between current smokers and ex-smokers and the half-life of the effect of having formerly been a smoker on biological age is 3.5 years. **Conclusions:** Proteins more accurately predict chronological age than glycans and can track the benefits of giving up smoking. Multi-omics clocks appear to track both overlapping and distinct aspects of aging and offer the prospect of identifying distinct aging pathways.

**2555F**

**Exome variants associated with healthy aging: Findings from the Long Life Family Study (LLFS).** *B. Vardarajan<sup>1</sup>, B. Thyagarajan<sup>2</sup>, A.I. Yashin<sup>3</sup>, J.M. Zmuda<sup>4</sup>, T. Perls<sup>5</sup>, M. Province<sup>6</sup>, J.H. Lee<sup>1</sup>*. 1) Columbia University, New York, NY; 2) University of Minnesota, Minneapolis, MN, USA; 3) Duke University, Durham, NC, USA; 4) University of Pittsburgh, Pittsburgh, PA, USA; 5) Boston University, Boston, MA, USA; 6) Washington University, St. Louis, MO, USA.

**Background:** Exceptional longevity (EL) is a complex trait that is likely the result of an interaction between environmental, behavioral, genetic and stochastic factors. However, recent evidence from the Long Life Family Study (LLFS) suggests that the EL phenotype may also have strong genetic determinants. **Methods:** We selected 420 unrelated individuals from the LLFS families by computing a summary disease score (SDS) by summing across phenotypes in eight health domains - heart disease, stroke, lung disease, hypertension, diabetes, peripheral artery disease, cancer and dementia. Whole exome sequencing (WES) was conducted on 420 individuals (HiSeq 2500 sequencer, Roche exome capture) and rare coding variants were analyzed. We used independent WES data in 894 healthy elderly individuals from the Washington Heights and Inwood Community Aging Project (WHICAP) to compare LLFS variants in variant and gene-based tests. In addition, we replicated variants in 100 centenarians from Chinese Longitudinal Healthy Longevity Survey cohort. **Results:** We identified 13 potentially deleterious missense mutations that were found in at least four LLFS samples and absent in the ExAC database. Interestingly we found two damaging mutations in the *REST* gene and one in *SALL1* that segregated in elderly LLFS individuals. One variant in *REST* was also found in four centenarians in the CLHLS cohort. Variants in *REST* (putative master negative regulator of neurogenesis) confer susceptibility to cognitive aging and has been implicated in stress resistance in aging and Alzheimer's disease. Comparing single variants in LLFS with WHICAP, we found a frameshift mutation in *NOTCH2* ( $p=1.9e-07$ ) that is more frequent in LLFS elderly individuals compared to the general WHICAP population. **Conclusions and Relevance:** We identified variants that confer susceptibility to EL in the LLFS cohort. We will present further evaluation of the genes discovered in independent long-living cohorts. Identifying the genetic determinants of EL could also lead to the discovery of genes that affect the rate of aging and predisposition for or against age-related diseases. Such discoveries would be helpful in the prediction, prevention and treatment of age-related diseases as well as predictors of and strategies for healthy aging.

**2556W****Decreased burden of pathogenic variants in a healthy elderly cohort.**

A. Telenti, S. Topol, E. Topol, A. Torkamani, J. di Iulio. The Scripps Research Institute, La Jolla, CA.

**Background.** Healthy aging is a distinct phenotype from extreme longevity and has been shown to be genetically driven. Here, we investigate whether the decreased burden of deleterious genetic variants contributes to healthy aging in the WellDlderly cohort. **Methods.** The healthy aging individuals (WellDlderly) cohort includes 1,152 individuals > 80 years old, without any chronic disease, and of non-finish European ancestry. As control group, we included non-finish European individuals from the gnomAD consortium (NFE, N=7,507), though to represent a younger representation of the general population. Pathogenic and benign variants were obtained from ClinVar. We focused on (i) cancer inherited genes and (ii) all genes annotated with pathogenic variants. **Results.** To confirm the experimental design, we first assessed the depletion of rs429358, marker of *APOE\*E4* associated with early onset Alzheimer. Allelic frequency (af) in the WellDlderly population vs controls was af=0.09 versus 0.14,  $p=1.9e-10$ . In particular, rates of homozygosity decreased to af=0.006 from 0.02,  $p=0.0009$ . As control, we compared the cumulative frequency of benign variants in 21 cancer inherited genes to confirm that the af were similar in both cohorts (mean and median ratio (af NFE/ af wellDlderly) were 1.016 and 0.985. To prevent biases due to the use of different pipeline to call variants in the 2 cohorts, we applied a *double ratio*: ((af pathogenic variants in WellDlderly / af benign variants in WellDlderly) / (af pathogenic variants in NFE/ af benign variants in NFE)). We identified a depletion of inherited cancer variants in the WellDlderly for 15 out of 21 genes. To assess whether the results extended to non-inherited cancer related genes, we investigated genes that were annotated with at least 1 pathogenic and 1 benign variant in ClinVar and variable in at least one individual in the cohort (N=877). 60% of those genes showed a *double ratio* below 1 (=depletion). The strongest depletion was found in the set of most essential genes ( $pLI>0.9$ , N=67, median *double ratio* of 0). **Conclusion.** There is a decreased burden of pathogenic variants in the WellDlderly cohort. This approach supports analyses of the population impact of pathogenic variants on life span and the modelling of the health benefits of genetic screening.

**2557T****Associations between a polygenic score for leukocyte telomere length and telomere length measures from multiple human tissues.** M.B.

Chernoff<sup>1</sup>, K. Demanelis<sup>1</sup>, L. Tong<sup>1</sup>, F. Jasmine<sup>1</sup>, M.G. Kibriya<sup>1</sup>, J. Shinkle<sup>1</sup>, J. Doherty<sup>2</sup>, B. Pierce<sup>1,2</sup>, the GTEx Project. 1) The Department of Public Health Sciences, The University of Chicago, Chicago, IL; 2) The Department of Human Genetics, The University of Chicago, IL; 3) The Huntsman Cancer Institute and Department of Population Health Sciences, University of Utah, Salt Lake City, UT.

**Background:** Telomere length regulates the replicative capacity of cells and may contribute to the risk of developing cardiovascular disease and multiple cancer types. Previous genome-wide association studies (GWAS) have identified single nucleotide polymorphisms (SNPs) associated with leukocyte telomere length (TL), many of which reside in or near telomere-associated genes. However, it is unknown if these SNPs similarly influence TL in other human tissues. Here, we evaluate associations between known TL-associated SNPs and relative TL (RTL) measurements in 12 different tissue types from the Genotype-Tissue Expression (GTEx) Project. **Methods:** We used a Luminex-based method to measure RTL (i.e. telomere repeat abundance) for >4,500 GTEx tissue samples, restricting our analysis to tissues with >100 individuals with genotype data: whole blood, esophageal mucosa, pancreas, lung, stomach, colon, thyroid, testis, cerebellum, kidney, prostate, and ovary (ordered by descending sample size). The largest sample was whole blood with 444 individuals included. We used GTEx genotype data to calculate a genetic score for TL using 8 TL-associated SNPs identified from GWAS of leukocyte TL. We used linear models to assess the association of these SNPs and the SNP score with RTL in each tissue. We also built a linear mixed model for RTL, treating tissue as a random effect and SNP score as a fixed effect. **Results:** While individual SNPs did not show significant associations with RTL in any tissue, we observed a significant, positive association ( $p < 0.05$ ) between the SNP score and RTL measured in whole blood and the cerebellum. Associations between the SNP score and TL were positive in 9 out of 12 tissues ( $p=0.05$  based on a binomial test), showing that SNP scores reflecting long TL tend to associate with tissue-specific TL measurements in the expected direction. In the mixed model including all tissues, the SNP score was positively, but not significantly, associated with RTL ( $p=0.1$ ), explaining only 0.3% of RTL variation. **Conclusion:** Our results suggest that a SNP score for leukocyte TL may also predict TL in other human tissues. The small number of samples for each tissue limited our ability to detect statistically significant associations, thus we are currently measuring RTL for additional GTEx samples. We are also exploring the use of multivariate association methods that borrow information across tissues to increase the power to detect SNPs affecting TL in multiple tissues.

**2558F**

**Genetically predicted telomere length and aging-related physical and cognitive traits among the UK Biobank participants.** *K. Demanelis, L. Tong, B.L. Pierce.* Public Health Sciences, The University of Chicago, Chicago, IL.

Telomere length (TL) shortens in most human cell types and is a potential biomarker and cause of aging. However, the causal relationship between TL and physical and cognitive age-related decline has not been extensively examined. Using a Mendelian randomization (MR) approach, we estimated genetically predicted TL (GP-TL) and assessed its association with over 50 aging-related traits in 337,545 UK Biobank (UKB) participants age 39-72 years. We manually curated aging-related traits among the cognitive function, physical measures, and self-reported questionnaire variables across 11 health domains. The effect estimates from 9 TL-associated SNPs were extracted from the ENGAGE consortium GWAS of leukocyte TL. We estimated GP-TL in base pairs (bp) by constructing a weighted linear combination of the TL-associated SNPs. Multivariate regression models assessed the relationship between GP-TL and each aging-related trait, adjusting for age, sex, and 10 genotyping principal components. We obtained MR estimates from the two-sample inverse weighted (IVW) meta-analysis approach. Under MR assumptions, the MR estimate was interpreted as the effect corresponding to one standard deviation (SD) increase in TL. We identified 12 age-related traits associated with GP-TL with  $p < 0.05$ ; however, only 5 traits reached Bonferroni-corrected significance ( $p < 10^{-3}$ ). Pulmonary traits, forced expiratory volume (FEV1) and vital capacity (FVC), increased by 29 ( $p=3 \times 10^{-4}$ ) and 43 ( $p=1 \times 10^{-5}$ ) mL per 1,000 bp GP-TL. Half of the UKB participants were hypertensive, and unexpectedly, we observed that pulse pressure (PP), systolic (SBP) and diastolic (DBP) blood pressure increased by 1.2 ( $p=6 \times 10^{-14}$ ), 1.9 ( $p=5 \times 10^{-16}$ ) and 0.6 ( $p=9 \times 10^{-6}$ ) mmHg per 1,000 bp GP-TL. From IVW MR analyses, TL increased PP, SBP, and DBP by 1.5 ( $p=2 \times 10^{-3}$ ), 2.3 ( $p=4 \times 10^{-6}$ ) and 0.8 ( $p=1 \times 10^{-3}$ ) mmHg per SD, respectively, while FEV1 and FVC increased by 35 ( $p=1 \times 10^{-2}$ ) and 52 ( $p=4 \times 10^{-3}$ ) mL per SD in TL. Other two-sample MR methods yielded similar results; however, the MR-Egger intercept test differed from 0 for SBP ( $p=5 \times 10^{-4}$ ), suggesting possible bias in its IVW MR-estimate. Under MR assumptions, these findings suggest that longer TL favorably increased pulmonary function while it adversely increased blood pressure. Further research is necessary to understand the relationship among GP-TL, measured TL, and blood pressure, to assess potential pleiotropy, and to evaluate GP-TL in cardiovascular and pulmonary age-related decline risk.

**Novel genetic loci identified for telomere length leveraging 50,000 whole genome sequences in the trans-omics for precision medicine (TOPMed) project.** *M.A. Taub<sup>1</sup>, K. Iyer<sup>2</sup>, J. Weinstock<sup>3</sup>, A.R. Keramati<sup>4</sup>, J. Lane<sup>5</sup>, T. Blackwell<sup>5</sup>, L.R. Yanek<sup>4</sup>, N. Pankratz<sup>5</sup>, G. Abecasis<sup>5</sup>, R.A. Mathias<sup>4</sup> on behalf of the NHLBI TOPMed Consortium.* 1) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 2) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 3) Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI; 4) The GeneSTAR Research Program, Johns Hopkins School of Medicine, Baltimore, MD; 5) Department of Laboratory Medicine and Pathology, University of Minnesota School of Medicine, Minneapolis, MN.

Prior GWAS have identified 11 loci harboring common genetic determinants of telomere length (TL); several of these loci have been implicated in human disease. These studies have relied on genotype array/imputation data and TL generated through qPCR or Southern Blot. Large-scale whole genome sequencing (WGS) gives the opportunity to analyze TL data on large numbers of subjects with extensive phenotyping to (1) generate estimates of TL; (2) expand our knowledge of genetic determinants of TL; and (3) add to our understanding of the role these variants may play in disease etiology. WGS data were generated within the NHLBI Trans-Omics for Precision Medicine (TOPMed) project, and TL was estimated on 93,219 samples using TelSeq software. We performed single variant association tests using mega-analysis, combining data from 27 TOPMed studies on a subset of 49,899 subjects within the current genotype data freeze in TOPMed (~86 million variants after filtering sites with minor allele count below 5). We used a two-stage approach, initially screening variants with a standard linear model adjusting for sex and study, followed by a linear mixed-model also adjusting for population structure and relatedness on the subset of variants with  $p < 0.01$  from the first-stage analysis (conducted on the Analysis Commons, <http://analysiscommons.com/>). We discovered four novel TL loci with common variants (MAF > 1%), including three with strong biological interest: (1) *TERF1* ( $p=4.8 \times 10^{-9}$ ), encoding a telomeric repeat-binding factor; (2) *RFD3* ( $p=2.7 \times 10^{-9}$ ), encoding a protein involved in DNA damage repair; and (3) *TINF2* ( $p=3.5 \times 10^{-10}$ ), a component of the shelterin complex, which protects against telomere shortening; and (4) *LINC01429* ( $p=3.0 \times 10^{-8}$ ). There were 47 rare variants that achieved genome-wide significance for TL. We replicated 6 common loci previously associated with TL: *NAF1* ( $p=4.2 \times 10^{-11}$ ), *OBFC1* ( $p=6.4 \times 10^{-16}$ ), *TERC* ( $p=4.9 \times 10^{-20}$ ), *TERT* ( $p=1.3 \times 10^{-26}$ ), *ZNF208/ZNF676* ( $p=1.5 \times 10^{-8}$ ), and *RTEL1* ( $p=7.8 \times 10^{-11}$ ). Our TOPMed Working Group is examining methods to correct for batch effects in these TL data. In the near future, we will include an additional ~45,000 TOPMed subjects with WGS that will improve our ability to (1) fine-map the common variant loci; (2) identify novel loci through gene-based approaches; and (3) given known differences in TL by population, maximize our power to identify genetic determinants within groups.

**2560T****The curious parental age and genetic effects on newborn telomere**

**length.** *W. Wong<sup>1</sup>, B. Solomon<sup>2</sup>, X. Liu<sup>1</sup>, W. Zhu<sup>1</sup>, J. Niederhuber<sup>1,3</sup>.* 1) Inova Translational Medicine Institute, Falls Church, VA; 2) GeneDx, Gaithersburg, MD; 3) Department of Public Health Sciences, University of Virginia, Charlottesville, VA.

Telomeres play a vital role in maintaining genomic integrity and chromosomal stability in humans. Previous studies have shown that the child's leukocyte telomere length (TL) is correlated with the father's age at conception and that the mechanism for elongation of telomere lengths in the sperm is not via the more common telomerase reverse transcriptase (TERT) pathway, but via the alternative lengthening of telomeres (ALT) pathway. The ALT pathway is characterized by elevation of TL heterogeneity whereas the TERT minimizes that. Most of these studies suffer from small sample sizes and incomplete family members, as well as studying as an adult, where measurement is a combination of initial TL and the TL attrition during aging. In this study, we estimate the TLs using the software telseq and telomerecat in 1,235 whole genome sequenced (~40X) newborns and their parents. This cohort is part of the "Childhood Longitudinal Study" at the Inova Translational Medicine Institute. Using multiple linear regression, we find that the TL of the newborn child is positively correlated with both parents' TLs ( $P < 10^{-10}$ ), and is negatively correlated with gestational age ( $P = 1.26 \times 10^{-8}$ ) male gender ( $P = 9.57 \times 10^{-5}$ ) and paternal age at conception, whereas maternal age does not appear to be correlated with newborn's TL. While we did not detect a significant change in the slope among older fathers ( $P = 0.95$ , father's age > 33.49, median father's age), there is a significant difference in the variance in newborn's TL from older vs. younger fathers ( $P = 0.003$ ). On the contrast, there is no difference in variance in the TLs in either mothers or fathers when divided into two groups by their median age ( $P > 0.1$ ). Further, using the public GWAS data, we use 11 loci that are significantly associated with leukocyte TLs to calculate the polygenic risk scores (PRS) for TLs for each individual. These loci are mostly located near genes involved in TL maintenance and regulation. We show that only PRS from mother is significantly associated newborn's TL ( $P = 0.08$ ) after accounting for both parents' TLs. Interestingly, when we separate the PRS into transmitted and untransmitted alleles from the parents, only the transmitted PRS from the mother is significantly associated with newborn's TL ( $P = 0.08$ ). Taken together, these observations suggest female-based transgenerational telomere erosion, whereas the elongation of TLs in spermatozoa may be of a different mechanism from that in the leukocyte.

**APOE is associated with declining BMI in older adults.** *C.R. Bauer<sup>1</sup>, M.T. Oetjens<sup>2</sup>, G. Chittoor<sup>2</sup>, E.D.K. Cha<sup>2</sup>, A.E. Justice<sup>2</sup>, S.A. Pendergrass<sup>1</sup>.* 1) Geisinger, Rockville, MD; 2) Geisinger, Danville, PA.

To better inform health policies, medical decisions, and our understanding of the pathogenesis of obesity, a refined understanding of the dynamic nature of body mass is needed. Specifically, how and why obesity changes across the life course and what health risks are associated with specific trajectories. Elevated body mass index (BMI) is a well-established risk factor for cardiometabolic diseases and excess body weight is a leading contributor to mortality in the developed world. Additionally, low BMI and weight loss can also be risk factors, especially in the elderly. However, few studies to date have considered the dynamic nature, the ultimate impact on health, and the underlying genetic contributors to the variability of BMI across the life course. To address these gaps in our understanding, we set out to identify the genetic determinants of longitudinal BMI changes using electronic health record (EHR) data in Geisinger's MyCode Community Health Initiative that is linked to genetic data as a part of the DiscovEHR collaboration. Our sample included 69,215 adults of European descent with at least 5 measurements of weight (median = 46) spanning at least 5 years (median = 13.8 years) and whole genome array data imputed to the Haplotype Reference Consortium (HRC) reference panel. For each patient, we modeled BMI as a linear function of age (BMI slope) and performed associations with the BMI slope, assuming an additive genetic model, and adjusting for age at baseline, sex, mean BMI across encounters, and principal components to control for population structure. We identified a variant in *APOE* (rs429358, MAF = 0.13) that was significantly associated with declining BMI in adults over the age of 50 ( $p = 4 \times 10^{-9}$ ,  $\beta = -0.03 \text{ kg/m}^2\text{year}$ ). *APOE* variants are associated with a variety of conditions that are generally comorbid with obesity such as atherosclerosis as well as neurodegenerative diseases such as Alzheimer's. However, we find that the age-related decline in BMI linked to *APOE* is not attenuated by conditioning on these variables and our results may help to explain conflicting reports that obesity can be both protective or a risk factor for Alzheimer's disease, depending on age. Our future directions include further investigations of genetic variants influencing weight change and elucidating the extent to which changes in adiposity at various life stages influences downstream disease outcomes.

The World Health Organization (WHO) identified asthma, a chronic inflammatory disease of the airways affecting over 235 million individuals worldwide, as the most prevalent non-communicable disease (NCD) among children. Earlier studies estimated that genetic factors contribute to 35%-95% of asthma heritability, of which only a small portion may be explained by known loci. We hypothesize that the missing heritability lies in part within interactions among genes as well as between genes with environmental exposures. Using genomics data from the Canadian Healthy Infant Longitudinal Development study (CHILD; N=3455), we investigate the effects of common and rare genetic variants as well as their interactions with modifiable exposures on risk of asthma and asthma related outcomes throughout early childhood. We obtained genomic data using the Illumina HumanCoreExome BeadChip. After quality control and imputations, 22 million variants from 2830 children were included for analysis of recurrent wheeze reported from age 2-5, which is strongly correlated with asthma outcomes. Our exploratory genome-wide association study (GWAS) identified loci on chromosome 17q12, which has been repeatedly linked with childhood-onset asthma. Moreover, a weight-based association analysis of common (Genetic risk score analysis; GRS) and rare variants (SNP-set kernel association test; SKAT), identified sets of genetic variants significantly associated with wheeze, some of which are novel. In addition, gene-environment interaction analysis identified numerous variations correlated with increased prevalence of wheeze only in children who were exposed to prenatal smoking. Finally, epistatic interactions among genes were studied by constructing a network of inter-correlated variants via hierarchical clustering, a conventional machine learning method for grouping elements based on similarity. This analysis identified 8 clusters of genetic variants associated ( $p < 0.05$ ) with childhood wheeze in our birth cohort. Our preliminary results indicate that both genes and environmental exposures contribute and interact to predispose to asthma and that these association signals may be detected in early childhood, prior to clinical diagnosis of asthma. On-going analyses include additional asthma-related outcomes such as longitudinal lung function and positive skin prick tests to allergens as well as examining more environmental variables such as pet ownership and nutrition.

Barnes<sup>1</sup>. 1) Department of Medicine, University of Colorado, Aurora, CO, USA; 2) University of Texas Southwestern Medical Centre, Dallas, TX, USA; 3) University of West Indies at Cavehill, Barbados, WI; 4) Faculty of Medical Sciences, The University of the West Indies, Queen Elizabeth Hospital, Bridgetown, St. Michael, Barbados; 5) Department of Biostatistics, Bloomberg School of Public Health, JHU, Baltimore, MD, USA; 6) Edmund Cohen Laboratory for Vascular Research, The George Alleyne Chronic Disease Research Centre, The University of the West Indies at Cave Hill, Barbados, W.I; 7) Department of Epidemiology, Bloomberg School of Public Health, JHU, Baltimore, MD, USA.

**RATIONALE:** The human leukocyte antigen (HLA) complex encodes genes of the major histocompatibility complex and plays a central role in regulating the immune system. In this study, we use whole genome sequence (WGS) data from the Barbados Asthma Genetics Study (BAGS) generated through the NHLBI-supported Trans-Omics in Precision Medicine (TOPMed) program to call HLA genotypes and explore relationships between HLA genotypes and atopy. **METHODS:** HISAT-genotype is a novel software program for calling HLA genotypes by using a graph-based approach to align sequences from WGS data against HLA reference sequences from the IPD-IMGT/HLA Database. We used HISAT-genotype to perform HLA genotype calling on 998 samples from BAGS passing QC criteria. Carrier status for an HLA-allele (digit 1 & 2) was defined as having a called probability  $\geq 0.4$ . Carrier status was tested for association with a number of atopy phenotypes: any cockroach skin prick test (SPT, n=266), *Der p*. SPT (n=266), *Blomia Tropicalis* specific IgE (n=281), *Der p* 2 specific IgE (n=316), phadiatop measures (n=795), and measures of total serum IgE (tIgE) in asthmatics (n=410) and non-asthmatics (n=459). Association analysis was performed using mixed effect models including relevant covariates (asthma, age, sex, tIgE batch, principal components). For each phenotype, p-values were corrected using the Benjamini & Hochberg method to control the false discovery rate (FDR). **RESULTS:** HLA A, B, C, DQA1, DQB1 had high call rates (92.0%, 96.0%, 98.3% and 99.6% respectively) and low Mendelian error rates (0.65%, 1.74%, 1.00% and 0.48% respectively), but HLA DRB1 had a relatively low call rate (79.8%) and high rates of Mendelian errors (35.6%). HLA DRB1 was therefore excluded from our association analysis. The HLA DQB1 06:09 allele was associated with increased tIgE in asthmatics (FDR p=0.077, uncorrected p= 0.0008, carrier frequency=3.1%), but the association was not observed in non-asthmatics (uncorrected p=0.67). No other alleles had FDR-corrected p-values  $< 0.1$ . **FUTURE WORK:** We will use HIBAG, an HLA imputation algorithm that uses SNP data to impute HLA genotypes, to call DRB1 alleles and to call HLA genotypes in additional subjects from this study with SNP array data (but no sequence data). In addition, we are in the process of measuring *Blomia tropicalis* specific IgE, a common allergen in the tropics, in all subjects included in this study.

**Analysis of deep whole genome sequencing data from African American asthmatics.** P.M.A. Sleiman, L. Tian, J. Glessner, X. Chang, Y. Liu, F. Mentch, H. Hakonarson. Children's Hospital of Philadelphia, Philadelphia, PA.

Asthma is one of the most common chronic diseases of childhood. Asthma prevalence varies significantly among racial/ethnic groups, African-Americans are disproportionately affected with 1.6 times the level of current asthma compared with white children and 7.6 times higher death rate, 2.6 times higher ED visits, 3 times higher hospitalizations, yet despite the increased incidence and adverse outcomes the genetic causes of asthma in African Americans remain understudied. We have generated deep (> 30X) whole genome sequencing on 4,400 African American asthmatics and controls as part of the TOPMed program. Detailed phenotypic and clinical measures were collected on all participants including spirometry, bronchodilator response, skin prick testing and IgE measurements. We geocoded the cohort to extrapolate environmental and socioeconomic traits including a deprivation index and two air pollution measures, daily spatial surfaces of O<sub>3</sub> (ppb) and PM<sub>2.5</sub> (ug/m<sup>3</sup>). We present the results of WGS-derived burden and structural variant analyses as well as gene by environment analysis against the air pollution measures.

**Gene expression responses at the 17q12-21 asthma locus to microbial exposures in nasal epithelial cells.** M.M. Soliai<sup>1,2</sup>, A. Kato<sup>3</sup>, C.T. Stanhope<sup>2</sup>, J.E. Norton<sup>2</sup>, K.A. Naughton<sup>2</sup>, A.I. Klinger<sup>2</sup>, R.C. Kern<sup>4</sup>, B.K. Tan<sup>5</sup>, R.P. Schleimer<sup>3</sup>, D.L. Nicolae<sup>1,2,3,6</sup>, J.M. Pinto<sup>7</sup>, C. Ober<sup>1,2</sup>. 1) Committee on Genetics, Genomics and Systems Biology, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 4) Otolaryngology-Head and Neck Surgery, Northwestern University Feinberg School of Medicine, Chicago, IL; 5) Department of Medicine, University of Chicago, Chicago, IL; 6) Department of Statistics, University of Chicago, Chicago, IL; 7) Department of Surgery, University of Chicago, Chicago, IL.

Genome-wide association studies (GWAS) of asthma identified the 17q12-21 (17q) locus as one of the most significant and most replicated genetic risks for childhood-onset asthma. We and others reported that genetic variants at this locus are associated with asthma risk only in children with rhinovirus (RV)-associated wheezing illness and with asthma protection in children exposed to barn animals in early life. SNPs at this locus are eQTLs for 2 genes, *ORMDL3* and *GSDMB*, and expression of both increased in response to RV in peripheral blood mononuclear cells (PBMCs). These data suggested that genetic risk at this important locus is environment-specific. To further explore these observations, we used a nasal epithelial cell (NEC) cell model of genotype by microbe interactions to study the effects of microbial exposures on 17q genes in individuals with and without asthma. We cultured NECs from 111 adults in the presence of RV-A16 or heat-killed *Staphylococcus aureus* (SA), and corresponding vehicles (RVveh and SAveh) for 48 and 24 hours, respectively. RNA was collected from NECs for RNA-seq (50 bp, single-end). In contrast to studies in PBMCs, *ORMDL3* expression decreased in the presence of RV or SA compared to vehicle ( $p < 10^{-10}$ ). Moreover, *ORMDL3* expression was higher in NECs from 42 asthmatics compared to 53 non-asthmatics in the vehicle-treated samples ( $p < 10^{-2}$ ); but similar after exposure to RV or SA ( $p > 0.4$ ). *GSDMB* expression was similar in all 4 treatments ( $p > 0.10$ ). Finally, 17q SNPs were strong eQTLs for *ORMDL3*, but not *GSDMB*, in vehicle and treated samples (rs2290400:  $p < 3 \times 10^{-6}$  and  $< 0.030$ , respectively), with the asthma risk allele associated with increased *ORMDL3* expression. These results indicate that in cultured upper airway epithelial cells, *ORMDL3*, but not *GSDMB*, responds to microbes and is associated with genotype. *ORMDL3* expression decreased in response to both viral and bacterial exposures and was higher in asthmatics compared to non-asthmatics in untreated samples. These results suggest that higher constitutive expression of *ORMDL3* in airway epithelial cells, especially in individuals with the high-risk genotype, contributes to risk for childhood-onset asthma at the 17q21 locus. Supported by U19 AI106683; MMS was supported by T32 GM007197.

Asthma is a complex disease with sex-specific differences in prevalence, clinical and biological features. Asthma is more prevalent in males during childhood, while it becomes more frequent in females in adolescence and adulthood. The mechanisms behind these sex-specific differences are not well understood and may involve hormonal changes together with differential genetic predisposition. To identify genetic variants interacting with sex that influence time-to-asthma onset (TAO), we conducted a large-scale meta-analysis of nine gene-environment-wide interaction studies (GEWIS) of TAO (totaling 7,104 men and 6,970 females of European ancestry) by using survival techniques applied to pediatric and adult asthmatic and non-asthmatic subjects. We detected eight independent loci showing SNP×Sex interaction at the  $10^{-5}$  level. Among these loci, three were sex-specific TAO risk loci. The most significant association with TAO was female-specific in an intergenic region at 5q32 ( $P_{\text{female}} = 9.1 \times 10^{-8}$  versus  $P_{\text{male}} = 0.56$ ). The other two associations were male-specific: within *SORCS2* intron 2 at 4q16 ( $P_{\text{male}} = 1.3 \times 10^{-7}$  versus  $P_{\text{female}} = 0.15$ ) and within *DGKB* intron 1 at 7p21 ( $P_{\text{male}} = 3.9 \times 10^{-7}$  versus  $P_{\text{female}} = 0.23$ ). The remaining five loci showed effects in opposite directions between males and females: 1p12 (within *GDAP2*,  $P_{\text{male}} = 7.3 \times 10^{-4}$  versus  $P_{\text{female}} = 4.6 \times 10^{-3}$ ), 2q32 (near *NCKAP1*,  $P_{\text{male}} = 3.7 \times 10^{-3}$  versus  $P_{\text{female}} = 3.7 \times 10^{-4}$ ), 3q26 (within *NLGN1*,  $P_{\text{male}} = 7.3 \times 10^{-4}$  versus  $P_{\text{female}} = 5.8 \times 10^{-6}$ ), 4p14 (in an intergenic region between *PCDH7* and *ARAP2*,  $P_{\text{male}} = 6.2 \times 10^{-3}$  versus  $P_{\text{female}} = 4.9 \times 10^{-5}$ ) and 7q34 (within *TBXAS1*,  $P_{\text{male}} = 3.4 \times 10^{-4}$  versus  $P_{\text{female}} = 4.9 \times 10^{-3}$ ). None of these loci had been previously associated with asthma phenotypes. Functional annotations indicated colocalization of these genetic variants with DNA regulatory elements in fibroblasts, lung or blood. By testing gene-by-sex interactions, we identified novel loci influencing asthma risk in a sex-specific manner. Most of the candidate genes in these loci are involved in inflammatory process and immune cell regulation. Further replication of these findings are ongoing.

**A cell model of gene-environment interactions at the 17q21 asthma locus.** C.W. Washington<sup>1</sup>, J. Huffman<sup>1</sup>, C. Tisler<sup>2</sup>, Y.P. Liu<sup>2</sup>, J.E. Gern<sup>2</sup>, D.J. Jackson<sup>2</sup>, R.F. Lemanske<sup>2</sup>, J.A. Smith<sup>2</sup>, C. Ober<sup>1</sup>. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Division of Allergy, Immunology and Rheumatology, Department of Pediatrics, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA.

Asthma is a common complex disease characterized by lower airway inflammation, resulting in airflow obstruction and clinical symptoms of wheezing, coughing, and breathlessness. However, the biological basis of asthma is largely unknown and diagnosis is often based on these clinical features. Heritability estimates of asthma span from 35% to 70%, but risk of asthma is also affected by a host of environmental factors. One particularly important exposure is rhinovirus (RV) infection, which is associated with wheezing illness in early life and asthma exacerbations throughout life. Asthma GWAS revealed a novel locus on chromosome 17q21 that is the most replicated and most significant asthma locus identified to date. Surprisingly, risk associated with this locus is confined to children with RV-associated wheezing illness in the first 3 years of life. We further explored this genotype-exposure interaction in a cell model to uncover genetic variation that influences transcriptional response to RV. In a previous study, we demonstrated that CD19+ B cells showed the highest fold-change of *ORMDL3* in response to RV infection of peripheral blood mononuclear cells (PBMCs) and the strongest genotype-specific responses. Here, we focused our studies on these cells from 120 children participants in the Childhood Origins of ASThma (COAST) prospective birth cohort. PBMCs were treated with either RV-A16 or vehicle. After 30 hours, CD19+ B cells were isolated and RNA was extracted for gene expression studies. Paired analysis of RV- and vehicle-treated samples revealed a strong treatment effect on expression of genes at the 17q locus with *ORMDL3* and *GSDMB* exhibiting an increased fold-change of 0.69 and 0.61, respectively ( $p < 5 \times 10^{-4}$ ). Genotype for rs7216389, the lead SNP in the first asthma GWAS, was an eQTL for *ORMDL3* and *GSDMB* in both RV- and vehicle-treated samples, but there was neither a genotype effect on response nor genotype by RV interaction effects on response. Moreover, there were no differences in expression among children stratified by asthma at age 6 or by wheezing in the first 3 years of life. These data suggest that the previously observed interaction between rs7216389 genotype and RV-wheezing may be developmentally specific and/or other tissues (e.g., airway cells) may be the relevant site of interaction. **De novo indels within introns contribute to ASD incidence.** A. Munoz<sup>1</sup>, B. Yamrom<sup>1</sup>, Y.H. Lee<sup>1</sup>, P. Andrews<sup>1</sup>, S. Marks<sup>1</sup>, K.T. Lin<sup>1</sup>, Z. Wang<sup>1</sup>, A.R. Krainer<sup>1</sup>, R.B. Darnell<sup>2,3,4</sup>, M. Wigler<sup>1,2</sup>, I. Iossifov<sup>1,2</sup>. 1) Quantitative Biology, Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) New York Genome Center, New York, NY; 3) Laboratory of Molecular Neuro-oncology, Rockefeller University, New York, NY; 4) Howard Hughes Medical Institute, Rockefeller University, New York, NY.

Over the past several years, analysis of whole-exome sequencing and microarray hybridization data from collections of families of children with autism like the Simons Simplex Collection (SSC) has increased our understanding of the genetic architecture of autism. Contributions from de novo (DN) mutation, rare and common variants have been established, but most progress has been made in the study of DN variants. DN germ line likely gene-disrupting (LGD), missense and copy number variants have been estimated to jointly contribute to approximately 30% of the autism in SSC [1]. The observed DN mutations in the ~5,000 affected children enabled the identification of lists of few hundred genes that with high confidence are involved in autism's etiology. For example, half of the 546 genes targeted by published DN LGD mutations (LGD targets) are expected to be true autism genes. We explored the contribution of DN noncoding mutation by focusing on the introns of the LGD targets. We analyzed whole genome data generated from the father, mother, a child with autism and an unaffected child of 1,886 families from the SSC. The 150bp paired-end dataset was generated at the New York Genome Center with average depth of 30x. About 80,000 de novo intronic substitutions (DIS) and 8,000 de novo intronic indels (DII) were identified. There was no significant difference between the numbers of all DIS and all DII between the affected and unaffected children. But in the introns of the 546 LGD target genes, we identified 273 DII in the 1,886 affected while we found only 218 in the 1,886 unaffected children. The difference of 55 events is significantly larger than 0 (p-value: 0.006). If we restrict to the half of the LGD targets that are more intolerant to damaging variants in human population and are expected to be even more enriched for autism genes [2], the difference raises from 55 to 59 and the significance increases (p-value: 0.0003). The increase of rates of DIIs in affected individuals was specific for the high quality autism candidate genes and was not observed in control gene lists. We did not observe a similarly convincing increase of the rates of DIS due to the larger background rates of the DIS. From the observed increase in DIIs rates in children with autism, we estimated that DN intronic variants might contribute ~15% of the autistic children in simplex families. 1. **Genome-wide linkage study meta-analysis of male sexual orientation.** A.R. Sanders<sup>1,2</sup>, G.W. Beecham<sup>3</sup>, S. Guo<sup>3</sup>, J.A. Badner<sup>4</sup>, S. Bocklandt<sup>5</sup>, B.S. Mustanski<sup>6</sup>, D.H. Hamer<sup>6</sup>, E.R. Martin<sup>3</sup>. 1) Center for Psychiatric Genetics, NorthShore University HealthSystem, Evanston, IL; 2) Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL; 3) Department of Human Genetics, University of Miami, Miami, FL; 4) Department of Psychiatry, Rush University Medical Center, Chicago, IL; 5) Laboratory of Biochemistry, National Cancer Institute, National Institutes of Health, Bethesda, MD; 6) Department of Medical Social Sciences, Northwestern University, Chicago, IL.

Male sexual orientation is a scientifically and socially important trait shown by family and twin studies to be influenced by environmental and complex genetic factors. Individual genome-wide linkage studies (GWLS) have been conducted, however, jointly analyzing the available GWLS datasets should maximize linkage information on the trait. Two main datasets account for >90% of the published GWLS concordant sibling pairs on the trait and are jointly analyzed here: Sanders (409 concordant sibling pairs in 384 families with 45,387 SNPs) and Hamer (155 concordant sibling pairs in 145 families with 408 STRPs). We conducted multipoint linkage analyses with Merlin on the datasets separately since they were genotyped differently. To integrate, we found the genetic positions of the respective markers in the Rutgers Map v.3 (hg19 build), and then used the non-parametric S-pairs and grid 1cM options to run multipoint linkage on both data sets, followed by combining LOD scores at each grid position across the marker sets. We continue to find the strongest linkage support at pericentromeric chromosome 8 and chromosome Xq28. We note that the pericentromeric chromosome 8 linkage peak contains a SNP with evidence from GWAS for the trait. Besides reporting these findings, we will report on incorporating the remaining published GWLS dataset (on 55 families) by using the multiple-scan probability approach on published summary statistics. This knowledge will maximize the positional information from GWLS of currently available family resources and help prioritize findings from GWAS and other approaches. Although increasing evidence highlights genetic contributions to male sexual orientation, our current understanding of contributory loci is still limited, consistent with the complexity of the trait. Further increasing genetic knowledge about male sexual orientation, especially via large GWAS, should help advance our understanding of the biology of this important trait. This work was supported NIH grants R01HD041563 and R21HD080410.

**Contribution of transposable elements to disease and complex trait heritability.** F. Hormozdiari<sup>1,2</sup>, O. Weissbrod<sup>1,2</sup>, C. Ju<sup>3</sup>, B. Geijn<sup>1,2</sup>, M. Hujuel<sup>1,2</sup>, S. Gazal<sup>1,2</sup>, F. Hormozdiari<sup>4,5</sup>, A. Price<sup>1,2</sup>. 1) T.H. Chan School of Public Health, Harvard University, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 3) Department of Computer Science, University of California, Los Angeles, California, USA; 4) Genome Center MIND Institute University of California, Davis, California, USA; 5) Department of Biochemistry and Molecular Medicine, School of Medicine University of California, Davis, California, USA.

Transposable elements (TEs), also called "repeat elements", comprise roughly half of the human genome. TEs were once dismissed as "junk DNA", but are now believed to be widely involved in gene regulation (Chuong et al. 2017 Nat Rev Genet). However, the contribution of TEs to disease and complex trait heritability has yet to be quantified. Here, we applied stratified LD score regression with the baseline-LD model (Gazal et al. 2017 Nat Genet) to 41 independent diseases and complex traits (average  $N=320K$ ) to estimate the heritability explained by each of 856 TE annotations, including broad TE classes as well as specific TE families. We define enrichment as  $(\% \text{ of heritability})/(\% \text{ of SNPs})$ ; a value less than 1 implies depleted heritability. We reached 5 main conclusions. First, the set of all TEs in the genome (54% of SNPs) was significantly depleted for trait heritability: enrichment (meta-analyzed across traits) of  $0.67 \pm 0.03$ . The depletion varied across major TE classes, with enrichment estimates ranging from  $-0.02 \pm 0.08$  for LTR (9.8% of SNPs;  $P < 10^{-12}$  for depletion; consistent with heritability close to 0) to  $0.86 \pm 0.10$  for SINEs (16% of SNPs;  $P=0.08$  for depletion). Second, although most TE families were depleted for heritability, we identified 24 TE families that were significantly enriched ( $P < 0.05/856$ , corrected for multiple-testing), including  $6.58 \pm 0.42$  enrichment for AmnSINE1. Third, most depletions were fully explained by the correlations between TE annotations and the annotations of the baseline-LD model (includes a broad set of coding, conserved, regulatory and LD-related annotations), providing a strong validation for the informativeness of the baseline-LD model; in particular, most TE families were depleted for regulatory function. In addition, the mean values of 3 measures of negative selection (nucleotide diversity, predicted allele age and McVicker B statistic) within these TE annotations mirror our findings. Fourth, older repeats explained more disease heritability than younger repeats, consistent with their stronger overlap with functional annotations. Finally, we identified 3 TE families that explained significantly more heritability for brain-related traits than for other traits ( $P < 0.05/856$  for difference), including enrichment estimates of  $0.89 \pm 0.22$  for brain-related traits vs.  $-0.11 \pm 0.12$  for other traits for *ERV1* (5.9% of SNPs). In conclusion, we show that TE contribute depleted but substantial heritability to diseases and complex traits.

Over the past decade, thanks to the development of affordable large-scale genotyping technologies, genome-wide association studies (GWAS) have been providing invaluable insights into the genomic basis of various traits and disorders. The mission of the NHGRI-EBI GWAS Catalog ([www.ebi.ac.uk/gwas](http://www.ebi.ac.uk/gwas)) is to provide a highly curated, comprehensive collection of all GWAS publications and the discovered associations. Since 2008 the GWAS Catalog has collected and made publicly available more than 69,000 associations from more than 3,300 publications. To fulfill our aim of providing the best possible service for the scientific community, we continue to develop our resource to ensure users can efficiently extract association and study related meta-data satisfying their needs. Here we introduce our RESTful API that provides programmatic access to the GWAS Catalog data, enabling users to retrieve data from our database in a high-throughput manner. The RESTful API also enables integration of the GWAS Catalog into custom applications and services, so the returned data is always up to date without the need of constant maintenance of local datasets. To advance the accessibility of GWAS Catalog data we have enhanced the Catalog's web interface to better support common user queries. Our new publication, trait and variant-specific pages are designed to provide structured GWAS Catalog data and visualisations, along with links related to external data. For example, our newly developed publication page lists all GWAS analyses carried out in the paper and provides direct links to all discovered associations, while the trait page contains all publications, studies and associations reporting a specific trait. The variant page provides the details of the discovered associations and an insight into the genomic context of the variant, including LD information in the 1000 Genomes populations, and other already known phenotypes in the vicinity. These developments will vastly improve the utility of the GWAS Catalog to the scientific community, extending the use of Catalog data in investigations to identify causal variants, understand disease mechanisms, and establish targets for novel therapies..

**Evaluation of genetic factors for morphine requirement prediction.** J. Li<sup>1,2</sup>, Z. Wei<sup>3</sup>, J. Zhang<sup>3</sup>, H. Hakonarson<sup>1</sup>, S.D. Cook-Sather<sup>1</sup>. 1) Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) Tianjin Medical University, Tianjin, China; 3) New Jersey Institute of Technology, Newark, NJ, USA.

Acute postoperative pain and opioid responsiveness analgesia demonstrate inter-individual variability and polygenic influence. Heritability estimates for acute experimental pain and opioid analgesia range from 12 to 60%. In 241 children of African American (AA) and 277 of European Caucasian (EC) ancestry, we sought to assess select candidate gene associations with morphine dose, high ( $\geq 7/10$ ) pain, and low ( $\leq 3/10$ ) pain and to develop dose prediction models that estimate dose prediction limits based on genetic factors. All subjects in the study were 4-18 years of age and had morphine as the sole intravenous analgesic component of a general anesthetic. All were genotyped using Illumina HumanHap550 or Human610-Quad arrays. Regression analyses revealed age, BMI and physical status as covariates for morphine dose. The Gene Database from the National Center for Biotechnology Information was queried to identify genetic loci affecting acute postoperative or experimental pain and morphine analgesic response as supported by both clinical and basic sciences research. Then association analyses between the candidate genetic loci and morphine dose, postoperative pain were performed via a linear regression model including significant covariates. Few associations replicated: morphine dose (mcg/kg) in African American children and *ABCB1* rs1045642 ( $\beta = -9.30$ ,  $p = 0.02$ ) and *OPRM1* rs1799971 ( $\beta = 23.29$ ,  $p = 0.02$ ); *KCNJ6* rs2211843 and high pain in AA subjects (OR 2.08,  $p = 0.01$ ) and in congruent European Caucasians pain phenotypes; and *COMT* rs740603 for high pain in European Caucasian subjects (OR 0.69,  $p = 0.046$ ). Top SNP candidate gene models with age, BMI and physical status covariates explained a maximum of 24.2% (EC) and 14.6% (AA) of morphine dose variance.

**ATG16L1 and ATG12 are involved in the pathogenesis of gastric mucosal atrophy in Japanese patients.** K. Obata<sup>1</sup>, H. Ueda<sup>1</sup>, M. Hirado<sup>1</sup>, M. Taira<sup>1</sup>, T. Inamine<sup>1</sup>, D. Fukuda<sup>2</sup>, K. Nakao<sup>3</sup>, H. Isomoto<sup>3</sup>, K. Tsukamoto<sup>3</sup>. 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 2) Dept Gastroenterology and Hepatology, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 3) Div Med and Clin Sci, Dept Multidisciplinary Int Med, Faculty of Med, Tottori Univ, Yonago, Japan.

**Purpose:** It has been known that *Helicobacter pylori* (*H. pylori*) infection causes chronic gastritis, which leads to gastric mucosal atrophy, intestinal type of metaplasia, and eventually gastric cancer. Autophagy, a cellular degradation process, is involved in infection and inflammation. We investigated association between single nucleotide polymorphisms (SNPs) of autophagy-related genes and gastric mucosal atrophy of *H. pylori*-positive subjects to identify host genetic determinants of the disease progression. **Methods:** Colonization of *H. pylori* and gastric mucosal atrophy were evaluated based on concentration of anti-*H. pylori* antibody and serum pepsinogen, respectively. Two hundred Japanese subjects infected with *H. pylori* included 94 patients with atrophic gastritis and 106 subjects without atrophy. A total of 25 SNPs in the 4 genes (*ATG5*, *ATG10*, *ATG12*, and *ATG16L1*) were genotyped by polymerase chain reaction (PCR)-restriction fragment length polymorphism, PCR-high resolution melting curve analysis, and PCR-direct DNA sequencing. **Results:** Five SNPs (rs6431655, rs6431659, 6758317, rs7587051, and rs4663136) within *ATG16L1* and rs26537 within *ATG12* were significantly associated with mucosal atrophy of *H. pylori*-positive subjects. Among *ATG16L1* SNPs, rs6431655 showed the strongest association. The frequency of G/G genotype of rs6431655 was significantly increased in patients with mucosal atrophy ( $P = 0.005$ , OR = 2.838). Conversely, the frequency of C/C genotype of rs26537 within *ATG12* was significantly decreased in the atrophic patients ( $P = 0.033$ , OR = 0.357). **Conclusions:** The current study demonstrated association between autophagy-related genes and gastric mucosal atrophy induced by *H. pylori* infection for the first time. Genetic variants of autophagy pathway might be one of host genetic factors involved in the development of *H. pylori*-induced atrophy in Japanese.

**The Ophthato™ Knowledgebase : A curated knowledgebase of over 500,000 ocular disease phenotypic records with ability to build complex queries to enable analyses of disease progression, prognosis, genotype-phenotype correlation and drug development.** A. Das<sup>1</sup>, S. S. Nagasamy<sup>2</sup>, P. Raj<sup>3</sup>, B. Muthu Narayanan<sup>2</sup>, J. Somasekhar<sup>2</sup>, T. Chandrasekhar<sup>2</sup>, D. Kumar<sup>2</sup>, A. Ghosh<sup>2</sup>, S. Das<sup>2</sup>, S. Tejwani<sup>3</sup>, P. Narendra<sup>2</sup>. 1) MedGenome Inc, Foster city, CA., Select a Country; 2) MedGenome Labs, Bangalore, India; 3) Narayana Nethralaya, Bangalore, India.

Ocular disorders comprise a wide spectrum of diseases affecting anterior or posterior segments of the eye, caused by infections, genetic changes (monogenic or complex), environmental stress and trauma. While advancements in genetic, molecular and proteomics technologies has led to a better understanding of disease pathology, specific treatment modalities and drug development for various complex ocular diseases remain. Challenges still exist in utilizing knowledge from genome wide association studies (GWAS) to identify disease relevant variants due to: a) lack of reproducibility of the same results in a replication study in a different population b) and limited well characterized phenotypic data to draw genotype to phenotype correlations across different populations. Complex diseases with a diverse manifestation of phenotypes and sub-phenotypes require studies on larger cohorts with comprehensive longitudinal phenotype and clinical data to address the unmet research needs in ocular diseases. To enable genomic, pharmacogenomic discovery or clinical research in ocular diseases, MedGenome Inc has launched the Ophthato™ Knowledgebase: a comprehensive collection of clinical, phenotype and biochemical data providing researchers and clinicians with a platform to design studies that address critical unmet needs in eye disorders. The searchable interface enables complex queries to select specific disease cohorts based on demographics, specific tissue affected, disease type and subtype, disease course or severity, drug response and many other clinical and phenotypic parameters. We will present case studies to showcase the utility of the Ophthato Knowledgebase. As a complete solution, we also provide access to genomic sequencing for cohorts of interest to enable a) validation of the disease relevant variants in a different population b) design GWAS studies and perform phenotype-genotype correlations c) novel biomarker discovery.

**2575T**

Katsanis<sup>3</sup>. 1) MIT CSAIL, Massachusetts Institute of Technology (MIT), Cambridge, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC; 4) Division of Genetics, Brigham and Women's Hospital, Boston, MA; 5) Department of Medicine, Harvard Medical School, Boston, MA; 6) Laboratoire de Génétique Médicale, Institut de Génétique Médicale d'Alsace, INSERM U1112, Fédération de Médecine Translationnelle de Strasbourg (FMTS), Université de Strasbourg, Strasbourg, France; 7) Laboratoire de Diagnostic Génétique, Institut de Génétique Médicale d'Alsace (IGMA), Hôpitaux Universitaires de Strasbourg, 1 place de l'hôpital, Strasbourg, 67091, France; 8) Molecular Neurogenetics Unit and Psychiatric and Neurodevelopmental Genetics Unit, Center for Genomic Medicine, and Department of Neurology, Massachusetts General Hospital, Boston, MA; 9) Program in Population and Medical Genetics and Genomics Platform, The Broad Institute of MIT and Harvard, Cambridge, MA; 10) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 11) Department of Ophthalmology, Baylor College of Medicine, Houston, TX; 12) Program in Bioinformatics and Integrative Genomics, Division of Medical Sciences, Harvard Medical School, Boston, MA; 13) Department of Biomedical Informatics, Harvard Medical School, Boston, MA.

The importance of genetic background on driver mutations is well established but, the mechanisms by which the background interacts with Mendelian loci remains unclear. This challenge is particularly acute in rare disorders with low allele frequencies for both causal variants and secondary-locus contributory alleles (i.e. alleles in loci other than the primary locus), with population-based studies being hampered by the lack of statistical power due to very few events. To address the contribution of background genetic burden, we studied secondary-locus variation in two independent Bardet-Biedl syndrome (BBS) cohorts (n=191) with known recessive biallelic pathogenic mutations. We found that ultra-rare nonsynonymous variants are enriched in secondary loci, both versus population controls (N=850) and versus non-BBS diagnosis individuals with biallelic variants in the same recessive genes (N=50), using either in-cohort (MAF<0.2%; p=0.001; OR=2.11) or population-based (MAF<0.0001%; p=0.02; OR=2.88) minor allele frequencies. The secondary-locus variants preferentially disrupted overlapping functional genomic elements and thus are more likely to be deleterious and detrimental to protein function (p=0.025); were specific for nonsynonymous changes (synonymous variants were equally distributed between cases and controls (p=0.21), arguing against population stratification as a confounder); and concentrated in chaperonin-encoding genes (*MKKS*, *BBS10* and *BBS12*), a finding that was further corroborated by the observation of epistatic interactions involving this complex *in vivo*. These data intimate a complex genetic architecture involving the identification of secondary-locus variants that are likely to contribute to disease penetrance and expressivity, across multiple genes within biologically-relevant pathways. Though our observations are based on the study of a single recessive disorder (BBS), we postulate that this currently-untapped component of genetic architecture complexity is likely to be relevant for several other recessive and/or dominant disorders.

**2576F**

**Are there genetic variants to explain the phenomenon of donor cell survival following blood transfusion?** R. Hirani<sup>1</sup>, M. Hobbs<sup>2</sup>, A. Statham<sup>2</sup>, M. Dinger<sup>2,3</sup>, D.O. Irving<sup>1</sup>. 1) Research and Development, Australian Red Cross Blood Service, Sydney, New South Wales, Australia; 2) GenomeOne, 370 Victoria Street, Darlinghurst, Sydney NSW 2010; 3) Kinghorn Centre for Clinical Genomics, 370 Victoria Street, Darlinghurst, Sydney NSW 2010.

**Background:** Despite the introduction of leukodepleted blood components, it has been shown that donor leukocyte engraftment (transfusion-associated microchimerism (TAM)) remains a long-term consequence of red blood cell (RBC) transfusion in some patient groups. The mechanism by which donor leukocytes survive following blood transfusion is unclear and it has been speculated that genetic factors may be one possible reason. This study was conducted to determine whether there is any association between an individual's genetic profile and the establishment of TAM in blood transfusion recipients. **Methods:** Australian trauma patients (n = 86) transfused with RBC units between 2000 and 2012, with an injury severity score of greater than 15, were recruited. Twelve of these patients were found to have TAM. To date, whole exome sequencing was conducted on four patients with TAM and four patients without TAM. Alignment of the exome data to the human genome reference sequence assembly GRCh37 was conducted and analysis of differential genetic variations was carried out. Variations unique to at least 50% of patients in each group were further investigated, with a primary focus on genes associated with immune regulation. **Results:** Preliminary analysis has been performed. Many of the changes found in 2 of the four patients with TAM, were present in highly heterogeneous genes including zinc finger protein genes and the human leukocyte antigen genes (HLA-B and HLA-DRB1). Some of the most interesting changes were found in genes with unknown function such as Chr4 70257329 variant ID248066. In addition changes were found in the following genes, BTN3A1 gene (Chr6 26405815 variant ID 340887) which plays a role in the regulation and proliferation of T-cells and in the CCL8 gene (chr 17 32647356 variant ID 847320) which is a chemokine which contributes to tumor associated leukocyte removal. **Conclusion:** Next generation (whole exome) sequencing technologies allow for the exploration of genetic variations across different population groups, which can provide clues for the potential indications of mechanisms by which TAM may establish in certain patients. This preliminary analysis provides potential genetic changes that could involve genes that have a role in T-cell regulation and proliferation. It is expected that further analysis with expanded patient numbers will allow for this genomic data to be explored in more detail.

**Clinical utility of genotype screening in unselected individuals for personalized medicine.** K.P. Lubieniecki<sup>1,2,3</sup>, L.M. Fricke<sup>1</sup>, J.M. Lubieniecka<sup>1,2,3</sup>, M.M. Moore<sup>1</sup>, B. Tucker<sup>1</sup>, M. Mboob<sup>1</sup>, C.F. Boerkoel<sup>1</sup>, M.M. Soe<sup>1</sup>, C.J. Carlson<sup>1</sup>, S.J. Ahuja<sup>1</sup>, D.W. Lee<sup>1</sup>, M.E. Cornwell<sup>1</sup>, C. Hajek<sup>1,2</sup>, L. Carmichel<sup>1,2</sup>, P. Cherukuri<sup>1,2,3</sup>, R.E. Pyatt<sup>1,2,3</sup>. 1) Sanford Health, Imagenetics, Sioux Falls, SD; 2) Sanford School of Medicine, University of South Dakota, Sioux Falls, SD; 3) Sanford Research Center, Sioux Falls, SD.

**Background:** Development of high-throughput and high accuracy (>99%) SNP genotyping platforms significantly reduced the per marker cost of genotyping. Inclusion of pathogenic and likely pathogenic variants identified by the American College of Genetics and Genomics (ACMG), as well, as pharmacogenetic variants recommended by Clinical Pharmacogenetics Implementation Consortium (CPIC) on a high throughput SNP screening array can enable preemptive screening for unselected patients. Based on the estimates of secondary finding from whole genome and exome sequencing studies we predict that approximately 1-2% of our patient population would be positive for a Medically Actionable Predisposition (MAP) finding. Based on published population frequencies, the frequency of variants affecting drug metabolism is expected to be at least 30%. **Methods:** To evaluate the technical performance of a custom version of the Illumina Global Screening Array (GSA), a cohort of 67 samples submitted for diagnostic testing to the Sanford Medical Genetic and Genomics Laboratories was analyzed retrospectively. To establish the reportable data set, we first removed variants targeted by probes that failed clinical and/or analytical validation. The remaining set was manually curated for pathogenic and likely pathogenic variants considered medically actionable genetic predispositions for adult onset disorders and medication efficacy. We confirmed all positive findings by Sanger sequencing or Taqman assays. **Results:** We identified 2 carriers of pathogenic variants in MUTYH and one carrier of pathogenic variant in MYBPC3 genes causing susceptibility for MYH-associated polyposis, pilomatixoma and familial hypertrophic cardiomyopathy-4, dilated cardiomyopathy-1A, respectively. All three positive cases were confirmed by Sanger sequencing. Frequencies of the pharmacogenomic phenotypes associated with 8 metabolic genes are presented in Table 1. We discuss the variants reported, the discordance between GSA results and results from orthologous tests, the need for supplemental testing, and the detection rates within the screened population. Table 1

**Accurate prediction of multiple pigmentation phenotypes.** *B. Alipanahi, P. Fontanillas, M. Multhaup, S. Shringarpure, C. Wilson, M. Johnson, S. Pitts, A. Auton, R. Gentleman, 23andMe Research Team. 23andMe, Inc., Mountain View, CA.*

Genetic studies, in particular, genome-wide association studies (GWAS), have established that pigmentation traits (eye color, skin color, and hair color) are highly polygenic in humans. They also have shown that the genetic architecture of these traits is largely overlapping and have suggested epistasis between the main loci. The shared genetic architecture of pigmentation phenotypes has not been exploited for predicting pigmentation thus far. Most prediction efforts have achieved relatively high accuracy in predicting the extremes of the human pigmentation distributions but suffer lower predictive accuracy for the intermediate phenotypes. Here, we applied a two-hidden layer deep neural network on self-reported pigmentation phenotypes from a large cohort of 23andMe research participants of European ancestry for joint-prediction of eye, hair, and skin colors. The collected phenotypes have eight, six, and six levels for eye color, hair color, and skin color, respectively, and provide fine-grained self-reporting of these phenotypes. Our model is trained on over 1,100 SNPs and 103,000 individuals and shows excellent prediction performance: When tested on out-of-sample data it achieves an aggregate AUC of 86%, 81%, and 76% for predicting eye color, hair color, and skin color levels. Although trained on categorical responses, the distribution of predicted eye color and hair color scores approximately matches the natural distribution of quantitatively-measured M index for eye color and C' score for skin color [1]. Our analysis identifies significant epistatic interactions between *SLC45A2* and *SLC24A4*, *IRF4*, *SLC24A4*, *MC1R*, and the *HERC2/OCA2* locus, among others. Notably, the effects of these interactions are different on each pigmentation phenotype. This model is a useful tool to predict the pigmentation phenotypes while preserving their inherent correlations, to understand and investigate the genetic architecture of these traits, and to analyze their involvement in skin cancer risk or other pigmentation-associated disorders. References [1] Genome-wide association studies of quantitatively measured skin, hair, and eye pigmentation in four European populations. Candille et al., PLoS One. 2012;7(10):e48294.

**Itchy and scratchy: Polygenic risk scores predict self-reported mosquito attraction and bite response.** *J.R. Ashenurst, S. Laskey, M. Multhaup, O. Sazonova, N. Furlotte, B. Koelsch, The 23andMe Research Team. 23andMe, Inc, Mountain View, CA, CA.*

Mosquitos present not merely an annoyance but also a significant threat to global public health. As such, susceptibility and response to mosquito bites are phenotypes of substantial interest. Previous research identified 15 independent genetic loci associated with self-reported attractiveness to mosquitoes, bite size, or itch intensity (Jones et al., 2017), and suggested shared phenotypic and genetic etiology. In the present study, we use a large ( $n = 311,556$ ) cohort of unrelated 23andMe research participants of European descent to assess the predictive power of polygenic risk scores (PRS) for each of these three phenotypes. We performed novel GWAS of each phenotype, yielding 139, 105, and 128 independent markers ( $p < 5e-6$ ) for mosquito attraction, bite size, and bite itchiness respectively. Tissue and gene set enrichment analyses implicated genes associated with these loci in blood and lymph tissues, and in gene sets involved in hematopoiesis, myelopoiesis, and leukocyte activation. Additive linear models trained in the GWAS discovery sample using these SNPs as features explained 1-2% of the variation in the three phenotypes in a held-out replication cohort ( $n = 77,890$ ). Addition of age and sex features to create a combined risk score (CRS) increased the variance explained to 6-12%. Despite their modest predictive power, CRS meaningfully stratify participants by phenotype. For example, we observe a four-fold increase (59.5% vs 14.7%) in the fraction of participants rating themselves as "more attractive" to mosquitos than their peers among those above the 95th vs. those below the 5th percentiles of the CRS. The three self-reported phenotypes and corresponding PRS were highly correlated (mean Pearson's  $r = 0.55$  and  $0.69$  respectively), and previous analyses implied a causal relationship from bite size to perception of mosquito attractiveness (Jones et al., 2017). As such, prediction using the combination of variants associated with these highly correlated phenotypes may yield stronger models of each. Indeed, PRS trained using the union of the three sets of markers (285 variants) resulted in minor improvement in model performances (mean increase in  $r^2 = 0.04\%$ ), and highly correlated PRS (mean  $r = 0.94$ ). Notwithstanding their modest predictive power, these PRS could be used to identify individuals who might benefit from protective strategies to avoid mosquitos.

**Enrichment of deleterious variation on down-regulated haplotypes due to the regulation-dependent penetrance of coding variants.** *R. Brown, S. Sankararaman.* University of California, Los Angeles, Los Angeles, CA.

Recent work with allele-specific expression data has shown that rare deleterious coding variants tend to lie on haplotypes with reduced gene expression (Castel, 2018); consistent with a model in which natural selection tends to reduce the frequency of pairs of haplotypes associated with higher penetrance at these variants. Here we study the population genetics of deleterious mutations whose penetrance is modulated by linked regulatory variation and empirically investigate the distribution of regulatory-linked enrichment for rare deleterious variation. We use simulations to understand the selection dynamics and steady-state population-level distributions of deleterious coding variation as a function of regulation and gene length. Simulations demonstrate that a single de novo deleterious variant is able to drift to a higher frequency and persists for longer when it occurs on down-regulated haplotypes. Since genes are subject to repeated random de novo mutation at multiple sites, the difference in selection efficacy results in down-regulated haplotypes carrying a greater number of deleterious variants than up-regulated haplotypes. The difference in the number of deleterious variants carried by the up- and down-regulated haplotypes increases with increasing gene length, mutation rate and eQTL effect. We show that these patterns persist in real data using 1000 Genomes phased-genotypes, eQTLs calls from GTEx and CADD scores for the predicted variant deleteriousness. We observe an enrichment of deleterious variation on down-regulated haplotypes on average across genes. Down-regulated haplotypes contain 1.21 (s.e. 0.036) alternate alleles per kb across all CADD scores while up-regulated haplotypes contain 1.10 (s.e. 0.024) indicating decreased tolerance of variation (paired t-test p-value =  $4.9 \times 10^{-6}$ ). On average 47.2% of down-regulated haplotypes contain at least one variant at or exceeding a CADD score of 10 while only 46.2% of up-regulated haplotypes do, a marginally significant difference (paired t-test p-value = 0.042). These observations demonstrate that regulation affects the selection strength against deleterious variation in coding regions and results in an enrichment of deleterious variation on down-regulated haplotypes. Since most GWAS hits occur outside of coding regions, we further hypothesize that GWAS hits in regulatory regions may be tagging down-regulated haplotypes that are enriched for rare deleterious coding variants. .

**Genome-wide association studies of human facial width-to-height ratios.** *M. Lee<sup>1</sup>, J. Roosenboom<sup>1</sup>, E. Feingold<sup>2</sup>, M.L. Marazita<sup>1</sup>, J.R. Shaffer<sup>2</sup>, S.M. Weinberg<sup>1</sup>.* 1) Center for Craniofacial and Dental Genetics, Department of Oral Biology, University of Pittsburgh, Pittsburgh, PA, USA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA, USA.

The ratio of facial width to height is sexually dimorphic in humans and has been correlated with testosterone levels and related behavioral effects in numerous studies. Because most aspects of facial morphology are heritable, these types of quantitative facial traits are also likely to be influenced by genes. This has been borne out by GWAS, which have showed associations between many common genetic variants and normal-range variation in facial morphology. To better understand the genetic basis of facial width-to-height ratio, we calculated 5 facial indices based on various horizontal and vertical distance measures derived from either direct anthropometry or 3D facial surface images. We performed GWAS on these indices in 2,156 healthy unrelated individuals genotyped on the Illumina OmniExpress + Exome v1.2 array and imputed to the 1000 Genomes phase 3 reference panel. All measures were adjusted by sex, age and body size, then subjected to GWAS in PLINK adjusting for ancestry principal components. We also performed sub-analyses in males and females separately, and in post-pubertal individuals (>14y). We observed five genome-wide significant associations ( $p < 5 \times 10^{-8}$ ). Two genes showed strong associations with the index involving total facial width by total facial height: *DNAH5* (rs1971860, 5p15.2;  $p = 4.22 \times 10^{-9}$ ) in the over 14 subset and *DYNC2H1* (rs601446,  $p = 4.17 \times 10^{-9}$ ) in the female subset. *WDR72* (rs141781189;  $p = 2.94 \times 10^{-9}$ ) showed a significant association with indices specifically involving the upper face. Both *HLS-DOA* (rs409443;  $p = 2.44 \times 10^{-9}$ ) and *CNTNAP4* (rs117438273;  $p = 3.79 \times 10^{-9}$ ) were associated with the index involving the lower portion of the face. Additionally, several suggestive loci ( $p < 5 \times 10^{-6}$ ) were observed. These results provide further insight into genetic pathways and mechanisms underlying normal variation in human facial morphology. Moreover, they suggest that traits commonly held to reflect the action of androgens during the human growth phase are also influenced by additional factors.

**2582F**

**Low-frequency genetic variants contribute to human craniofacial morphology.** D. Liu<sup>1</sup>, M.K. Lee<sup>2</sup>, J. Roosenboom<sup>2</sup>, J.T. Hecht<sup>3</sup>, G.L. Wehby<sup>4</sup>, L.M. Moreno<sup>5</sup>, C.L. Heike<sup>6</sup>, M.L. Marazita<sup>6</sup>, E. Feingold<sup>1</sup>, S.M. Weinberg<sup>2</sup>, J.R. Shaffer<sup>1</sup>. 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA, 15261; 2) Department of Oral Biology, University of Pittsburgh, Pittsburgh, PA, 15219; 3) Department of Pediatrics, University of Texas McGovern Medical Center, Houston, TX; 4) Department of Health Management and Policy, University of Iowa, Iowa City, IA; 5) Department of Orthodontics, University of Iowa, Iowa City, IA; 6) Department of Pediatrics, Seattle Children's Craniofacial Center, University of Washington, Seattle, WA.

The genetic basis of normal variation in human craniofacial traits is still poorly understood. Several GWAS and candidate genes studies have focused on identifying associations with common genetic variants, with moderate success to date. The influence of low-frequency variants has not been evaluated, and their contribution to facial morphology remains elusive. In order to better understand the genomic architecture of normal-range facial traits, we used burden-style tests to evaluate the role of low-frequency variants against 24 quantitative facial measurements derived from the 3D surface images. A cohort of 2447 healthy individuals of European ancestry were genotyped on Illumina OmniExpress+Exome v1.2 array. Two complementary statistical tests, Sequence Kernel Association Test (SKAT) and Combined Multivariate and Collapsing (CMC) method were performed using two ranges of minor allele frequency cutoffs (1% and 5%). A total of ~92,000 variants grouped into ~12,950 genes were included, and significance threshold was defined by Bonferroni method taking into account the number of phenotypes and the number of genes tested. We observed associations involving two genes. *GRAMD1B* was associated with the morphology of the lower lip (SKAT p-value =  $6.34 \times 10^{-12}$ , CMC p-value =  $1.64 \times 10^{-7}$ ). There were 3 variants with MAF < 1% in this gene and single variant linear regression showed a significant effect for a missense variant (rs191981781; p-value =  $2.83 \times 10^{-11}$ ; MAF = 0.0008). *OR2C1* was associated with the height of the entire face (CMC p-value =  $3.05 \times 10^{-8}$ , SKAT p-value =  $3.86 \times 10^{-6}$ ). There were 7 variants with MAF < 5% and single variant analysis showed suggestive significance for one variant (rs62000975; p-value =  $1.90 \times 10^{-6}$ ). *GRAMD1B* and *OR2C1* have not previously been implicated in human facial traits, and we consider them as potential candidate genes worthy of follow up in future studies. Our findings demonstrate that low-frequency variants contribute to normal-range human facial morphology.

**The role of glycaemic, lipid, obesity and blood pressure risk factors as mediators of the effect of height on coronary artery disease and type 2 diabetes mellitus: A Mendelian randomisation study.** E. Marouli<sup>1</sup>, F. Del Greco M.<sup>2</sup>, C.M. Astley<sup>3,6</sup>, J. Yang<sup>7,8</sup>, R.J.F. Loos<sup>4</sup>, Z. Kutalik<sup>5</sup>, J.N. Hirschhorn<sup>3,6</sup>, P. Deloukas<sup>1</sup>, *Genetic Investigation of Anthropometric Traits (GIANT) Consortium*. 1) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK; 2) Institute for Biomedicine, Eurac Research, Affiliated Institute of the University of Lübeck, Bolzano, Italy; 3) Boston Children's Hospital, MA, USA; 4) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 5) Institute of Social and Preventive Medicine, Lausanne University Hospital, Lausanne, Switzerland; 6) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 7) Institute for Molecular Bioscience, University of Queensland, Brisbane, Australia; 8) Queensland Brain Institute, The University of Queensland, Brisbane, Queensland, Australia.

Evidence from observational studies suggests that shorter stature is associated with cardiometabolic diseases. However, it is unclear whether this is a causal relationship or whether it is confounded by other factors. Using a Genetic Score for height (defined as adult stature) and Mendelian randomisation (MR), we investigated the causal effect of height on coronary artery disease (CAD) and type 2 diabetes (T2D). We also assessed whether these effects are mediated by known cardiometabolic risk factors (e.g. BMI, glycaemic traits, lipids, blood pressure) based on genetic evidence. We used UK Biobank (449,094 unrelated British individuals) to investigate by several MR analyses: (1) the causal effect of height on CAD (23,755 cases vs 425,339 controls) and T2D (29,427 cases vs 416,908 controls), (2) the causal effect of height on possible mediators (known cardiometabolic risk factors), and (3) the extent to which these factors mediate any effect that height may have on CAD and T2D. In parallel, we used publically available summary statistics data from large consortia (GIANT, CARDIOGRAMplusC4D, DIAGRAM, MAGIC, GLGC) to perform two-sample MR analyses. Two-sample MR analyses showed that one SD higher genetically determined height (~6.5 cm) was associated with decreased risk of CAD (OR: 0.83, 95% CI: 0.80-0.87). This association remained significant (OR: 0.86, 95% CI: 0.79-0.94) after performing sensitivity analyses. The height-CAD effect was reduced by 1-2%, in terms of magnitude, after adjustment for glycaemic (glucose, insulin, HbA1c, 2hGlu), lipid (Total Cholesterol, Low Density Lipoprotein, High Density Lipoprotein, Triglycerides) or blood pressure (BP; Systolic BP, Diastolic BP, Pulse Pressure) traits in Multivariate MR analyses. We observed a causal effect of height on T2D (OR: 0.93, 95% CI: 0.90-0.96, p=0.01), but it was entirely driven by its indirect effect through BMI (OR: 0.95, 95% CI: 0.92-0.99, p=0.12). There was no evidence for a causal relation between adult height and T2D adjusted for BMI (OR: 0.99, 95% CI: 0.96-1.02, p=0.95). In summary, one SD higher genetically determined height reduces CAD risk by 17% and the association does not seem to be mediated by glycaemic, lipid and blood pressure traits, suggesting the observational association is due to a causal effect. On the other hand, we observed no direct causal effect of height on T2D risk, once its effect on BMI is taken into account.

**2584T**

**DNA methylation in nasal epithelial cells and sensitization to aeroallergens.** A. Morin<sup>1</sup>, C. McKennan<sup>2</sup>, K. Naughton<sup>1</sup>, D. Vercelli<sup>3</sup>, D. Nicolae<sup>1,2,4</sup>, K. Bønnelykke<sup>5</sup>, H. Bisgaard<sup>5</sup>, C. Ober<sup>1</sup>, the COPSAC study. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Statistics, University of Chicago, Chicago, IL; 3) Department of Cellular and Molecular Medicine, Arizona Center for the Biology of Complex Diseases, and Asthma and Airway Disease Research Center, University of Arizona, Tucson, AZ; 4) Section of Genetic Medicine, Department of Medicine, University of Chicago, Chicago, IL; 5) Copenhagen Prospective Studies on Asthma in Childhood, Herlev and Gentofte Hospital, University of Copenhagen, Copenhagen, Denmark.

DNA methylation is an epigenetic mark that responds to the environment and, therefore, can serve as a proxy for understanding how exposures influence gene expression and disease pathogenesis. Airway epithelia are in direct contact with inhaled exposures and are likely the site of interactions. In particular, sensitization to aeroallergens during early life impacts the development of childhood diseases such as asthma and allergies. To better understand the mechanism through which environmental exposures impact disease, we collected DNA from nasal epithelial cell brushings at age 6 from 517 children in the Copenhagen Prospective Studies on Asthma in Childhood (COPSAC)<sup>2010</sup> birth cohort. DNA methylation profiles were assessed using the Illumina 850k EPIC array. We used a linear model (limma) with sex and confounding variables identified by PCA as covariates to assess differential DNA methylation between children with and without sensitization to aeroallergens. Batch effects were adjusted using ComBat. We also removed additional unwanted variation by protecting the phenotype of interest using an in-house method (unpublished). We identified 20 CpGs associated with sensitization to aeroallergen (FDR 5%): 16 were less methylated and four were more methylated in sensitized children. Among these were 7 CpGs that were associated with atopic asthma or Immunoglobulin (Ig) E levels in previous studies, including cg04983687 (*ZFPM1* intron;  $p=2.48e-14$ ;  $q=1.94e-8$ ), cg20372759 (intergenic between *METTL1* and *CYP27B1*;  $p=1.32e-10$ ;  $q=3.44e-5$ ) and cg21220721 (*ACOT7* exon;  $p=7.18e-10$ ;  $q=1.12e-4$ ). Of the 13 newly identified CpGs, 9 are specific to the EPIC array, which was not used in any previous studies. The most significant association on the EPIC array was at cg16911809 ( $p=2.35e-11$ ;  $q=9.18e-6$ ), which is located in an intron of *CCL26*, a chemokine that has been previously associated with asthma and allergies in multiple studies. Furthermore, another CpG located in an intron of *CCL26* was differentially methylated in bronchial epithelial cells from asthmatic and non-asthmatic subjects. These data suggest a link between nasal epithelial cell DNA methylation and sensitization to aeroallergens. Ongoing analyses are exploring the impact of DNA methylation in on gene expression in the same samples. This work is supported by NIH R01 HL129735.

**A characterization of eQTLs directions in complex traits inspired by the omnigenic model.** O. Naret, J. Fellay. EPFL, Lausanne, Switzerland.

The genetic architecture of extreme polygenic traits and its biological underpinning remain open questions. As an extreme example of polygenicity, it was estimated through genome-wide association studies (GWAS) that up to 100,000 independent variants exert a causal effect on height. While some of the top signal variants could be mapped to meaningful biological pathways or features, most of them fall in the regulatory regions of supposedly irrelevant genes. This leaves the bulk of the biology of height heritability unexplained. Relying on the observation that any gene can be associated with a trait as long as it is expressed specifically or broadly in a relevant cell or tissue, Boyle et al. (2017) proposed the omnigenic model to classify them in two categories. First, a minority of core genes that are specific to the biology of the trait. Second, a majority of peripheral genes that interact with core genes through the small world property of the regulatory network. Under this model, we tested if the effect of peripheral genes could result from a competition for resources with core genes, at the level of transcription. Under this assumption, the peripheral genes direction of expression should be correlated with the direction of their association with the phenotype of interest (as expressed in the + or - sign of their effect size), while opposite correlations should be observed for the core genes. To test our model, we leveraged the gene expression data reported by the GTEx consortium in different tissues, and the summary statistics from UK Biobank GWAS for height, BMI, and depression. We did not observe any evidence of associations between the direction of RNA expression and the direction of the genetic association. The small world property of the regulatory networks can imply complex interactions that will be challenging to understand. To accept the omnigenic model, the causality of peripheral genes needs to be further characterized.

**2586W****Genetic predisposition for myalgic encephalomyelitis/chronic fatigue syndrome: Pilot study.**

*L. Nathanson<sup>1,2</sup>, M. Perez<sup>1,2</sup>, R. Jaudoo<sup>1,3</sup>, T.J.A. Craddock<sup>1,3</sup>, K. Gaunt<sup>1,2</sup>, K. Gemayel<sup>1,2</sup>, A. Del Alamo<sup>1,2</sup>, M.A. Fletcher<sup>1,2</sup>, N.G. Klimas<sup>1,2</sup>.* 1) Institute for Neuro Immune Medicine, Nova Southeastern University, Fort Lauderdale, FL; 2) Kiran C Patel College of Osteopathic Medicine, Nova Southeastern University, Fort Lauderdale, FL; 3) College of Psychology, Nova Southeastern University.

**Background:** Myalgic Encephalomyelitis/Chronic Fatigue Syndrome (ME/CFS) is a debilitating disease with unknown causes. It is associated with a variety of symptoms including fatigue, memory problems, muscle and joint pain, gastrointestinal issues, neurological problems, hormonal imbalance and immune dysfunction. Currently, treatment relies solely on symptom management but does not address the underlying mechanisms of disease. It is known that single nucleotide polymorphisms (SNPs) play an important role in gene expression changes that can manifest as phenotypic changes. Prior to this ongoing study, there existed no known databases of SNPs in patients diagnosed with ME/CFS. **Objectives:** Our objectives are to identify possible genetic predisposition to ME/CFS. We are creating a novel database of SNPs that are specific for ME/CFS patients to identify the relative frequency in our cohort of specific SNPs warranting further research. **Methods:** A genetic database was created on-site through the use of a secure user-friendly online platform, REDCap, for participants to upload their raw genetic data, acquired from 23andMe. The uploaded de-identified genetic data acquired from RedCap have been modified and filtered to include only nonsense and non-synonymous SNPs from protein coding regions (exons), microRNAs, and SNPs that are close to splice sites. The frequencies of each SNP have been calculated within our cohort, compared to the public database (Kaviar) and those SNPs of differing prevalence are noted for future analysis. **Results:** Over 800 ME/CFS patients have been recruited for the study so far. Recruitment is ongoing, and new data are being collected. 383 ME/CFS patients uploaded their data to RedCap. Analysis of this data revealed 387 SNPs that have the frequency at least 10% in either healthy or ME/CFS patients cohort and have at least five-fold difference between healthy and ME/CFS patients cohorts. Pathway analysis showed that the most affected are cell signaling (including MAPK-, calcium-, Wnt-, cytokine-cytokine receptor signaling, etc.) and immune pathways. **Conclusion:** This data show possible genetic predisposition for ME/CFS. Studies of larger cohorts are needed.

**2587T**

**Genome-wide association study identifies gene polymorphisms associated with the analgesic effect of fentanyl in the preoperative cold pressor-induced pain test.** *D. Nishizawa<sup>1</sup>, K. Takahashi<sup>1,2</sup>, K. Yoshida<sup>1,2</sup>, S. Kasai<sup>1</sup>, J. Hasegawa<sup>1</sup>, K. Nakayama<sup>1</sup>, Y. Ebata<sup>1</sup>, Y. Koukita<sup>2</sup>, K. Fukuda<sup>3</sup>, T. Ichinohe<sup>2</sup>, K. Ikeda<sup>1</sup>.* 1) Psychiatry and Behavioral Science (Addictive Substance Project), Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 2) Department of Dental Anesthesiology, Tokyo Dental College, Tokyo, Japan; 3) Department of Oral Health & Clinical Science, Tokyo Dental College, Tokyo, Japan.

**Purpose:** Opioid analgesics are widely used for the treatment of moderate to severe pain. The analgesic effects of opioids are well known to vary among individuals. Such individual differences in opioid sensitivity may at least partly be attributable to genetic factors. The present study focused on the genetic factors that are associated with interindividual differences in opioid and pain sensitivity. **Methods:** We conducted a multistage genome-wide association study (GWAS) in subjects who were scheduled to undergo mandibular sagittal split ramus osteotomy and were not medicated until they received fentanyl for the induction of anesthesia. We preoperatively conducted the cold pressor-induced pain test before and after fentanyl administration. Whole-genome genotyping was performed with iScan System (Illumina, San Diego, CA, USA) and mainly two kinds of BeadChip, Human1M v1.0 and Human1M-Duo v3. **Results:** As a result of GWAS with approximately 300,000 polymorphic markers in surgical patients, the rs13093031 and rs12633508 single-nucleotide polymorphisms (SNPs) near the *LOC728432* gene region and rs6961071 SNP in the *tcag7.1213* gene region were significantly associated with the analgesic effect of fentanyl, based on differences in pain perception latency before and after fentanyl administration. The associations of these three SNPs that were identified in our exploratory study have not been previously reported. The two polymorphic loci (rs13093031 and rs12633508) were shown to be in strong linkage disequilibrium. Subjects with the G/G genotype of the rs13093031 and rs6961971 SNPs presented lower fentanyl-induced analgesia. However, no SNPs were identified as genome-wide significant in their associations with pain sensitivity. **Conclusions:** Our findings provide a basis for investigating genetics-based analgesic sensitivity and personalized pain control, in which the G alleles of the rs13093031 and rs6961971 SNPs are associated with lower opioid sensitivity.

**2588F**

C-reactive protein (CRP) is a well-established biomarker of acute and chronic inflammation and a predictor of cardiovascular disease, immunity-related disorder, and mortality risk. The largest genome-wide association study meta-analysis in European populations (>80,000 subjects) identified eighteen loci; however, loci may contain multiple distinct signals with differing regulatory roles, and additional genetic determinants remain to be discovered in diverse ancestral populations. We performed a multi-ancestry whole genome sequence association analysis of single nucleotide and small insertion/deletion polymorphisms with C-reactive protein levels in 23,283 individuals (average age 59.2 years, 32% male; predominantly European (64.7%) and African American (28.1%) ancestry) from nine cohorts from the Trans-Omics for Precision Medicine (TOPMed) program. The analysis was performed on the University of Michigan ENCORE server using the Scalable and Accurate Implementation of Generalized mixed model (SAIGE) R package to control for sample relatedness. Inverse normalized CRP was adjusted for sex, age, study and self-reported ancestry indicator variables, as well as principal components derived from the sequence data. Analyses for variants with a minor allele frequency >0.1% (n=25,949,369) showed little evidence of inflation ( $\lambda=1.045$ ). At a significance threshold of  $1 \times 10^{-9}$ , we identified 8 previously known loci (*CRP*, *APOE*, *HNF1A*, *LEPR*, *GCKR*, *IL6R*, *IL1F10*, *NLRP3*). Notably, six of these loci had different lead variants than those identified in previous studies; for example, the *APOE* locus was refined to rs429358 (a coding variant which defines APOE- $\epsilon$ 4 allele status) as opposed to noncoding variants which likely tagged this signal. The *CRP* locus demonstrated evidence of twelve conditionally distinct signals using TOPMed sequencing data and Genome-wide Complex Trait Analysis Conditional & joint (GCTA-COJO) analysis, including low frequency (minor allele frequency <5%, rs375458630, rs78069458) and non-European (e.g., functional DARC null red cell phenotype variant rs2814778, rs111245605) signals. We also found evidence for multiple distinct signals at *LEPR* and *HNF1A*. We are currently refining these association signals using functional annotation and fine-mapping approaches and seeking additional replication. For further discovery of CRP-related loci, larger sample sizes from diverse populations will be required.

**The impact of genotype imputation on the statistical power of rare variant association tests.** D.M.H. Tong<sup>1</sup>, R.D. Hernandez<sup>1,2,3,4,5</sup>. 1) University of California, Berkeley - University of California, San Francisco Graduate Program in Bioengineering, San Francisco, CA; 2) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA; 3) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 4) Quantitative Biosciences Institute, University of California, San Francisco, San Francisco, CA; 5) Institute for Computational Health Sciences, University of California, San Francisco, San Francisco, CA.

We are now entering the era of million-member genome-wide association studies (GWAS), with incredible success so far. Despite these successes, the common genetic variants associated thus far only explain a portion of the expected trait heritability. Rare variants, with minor allele frequencies below 1%, constitute the vast majority of human genetic variation discovered from sequencing studies, and population genetic modeling suggests that there are some scenarios in which rare variants make up a substantial source of that "missing heritability". Rare variant association tests (RVATs) were designed to make associations with these rare variants, but the anticipated explosion in rare variant associations has not happened. One likely reason is that the statistical properties of these RVATs are poorly understood across different potential genetic architectures and study designs. This limitation has hampered our ability to predict the power of RVAT study designs, and as such, we are attempting to use the same methods on different data blindly. Here, we present a simulation study to interrogate RVAT power across different genetic architectures and study designs, by simulating realistic studies using whole genome sequencing (WGS) and genotyping followed by imputation against massive imputation reference panels. We find that power to associate rare variants is low across all situations, that power is lowest when rare variants represent most of the trait heritability, and that large-scale genotyping followed by imputation results in only a slight decrease in power compared to whole genome sequencing. Our results highlight the fact that existing RVATs are severely under-powered, and that future RVATs will need to take into account the forces of natural selection and demography to improve our understanding of trait architectures.

**Genetic sex differences are generated by embryonic developmental mechanisms.** *M. Traglia, L.A. Weiss.* Department of Psychiatry and Institute for Human Genetics, University of California San Francisco, 401 Parnassus Ave, LangPorter, San Francisco, CA.

Sex differences in susceptibility, prevalence, symptoms as well as co-morbidities have been observed in a large set of complex disorders and quantitative phenotypes risk factors for common diseases. During puberty, evident physical differences in secondary sex characteristics emerge. We thus used available anthropometric traits to identify SNPs differentially associated by sex with height, weight, waist and hip measurements [GIANT, 2013]. We then showed that the set of anthropometric sex-heterogeneous SNPs (AH SNPs) strongly contribute to the genetic architecture of complex traits and disorders including autism, WTCCC-studied diseases, and GIANT consortia traits [Mitra et al., 2016; Traglia et al 2017]. This evidence suggests that observed disease differences by sex might be generated by the same pleiotropic mechanisms determining secondary sex characteristics, and we therefore wanted to better-define the relevant mechanisms. Based on the observation of a small but significant overlap between AH SNPs and androgen and estrogen-responsive genes (empirical  $P < 0.01$ ), we hypothesized enrichment in functional elements. We thus annotated 8,140 SNPs with the nearest genes using ANNOVAR [Wang et al, 2010] and investigated whether the 1,367 independent AH genes were overrepresented in KEGG and Reactome pathways, GO biological processes and molecular functions (FDR  $< 0.05$ ) using PANTHER [Mi, et al 2017]. To assess significance, we generated 100 permuted SNP lists (matching the number of AH SNPs and the association  $P$  in sex-combined analysis) and we calculated an empirical  $P$ . After multiple test correction and permutation, we observed significant overrepresentation of these genes in crucial signaling pathways for early body development such as WNT and cadherin signaling, angiogenesis, axon guidance mediated by netrin and gonadotropin-releasing hormone receptor pathways (emp  $P < 0.05$ ). These genes and pathways are mainly implicated in ectoderm (emp  $P = 0.03$ ) and nervous system development (emp  $P = 0.04$ ). During gastrulation, the ectoderm differentiates into the nervous system and into the sensory epithelia and mammary glands that are all significantly enriched in AH genes (emp  $P < 0.01$ ). The observation that fundamental prenatal development processes, responsible for the biology of traits and diseases later in life, are enriched in sexually dimorphic key genes and pathways, demonstrate the essential link between genetic sex differences and pathophysiology.

**The “avocado gene” and nutrigenetics: New evidence for olfaction’s role in food preferences and genetic correlations with health outcomes.** *J.F. Wilson, E.J. Grzeszkowiak, N. Pirastu.* University of Edinburgh, Edinburgh, United Kingdom.

It is estimated that diet is the second strongest risk factor for early death, influencing the incidence of the top killers in developed societies, including cardiovascular disease, cancer, diabetes, and dementia as it contributes to at least 678,000 deaths in the US each year. Nutrigenetics offers a unique opportunity for estimating dietary behaviour from individual genetic makeup and assessing its impact on disease risk. The conventional approach focusses on studying self-reported food consumption and converting specific food items to macronutrients. It has been suggested that food preferences may better predict actual food consumption than food frequency questionnaires. After measuring preferences for >60 different food and drink items in four different European cohorts ( $n = 4,781$ ) on a 9-point scale, we ran GWAMA on each of the studied traits. We detected a number of genome wide significant hits, some of which were population specific. For example, we detected a novel significant association between the olfactory receptor gene *OR2L13* and avocado liking. We also show a range of novel associations for specific foods that have been previously linked to diet-related diseases such as the association between liking of acidic food and *PTPRN2* (related to obesity and colorectal cancer). In addition, we replicated some of the associations for food preferences from previous studies (Pirastu 2016). Furthermore, we calculated the genetic correlations between specific foods and diet-related traits which reveal a previously under-studied genetic link between food-liking and health outcomes. Our results strongly suggest that studying food preferences rather than macronutrient intake increases the chance of detecting genetic signals that may influence food consumption. Despite a relatively small sample size, our study has produced more hits than larger studies on macronutrient intake. We have also demonstrated that olfaction and the genetic variation within olfactory receptor genes may play an essential role in determining food preferences and consequently influencing health. Given the genetic correlations with health outcomes and overlap with the associations for diet-related diseases we conclude that in the future nutrigenetics may play an increasingly important role in personalised nutrition and disease prevention. Further studies with larger sample sizes and additional food and drink items are needed to further explore this under-studied area of human genetics.

**Re-examining high altitude adaptation (HAA) associated genes in tibetan populations with a focus on the evolutionary history of EPAS1 gene.** X. Zhang<sup>1</sup>, K. Witt Dillon<sup>1</sup>, X. Jin<sup>2</sup>, A. Asan<sup>2</sup>, R. Nielsen<sup>3</sup>, E. Huerta-Sanchez<sup>1</sup>. 1) School of Natural Sciences, University of California, Merced; Merced, CA, USA 95343; 2) BGI-Shenzhen; Shenzhen, China 518083; 3) Department of Integrative Biology, University of California, Berkeley; Berkeley, CA, USA 94720.

Tibetan population is one of the three human populations that is well adapted to high altitude hypoxic environment. A number of candidate genes, including EPAS1, were previously reported to be strongly associated in the physiological responses leading to high altitude adaptation (HAA). In addition, the selected EPAS1 haplotype showed evidence of being adaptively introgressed from admixture event between modern humans and Denisovan-like archaic human groups (Huerta-Sanchez et al. 2014). However, many important questions remain to be answered. For example, there was limited evidence to convincingly exclude Neanderthals as a potential source of the beneficial EPAS1 haplotype. Besides, a recent study showed that two waves of introgression with Denisovans likely to have occurred in East Asia (Browning et al. 2018) - which event the EPAS1 haplotype was associated with requires further analysis. In this study, DNA samples of 148 individuals from Tibet were obtained, with altitude ranging from 3000 to 4800 meters above sea level. 23 HAA candidate genes were sequenced with 30x depth for the continuous core segment (> 60kb), plus 20 1kb-long segments that were evenly spaced every 20kb upstream and downstream of each gene (Yi et al. 2010; Beall et al. 2010, Simonson et al. 2010, and Bigham et al. 2010). By comparing the *Fst* between Tibetans and Han Chinese (CHB, 1000 Genomes Project), we identified one highly differentiated locus upstream of the EPAS1 core region (*Fst* = 0.8; intergenic variant). By comparing the pairwise differences between the most-common Tibetan haplotype with archaic individuals, we replicated the previous reports that the most common Tibetan EPAS1 haplotype was most similar to Denisovans than to Han Chinese. The difference of EPAS1 haplotype between Tibetans and Denisovans was larger than the Neanderthal-Neanderthal genome-wide divergence, but smaller than the divergence between Denisovan-Neanderthals. Therefore, we showed that the source of EPAS1 beneficial haplotype in Tibetans was most likely to be Denisovans instead of Neanderthals. By applying the SPrime method (Browning et al. 2018), we showed that the source of EPAS1 beneficial haplotype in Tibetans was likely to have originated from the East Asian-unique Denisovan introgression event (second wave).

**A genome-wide analysis in consanguineous families reveals chromosomal loci in specific language impairment (SLI).** M.H. Raza<sup>1</sup>, E.M. Andres<sup>1</sup>, H. Hafeez<sup>2</sup>, A. Yousaf<sup>3</sup>, S. Riazuddin<sup>3</sup>, M.L. Rice<sup>1</sup>, M.A.R. Basra<sup>2</sup>. 1) Child Language Doctoral Program, The University of Kansas, Lawrence, KS; 2) Institute of Chemistry, University of the Punjab, Lahore Pakistan; 3) Allama Iqbal Medical College, Lahore Pakistan; 4) Department of Biotechnology, International Islamic University, Islamabad Pakistan.

Specific language impairment (SLI) is a developmental disorder that delays language skills in children who are otherwise typically developing. Children with SLI experience lifelong impacts in academic learning and social relationships. Genetic studies have identified a number of chromosomal loci and several candidate genes for SLI. Although these are important findings in the genetics of SLI, they explain a small proportion of the genetic variance. Additional genetic studies are needed in extended SLI families. We performed genome-wide parametric linkage analysis and homozygosity mapping in 14 consanguineous families from Pakistan segregating SLI. Linkage analysis revealed a multi-point LOD score of 4.18 at chromosome 2q in family PKSLI05 under a recessive mode of inheritance. Another linkage with a multipoint LOD score of 3.85 was observed in family PKSLI12 at a non-overlapping locus on chromosome 2q. Two other suggestive linkage loci were found in family PKSLI05 on chromosome 14q and 22q with LOD scores of 2.37 and 2.23, respectively. These loci were also replicated in homozygosity mapping. Reduction to homozygosity was also observed in regions on chromosomes 2q, 14q, 22q, 5p, 8q and 17q. These homozygosity regions occurred in affected individuals of PKSLI families but were absent in most of the unaffected or unknown individuals. Our findings confirm previously analyzed suggestive SLI linkage loci on chromosomes 5, 14, 17 and 22 reported in the Robinson Crusoe Island founder population. These findings indicate that linkage and homozygosity mapping in consanguineous families can improve genetic analyses in SLI, and suggest the involvement of additional candidate genes for this disorder.

**Programmable nuclease-based integration into novel extragenic genomic safe harbor identifies from Korean-population based CNV analysis.** S. Moon<sup>1</sup>, E-S. Lee<sup>2</sup>, Y.J Kim<sup>1</sup>, M.Y. Hwang<sup>1</sup>, H. Kim<sup>3</sup>, B-J. Kim<sup>1</sup>. 1) Korea National Institute of Health, Cheongju-si, Chungcheongbuk-do, Korea, Republic of; 2) Department of Chemical and Biological Engineering, Seoul National University; 3) Department of Pharmacology, Yonsei University.

One of the critical needs in biomedical field is the ability to stably insert functional transgenes and other genetic elements into human genome without the disrupting genes or perturbing their transcription. Several diseases have been successfully treated with stable insertion of therapeutic genes such as Parkinson's disease. However, random integration of transgenes can cause insertional mutagenesis altering the expression levels of neighbor genes. The most common approach to integrate transgenes in human cells is using retroviral vector. Uncontrolled insertional mutagenesis can cause cancer such as leukemia and lymphoma by perturbing proto-oncogenes or tumor suppressors. Instead of using viral vectors, the use of engineered nucleases, Zinc finger Nucleases, Transcription Activator-Like Effector nucleases and CRISPR-Cas system, has become the alternative approach. Despite of the advance in these engineered nucleases, there are only few up-to-date identified and validated genomic safe harbors (GSHs). GSHs are intra/extragenic regions that can support predictable transgene expression while minimizing the neighboring gene perturbation. AAVS1 site on chromosome 19 is the most popular GSH due to its ability to support transgene expression in multiple cell types, yet at the same time it was known that AAVS1 locus can be silenced by the mechanism including DNA methylation. Here, we discovered GSH candidates and examined disease correlation. Moreover, we investigated the neighboring gene perturbation near the site of integration. To these ends, we used 3,601 multi-class copy number variation (CNV) regions from the previous CNV study using 4,694 Koreans. We examined CNV regions which satisfy the following criteria: (1) 5-25% minor allele frequency; (2) distance of >300Kb away from any gene and genes that are implicated in cancer and miRNA; (3) lack of disease correlation. As a result, we selected two candidates on chromosome 3 and 8 which satisfied selection criteria. In particular, based on cohort epidemiological data, we examined the disease correlation using 31 traits related to complex diseases including type 2 diabetes and obesity. Then, we found lack of disease correlations with two candidates. Finally, we were able to achieve efficient site-specific integration and the neighboring gene perturbation near integration site. We proved that these two CNV regions could derive robust transgene expression without significantly altering neighboring genes.

**Taiwan Biobank: An open access resource for conducting the biomedical research.** H. Chu<sup>1,2</sup>, C. Shen<sup>1,2</sup>. 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Taiwan Biobank, Academia Sinica, Taipei, Taiwan.

To understand the cause for common disease is challenging. These conditions are caused by a combination of genetics, environmental exposure, and lifestyle. In order to clarify these complex interactions, the Taiwan Biobank (TWB) is establishing a scientific infrastructure accessible to biomedical researchers. TWB is a large and comprehensive prospective study with 200,000 participants, who age 30–70 years, from the general population without history of cancer, and another 100,000 patients with chronic diseases of public health importance. Our aim is to improve the health of future generations. This study has collected extensive phenotypic and genotypic details from individual participants, including the data from questionnaires, physical examination, biomedical test, image inspection, experimental information, biospecimens, and longitudinal follow-up for a wide range of health-related outcomes. This huge and challenging effort is to elucidate risk factors and molecular pathogenesis of disease. This effort will lead to both disease prevention, progression prediction and facilitation of the development of individualized therapies. In order to study the variance of molecular markers in a large number of participants, TWB aims to generate multi-omics experimental information to study the genome, epigenome, transcriptome, proteome and metabolome from a large number biospecimens of participants. In genomics, TWB has already accomplished 28,000 whole genome genotypings, 2,000 whole genome sequencings, and 1,100 NGS-based HLA typings. TWB has also done 1,500 DNA methylation chips in epigenomics and 400 NMR-based metabolites identifications in metabolomics. The genomic summary statistics have been released through a publicly accessible web-based calculation platform, Taiwan View (<https://taiwanview.twbiobank.org.tw/>). TWB is available for open access to any bona fide researchers who wish to use it to conduct research. Additionally, most of participants have provided inform consent to authorize Taiwan Biobank to link their electronic health records. The release of this large-scale population data, omics information, and electronic health records will greatly benefit human biomedical research.

**Association analyses of common SNPs and indels from whole genome sequencing of orofacial cleft (OFC) trios of European ancestry.** *N. Mukhopadhyay<sup>1</sup>, E. Feingold<sup>2</sup>, E.J. Leslie<sup>3</sup>, G.L. Wehby<sup>4</sup>, L.M. Moreno-Uribe<sup>5</sup>, J.T. Hecht<sup>6</sup>, F.W.B. Deleyiannis<sup>7</sup>, S.M. Weinberg<sup>1,2</sup>, T.H. Beaty<sup>8</sup>, J.C. Murray<sup>9</sup>, M.L. Marazita<sup>1,2</sup>.* 1) Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) Department of Human Genetics, Emory University, Emory, GA; 4) Department of Health Management and Policy, University of Iowa, Iowa City; 5) Department of Orthodontics & the Iowa Institute for Oral Health Research, University of Iowa, IA; 6) Department of Pediatrics, McGovern Medical School and School of Dentistry UT Health at Houston, Houston, TX; 7) Department of Surgery, Plastic and Reconstructive Surgery, University of Colorado School of Medicine, Denver, CO; 8) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 9) Department of Pediatrics, University of Iowa, Iowa City, IA.

Orofacial clefts (OFCs) represent the most common type of craniofacial birth defects in humans, and they have a complex and heterogeneous etiology with multiple genetic and environmental risk factors. Through the NIH Gabriella Miller Kids First Pediatric Research Program (Kids First), whole genome sequencing (>30x) was done for 415 nonsyndromic OFC trios of European ancestry, drawn from an ongoing study of OFC families. Cumulatively, this research has included molecular, candidate gene, whole-genome linkage and whole-genome association studies, and has identified several genes controlling risk to OFC. Here, we present results from whole-genome sequencing (WGS) of 327 case-parent trios using approximately  $4 \times 10^6$  common biallelic single nucleotide polymorphisms (SNPs) and indels with high call quality. All cases had cleft lip only (CL), cleft palate only (CP), or cleft lip with cleft palate (CLP). Tests of association and linkage were assessed for each SNP/indel using the allelic transmission disequilibrium test (TDT). A subset of the trios affected with CL or CLP were also analyzed together (CL/P subgroup). Outcomes include a genome-wide significant association at 8q24 ( $p < 10^{-9}$ ) and near-significant association for markers at *PAX7* ( $p < 10^{-7}$ ) in the CL/P subgroup; both of which have been reported in earlier studies. Suggestive associations ( $p < 10^{-6}$ ) at other recognized risk genes were also observed in the complete set of OFC trios, including the *MAPT* and *CRHR1* genes on chr17q21.31 (Park et al. 2006), and *ARHGAP8* on chromosome 22q13.31 (Ludwig et al. 2012). A new genome-wide significant association was observed in chromosome 12q13.13 (lead SNP rs7312514,  $p < 10^{-8}$ ), and a second locus approaching significance on chromosome 6q16.3 (lead SNP rs111364373,  $p < 5 \times 10^{-8}$ ) in the complete set of OFC trios. This preliminary investigation of Kids First WGS data identified several genomic regions associated with risk to OFCs, some recognized and some novel. Detailed investigation to identify novel genes in the new loci, as well as causal variants and/or regulatory pathways for all putative risk genes is currently underway. This work was supported by grants R01-DE016148, X01-HL132363, R01-DE014581, R01-DD000295 and R03-DE026469.

**2597F**

**Finding subgroups of Chronic Obstructive Pulmonary Disease (COPD) in a diverse population using clinical data from Electronic Health Records.** *A.O. Basile<sup>1</sup>, A. Frase<sup>2</sup>, A. Lucas<sup>2</sup>, M.D. Ritchie<sup>2</sup>, N.P. Tatonetti<sup>1</sup>.* 1) Biomedical Informatics, Columbia University, New York, NY; 2) Department of Genetics, Institute for Biomedical Informatics, University of Pennsylvania, Philadelphia, PA.

Complex diseases are heterogeneous in nature; instead of representing a single disease they may be comprised of multiple disorders with varying symptoms, clinical presentations, and etiology. Trait heterogeneity is a confounding issue largely overlooked in traditional genetic approaches. It complicates patient diagnoses, and has been shown to decrease both statistical power to detect associations and the risk attributed to susceptibility variants. The copious amounts of biomedical data present in Electronic Health Record (EHR) systems can be leveraged using data-driven approaches to overcome trait heterogeneity and detect homogeneous patient subsets. Similarity Network Fusion with spectral clustering was used to group 57,574 COPD patients of mixed race (20% Hispanic, 11% African and 37% European American) from Columbia University/NY Presbyterian Hospital using EHR extracted clinical lab measures, COPD comorbidities, and demographics. Analysis on 19,627 females identified 2 clusters, with cluster 1 characterized by older patients (mean age 87) who more frequently exhibit renal (33% chronic kidney disease (CKD)) and cardiac (40%) traits, and cluster 2 defined by younger subjects (mean 63) with respiratory traits (54% asthmatic). Analysis on 18,379 males identified 3 clusters. Cluster 1 is composed of younger patients (mean 33) with higher liver enzymes and more frequent asthma diagnoses (44%). Cluster 2 is defined by older patients (mean 84) who exhibit renal and cardiac (46% cases) traits. Cluster 3 is defined by patients with a mean age of 69 and a higher bronchitis diagnosis (43%). For both sexes, the aforementioned traits showed statistically significant (Bonferroni  $p < 5 \times 10^{-4}$ ) differences between clusters when assessed with Wilcoxon or ANOVA and chi-squared tests. Recursive feature elimination with a random forest classifier performed separately on each sex identified similar top predictors in both cohorts including age, BUN, and diagnosis of CKD, asthma, and heart disease. Also, while the number of clusters differed, the sex stratified analyses identified groups with similar clinical characteristics: younger asthmatic patients versus older patients with renal and cardiac traits. Likewise, variables such as chronic cough, HDL, and obesity had consistent patterns without significant differences between the clusters for both sexes. This analysis successfully utilizes EHR-extracted data to elucidate clinical patterns and address heterogeneity in COPD.

**2598W****Gene expression and splicing QTLs inform the biology of complex traits.**

*R. Bonazzola, GTEx Consortium.* Section of Genetic Medicine, Department of Medicine, University of Chicago, Chicago, Illinois, USA.

Huge progress has been made uncovering thousands of genetic variants robustly associated with complex traits. Most of these are non-coding and are thought to regulate mRNA levels and splicing, whose cascading effects alter phenotypes. We report the analysis of the V8 release of GTEx with 838 whole genomes and 17,382 RNA-sequenced samples from 49 tissues. After uniform harmonization of thousands of GWAS results covering diverse human phenotypes and imputation to a uniform variant set in hg38, we performed colocalization and PrediXcan analyses to identify xQTLs (expression and splicing) that underlie complex trait mechanisms. Here we identify candidate genes at more than half of the examined GWAS loci. We demonstrate that disease-associated genetic variation frequently perturbs distal gene regulation and is often associated with the expression of more than one gene. The unprecedented depth of the GTEx catalog enabled the identification of conditionally independent xQTL signals at a large fraction of human genes. We also find that secondary xQTLs are frequently co-localized with GWAS signals even when the primary signal is not. Moreover, we demonstrate that top xQTLs tend to have smaller GWAS effect sizes than secondary xQTLs. In contrast, jointly finemapped eQTLs (DAP-G) ranked by their effects on expression tend to have more significant downstream effects. These results suggest that the current practice of focusing on top xQTLs should be discouraged. Gene-level analysis with PrediXcan replicated many known disease genes while dramatically expanding the catalog of genes with roles in complex trait biology. We replicate our candidate causal complex trait genes with a test based on an enrichment of rare, loss-of-function coding mutations in genes with related phenotypes, demonstrating that many human phenotypes are affected by an allelic series, where common variation that affects expression has a milder range of related phenotypic effects relative to mendelian mutations. As expected from the widespread sharing of xQTLs across tissues, multi-tissue analysis allows for more discoveries than any single tissue. We find tissue-shared and tissue-specific gene-level association with PrediXcan, suggesting intricate patterns of context specificity of the etiology of complex traits. Given the extensive coverage of human tissues and phenome-wide scope of our analysis, we expect that findings of our analysis will shape the guidelines for future GWAS-xQTL analysis.

**2599T****Pedigree-focused linkage analysis of specific language impairment reveals multiple suggestive loci.** *E.M. Andres, M.L. Rice, M.H. Raza.* Child Language Doctoral Program, University of Kansas, Lawrence, KS.

Specific language impairment (SLI) is described as a deficit in language despite average or above average nonverbal intelligence (IQ) and no other behavioral diagnoses or hearing loss. The estimated prevalence of SLI is 7%. The causes of SLI are not well understood, but family aggregation studies provide evidence that genetic factors are involved in the transmission of SLI. The current study used pedigree-based parametric linkage analysis of six SLI families that are followed longitudinally for language measures. We performed whole genome SNP genotyping using Illumina Infinum QC Array-24 and genotyping of microsatellite markers within the identified linkage loci. Linkage analysis was completed under autosomal dominant and recessive modes of inheritance with variable disease penetrance. Performance on an age appropriate standardized omnibus language measure was used to assign affected status categorically for all individuals. Single-point LOD scores above 2.0 were identified on chromosomes 4q (family 1), 3p, 9q, 15q (family 2), 6q, 10q, 12p (family 4), and 14q (family 6). The highest LOD scores were consistently found under the recessive mode of inheritance, with the exception of one locus (3p in family 2). Multipoint linkage analysis, under recessive mode of inheritance with full penetrance, showed maximum LOD scores of 2.41 on chromosome 4q, 2.39 on 14q, and a maximum LOD score of 2.65 on 6q, 10q and 12p (all found in family 4). The large size of family 2 does not allow multipoint linkage analysis for the loci on chromosomes 3p, 9q and 15q. These results indicate genetic heterogeneity of SLI and provide support for the previous hypotheses that SLI is polyphenic and polygenic. Further investigation of these loci in other populations may provide additional support for these candidate SLI loci.

**2600F****Gene-smoking interaction in Fuchs endothelial corneal dystrophy:**

**A GWAS analysis.** Y.J. Li<sup>1,2</sup>, R.P. Igo<sup>3</sup>, N.A. Afshari<sup>4</sup>, S.K. Iyengar<sup>2</sup>, Fuchs Genetics Consortium. 1) Biostatistics and Bioinformatics, Duke University Medical Center, Durham, NC; 2) Duke Molecular Physiology Institute, Duke University Medical Center, Durham, NC; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, Ohio; 4) Shiley Eye Institute, University of California, La Jolla, California.

Fuchs endothelial corneal dystrophy (FECD) is a common ocular disease causing corneal edema, decreased vision, and eventually leading to transplantation. Genetic predisposition is considered the best predictor for FECD with four validated loci (*TCF4*, *LAMC1*, *KANK4* and *LINC00870/ATP1B1*), as reported in our genome wide association study (GWAS) (Afshari et al. 2017. *Nat Commun* 8, 14898). Environmental exposures, UV light and smoking, have been linked to FECD as risk factors, but their role in disease etiology is not well understood. Herein, we focus on the role of smoking (having ever smoked) and the gene-smoking interaction on FECD. We also evaluate the impact of smoking on the four known FECD genes. Genotyping was performed on 3968 samples (1404 FECD cases, 2564 controls) using Illumina HumanOmni2.5-4v1\_H array by the Center for Disease Research; Of these, we analyzed 1294 cases and 2317 controls with smoking data for ~1.5 Million variants (MAF > 0.02). Multivariable logistic regression was used to test the effect of smoking on FECD while controlling for age and sex. We then conducted genome-wide SNP-smoking interaction tests with adjustment of SNP, smoking, age, sex, and six principal components. For the four known FECD gene regions, we repeated the same regression model as the one in our prior GWAS except adding the smoking factor. By itself smoking showed significant protective effects on FECD after adjusting for age and sex (OR=0.54, 95% CI= (0.47, 0.63),  $p < 0.0001$ ). GWAS of SNP  $\times$  smoking revealed 7 SNPs meeting  $p < 10^{-5}$ . Among them, three common SNPs (MAF=0.45-0.5) in *CD274*, an immune checkpoint protein, revealed strong SNP  $\times$  smoking interaction effects on FECD. SNP rs7042084 showed the most significant SNP  $\times$  smoking, with the nucleotide A  $\times$  smoking increasing the risk of FECD (OR=1.72, 95%CI = (1.39, 2.14),  $p=8.3 \times 10^{-7}$ ) and the main effects of both SNP and smoking are also significant ( $p=0.0009$  and  $3.5 \times 10^{-17}$ , respectively). However, the other two SNPs in *CD274* showed significant SNP  $\times$  smoking (max  $p=8.0 \times 10^{-6}$ ) but no significant main effects. Variants at four known FECD genes remain significantly associated with the disease after adjusting for smoking factor. As the SNP  $\times$  smoking in these four genes shows only nominal association with FECD, we confirm that their effects on FECD are primarily driven via the main effect. In conclusion, this will be the first report on genes associated with FECD modifiable through one's life style, such as smoking.

**Circadian misalignment accentuates genetic risk to obesity.** A.R. Wood<sup>1</sup>, S.E. Jones<sup>1</sup>, Z. Kutalik<sup>2</sup>, H. Yaghoobkar<sup>1</sup>, R.N. Beaumont<sup>1</sup>, M.A. Tuke<sup>1</sup>, K.S. Ruth<sup>1</sup>, R.M. Freathy<sup>1</sup>, A. Murray<sup>1</sup>, J.T. Tyrrell<sup>1</sup>, T.M. Frayling<sup>1</sup>, M.N. Weedon<sup>1</sup>. 1) Genetics of Complex Traits, University of Exeter Medical School, Exeter, Devon, United Kingdom; 2) Institute of Social and Preventive Medicine, University Hospital of Lausanne, Switzerland.

**Introduction** Gene-lifestyle interactions in humans have been difficult to identify and replicate. Some putative interactions have been observed between self-report behaviours (e.g. sleep) and genetic variants associated with complex traits, but most are not validated with objective measures. Using individuals from the UK Biobank, we tested the hypothesis that misalignment between genetic estimates of circadian timing, based on self-reported chronotype ("morningness"), and accelerometer-derived estimates of circadian timing (activity and sleep timing) would increase susceptibility to obesity. **Methods** We derived objective measures of circadian timing using 82,322 unrelated European individuals from the UK Biobank. These measures included timing of the least and most active periods of the day, and a relative amplitude of these measures to estimate rest-activity rhythms. We tested for interaction effects on BMI between the genetics associated with chronotype as a genetic risk score (GRS) and derived measures of circadian misalignment. Misalignment was defined as intra-individual disagreement between the GRS and accelerometer-based timing measures. For example, individuals were classified as having a misaligned circadian timing if they were in the top 20% for the GRS and bottom 20% for the accelerometer-derived estimates of circadian timing and vice versa. **Results** Circadian misalignment was associated with higher obesity risk. For example, 16% of individuals with a high or low genetic predisposition to being a "morning" person were misaligned to estimates of sleep timing. Misaligned individuals were 1.78kg heavier (for individuals 1.75m tall) than aligned individuals. We observed an association between the chronotype GRS and higher BMI in the misaligned group ( $\beta=0.58\text{kg}$ , 95% CI 0.26,0.88,  $P=3 \times 10^{-4}$ ). We did not observe the same association within the aligned group ( $\beta=-3.15\text{kg}$ ; 95% CI -6.68,0.37;  $P=0.08$ ). Interaction analyses of the chronotype GRS and circadian misalignment measures provided evidence of accentuated effects on BMI ( $P_{int}=5 \times 10^{-6}$ ). **Conclusions** Using genetics and accelerometer data, we provide evidence that circadian misalignment accentuates obesity risk. However, individuals misaligned were more overweight at baseline and further analyses are needed to test the robustness of these interactions including negative control experiments. Our results highlight the potential of identifying gene-lifestyle interactions when using objective measures of lifestyle.

**2602T**

**Identifying disease subtypes from genotype data.** *H. Aschard, A. Vaysse, A. Bzili.* Centre de Bioinformatique, Biostatistique et Biologie Intégrative (C3BI), Institut Pasteur, Paris, France.

Several common diseases are not single entity but rather composed of multiple heterogeneous disease subtypes. For example, inflammatory bowel disease (IBD) encompasses Crohn's disease and ulcerative colitis, while breast cancer can be either estrogen receptor (ER)-positive or ER-negative. Subtypes are expected for many other diseases, but have not yet been characterized. Identifying such latent disease subtypes is important both for understanding the etiology of diseases, and for improving clinical treatment. Because known disease subtypes display genetic heterogeneity, it has been suggested that genetic data can be used to infer latent disease subtypes. More specifically, previous works proposed applying principal component analysis of genotypes in disease cases, and using the top principal component as a classifier to identify subtypes. While achievable in theory, this approach faces several issues making it of limited utility in existing data. The most important one is a very low power, so that extremely large sample size is required to achieve sufficient discriminatory ability. Here we show first that sample size necessary to identify subtypes can be substantially decreased by cleverly pre-selecting variants with the largest differential effects between subtypes. Consider for example a disease with two sub-types sharing half of their causal variants (the remaining causals being subtype-specific). Our simulations shows that a predictive model using only the subtype-specific variants can achieve high discriminatory ability (e.g. AUC>0.80) in situations where the naive approach using all available genetic variants would have almost no discriminatory power (AUC < 0.55). We further explored various strategies and metrics to pre-select these subtype-specific variants. Our analyses show that they can be partly identified by comparing the observed contingency table of genotypes in cases and controls against the expected one under the assumption of homogeneity of genetic effect (i.e. in the absence of disease subtypes). Thus, our approach has the potential to dramatically reduce the required sample size to achieve detection of subtypes, making application in existing cohorts possible.

**Identifying genetic architecture of facial morphology in Uyghurs.** *H. Chen<sup>1</sup>, Y. Huang<sup>1</sup>, J. Zhang<sup>2</sup>, L. Ma<sup>1</sup>, Q. Liu<sup>1</sup>, Y. Liu<sup>1</sup>, H. Wu<sup>1</sup>, K. Xiang<sup>1</sup>, W. Yuan<sup>1</sup>, C. Shi<sup>1</sup>, H. Shi<sup>3</sup>, B. Su<sup>4</sup>, J. Xie<sup>2</sup>.* 1) Beijing Institute of Genomics, CAS, Beijing, China; 2) Shihezi Medical School, Shihezi, Xinjiang, China; 3) Kunming School of Science and Technology, Kunming, China; 4) Kunming Institute of Zoology, CAS, Kunming, China.

Human facial morphogenesis is generated synthetically by craniofacial, skin and muscle developmental processes. Twin studies found that the heritability of facial features is around 80%. In this study, we conducted a genome-wide association analysis of facial morphological phenotypes measured from 3D facial images of 1,400 Uyghur individuals. Based on seventeen landmarks of facial 3D images, we used four schemes to efficiently characterize the facial morphological variations: traditional inter-landmark distances, geometric measurements of landmarks, principal components of clustered inter-landmark distances, and partial generalized procrustes analysis of landmarks. We identified ten genome-wide significant SNPs of seven genes: DRD1, CNBD1, SBF2, SOX9, ALG10B, EDAR and CASC17. In particular, deficiency of SOX9 can lead to the skeletal malformation syndrome, campomelic dysplasia and cleft palate. In addition, we also found that several pleiotropic SNPs, e.g., rs3827760 in the exonic region of EDAR, are associated with facial and multiple other phenotypes. Our study thus provides insights into the genetic mechanisms of facial morphogenesis.

**2604W**

**New genetic loci associated with permanent tooth eruption.** *F. Geller<sup>1</sup>, J. Fadista<sup>1</sup>, E.A. Nøhr<sup>2</sup>, J. Bybjerg-Grauholm<sup>3</sup>, D.M. Hougaard<sup>3</sup>, S. Kreiborg<sup>4</sup>, B. Feenstra<sup>1</sup>, M. Melbye<sup>1,5,6</sup>.* 1) Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 2) Research Unit of Gynaecology & Obstetrics, Institute of Clinical Research, University of Southern Denmark, Odense; 3) Department for Congenital Disorders, Statens Serum Institut, Copenhagen, Denmark; 4) Institute of Odontology, Section of Pediatric Dentistry and Clinical Genetics, Faculty of Health and Medical Sciences, University of Copenhagen, Denmark; 5) Department of Clinical Medicine, University of Copenhagen, Denmark; 6) Department of Medicine, Stanford University School of Medicine, California, USA.

The timing of permanent tooth eruption is highly heritable and can have orthodontic consequences even later in life. We extended our genome-wide association study of permanent tooth eruption to 14,000 children with dental records between age 6 and 14 years. Age-adjusted standard deviation scores averaged over multiple time points were calculated for both sexes and then analyzed jointly as quantitative trait on dosages of 7.3 million variants imputed from Haplotype Reference Consortium release 1.1 reference panel. We identified 11 new loci at genome-wide significance ( $P < 5 \times 10^{-8}$ ). Two loci (*BMP4*, *RAD51L1*) provided further evidence that there is substantial overlap between genetic variants underlying primary and permanent tooth eruption. Another locus was previously reported for adult height (*PEX2*), also showing an effect on infant length. Further signals were in the vicinity of genes playing a role in growth and development (*VEGFA*, *IRX5*, *FOXF1*). By performing a genome-wide association study on a large group of individuals with extensive childhood dental records, we were able to substantially increase the number of known loci for tooth eruption and these genomic regions harbor several candidate genes for functional follow-up.

The normal menstrual cycle requires a delicate interplay between the hypothalamus, pituitary, and ovary. Therefore, its length is an important indicator of female reproductive health. Menstrual cycle length has been shown to be partially controlled by genetic factors, especially in the follicle stimulating hormone beta-subunit (*FSHB*) locus. GWAS meta-analysis of menstrual cycle length in 44,871 women of European ancestry confirmed the previously observed association with the *FSHB* locus and identified four additional novel signals in, or near, the *GNRH1*, *PGR*, *NR5A2* and *INS-IGF2* genes. These findings align with what is known about the endocrine control of menstrual cycle length, and confirm the role of the hypothalamic-pituitary-gonadal axis in the genetic regulation of menstrual cycle length, but also highlight potential novel local regulatory mechanisms, such as those mediated by *IGF2*.

**Genome-wide meta-analysis identifies novel loci associated with free triiodothyronine and thyroid-stimulating hormone.** A. Matana<sup>1</sup>, M. Popović<sup>1</sup>, V. Torlak<sup>2</sup>, T. Boutin<sup>3</sup>, D. Brdar<sup>2</sup>, I. Gunjača<sup>1</sup>, N. Vidan<sup>1</sup>, D. Kaličanin<sup>1</sup>, I. Kolčić<sup>1</sup>, V. Boraska Perica<sup>1</sup>, A. Punda<sup>2</sup>, O. Polašek<sup>1</sup>, M. Barbalčić<sup>1</sup>, C. Hayward<sup>3</sup>, T. Zemunik<sup>1</sup>. 1) Department of Medical Biology, University of Split, School of Medicine, Šoltanska 2, Split, Croatia; 2) Department of Nuclear Medicine, University Hospital Split, Spinčičeva 1, Split, Croatia; 3) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, United Kingdom; 4) Department of Public Health, University of Split, School of Medicine, Šoltanska 2, Split, Croatia.

**Background:** Thyroid hormones are essential for the normal function of almost all human tissues, and have critical roles in metabolism, differentiation and growth. Although twin and family studies have estimated that up to 65% of serum free triiodothyronine (fT3), free thyroxine (fT4) and thyroid-stimulating hormone (TSH) variation is genetically determined, most of the heritability is yet unexplained. Moreover, no genome-wide significant signals have been identified for an association with fT3 levels so far. **Methods:** We performed a genome-wide meta-analysis in up to 1731 euthyroid individuals originating from three Croatian cohorts: City of Split and the Islands of Korčula and Vis. Euthyroid participants were selected based on detailed thyroid status that includes biochemical measurements of thyroid function (including measurements of fT3, fT4, TSH, TgAb and TPOAb) and anamnestic data. A total of 7 411 206 variants, imputed using the 1000 Genomes reference panel, were analyzed for an association. Genome-wide association study (GWAS) within each data set was carried out under an additive model, controlling for age, gender and relatedness. Meta-analysis was performed using the inverse-variance fixed-effects method. Additionally, we also conducted multiple-trait GWAS to test the association between each variant and the two intermediately correlated traits fT3 and fT4 simultaneously. **Results:** The *EPHB2* gene variant rs67142165 reached genome-wide significance for association with fT3 plasma levels ( $P=9.27 \times 10^{-9}$ ), and its significance was confirmed in the multiple-trait GWAS ( $P=9.72 \times 10^{-9}$ ). We also found a genome-wide significant association for variant rs13037502 upstream of the *PTPN1* gene and TSH serum levels ( $P=1.67 \times 10^{-9}$ ). **Conclusion:** To the best of our knowledge, this is the first GWAS of these traits performed in minutely selected euthyroid subjects. We identified the first genome-wide significant association for fT3 level to date, as well as a novel association with TSH level. Furthermore, we carried out the first reported multiple-trait GWAS of fT3 and fT4, which resulted in the identification of *EPHB2* as a potential pleiotropic gene. These findings are biologically relevant and add new knowledge to the genetics of observed thyroid-related traits.

**2607W**

**Genetic analyses of Fuchs endothelial corneal dystrophy in a Japanese population.** M. Nakano<sup>1</sup>, Y. Tokuda<sup>1</sup>, H. Adachi<sup>1</sup>, Y. Ikeda<sup>2</sup>, M. Ueno<sup>2</sup>, C. Sotozono<sup>2</sup>, S. Kinoshita<sup>3</sup>, K. Tashiro<sup>1</sup>. 1) Department of Genomic Medical Sciences, Kyoto Prefectural University of Medicine, Kyoto, Japan; 2) Department of Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan; 3) Department of Frontier Medical Science and Technology for Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan.

Fuchs endothelial corneal dystrophy (FECD, MIM: 136800) is a degenerative disease that causes progressive endothelial cell loss, resulting in vision loss. In United States, FECD is regarded as a common disease - ~4% of the population over 40 years old suffer from the disease, whereas the prevalence of FECD is rare in Japanese. According to the results of a genome-wide association study (GWAS) and the following genetic study in Caucasian, a single nucleotide variant (rs613872) and the trinucleotide repeat (TNR) variant within the introns of transcription factor 4 (*TCF4*) gene were identified as the significant risk factors of late-onset FECD. However, in a Japanese population, we found that rs613872 was monomorphic and the frequency of FECD patients with expanded TNR was less than the Caucasian patients. Moreover, some novel variants from the genes other than *TCF4* have been identified by recent GWAS in Caucasian. Consequently, these results suggested that it should be important to conduct further genetic analyses using Japanese population to reveal the different epidemiology and/or etiology of FECD arisen from different genetic backgrounds. To this end, we performed an association study using the genotype data of 278,032 autosomal variants obtained by Infinium HumanCoreExome BeadChip (Illumina, Inc) derived from 55 FECD patients and 445 controls. None of the loci, which were previously reported in Caucasian, were confirmed to be significant in our population. In contrast, we identified an interesting locus at 6q15 including a genome-wide significant variant ( $P < 5.0 \times 10^{-8}$ ) from the gene involved in ribosome biogenesis and some suggestive variants ( $P < 1.0 \times 10^{-5}$ ) from an adjacent apoptosis-related gene located on the same LD block. We therefore targeted the 6q15 locus and some other suggestive loci (~500 kb, in total) that seemed to be uniquely associated with Japanese FECD patients by means of HaloPlex HS system (Agilent Biotechnologies, Inc), and generated sufficient amount of sequence data to perform further analyses. We are also trying hard to recruit additional FECD patients to perform replication study in an independent population. Overall, the approach shown here should provide not only the genetic information to reveal the molecular mechanism of FECD pathogenesis in Japanese, but also the foundation to explain the mechanism determining the different epidemiology and/or etiology of different populations.

**2608T****Effects of HLA class II genotypes on a response to HB vaccine in**

**Japanese population.** N. Nishida<sup>1,2</sup>, M. Sugiyama<sup>1</sup>, H. Sawai<sup>2</sup>, J. Ohashi<sup>3</sup>, S. Khor<sup>2</sup>, T. Tsuchiura<sup>1</sup>, K. Tokunaga<sup>2</sup>, M. Mizokami<sup>1</sup>. 1) National Center for Global Health and Medicine, Ichikawa, Japan; 2) Department of Human Genetics, The University of Tokyo, Bunkyo-ku, Japan; 3) Department of Biological Sciences, The University of Tokyo, Bunkyo-ku, Japan.

Approximately 5-10% of individuals, who are vaccinated with a hepatitis B (HB) vaccine designed based on the HBV genotype C, fail to acquire protective levels of antibodies. In our previous study, GWAS and HLA association tests revealed that HLA class II genes and *BTNL2* gene are host genetic factors related with a response to the HB vaccine in the Japanese population. Here, we assessed the effects of HLA class II genotypes on a response to the HB vaccine. HLA association tests were carried out using a total of 1,103 Japanese individuals including 94 low responders (HBsAb  $\leq 10$  mIU/mL), 323 intermediate responders (10 mIU/mL < HBsAb < 100), and 686 high responders (HBsAb  $\geq 100$  mIU/mL). Classical HLA class II alleles were statistically imputed using the genome-wide SNP typing data. HLA association tests showed that odds ratios in a comparison between low-responders and high-responders were higher than ones in a comparison between low-responders and intermediate- plus high-responders. These results implied that there may exist ambiguous individual(s) who need to be re-categorized into low or high responders among intermediate responders. We next compared genotype frequencies of HLA class II alleles and haplotypes between low responders and high responders. Odds ratios for low response to the HB vaccine were higher for those with both HLA-*DRB1* susceptibility alleles (*DRB1\*04\*05* and *DRB1\*14:06*) than for those with only one susceptibility allele; therefore, effects of susceptibility alleles were additive for risk of low response to the HB vaccine. Notably, compound-heterozygote of susceptibility alleles (*DRB1\*04\*05*, *DRB1\*14:06*, and *DQB1\*04:01*) and protective alleles (*DRB1\*08\*03*, *DRB1\*15:01*, *DQB1\*05:01*, and *DQB1\*06:02*) was significantly associated with protection against low response to the HB vaccine, which indicated that one protective HLA-*DRB1* or *DQB1* molecule can provide dominant protection. Identification of the HLA-*DRB1*, *DQB1* genotypes associated with susceptibility to and protection from low response to the HB vaccine is essential for future analysis of the mechanisms responsible for immune recognition of hepatitis B surface antigens by HLA-*DRB1*, *DQB1* molecules.

**2609F****A whole-genome study identifies genetic risk factors for systemic hypertension in high altitude Indian population.**

K. Sharma<sup>1,2</sup>, S. Kohli<sup>1</sup>, M.A. Syed<sup>2</sup>, G. Mohammad<sup>2</sup>, T. Thinlas<sup>3</sup>, M.A.Q. Pasha<sup>1,4</sup>. 1) CSIR-Institute of Genomics and Integrative Biology, Delhi, India; 2) Department of Biotechnology, Jamia Millia Islamia, New Delhi; 3) Department of Medicine, Sonam Norboo Memorial Hospital, Leh, Ladakh, Jammu and Kashmir, India; 4) Indian Council of Medical Research, New Delhi, India.

Systemic hypertension (SH) is a multifactorial disease that tends to increase at high altitude (HA). A genetic predisposition has been suggested for SH; however, the pathogenesis remains largely unknown. In the present study, we used a single nucleotide polymorphism (SNP) chip representing over 2.5 million SNPs to analyze DNA from hypertensive highlanders (HHLs) and normotensive highlanders (NHLs). To the best of our knowledge, this is the most comprehensive genome-wide association study of a HA cohort conducted to date in relation to SH. Here, 1600 SNPs spanning across 162 genes were identified as candidates for association with SH (adjusted  $P$   $2 \times 10^{-3}$  -  $5.19 \times 10^{-6}$ ). Whereas the majority of these SNPs are represented in non-coding regions of the genome, thirty-six SNPs were identified in the coding region of their respective genes. Among these, nine SNPs resulted in missense substitutions (MS). Further, the top MS of dynein axonemal heavy polypeptide 11 (*DNAH11*) gene (rs2214326,  $P \leq 0.0005$ ; missense\_Ala3467Thr) was found to be significant (odds ratio (OR) = 1.5,  $P \leq 0.005$ ) when screened in a larger sample size. Integrated analysis of 162 genes indicates 47 biological pathways including novel pathways in relation to SH. Also, decreased level of nitric oxide and apelin were found to be significantly associated with SH ( $P \leq 0.05$ ). Further, copy number variation (CNV) analyses of genome-wide data revealed that the number of autosomal CNVs was significantly higher in HHLs as compared to NHLs ( $P \leq 0.005$ ). Interestingly, deletion variations in HHLs were found to be significantly more when compared with NHLs. Also, the average size of deletion variation in kb was found to be 1.64-fold more in HHLs as compared to NHLs. Our findings are encouraging albeit, further validation of these variants may help identify contributing factors to the pathophysiology of SH, as well as categorize potential targets for medical intervention strategies.

**Novel susceptibility loci for tanning ability in a Japanese population identified by genome-wide association study from ToMMo cohort study.** K. Shido<sup>1,2</sup>, K. Kojima<sup>2,4,5</sup>, K. Yamasaki<sup>1</sup>, A. Hozawa<sup>2,4</sup>, G. Tamiya<sup>2,4</sup>, S. Ogishima<sup>2,4</sup>, N. Minegishi<sup>2,4</sup>, Y. Kawai<sup>6</sup>, K. Tanno<sup>3</sup>, Y. Suzuki<sup>2,4</sup>, S. Aiba<sup>1</sup>, M. Nagasaki<sup>2,4,5</sup>. 1) Department of Dermatology, Tohoku University Graduate School of Medicine, Sendai, Miyagi, Japan; 2) Tohoku Medical Megabank Organization, Tohoku University; 3) Iwate Tohoku Medical Megabank Organization, Iwate Medical University; 4) Graduate School of Medicine, Tohoku University; 5) Graduate School of Information Sciences, Tohoku University; 6) Department of Human Genetics, Graduate School of Medicine, Tokyo University.

Skin types of the Japanese population are classified into Fitzpatrick skin Type III and IV, which are the most abundant skin types in worldwide. Since the information about genes affecting Fitzpatrick skin Type III and IV is limited, we performed the genome-wide association studies (GWAS) for skin types on 9,187 Japanese individuals, using the dataset from the prospective cohort study by the Tohoku Medical Megabank Organization (ToMMo). Skin type information was obtained from the cohort study questionnaires and classified into the Japanese skin type J-I to J-III, which correspond to Fitzpatrick skin Type III and IV. We identified two SNPs reaching genome-wide significance level of  $5 \times 10^{-8}$ : chr15:28228553 C>T (rs74653330) at 15q12-13 (Oculocutaneous albinism II, OCA2) and chr9:16795790 C>A (rs16935073) at 9p22.3-22.2 (Basonuclin 2, BNC2) in the discovery set of 4,475 populations in Miyagi prefecture as well as in the replication set of 4,712 populations in Iwate prefecture. We additionally found the following six loci in the combined analysis of Miyagi and Iwate population: SLC6A17 rs6689641, RAB32 rs78620166, KITLG rs11104947, MC1R rs33932559, DBNDD1 rs138160245, and MSFD1 rs2240751. The GWAS from the ToMMo cohort study revealed novel susceptible loci of tanning ability in the Japanese population by classifying Fitzpatrick skin Type III and IV into the Japanese skin type J-I to J-III.

**Genetic basis of falling risk susceptibility.** K. Trajanoska<sup>1,2</sup>, F. Day<sup>1,3</sup>, C. Medina-Gomez<sup>1</sup>, A. Uitterlinden<sup>1</sup>, J. Perry<sup>1,3</sup>, F. Rivadeneira<sup>1,2</sup>. 1) Department of Internal Medicine, Erasmus Medical Center, Rotterdam, The Netherlands; 2) Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 3) MRC Epidemiology Unit, University of Cambridge School of Clinical Medicine, Cambridge, UK.

**Background:** Falls and fall-related injuries are growing healthcare problem in elderly people. Approximately one out of three older adults will experience at least one fall. Multiple factors can increase the risk of falling. We aimed to determine how much of an individual's fall susceptibility can be attributed to genetics. **Methods:** We conducted the first genome-wide association study (GWAS) to evaluate the genetic variation in fall risk in 89,076 cases and 362,103 controls from the UKBiobank. Individuals were genotyped with the Affymetrix UKBiobank chip. Model included age and sex analysed with BOLT-LMM v.2.3.1. Next, we tested the predictive value of polygenic risk scores (PRS) across diverse significance thresholds in relation to falls using individual level data from the Rotterdam Study. Finally, we used LD score regression to: 1). estimate falling risk heritability 2). test for genetic correlation with other traits and 3). identify tissues where expression of genes related to fall-associated variants are enriched. **Results:** We identified two novel fall loci mapping near *PER4* on 7p21.3 (rs2709062, OR=1.03, P=3.4x10<sup>-06</sup>) and near *TSHZ3* on 19q12 (rs2111530, OR=1.03, p=1.2x10<sup>-06</sup>). Falling risk heritability was modest (2.5%). PRS (10<sup>-02</sup> to 10<sup>-03</sup> thresholds) were significant explaining small proportion of the trait variance. Falls had strong positive genetic correlation with fracture risk (rg=0.35, se=0.05), insomnia (rg=0.42, se=0.05), neuroticism (rg=0.26, se=0.08) and ADHD (rg=0.44, se=0.14); and strong negative genetic correlation with muscle strength (rg=-0.24, se=0.04), intelligence (rg=-0.12, se=0.04) and social well-being (rg=-0.29, se=0.05). Brain and in particular cerebellum tissue showed the highest gene expression enrichment (FDR<5%) for fall-associated variants. **Conclusions:** Falling risk constitutes a heritable, heterogeneous and polygenic trait. Strong evidence link it to fracture risk and grip strength. Genes expressed in the cerebellum are enriched for falls-associated variants, indicating genetic interplay between postural balance and falls.

**A genome-wide association study identifies uric acid-related genetic variants in the Taiwanese population.** J. Wei<sup>1</sup>, W. Chen<sup>1,2</sup>, Y. Liu<sup>3</sup>, S. Tsa<sup>4,5</sup>, P. Kuo<sup>6</sup>. 1) Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 2) Department of Psychiatry, Taipei City Psychiatric Center, Taipei City Hospital, Taipei; 3) Center for Neuropsychiatric Research, National Health Research Institutes, Miaoli County, Taiwan; 4) Department of Psychiatry, Taipei Veterans General Hospital, Taipei, Taiwan; 5) Division of Psychiatry, National Yang-Ming University, Taipei, Taiwan; 6) Research Center for Genes, Environment and Human Health, National Taiwan University, Taipei, Taiwan, Taiwan.

Uric acid (UA), which has been found to be associated with many physical conditions, is one of the important biomarkers for the health of humans' body as small changes in UA levels can make a substantial impact. Previously, several genetic loci were reported to be associated with serum UA levels in different ethnic groups. We conducted a genome-wide association study (GWAS) to identify UA-related genetic variants in the Taiwanese general population with 10,295 subjects from Taiwan Biobank. All subjects were genotyped using Affymetrix TWB array with 646,735 markers, and serum UA levels were examined. Standard procedures of quality controls for GWAS data were performed, and 10,095 individuals remained in data analysis. Our results demonstrated that 88 loci were associated with UA levels while adjusted for sex and age. Marker rs3775948 (beta= -0.2556, p-value= 6.582E-47) and rs2231142 (beta= 0.2623, p-value= 2.391E-43) showed the most significant association with UA levels, which were located on the *SLA2A9* (solute carrier family 2, member 9) and *ABCG2* (ATP Binding Cassette Subfamily G Member 2) gene regions, respectively. These two variants were independently associated with UA concentration in conditional analyses. These two genes were also implicated in influencing UA levels in previous association studies. Replication studies will be performed in an additional sample, and the effects of these genetic variants on other UA related phenotypes are under investigation.

**Integrative analysis of omics summary data reveals putative mechanisms underlying complex traits.** Y. Wu<sup>1</sup>, J. Zeng<sup>1</sup>, F. Zhang<sup>1</sup>, Z. Zhu<sup>1</sup>, T. Qi<sup>1</sup>, Z. Zheng<sup>2,1</sup>, L. Lloyd-Jones<sup>1</sup>, R. Marioni<sup>4,5</sup>, N. Martin<sup>6</sup>, G. Montgomery<sup>1</sup>, I. Deary<sup>3</sup>, N. Wray<sup>1,2</sup>, P. Visscher<sup>1,2</sup>, A. McRae<sup>1</sup>, J. Yang<sup>1,2</sup>. 1) Institute for Molecular Bioscience, The University of Queensland, Brisbane, Queensland 4072, Australia; 2) Queensland Brain Institute, The University of Queensland, Brisbane, Queensland 4072, Australia; 3) The Eye Hospital, School of Ophthalmology & Optometry, Wenzhou Medical University, Wenzhou, Zhejiang 325027, China; 4) Medical Genetics Section, Centre for Genomics and Experimental Medicine, Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, EH4 2XU, UK; 5) Centre for Cognitive Ageing and Cognitive Epidemiology, Department of Psychology, University of Edinburgh, 7 George Square, Edinburgh, EH8 9JZ, UK; 6) Genetics and Computational Biology, QIMR Berghofer Medical Research Institute, Brisbane, Queensland 4029, Australia.

The identification of genes and regulatory elements underlying the associations discovered by GWAS is essential to understanding the aetiology of complex traits (including diseases). Here, we demonstrate an analytical paradigm of prioritizing genes and regulatory elements at GWAS loci for follow-up functional studies. We perform an integrative analysis that uses summary-level SNP data from multi-omics studies to detect DNA methylation (DNAm) sites associated with gene expression and phenotype through shared genetic effects (i.e., pleiotropy). We identify pleiotropic associations between 7,858 DNAm sites and 2,733 genes. These DNAm sites are enriched in enhancers and promoters, and >40% of them are mapped to distal genes. Further pleiotropic association analyses, which link both the methylome and transcriptome to 12 complex traits, identify 149 DNAm sites and 66 genes, indicating a plausible mechanism whereby the effect of a genetic variant on phenotype is mediated by genetic regulation of transcription through DNAm.

**2614T**

**Replicated association of *CYP4F2* variant with change in plasma vitamin E level after supplementation.** J. Xu<sup>1</sup>, N.C. Gaddis<sup>2</sup>, R.S. Parker<sup>3</sup>, A.G. Clark<sup>4</sup>, P.J. Goodman<sup>5</sup>, S.M. Lippman<sup>5,6</sup>, D.B. Hancock<sup>7</sup>, P.A. Cassano<sup>1</sup>. 1) Division of Nutritional Sciences, Cornell University, Ithaca, NY; 2) Research Computing Division, RTI International, Research Triangle Park, NC; 3) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY; 4) SWOG Statistical Center, Fred Hutchinson Cancer Research Center, Seattle, WA; 5) Moores Cancer Center, University of California, San Diego, CA; 6) Department of Medicine, Division of Hematology-Oncology, University of California, San Diego, CA; 7) Behavioral and Urban Health Program, Behavioral Health and Criminal Justice Division, RTI International, Research Triangle Park, NC.

Randomized controlled trials (RCTs) have investigated whether supplementation of vitamin E (vitE), a nutrient with antioxidant properties, can reduce age-related inflammatory disease risks. Evidence from RCTs, however, is inconsistent, which could be due to variation in bioavailability of vitE supplementation among different subgroups of individuals. The only prior genome-wide association study of plasma  $\alpha$ -tocopherol response (denoted as  $\alpha$ -TOH, the main vitE form in plasma) to vitE supplementation ( $n=2,112$  male smokers from Finland) reported two statistically significant single nucleotide polymorphisms (SNPs) (Major et al. J Nutr 2012). We tested these SNPs for independent replication using the vitE-only arm of the Respiratory Ancillary Study (NCT00063453) to the Selenium and Vitamin E Cancer Prevention Trial (SELECT, S0000 and NCT00006392) in men aged 50+ ( $n=424$  European Americans [EAs],  $n=139$  African Americans [AAs]) with >3 years of supplementation with 400 IU/day  $\alpha$ -TOH. Plasma  $\alpha$ -TOH was measured at baseline and at year 3, and we tested SNP associations with change in plasma  $\alpha$ -TOH level from baseline to year 3. One SNP met the replication threshold ( $P<0.025$ , accounting for multiple testing): the *CYP4F2* missense SNP rs2108622. *CYP4F2* is a biologically plausible gene for vitE metabolism, given its function as a tocopherol- $\omega$ -hydroxylase, which initiates the oxidative catabolism of tocopherols. We found that the rs2108622-T minor allele (frequency=29% in EAs and 8% in AAs) was associated with a greater increase in plasma  $\alpha$ -TOH after supplementation (i.e., greater response) with similar magnitudes of effect across ancestries ( $\beta=0.15$ , SE=0.08, and  $P=0.04$  in EAs;  $\beta=0.26$ , SE=0.18, and  $P=0.15$  in AAs; and meta-analysis  $P=0.01$ ). The effect direction was consistent with the previous GWAS, where rs2108622-T was associated with a higher plasma  $\alpha$ -TOH level after supplementation. Follow-up analysis showed that rs2108622 is a potential expression quantitative trait locus for *CYP4F2* in whole blood tissue: its T allele was associated with lower *CYP4F2* expression ( $P=1.7\times 10^{-12}$ ,  $n=369$ ) in the Genotype-Tissue Expression Project. In summary, this independent replication finding adds to the evidence that rs2108622 is associated with plasma response to vitE supplementation and supports the hypothesis that genetic variation influences bioavailability of vitE supplementation across populations. Funding: R01HL071022, R21HL125574, HHSN268201100037C, U10 CA37429, 5UM1CA182883.

**Identifying novel genetic defects for radiation hypersensitive phenotypes through Next-Gen sequencing.** M. Gupta<sup>1</sup>, X. Liu<sup>2</sup>, S. Teraoka<sup>2</sup>, P. Concanon<sup>2</sup>, A. Quinlan<sup>1</sup>. 1) Department of Human Genetics, University of Utah, Salt Lake City, UT, USA; 2) Genetics Institute and Department of Pathology, Immunology and Laboratory Medicine, University of Florida, Gainesville, FL, USA.

Although ionizing radiation (IR) is an effective therapeutic agent for cancer treatment, it is also a potent carcinogen. Sensitivity to the cell-killing effects of IR vary across human population with a subset of individuals displaying extreme hypersensitivity, usually attributable to inherited defects in DNA damage response pathways. The present study aims to identify causative genetic defects in IR hypersensitive individuals that share clinical features with known Mendelian DNA damage response disorders Ataxia-telangiectasia and Nijmegen breakage syndrome but lack mutations in the causative genes *ATM* and *NBN*. This approach can shed light on novel proteins/pathways involved in DNA damage responses to radiation, and previous studies from our group have been successful in identifying and validating the role of new genes such as *MTPAP* and *ATIC* in radiation sensitivity (RS). Here, we performed whole genome and exome sequencing in a cohort of 84 radiation sensitive individuals to identify rare or novel loss of function (LoF) SNVs and INDELS, as well as copy number variants (CNVs). SNVs and INDELS were annotated with functional consequence predictions using GEMINI and prioritized under the assumption of a recessive model. We identified three novel frameshift, potential LoF variants in three genes (*LIMCH1*, *CTRB1* and *SLC2A5*) not known to be involved in RS or DNA damage pathways. In addition, we have also adopted an epistatic model to identify rare/novel heterozygous mutations in gene-pairs which might disrupt essential protein-protein interactions (PPIs) among RS genes. This approach led to identification of potentially deleterious novel and rare mutations in *ATM-ATR*, *TP53-TP53BP1* and *BRCA2-BARD1* gene pairs. Apart from SNVs, we have also detected large homozygous and heterozygous deletions and duplications across multiple genes in 5 individuals. We will report progress on the validation of these putative radiation sensitivity genes, through a two step process. Initially the genes are knocked down using shRNA in a cell line of normal radiosensitivity followed by testing for increased susceptibility to death by ionizing radiation. Genes passing this screen are then further tested by knockdown followed by colony survival assays. In conclusion, our robust methodology to detect and validate RS gene candidates can provide new insights into the mechanisms underlying radiation hypersensitivity.

**Gene expression analyses in thrombotic storm indicate dysregulation of coagulation and extracellular matrix pathways.** K. Nuytemans<sup>1</sup>, A.J. Griswold<sup>1</sup>, L. Gomez<sup>1</sup>, N. Hofmann<sup>1</sup>, P. Whitehead-Gay<sup>1</sup>, C.S. Kitchens<sup>2</sup>, D. Erkan<sup>3</sup>, L.R. Brandao<sup>4</sup>, A.H. James<sup>5</sup>, R. Kulkarni<sup>6</sup>, T.L. Ortel<sup>5</sup>, M.A. Pericak-Vance<sup>1</sup>, J.M. Vance<sup>1</sup>. 1) University of Miami, John P. Hussman Institute for Human Genomics, Miami, FL; 2) University of Florida, Gainesville, FL; 3) Hospital for Special Surgery, Weill Medical College of Cornell University, New York, NY; 4) Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 5) Duke University Medical Center, Durham, NC; 6) Michigan State University, East Lansing, MI.

Thrombotic storm (TS; www.thromboticstorm.com) is a rare and severe clinical phenotype that occurs in a small subset of patients with venous thromboembolic disease. It is characterized by more than two acute arterial and/or venous thromboemboli, frequent events in unusual locations, progressive/recent unexplained recurrence and frequent refractory and/or atypical response to therapy. As gene expression during thrombotic events compared to baseline presentation will help elucidate the underlying pathophysiology of active disease, our goal was to identify transcriptomic changes in blood in four TS patients during and after thrombotic storm event. All patients presented with both venous and arterial thrombi at time of event and two out of four patients had a history for antiphospholipid antibodies. Average age at thrombotic event was 25.7y (21-32). We performed gene expression analysis of all coding genes during and after the event, using a paired analyses model to correct for baseline expression differences across patients. A total of 71 genes (56 up-regulated, 15 down-regulated) were differentially expressed at FDR<0.05 (fold change range -2.5 – 6.0). Of the known thrombotic factors, we observed an upregulation of anticoagulation factor Protein S (*PROS1*), indicating a clear attempt of the endothelial cells to control the clotting. Other genes of interest include *ADAMTS1* and 2 and *ITGA2B* and *B3*; all elements involved in extracellular matrix/glycocalyx formation. Pathway analyses confirm and implicate coagulation cascades, extracellular matrix organization and actin cytoskeleton (upregulation), as well as O-glycosylation of proteins and negative regulation of cell proliferation (downregulation). These results support a dysfunction of coagulation pathways and indicate dysregulation of genes involved in extracellular matrix/glycocalyx stability and O-glycosylation at the time of thrombotic storm events. Interestingly, these data support our recent report on rare, high risk variants in genes involved in chondroitin sulfate, an O-glycosylation chain on proteins of the glycocalyx protecting the endothelium in TS patients. Studies as these are critical for our understanding of underlying mechanisms in TS and thrombosis in general; and might inform on therapeutic biomarkers for thrombotic disease.

**Inflammation derived molecular pathogenesis of keratoconus: An insight into disease onset.** M. Azam<sup>1</sup>, R. Qamar<sup>1,2</sup>, A. Ahmed<sup>1</sup>, S. Tahir<sup>1</sup>, M.K. Niaz<sup>3,4</sup>. 1) Translational Genomics Laboratory, Department of Biosciences, COMSATS University Islamabad; 2) Pakistan Academy of Sciences, Islamabad, Pakistan; 3) Armed Forces Institute of Ophthalmology, Rawalpindi, Pakistan; 4) Army Medical College, Rawalpindi, Pakistan.

Keratoconus (KC) is a corneal disorder in which cornea becomes thin and bulges outward in a cone-shape, resulting in myopia, irregular astigmatism substantially leading to visual impairment. It is a common corneal anomaly that is estimated to be 229 per 100,000 individuals in the population of the Sub-continent. KC is a multifactorial disease; both genetic and environmental factors contribute in its development. To date KC pathogenesis is undefined; however, the involvement of inflammatory pathways in disease development is noticeable. In our previous study, the role of endogenous factors; promoter region polymorphism rs1800629 (-308G>A) in the inflammatory pathway component *TNF-α*, tumor necrosis factor receptor 2 (*TNFR2*), v-rel avian reticuloendotheliosis viral oncogene homolog A (*RELA*) and interleukin 6 (*IL-6*) exhibited significant upregulation in the keratoconic tissues suggesting a strong correlation of *TNF-α*-induced higher expression of inflammatory pathway molecules in KC manifestation, thus implicating KC as an inflammatory condition. Therefore, in the present study, the role of other endogenous factors involved in inflammatory pathway whose deregulated expression could lead to KC development; interleukin 1β (*IL-1β*), hypoxia-Inducible Factor 1 (*HIF-1α*), matrix metalloproteinase 16 (*MMP16*) and eleven collagen genes (*COL1A1*, *COL1A2*, *COL4A4*, *COL6A1*, *COL6A2*, *COL8A1*, *COL11A1*, *COL11A2*, *COL12A1*, *COL16A1* and *COL28A1*), were investigated through expression profile studies in keratoconus corneal tissues (cases) and deceased donor corneal tissues (controls). Real-time quantitative PCR was performed and Mann-Whitney U test was applied for statistical analysis. Significant difference in expression of *IL-1β* (p=0.028), *HIF-1α* (p=0.028), *COL4A4* (p=0.029), *COL16A1* (p=0.029) and *COL28A1* (p=0.028) was observed between keratoconus and control corneal tissues. The current study is among one of the few studies suggesting a possible role of *IL-1β*, *HIF-1α*, *COL4A4*, *COL16A1* and *COL28A1* along with other inflammatory components involved in KC development. To the best of our knowledge, this is the first study regarding molecular pathogenesis of KC patients in Pakistan. This study primarily highlights the interrelated and intra-related association of multiple components of inflammatory pathway in the development of disease where their deregulation may imply towards keratoconus onset.

**Identifying gene targets for brain-related traits using transcriptomic and methylomic data from blood.** T. Qi<sup>1</sup>, Y. Wu<sup>1</sup>, J. Zeng<sup>1</sup>, F. Zhang<sup>1,2</sup>, A. Xue<sup>1</sup>, L. Jiang<sup>1</sup>, Z. Zhu<sup>1</sup>, K. Kemper<sup>1</sup>, L. Yengo<sup>1</sup>, Z. Zheng<sup>1,3</sup>, R. Marion<sup>1,4</sup>, G. Montgomery<sup>1</sup>, I. Deary<sup>5</sup>, N. Wray<sup>1,2</sup>, P. Visscher<sup>1,2</sup>, A. McRae<sup>1</sup>, J. Yang<sup>1,2,3</sup>. 1) Institute for Molecular Bioscience, The University of Queensland, Brisbane, Queensland 4072, Australia; 2) Queensland Brain Institute, The University of Queensland, Brisbane, Queensland 4072, Australia; 3) The Eye Hospital, School of Ophthalmology & Optometry, Wenzhou Medical University, Wenzhou, Zhejiang 325027, China; 4) Medical Genetics Section, Centre for Genomic and Experimental Medicine, Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, EH4 2XU, UK; 5) Centre for Cognitive Ageing and Cognitive Epidemiology, Department of Psychology, University of Edinburgh, 7 George Square, Edinburgh, EH8 9JZ, UK.

Understanding the difference in genetic regulation of gene expression between brain and blood is important for discovering genes for brain-related traits and disorders. Here, we estimate the correlation of genetic effects at the top associated *cis*-expression or –DNA methylation (DNAm) quantitative trait loci (*cis*-eQTLs or *cis*-mQTLs) between brain and blood ( $r_s$ ). Using publicly available data, we find that genetic effects at the top *cis*-eQTLs or mQTLs are highly correlated between independent brain and blood samples ( $r_s = 0.70$  for *cis*-eQTLs and  $r_s = 0.78$  for *cis*-mQTLs). Using meta-analyzed brain *cis*-eQTL/mQTL data ( $n = 526$  to  $1,194$ ), we identify 61 genes and 167 DNAm sites associated with 4 brain-related phenotypes, most of which are a subset of the discoveries (97 genes and 295 DNAm sites) using data from blood with larger sample sizes ( $n = 1,980$  to  $14,115$ ). Our results demonstrate the gain of power in gene discovery for brain-related phenotypes using blood *cis*-eQTL/mQTL data with large sample sizes.

**MR-pheWAS with stratification and interaction: Searching for the causal effects of smoking heaviness.** L.A.C. Millard<sup>1,2,3</sup>, M.R. Munafò<sup>1,4</sup>, K. Tilling<sup>1,2</sup>, G. Davey Smith<sup>1,2</sup>. 1) MRC Integrative Epidemiology Unit (IEU), Bristol Medical School, University of Bristol, Bristol, United Kingdom; 2) Population Health Sciences, Bristol Medical School, University of Bristol; 3) 3 Intelligent Systems Laboratory, Department of Computer Science, University of Bristol, Bristol, UK; 4) UK Centre for Tobacco and Alcohol Studies, School of Experimental Psychology, University of Bristol, Bristol, UK.

**Background** Mendelian randomization (MR) is an established instrumental variable approach for estimating the causal effect of an environmental exposure on a downstream outcome. The gene x environment (GxE) study design can be used within an MR framework to determine the extent to which a MR estimate of a causal effect may be biased if the genetic instrument affects the outcome through pathways other than via the exposure of interest (known as horizontal pleiotropy). MR phenome-wide association studies (MR-pheWAS) search for the causal effects of an exposure, and a recently published tool (PHESANT) means that it is now possible to do this comprehensively, across thousands of traits, in UK Biobank. In this study, we introduce the GxE MR-pheWAS approach, and search for the causal effects of smoking heaviness – stratifying on smoking status (ever versus never) – as an exemplar. If a genetic variant is associated with smoking heaviness (but not smoking initiation), and this variant affects an outcome (at least in part) via tobacco intake, we would expect the effect of the variant on the outcome to differ in ever versus never smokers. In the absence of horizontal pleiotropy (i.e. if this effect is entirely mediated by tobacco intake), we would expect to see an effect in ever smokers but no effect in never smokers. **Methods and findings** We used PHESANT to search for the causal effects of smoking heaviness, instrumented by the genetic variant rs16969968, among never and ever smokers respectively, in UK Biobank. We ranked results by: 1) the strength of effect of rs16969968 among ever smokers, and 2) the strength of interaction between ever and never smokers, accounting for the number of tests performed. We identified both established and novel causal effects of smoking heaviness, where associations of rs16969968 with a given outcome differed among ever versus never smokers, indicating an effect of the genetic variant on the outcome via tobacco intake. We replicated previously established causal effects of smoking heaviness, including a detrimental effect on lung function and pulse rate. Novel results included an effect of smoking heaviness on several brain phenotypes. **Conclusions** We have demonstrated a novel GxE MR-pheWAS approach to identify causal effects, while simultaneously assessing the extent to which estimated effects may be biased by horizontal pleiotropy. Our proof-of-principle analyses identified both known and novel causal effects of smoking heaviness.

**Introduction.** The gut microbiota is an important determinant of human health. It contains a large number of bacterial species with tremendous compositional variation across individuals. This diversity is influenced by multiple environmental factors but also by host genetic variation, as shown by heritability analysis. In the framework of the *Milieu Intérieur* Consortium, a population-based study aimed at dissecting the different sources of immune response variance within a healthy population, the commensal intestinal microbiota of 1000 healthy individuals was assessed by 16S rRNA sequencing. We conducted genome-wide association studies (GWAS) to detect associations between human genetic variants and gut microbiota diversity. **Methods.** A total of 1000 healthy individuals of west European ancestry, with a 1:1 sex ratio, and stratified across five-decades of life (age 20 – 69), were recruited in France and genotyped using the Illumina OmniExpress and HumanExome arrays. 16S rRNA profiles were obtained from stool samples of 862 individuals. We used linear regression to search for associations between >5 million SNPs and multiple indicators of variation in the gut microbiota, including  $\alpha$ - (Simpson's index) and  $\beta$ - (weighted UniFrac distances) diversity, as well as quantitative measurements of operational taxonomic units (OTUs). Furthermore, we used sequence kernel association test to investigate the potential associations of rare variants. The first two principal components of the genotyping data, age and sex were used as covariates in all tests. **Results and discussion.** No genome-wide significant associations were identified after Bonferroni correction for the number of phenotypes tested in the single-marker or in the burden (rare variant) analyses. We did not replicate previously reported associations between  $\beta$ -diversity and host genetics. Our study suggests that host genetic variation is likely to play a minor role in shaping the global diversity and the taxonomic composition of the gut microbiome in healthy populations. Because the putative effect of any associated gene variant will be small, our results also emphasize the need for adequate statistical power and large sample sizes in future assessments.

## 2621F

**Aberrant expressions of miRNA-206 target, FN1, in multifactorial Hirschsprung disease.** N.Y.P. Budi<sup>1</sup>, A.S. Kalim<sup>1</sup>, W. Santiko<sup>1</sup>, F.D. Musthofa<sup>1</sup>, K. Iskandar<sup>2</sup>, A. Makhmudi<sup>1</sup>, G. Gunadi<sup>1</sup>. 1) Pediatric Surgery Division, Departement of Surgery, Faculty of Medicine, Public Health and Nursing, UGM, Yogyakarta, Indonesia, Yogyakarta, Special Distric of Yogyakarta, Indonesia; 2) 6Department of Child Health, Faculty of Medicine, Public Health and Nursing, Universitas Gadjah Mada/UGM Academic Hospital, Yogyakarta 55291, Indonesia.

**Background:** MicroRNAs (miRNAs) have been associated with the Hirschsprung disease (HSCR) pathogenesis, however, the findings are still inconclusive. We aimed to investigate the effect of miRNA-206 and its targets, *fibronectin 1 (FN1)*, *serum deprivation response (SDPR)*, and *paired box 3 (PAX3)* expressions on multifactorial HSCR in Indonesia, a genetically distinct group within Asia. **Methods:** We determined the miRNA-206, FN1, SDPR and PAX3 expressions in both the ganglionic and aganglionic colon of HSCR patients and control colon by quantitative real-time polymerase chain reaction (RT-PCR). **Results:** Twenty-one sporadic HSCR patients and thirteen controls were ascertained in this study. The miRNA-206 expression was up-regulated (2-fold) in the ganglionic colon and down-regulated (1.5-fold) in the aganglionic colon compared to the control group ( $12.4 \pm 3.0$  vs.  $14.1 \pm 3.9$  vs.  $13.1 \pm 2.7$ ), but these differences did not reach significant levels ( $p=0.48$  and  $p=0.46$ , respectively). Interestingly, the FN1 expression was significantly increased in both the ganglionic (38-fold) and aganglionic colon (18-fold) groups compared to the control group ( $5.7 \pm 3.0$  vs.  $6.8 \pm 2.3$  vs.  $11.0 \pm 5.0$ ;  $p=0.001$  and  $p=0.038$ , respectively). Furthermore, the expressions of SDPR were similar in the ganglionic, aganglionic and control colon groups ( $2.4 \pm 0.6$  vs.  $2.2 \pm 0.4$  vs.  $2.1 \pm 0.6$ ;  $p=0.16$  and  $p=0.39$ , respectively), while no change was observed in the PAX3 expression between the ganglionic, aganglionic, and control colon groups ( $3.8 \pm 0.8$  vs.  $4.1 \pm 0.8$  vs.  $3.7 \pm 1.1$ ;  $p=0.83$  and  $p=0.44$ , respectively). **Conclusion:** Our study is the first report of aberrant FN1 expressions in the colon of patients with HSCR. These abnormal FN1 expressions might contribute to the pathogenesis of HSCR.

**2622W**

**Potential role of *STAT4* genetic variation in treatment decision-making for hepatitis B e antigen-positive chronic hepatitis B.** *H. Chen, J. Sun, B. Zhou, X.E. Liang, R. Fan, J.L. Hou, D.K. Jiang.* Infectious Diseases and Hepatology Unit, Nanfang Hospital, Southern Medical University, Guangzhou, China.

*Aim* Currently, peginterferon alfa (PegIFN $\alpha$ ) and nucleos(t)ide analogues (NUCs) are the two main first-line therapies for chronic hepatitis B (CHB). Unfortunately, both of them produce response in only minority of CHB patients. Previous study showed that a genetic variant in *STAT4* (rs7574865) is a reliable predictor of response to PegIFN $\alpha$  therapy for hepatitis B e antigen (HBeAg)-positive CHB patients (Jiang DK et al., *Hepatology* 2016). Our aim was to further evaluate the performance of rs7574865 in PegIFN $\alpha$  treatment as well as NUCs treatment for HBeAg-positive CHB patients. *Methods* A total of 1,860 HBeAg-positive CHB patients, including 254 patients (PegIFN $\alpha$  Cohort 1) and 708 patients (PegIFN $\alpha$  Cohort 2) treated with PegIFN $\alpha$ , 334 patients (NUCs cohort 1) and 564 patients (NUCs cohort 2) treated with NUCs, were enrolled. Treatment efficacy was assessed using sustained virologic response (SVR), which was defined as HBeAg seroconversion along with HBV DNA level <2000 IU/mL at week 72 for PegIFN $\alpha$  cohorts or at week 104 for NUCs cohorts. Early responders were defined as hepatitis B s antigen (HBsAg) < 1500 IU/mL and HBV DNA < 10<sup>5</sup> copies/mL at week 24. Genotyping of rs7574865 was performed by Sequenom MassArray platform. Cochran-Armitage trend test and logistic regression analysis were used to evaluate the association of rs7574865 with SVR. *Results* The association of rs7574865 with SVR was significant or marginally significant in PegIFN $\alpha$  cohorts (P-trend = 0.01, 0.07 and 0.004 in PegIFN $\alpha$  cohort 1, 2 and their combination, respectively), but not significant in NUCs cohorts (P-trend = 0.88, 0.59 and 0.81 in NUCs cohort 1, 2 and their combination, respectively). When stratified the patients in combined PegIFN $\alpha$  cohort according to HBV genotype, the SVR rates in HBV genotype B patients with rs7574865 GG, GT and TT genotype were 46%, 30% and 21%, respectively (P-trend = 0.002); while in HBV genotype C patients were 17%, 19% and 19%, respectively (P-trend = 0.66). For HBV genotype B patients, we further evaluated the performance of rs7574865 in early responders and non-early responders. We found that, in PegIFN $\alpha$  cohort 1, 2 and their combination, the SVR rates in early responders with rs7574865 TT genotype were as high as 100%, 67% and 72%, while in non-early responders with GG genotype were only 19%, 15% and 15%, respectively. *Conclusion* By clarifying the performance of rs7574865 in CHB patients, our research may guide physicians and patients in choosing better therapy.

**2623T**

**Next-generation sequencing (NGS) based pharmacogenomics panel testing revealed *CYP2C9* as a critical gene for warfarin dosing in Taiwan.** *Y.C. Chen<sup>1</sup>, Y.S. Liu<sup>1</sup>, P.L. Chen<sup>1,2,3,4</sup>.* 1) Medical Genomics and Proteomics, National Taiwan University of Medicine, Taipei, Taiwan; 2) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 3) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 4) Graduate Institute of Molecular Medicine, National Taiwan University College of Medicine, Taipei, Taiwan.

Pharmacogenomics is the study of the relationship between inherited genetic variations and drug response in individuals. It plays an important role in precise drug dosing. Here we established a pharmacogenomics testing platform using capture-based target region enrichment followed by next-generation sequencing (NGS). Our NGS panel covered 345 major pharmacogenomics genes including pharmacokinetics genes and pharmacodynamics genes, such as various CYP genes, *ABCB1*, *CFTR*, *DRYIP*, *EGFR*, *HLAs*, *KRAS*, *RYR1*, *TPMT*, *UGT1A1* and *VKORC1*, dedicated to identifying specific pharmacogenomic variations and biomarkers of adverse effects. We then applied the panel to 34 individuals, including 6 samples from Taiwan Biobank as controls and 28 patients with adverse drug reactions recruited from National Taiwan University Hospital. Our data confirmed that specific genetic variants are the main determinants for dosing of medications, especially warfarin. For example, our data suggested that, in Taiwan, patients carrying *CYP2C9*\*2 (c.430C>T, p.R144C, rs1799853) or *CYP2C9*\*3 (c.1075A>C, p.I359L, rs105910) would decrease activity of warfarin metabolism, therefore required lower doses to obtain similar efficacy of anticoagulation. Moreover, the distribution of cytochrome P450s genes/alleles is quite variable between population. Thus, it is important to genotype *CYPs* and identify the frequencies of CYP alleles with implications for personalized drug therapy and health programs. Therefore we set up a complete reference and analysis pipeline for *CYP* genes from whole genome sequencing data of ~1000 Taiwan Biobank participants.

**2624F****Genetic and transcriptomic variation in human hepatic pharmacogenes.**

K.G. Claw<sup>1</sup>, T.A. Thornton<sup>2</sup>, D.A. Nickerson<sup>3</sup>, E.G. Schuetz<sup>4</sup>, K.E. Thummel<sup>1</sup>.

1) Department of Pharmacaceutics, University of Washington, Seattle, WA; 2) Department of Biostatistics, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle, WA; 4) St. Jude's Children's Research Hospital, Toronto, Canada.

In the area of pharmacogenomics, the liver is an ideal system to study due to its role in defining the efficacy and toxicity response to drugs that target the liver (e.g., warfarin and statins). Nearly 75% of all commonly prescribed medications are metabolized to some degree in the liver, making it a controlling site for the clearance of thousands of therapeutic agents. Well-known pharmacogenes include the cytochrome P450s, UGT and SULT genes which are responsible for most of the drug biotransformation reactions that occur in the liver. However, knowledge about the regulation of these genes remains incomplete. We used next-generation sequencing to target the total mRNA, microRNA and long non-coding RNA and sequenced the exons of 84 pharmacogenes from 279 human livers, collected as part of an organ procurement program by St. Jude Children's Research Hospital and University of Washington School of Pharmacy. In addition, human liver microsomal and cytosolic protein and enzyme activities were collected for specific genes of interest. We identified 10,770 single nucleotide variants (SNVs) in the 84 genes and flanking regions. With this robust dataset, we identified associations between common genetic variants and transcription levels of pharmacogenes. Pharmacogenes of interest were *CYP3A5* and *VKORC1*. *CYP3A5/4* is a member of the P450 family and accounts for about 35% of drug metabolism. Within *CYP3A5*, a total of 57 variants were identified, of which 20 were singletons and 16 SNVs had MAF  $\geq$  1%. *VKORC1* was previously identified in genome-wide association studies as a significant contributor to variability in warfarin dose and the vitamin K cycle. Within *VKORC1*, a total of 26 variants were identified, of which 9 were singletons. Overall, we identified a total of 483 genetic variants that were significantly associated with the transcription levels of 35 pharmacogenes. Six common SNVs in *VKORC1* and 5 SNVs in *CYP3A5* were associated with mRNA transcription levels. Some variants were previously identified as reduced function variants, suggesting that our results are consistent with known associations. Further investigations may yield novel regulatory candidate genes that further account for interindividual variability. Regulatory elements influencing specific anabolic and catabolic pathways and genes, such as those controlling warfarin response (*VKORC1*, *CYP4F2*, *GGCX* and *CYP2C9*), can be further characterized with functional assays in liver tissue.

**2625W**

**Are drug targets with genetic support twice as likely to be approved? – Revised estimates of the impact of genetic support for drug mechanisms on the probability of eventual drug approval.** J.F. Degner, J.W. Davis, E.A. King. Computational Genomics, AbbVie, North Chicago, IL.

High drug prices can in large part be attributed to the cost of bringing new molecular entities (NMEs) from early evidence of disease relevance through the drug development process to eventual regulatory approval. On average, it is estimated to cost \$1.8 billion to take an NME to market. Despite strong vetting for disease activity, only 10% of candidate NMEs in early stage clinical trials are eventually approved and this probability of approval has a direct relationship to total cost per approved drug (Paul *et al* 2010; *Nat. Rev. Drug Discov.*). Analyzing historic data of the progress of drug compounds through the drug development pipeline, Nelson *et al.* 2015 (*Nat. Genet.*) concluded pipeline drug targets with human genetic evidence of disease association are twice as likely to lead to approved drugs. The specific claim of doubled approval probability, if true, could lead to fewer failed clinical programs thereby lowering drug development costs and costs to consumers. Despite our excitement about the implied transformative effect of current pharmaceutical investment in genomics research, there is room for skepticism. Determining drug genetic evidence requires many decisions, but it is not clear that safeguards against overfitting were employed. Since this paper, the number of SNP-trait associations in the GWAS Catalog has more than quadrupled, new drug target-indications pairings have been trialed, and development of others has advanced. We can now revisit these estimates on updated data and determine if genetic evidence predicts recent successes. Our work confirms genetically supported drug targets were more likely to progress since 2013, with the strongest effect on Phase II to III transitions. The effect of OMIM genetic evidence may be even larger than originally reported (2.2 fold effect on Phase II to III progression). However, GWAS genetic evidence effect estimates tend to be lower than originally reported (1.4-fold effect on approval from Phase I using updated clinical data) and near zero using only post-2013 genetic association data. Both estimates depend strongly on the similarity between the associated trait and drug indication and increase when controlling for target class. Target success prediction may be improved through a more nuanced understanding of the effects across different modalities of genetic architecture and by better methods for joint modeling of genetic evidence with other components of drug success probability.

**2626T**

**A missense change in *CFB* is a potential predictor of sustained virologic response to peginterferon alfa therapy of HBeAg-positive chronic hepatitis B patients.** D. Jiang, H. Chen, B. Zhou, X. Liang, R. Fan, J. Sun, J. Hou. Infectious Diseases and Hepatology Unit, Nanfang Hospital, Southern Medical University, Guangzhou, China.

**Objective** Nucleos(t)ide analogues (NUCs) and peginterferon alfa (PegIFN $\alpha$ ) are currently the main two first-line therapies for chronic hepatitis B (CHB). Unfortunately, both of them produce response in only minority of CHB patients. Predictors of treatment response are expected to optimize treatment of CHB. Till present, 14 SNPs were reported to be associated with susceptibility of CHB. This study was to assess whether these SNPs are potential predictors of response to treatment of CHB. **Methods** A total of 1,860 HBeAg-positive CHB patients, including 254 patients (PegIFN $\alpha$  Cohort 1) and 708 patients (PegIFN $\alpha$  Cohort 2) treated with PegIFN $\alpha$ , 334 patients (NUCs cohort 1) and 564 patients (NUCs cohort 2) treated with NUCs, were enrolled. Treatment efficacy was assessed by sustained virologic response (SVR), which was defined as HBeAg seroconversion along with HBV DNA level < 2000 IU/mL at week 72 for PegIFN $\alpha$  cohorts or at week 104 for NUCs cohorts. All 14 SNPs were genotyped by Sequenom MassArray platform. Cochran-Armitage trend test and logistic regression analysis were used to evaluate the association of SNPs with SVR. **Results** None of these SNPs was found to be significantly associated with SVR in both NUCs cohorts. But in both PegIFN $\alpha$  cohort 1 and 2, rs12416, which is a missense change of complement factor B (*CFB*), was significantly associated with SVR. That is, the SVR rate of patients with rs12416 CC genotype were 28.38%, 20.76% and 22.82% in PegIFN $\alpha$  cohort 1, 2 and their combination; while for patients with rs12416 TT/CT genotype, the SVR rate were only 5.26%, 6.82% and 6.35% in PegIFN $\alpha$  cohort 1, 2 and their combination (P-trend = 0.03, 0.02 and 0.002, respectively). This association remained significant even after adjusting baseline predictors and rs7574865 in *STAT4*, which was reported to be a reliable predictor of PegIFN $\alpha$  therapy in our previous study (Jiang DK et al., *Hepatology* 2016). We also found cumulative effect of rs12416 and rs7574865, i.e., the SVR rate decreased steadily as the number of unfavorable alleles of the two SNPs increasing. For example, in PegIFN $\alpha$  cohorts combination, the SVR rate of patients carried with 0, 1, 2, 3 and 4 unfavorable alleles were 32.93%, 24.23%, 18.71%, 3.13% and 0.00%, respectively (P-trend = 0.0001). **Conclusion** For HBeAg-positive CHB patients with PegIFN $\alpha$  therapy, rs12416 is an independent predictor of SVR. Moreover, by integrating rs12416 with rs7574865, we can further discriminate SVR patients from Non-SVR patients.

**High frequency of PM phenotype in pharmacogenomic actionable genes: Results support the need for pre-emptive genotyping across global populations to improve therapy.** D.K. Sanghera<sup>1</sup>, C. Bejar<sup>1</sup>, G.S. Wander<sup>2</sup>, S. Ralhan<sup>2</sup>. 1) University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma, USA; 2) Hero DMC Heart Institute, Ludhiana, India.

Diversity in drug response is attributed to both genetic and non-genetic factors. However, there is a paucity of pharmacogenetics information across ethnically and genetically diverse populations of India and the world. Here, we have analyzed 20 single nucleotide polymorphisms (SNPs) from 12 pharmacogenomics genes in Punjabi Sikhs of Indian origin (N= 1,616), as part of the Sikh Diabetes Study (SDS). We compared the allele frequency of poor metabolism (PM) phenotype among Sikhs across other HapMap populations. The PM phenotype of CYP1A2\*1F for slow metabolism of caffeine and carcinogens was significantly higher in Indians (SDS 43%, GIH (Gujarati) 51%) compared to Europeans (CEU 29%) (p=0.01). Similarly, Indians had a significantly higher frequency of CYP2C9\*3 (11% SDS, 13% GIH) vs.5% in CEU (p= 0.008) and 'T' allele of CYP4F2 (36% SDS, (43%) GIH vs. (21%) CEU (p=7.8x10<sup>-7</sup>); both associated with high risk of bleeding with warfarin. Both Sikhs (0.36) and Gujaratis (0.34) had a higher frequency of the NAT2\*6 allele (linked with slow acetylation of isoniazid) compared to Europeans (0.27). Additionally, the low activity 'C' allele of MTHFR (rs1801131) was highest in Sikhs compared to all other ethnic groups [SDS (44%), GIH (39%) and CEU (34%) (p=4.9x10<sup>-3</sup>)]. SNPs in the MTHFR affect the metabolism of statins, 5-fluorouracil, and methotrexate-based cancer drugs. These findings underscore the need for establishing a global benchmark for pre-emptive genotyping of drug metabolizing genes before beginning therapeutic intervention. **Acknowledgments** Authors thank all the participants of AIDS/SDS who made this study possible. This work was supported by NIH grant (R01DK082766) funded through the NIDDK, and Harold Hamm Diabetes Center, and Presbyterian Health Foundation of Oklahoma grants. Technical assistance provided by Bishwa Sapkota is acknowledged.

**Pharmacogenomic-associated medication prescribing trends in the Medicare and Medicaid population: Data-driven pharmacogenomic subpanel design.** *E.R. Scott<sup>1,2</sup>, A.O. Owusu Obeng<sup>2,3</sup>, M.R. Botton<sup>1,2</sup>, R.L. Wallsten<sup>1</sup>, A.J. Chen<sup>1</sup>, E.E. Schadt<sup>1,2</sup>, S.A. Scott<sup>1,2,3</sup>.* 1) Sema4, a Mount Sinai venture, Stamford, CT 06902; 2) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 3) Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY 10029.

Pharmacogenomic (PGx) associations with high levels of evidence include hundreds of genomic variants and unique medications across dozens of disease states, which results in PGx-associated medications being prescribed by a broad array of medical specialties. To better characterize PGx-associated prescribing practices across the U.S. and potentially employ these data to inform on clinical PGx panel design, publicly available Centers for Medicare & Medicaid Services (CMS) Part B and Part D provider prescribing data from 2014-2016 were interrogated. Analyses were restricted to physicians with approved reimbursement claims for at least 50 CMS beneficiaries ( $n > 450,000$ ), and the percentage of medicare beneficiaries prescribed a PGx-associated medication was calculated for each physician-medication pair. PGx prescribing rates were calculated by summing all PGx-associated medication prescriptions and dividing by a physician's total unique beneficiaries. Summary statistics of the identified PGx prescribing rates were assessed based on physician specialty, zip code, state, pharmacogene, and Clinical Pharmacogenomic Implementation Consortium (CPIC) evidence classification. CMS data recorded more than 28,000,000 CPIC Level A and 30,000,000 CPIC Level B PGx-associated medication prescriptions in each of the three years analyzed. Importantly, ~60% of physicians prescribed at least one of the 77 CPIC Level A (average of  $2.9 \pm 2.4$ ) or Level B (average of  $3.3 \pm 2.86$ ) medications each year. PGx prescribing rates varied significantly across physician specialty ( $p < 2e-16$ , MANOVA), with the highest rates observed in General Practice, Internal Medicine, and Family Practice. In addition to clustering groups of medical specialties by PGx prescribing rates, these data allowed for data-driven construction of novel PGx subpanels for 20 medical specialties. Moreover, choropleth maps of physician specialty prescribing rates for pharmacogene medication groups revealed dramatic variation across states, with Puerto Rico, Hawaii, and Oregon registering the greatest PGx-prescribing intensity. Taken together, our analysis of national provider prescribing data detected pervasive prescription of PGx-associated medications with clustered variation across geographic territories, medical specialties, and pharmacogenes. Importantly, these results also enabled the design of novel PGx gene panels based on medical practice specialty, which will likely have utility for PGx clinical implementation.

**Phenotypic and pharmacogenomics identification of intraoperative phenylephrine responses using electronic health records.** *Y. Zhang<sup>1</sup>, M.S. Poler<sup>2</sup>, V. Abed<sup>3</sup>, S.A. Perdergrass<sup>1</sup>, M.T.M. Lee<sup>1</sup>.* 1) Genomic Medicine Institute, Geisinger, Danville, PA; 2) Department of Anesthesiology, Geisinger, Danville, PA; 3) Biomedical Translational Informatics Institute, Geisinger, Danville, PA; 4) Biomedical Translational Informatics Institute, Geisinger, Rockville, MD.

**Background:** Patients treated with phenylephrine for hypotension may have substantial differences in blood pressure response. Genetic variation may contribute to this variable response to phenylephrine. In this study we used clinical data with measures of phenylephrine response from patients undergoing surgery and receiving anesthesia to identify genetic associations with phenylephrine response. **Methods:** Data used to define the phenylephrine response were retrieved from electronic health record. A total of 4027 subjects were available for study after data cleaning. Unsupervised machine learning was used to identify sub-populations of patients treated with phenylephrine based on infusion rate and systolic blood pressure during infusion. We performed GWAS on the subset of patients with genetic data using average infusion rate, as well as with the patient sub-groups identified through machine learning. Pathway analyses were also performed. **Results:** We identified three response sub-groups of patients to phenylephrine treatment: resistant, normal, and sensitive responders. Though resistant responders had higher incidence of potentially confounding conditions such as diabetes and heart failure, the overall comorbidity rates were low in all three groups. Subsequent GWAS identified 12 loci with  $P$ -value  $< 1 \times 10^{-5}$  associated with phenylephrine response. Vasoconstriction pathways were enriched ( $P$ -value  $< 0.05$ ) in the pathway analysis. **Conclusions:** Novel loci associated with average infusion rate and patient subsets were identified by GWAS. Our study highlights the value of integrative analysis to provide insights into the variability of response to phenylephrine treatment that could lead eventually to precision medicine strategies and new care paths for patients being treated with phenylephrine.

**Genome-wide polygenic scores for common diseases identify individuals with risk equivalent to monogenic mutations.** A.V. Khera<sup>1,2</sup>, M. Chaffin<sup>1</sup>, K.G. Aragam<sup>1,2</sup>, M. Haas<sup>1</sup>, C. Roselli<sup>1</sup>, S.H. Choi<sup>1</sup>, P. Natarajan<sup>1,2</sup>, E.S. Lander<sup>1</sup>, S.A. Lubitz<sup>1,2</sup>, P.T. Ellinor<sup>1,2</sup>, S. Kathiresan<sup>1,2</sup>. 1) Broad Institute of MIT and Harvard, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA.

A key public health need is to identify individuals at high risk for a given disease to enable enhanced screening or preventive therapies. Because most common diseases have a genetic component, one important approach is to stratify individuals based on inherited DNA variation. Proposed clinical applications have largely focused on finding carriers of rare monogenic mutations at several-fold increased risk. Although most disease risk is polygenic in nature, it has not yet been possible to use polygenic predictors to identify individuals at risk comparable to monogenic mutations. Here, we leverage recently developed algorithms and large population biobanks to develop and validate genome-wide polygenic scores for five common diseases. The approach identifies 8.0%, 6.1%, 3.5%, 3.2% and 1.5% of the population at greater than three-fold increased risk for coronary artery disease (CAD), atrial fibrillation, type 2 diabetes, inflammatory bowel disease, and breast cancer, respectively. For CAD, this prevalence is 20-fold higher than the carrier frequency of rare monogenic mutations conferring comparable risk. Moreover, practicing clinicians could not identify the 8% of individuals at >3-fold risk based on GPS<sub>CAD</sub> using conventional risk factors in the absence of genotype information. We propose that it is time to contemplate the inclusion of polygenic risk prediction in clinical care and discuss relevant issues.

## 2631W

**A genome-wide association meta-analysis of the nicotine metabolite ratio and five other smoking related traits in smokers of European descent.** J. Buchwald<sup>1</sup>, M. Smoking is the main preventable cause of mortality. Smoking behaviour is influenced by the nicotine metabolism rate, which varies among individuals and is highly heritable. Understanding its genetics will facilitate optimizing personalised smoking cessation interventions. We present the largest (N=5185) genome-wide association study (GWAS) to date of a biomarker of nicotine metabolism rate, the nicotine metabolite ratio (NMR, ratio of 3-hydroxycotinine to cotinine). In our sample of Finnish, North American and Australian smokers, we also ran GWASs for two self-reported tobacco exposure measures (cigarettes smoked per day (CPD) and pack-years (CPD x years smoked)), two objective exposure biomarkers (plasma cotinine (Cot), and a more sensitive biomarker constructed as the sum of cotinine and 3-hydroxycotinine (Cot+3HC)), and one biomarker of smoking intensity (Cot/CPD). Cot and 3HC were determined by liquid chromatography/mass spectrometry. To our knowledge, these represent the first GWASs of Cot/CPD and Cot+3HC. In total, we found 1902 genome-wide significant SNPs located in seven distinct loci. The table below shows for each locus and phenotype: - the top SNP and p-value - the relevant gene - whether the top SNP was a known eQTL or meQTL - the total phenotypic variance explained (PVE) by the shown top SNPs - the total number of SNPs (n(Credible set)) with a direct effect on the phenotype (via fine-mapping analyses using step-wise conditional regression with GCTA and a shotgun stochastic search with FINEMAP ([www.christianbenner.com](http://www.christianbenner.com)))

The chr 4 association for NMR is novel, and *TMPRSS11E* has previously only been reported in GWASs of corpuscular haemoglobin and volume. This is also the first GWAS to find associations for addiction phenotypes in *CNN3*, *TENM2* and *SMARCA2*, among others. Our study reveals novel genetic loci associated with smoking-related traits and sheds light on the genetic similarities and differences between nicotine metabolism and tobacco exposure phenotypes.

**A multi-trait GWAS (MTAG) for puberty timing in men.** *F.R. Day<sup>1</sup>, B. Hollis<sup>1</sup>, P. Timmers<sup>2</sup>, P. Joshi<sup>2</sup>, D. Thompson<sup>3</sup>, A.S. Busch<sup>1,4</sup>, K.K. Ong<sup>1</sup>, J.R.B. Perry<sup>1</sup>, 23andMe.* 1) MRC Epidemiology Unit, Cambridge, UK; 2) Centre for Global Health Research, Usher Institute for Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, Scotland; 3) Centre for Cancer Genetic Epidemiology, Department of Public Health and Primary Care, University of Cambridge, UK; 4) Department of Growth and Reproduction, Juliane Marie Centre, Copenhagen, Denmark.

**Background** The timing of puberty is highly variable and has important consequences for long-term health. Most genetic studies have been performed in women, while studies in men are few and smaller in scale. **Methods** Here, we combine genome-wide association study (GWAS) statistics for related recalled male puberty timing traits from the 23andMe (continuous age at voice breaking) and UK Biobank (relatively early/late age at voice breaking and relatively early/late age of first facial hair) studies, generating an effective sample size of 205,354 men, nearly four-fold larger than previously. **Results** We identify 78 GWAS signals for male puberty timing, including 29 not previously associated with puberty timing in either sex, and 5 with significant heterogeneity in their effects on puberty timing between sexes ( $P_{\text{heterogeneity}} < 6.4 \times 10^{-4}$ ) in/near: *ENDOD1*, *LEPR*, *TMEM18*, *TMEM38B* and *TMEM102*. Novel signals include three previously identified for natural hair colour (*HERC2*, *IRF4*, and *C16orf55*). Systematic testing across 124 reported hair colour signals demonstrate a stronger causal influence of darker natural hair colour on earlier puberty timing in males ( $P = 6.3 \times 10^{-63}$ ) than females (age at menarche:  $P = 2.2 \times 10^{-3}$ ), which supports similar phenotypic associations, and possibly reflects common effects of pituitary hormones in pigmentation and puberty timing. Mendelian randomization analyses infer a robust effect of higher body mass index (BMI) on earlier puberty timing in males (weighted median test:  $B = -0.259$  years/SD,  $P = 1.4 \times 10^{-16}$ ) but weaker than that in females ( $B = -0.623$  years/SD,  $P = 6.7 \times 10^{-47}$ ), consistent with the more variable phenotypic relationship in males than females. Additionally, we identify several negative genetic correlations between male puberty timing and health-related outcomes, including diabetes, hypertension, smoking and alcohol intake. Mendelian randomization analyses infer a causal relationship between later male puberty timing and greater lifespan, corresponding to 7 months per year later puberty (self-hazard protection ratio=0.061,  $P = 7.0 \times 10^{-5}$ ). **Conclusions** Puberty timing in males and females show only moderately overlapping genetic architectures ( $r_g = 0.68$ ,  $P = 2.6 \times 10^{-213}$ ). Our findings demonstrate the utility of MTAG to combine data across studies with related measures to provide novel insights into the regulation and consequences of puberty timing.

**A genetic atlas for reproductive health and disease in UK Biobank.** *B. Hollis, A.S. Busch, F.R. Day, K.K. Ong, J.R.B. Perry.* MRC Epidemiology Unit, University of Cambridge, Cambridge, United Kingdom.

**Background** Reproductive health and fertility vary considerably within populations and impact on social, economic and clinical outcomes. Despite this, progress identifying the genetic determinants and mechanisms driving this variability has lagged behind that of other complex traits. To help address this, we have performed the first large-scale, systematic assessment of genetic determinants of reproductive traits in half a million individuals from the UK Biobank study. **Methods** We performed genome-wide association studies for 175 reproductive quantitative traits and disease outcomes in the UK Biobank study (max N = 467,522). Individual traits were curated using a combination of hospital in-patient episode statistics and self-reported data. Analyses were conducted using linear mixed models and our threshold for individual variant significance reflected the total number of tests performed ( $P < 2.85 \times 10^{-10}$ ). **Results** A total of 870 SNP-trait associations reached significance across 735 distinct genomic regions. We identify at least one associated variant for 56 of the 175 traits (32%), including the first identified genetic determinants for many traits. While many of the associations were specific to particular diseases, some SNPs showed widespread associations with clinically relevant endpoints; rs11031005 near *FSHB* was associated with nine of the assessed outcomes including endometriosis, excessive and frequent menstruation and increased chance of having had an oophorectomy; rs78378222 in *TP53* was also associated with oophorectomy as well as having had a hysterectomy. We were also able to identify other loci such as the *ESR1*/*SYNE* locus (encoding estrogen receptor-1) associated with bilateral oophorectomy and endometriosis, uterine fibroids and breast cancer, and *WNT4* (endometriosis, bilateral oophorectomy, uterine fibroid and novel association with pelvic organ prolapse) where there were an number of index SNPs across the phenotypes. Several loci also showed important effects on sex-specific phenotypes, for example *SCGB1C1* which is associated with prostate hyperplasia and uterine fibroids/polyps. **Conclusions** Our study represents the first large-scale, multi-trait assessment of the genetic basis of reproductive health, identifying hundreds of novel associated genetic variants and genes. We aim to develop this into a community resource 'ReproPhen' to enable investigators from diverse biomedical disciplines to utilise these genetic data. .

***P2RX7* functional variants in localized aggressive periodontitis.** T. Harris<sup>1,2</sup>, M. Wallace<sup>3,4</sup>, H. Huang<sup>1</sup>, H. Li<sup>3</sup>, A. Mohiuddeen<sup>1</sup>, Y. Gong<sup>5</sup>, S. Walle<sup>6</sup>, T. Kompotiati<sup>1</sup>, P. Harrison<sup>1</sup>, I. Aukhil<sup>1</sup>, L. Shaddox<sup>1,2</sup>. 1) Dept. of Periodontology, University of Florida College of Dentistry, Gainesville, FL, USA; 2) Dept. of Oral Biology, University of Florida College of Dentistry, Gainesville, FL, USA; 3) Dept. of Molecular Genetics and Microbiology, University of Florida College of Medicine, Gainesville, FL, USA; 4) University of Florida Genetics Institute, Gainesville, FL, USA; 5) Dept. of Pharmacotherapy and Translational Research, University of Florida College of Pharmacy, Gainesville, FL, USA.

The purpose of this study is to investigate the involvement of the *P2X7* receptor in the inflammatory response in localized aggressive periodontitis (LAP). Peripheral blood was obtained from 220 African-Americans (103 with LAP and 117 Healthy patients). Four *P2RX7* SNPs encoding non-synonymous changes (rs1718119, rs2230911, rs208294, and rs3751143) were genotyped from DNA, and whole blood was stimulated with lipopolysaccharide (LPS) from *E.coli* (Ec) and *porphyromonas gingivalis* (Pg) followed by Luminex assay of secreted chemokines/cytokines. *P2RX7* SNP frequencies were compared between both populations and genotypes tested for correlation with LPS-stimulated cyto/chemokines levels. Three *P2RX7* SNPs were in perfect linkage disequilibrium, with a total of 4 haplotypes and 9 diplotypes identified among all patients. Diplotypes were grouped based on known haplotype functional effects: wild-type (WT), net gain of function, net loss of function, and mixed effect. These four diplotype group frequencies were compared within and between the two patient populations (LAP and controls), and tested for association with levels of LPS-stimulated cytokines and chemokines. In another study, *P2RX7* was compared to the cytokine/chemokine data based on number of ancestral alleles at each SNP. To measure the effect of extrinsic activation of the receptor, peripheral blood samples from 41 African-Americans (21 with LAP and 20 Healthy unrelated controls) were stimulated under three different treatments; *E.coli* LPS alone, LPS+ATP, and LPS+ATP+*P2X7* selective inhibitor. Levels of IL-2, IL-1 $\beta$ , and IL-12p40 were then measured. Stepwise regression found significant genetic association of the rs1718119 A allele with LAP versus healthy controls ( $p=0.0082$ ). Correlations were found between three *P2RX7* SNPs and LPS stimulated levels of several cyto/chemokines ( $P<0.05$ ). Significant cyto/chemokine differences were found between the homozygous ancestral allele group and the hetero-/homozygous non-ancestral allele group for all SNPs. A number of associations with cyto/chemokines were found both between and within the diplotypes for all patients ( $P<0.05$ ). The *P2X7* activation assays showed statistically significant differences for IL-1B levels in both LAP and healthy groups based on *P2RX7* genotypes, although there was no difference between the two populations. This is the first study to detect evidence of a biological relationship between *P2RX7* genetic variants and the inflammatory response in LAP.

**Genome-wide association study reveals sex-specific genetic architecture of facial attractiveness.** B. Hu<sup>1</sup>, N. Shen<sup>1</sup>, J. Li<sup>2,3</sup>, H. Kang<sup>1</sup>, J. Hong<sup>3</sup>, J. Fletcher<sup>4,5</sup>, J. Greenberg<sup>3,6</sup>, M. Mallick<sup>3,6</sup>, Q. Lu<sup>1,7</sup>. 1) Department of Statistics, University of Wisconsin-Madison, Madison, WI; 2) Department of Psychology, University of Wisconsin-Madison, Madison, WI; 3) Waisman Center, University of Wisconsin-Madison, Madison, WI; 4) La Follette School of Public Affairs, University of Wisconsin-Madison, Madison, WI; 5) Department of Sociology, University of Wisconsin-Madison, Madison, WI; 6) School of Social Work, University of Wisconsin-Madison, Madison, WI; 7) Department of Biostatistics and Medical Informatics, University of Wisconsin-Madison, Madison, WI.

Facial attractiveness is a fascinating and complex human trait of great interest in both academia and industry. It has profound influence on human behavior and literature on its sociological and psychological implications is rich. However, although twin-based studies have suggested substantial heritability for facial attractiveness, its genetic basis remains poorly understood, partly due to the scarcity of well-phenotyped attractiveness data with matched genotype information. In this study, we report the first genome-wide association study (GWAS) of facial attractiveness based on 3,928 samples in the Wisconsin Longitudinal Study (WLS). Facial attractiveness in WLS was measured based on each individual's high school yearbook photo by 12 raters (six females and six males). We stratified our association analyses by sex (of samples and raters) to better understand the distinct genetic architecture of male and female attractiveness as well as its perception among males and females. We identified two genome-wide significant loci on 10q11.22 (rs2999422,  $p=9.2e-10$ ) and 2p22.2 (rs10165224,  $p=3.4e-8$ ), and highlighted more than a dozen candidate genes via eQTL analyses and cross-tissue transcriptome-wide association mapping. Sex-specific genetic architecture of facial attractiveness was a recurrent pattern observed in all our analyses. Sex-stratified GWAS analyses identified distinct lists of associated loci. Additionally, several top candidate genes (e.g. *ANTRXL*) were specifically expressed in human tissues involved in reproduction and hormone synthesis, a pattern that was further confirmed via heritability enrichment analysis - testis and ovary were the most enriched tissues for male and female attractiveness, respectively (enrichment=3.0~5.7 across analyses). Further, we identified potentially pleiotropic loci shared with body-mass index (BMI), facial morphology, skin pigmentation, and hair color. Interestingly, only female attractiveness (especially when rated by males) showed strong and negative genetic correlation with BMI ( $p=4.7e-5$ ) while male attractiveness was more correlated with blood lipid levels ( $p=5.1e-4$ ) which are known to be involved in testosterone synthesis. Finally, we demonstrated that the selection pressure on negative associations of male attractiveness was substantially stronger than in females. These results revealed sex-specific genetic architecture of facial attractiveness and provided fundamental new insights into its genetic basis.

**Association of the NTCP S267F variant disabling of HBV receptor function with a reduced host risk to HBV infection and disease progression.** P. An<sup>1</sup>, Z. Zeng<sup>2</sup>, C.W. Winkler<sup>1</sup>. 1) Basic Research Laboratory, Center for Cancer Research, National Cancer Institute, Basic Science Program, Leidos Biomedical Research, Inc., Frederick National Laboratory for Cancer Research, Frederick, MD; 2) Department of Infectious Diseases, Peking University First Hospital, Beijing, China.

Sodium taurocholate cotransporting polypeptide (NTCP) is a cellular receptor for entry of Hepatitis B virus (HBV). The natural S267F variant in NTCP specifically present in the Asian population attenuates HBV receptor function of NTCP. We assessed the impact of S267F on host susceptibility to HBV resistance, HBV infection clearance, and HBV-related cirrhosis and hepatocellular carcinoma (HCC) in 1117 Han Chinese patients with distinct HBV infection outcomes using multivariate logistic regression analysis. The 267F variant allele prevalence was elevated in the group of HBV-resistance healthy controls compared with HBV-infected patients (odds ratio (OR) 0.32, 95% confidence interval (CI) 0.15-0.68, dominant model). The 267F variant genotypes were also associated with reduced risk for cirrhosis (OR 0.15, 95% CI 0.03-0.70) or HCC (OR 0.21, 0.06-0.72), when compared with those with chronic HBV infection. There was no association of the S267F variant with spontaneous HBV clearance. We demonstrated for the first time that NTCP S267F variant does not act synergistically with *HLA-DPA1* rs3077 variant, an HBV infection restriction factor, to modify HBV infection and chronic liver disease progression. In summary, carriage of the loss-of-function S267F variant in the HBV hepatocyte receptor NTCP confers innate resistance to HBV infection as well as restriction of progression to cirrhosis and liver cancer among those with chronic HBV infection. Our population genetic data support an *in vivo* role of NTCP as the primary entry receptor of HBV. (Funded by the National Cancer Institute Contract HHSN26120080001E).

**Genotype imputation of structural polymorphism with whole genome sequencing based haplotypes reference panel.** Y. Kawai<sup>1</sup>, T. Mimori<sup>2</sup>, K. Ueno<sup>3</sup>, Y. Hitomi<sup>1</sup>, O. Gervais<sup>2</sup>, S.S. Khor<sup>1</sup>, M. Kawashima<sup>1,3</sup>, N. Nishida<sup>1,4</sup>, M. Nakamura<sup>5</sup>, M. Nagasaki<sup>2</sup>, K. Tokunaga<sup>1</sup>. 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan; 3) Japan Science and Technology Agency (JST), Tokyo, Japan; 4) The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Japan; 5) Clinical Research Center, National Hospital Organization (NHO) Nagasaki Medical Center, Omura, Japan.

Genotype imputation based on the large haplotype reference has been successful in genome-wide association studies (GWASs) to date. Prediction of missing genotypes by genotype imputation not only boosts the power of GWAS but also enables to identify causal variants in post-GWAS analyses. Although the genotype imputation is routinely used in GWAS, the majority of studies have focused on the imputation of single nucleotide polymorphisms (SNPs). However, the structural variants (SVs) such as copy number variations (CNVs) and mobile element insertions (MEIs) are source of the genetic diversity among human populations and their variations can contribute phenotypic variations of complex traits. We discovered the SVs from the whole genome sequencing data of a general population in Japan. We found 17,314 CNVs, 7,072 MEIs and 869,590 short tandem repeats from 418 individuals. The SVs were phased together with tag SNPs, in which their probes were on SNP arrays used in GWAS, to conduct the genotype imputation. We evaluated the accuracy of the SV imputation by cross validation. The imputation accuracy tends to be higher in high frequency SVs as it has been reported for SNP imputation. We estimated a heritability of primary biliary cholangitis (PBC) explained by the imputed SVs. We found a small but significant fraction (~3%) of heritability of PBC can be accounted for by the SVs which were likely overlooked in previous studies which were estimated by SNPs.

**Imputing the effects of genetic variation on mRNA splicing in rare human samples.** A. Shah<sup>1</sup>, Y.I. Li<sup>2,3</sup>. 1) Committee on Genetics, Genomics, and Systems Biology, University of Chicago, Chicago, IL; 2) Section of Genetic Medicine, Department of Medicine, University of Chicago, Chicago, IL; 3) Department of Human Genetics, University of Chicago, Chicago, IL.

Over 90% of all disease-associated variants identified in genome-wide association studies (GWAS) are located outside protein coding regions, suggesting that these variants have gene regulatory function. While much of the work understanding disease-associated variants has focused on mapping the effects of genetic variation on gene expression levels, we have shown previously that mRNA splicing is the primary mechanism that links genetic variation to disease (Li et al., 2016), such that a substantial number of GWAS hits may affect disease risk by impacting RNA splicing. To better understand how variation in RNA splicing affects disease, we investigated the impact of genetic variation on RNA splicing in a large collection of 53 tissues from the Genotype-Tissue Expression (GTEx) project. Using a novel splicing quantification method, LeafCutter (Li et al., 2018), we identified over forty thousand unannotated splicing events across all tissues and mapped thousands of splicing quantitative trait loci (sQTLs) in each tissue. We found that 10-20% of splicing events show tissue specific patterns of inclusion, and that up to 40% of testis-specific splicing events were not observed in any other tissue. We found that sQTLs were enriched in nearly all GWAS traits examined, including autoimmune and neurodegenerative diseases. Notably, most sQTLs did not affect gene expression levels, confirming the widespread importance of measuring RNA splicing alongside expression. Finally, we quantified the concordance of sQTL effects on splicing events that are present across GTEx tissues using flashr, a statistical method that accurately estimates sharing of genetic effects on multiple phenotypes and/or samples (Wang and Stephens, 2018). Strikingly, our analysis revealed that 95% of sQTLs are shared across samples, compared to 70% for expression quantitative trait loci (eQTLs). The high amount of shared genetic effects on RNA splicing across tissues offers the possibility of accurately imputing the effects of genetic variation on RNA splicing in rare, and as of yet, inaccessible human samples. For example, using the imputed effects of genetic variants collected from large neuropsychiatric disease GWASs, we can study the impact of genetic variation on RNA splicing in developing fetal brains.

**Mosaic loss of chromosome Y (LOY) in leukocytes helps explain why men live shorter lives.** L.A. Forsberg<sup>1,2,3</sup>, J. Halvardson<sup>1</sup>, M. Danielsson<sup>1</sup>, J. Mattisson<sup>1</sup>, J. Dumanski<sup>1,2</sup>, B. Torabi Moghadam<sup>1</sup>, H. Davies<sup>1</sup>. 1) Dept. of Immunology, Genetics and Pathology, Uppsala University, Sweden; 2) Science for Life Laboratory, Uppsala University, Sweden; 3) Beijer Laboratory of Genome Research, Uppsala University, Sweden.

Men live shorter lives, but the reason(s) why has been poorly understood. Recent analyses show that mosaic loss of chromosome Y (LOY) in leukocytes of men is associated with increased risk for all-cause mortality, mortality and diagnosis of non-hematological cancer, increased risk for diagnose with Alzheimer's disease (AD), autoimmune conditions and major cardiovascular events. Published data show that LOY is the most common human mutation and unpublished data show that more than half of 93-year-old men harbor LOY-cells in their blood. Known risk factors for LOY include age, smoking as well as inherited SNP-variants. Hence, as a common and male specific genetic risk factor, LOY helps explain why men in the entire world on average dies about 5 years younger compared to women. How could LOY in leukocytes increase the risk for disease in other organs? One hypothesis to explain the associations between LOY in blood cells with increased risk for disease in other tissues, is that some normal functions of immune cells, such as orchestrating defense against and eradication of various disease and malignant processes, could be compromised after being affected with LOY. To address this question, we study the functional consequences of LOY in leukocytes using various tools. For example, we investigate dysregulated gene expression as an effect of LOY in single cell transcriptomic assays (10X Chromium and ddSEQ platforms) and well as in FACS-sorted immune cell fractions with AmpliSeq. Moreover, LOY mediated changes in plasma proteins are studied using PEA. Our preliminary data support the hypothesis that LOY could influence important immune cell properties and functions. For example, unpublished single cell RNA data shows that the gene expression of immune cells with LOY is profoundly dysregulated in a cell type specific and functionally relevant manner. Furthermore, new analyses of FACS-sorted cells show that cancer and AD patients may have LOY in different types of immune cells. LOY in leukocytes is associated with increased risk for death and major causes of male morbidity and mortality. LOY could therefore become a new and predictive biomarker for identification of men with increased risk for disease. To improve the clinical utility of LOY we are developing new tools for improved LOY-detection. Identification of men with LOY in leukocytes could lead to earlier diagnoses of ongoing disease in affected men, and thus, open up for better medical treatment options.

**2640W****Investigating the impact of smoking on mental and physical health**

**outcomes using genome-wide data.** C. Chen<sup>1,2,3</sup>, R. Walters<sup>1,3</sup>, L. Abbott<sup>6</sup>, D. Pulmer<sup>1,3</sup>, D. Howrigan<sup>1,3</sup>, A. Ganna<sup>1,3</sup>, C. Churchhouse<sup>1,3</sup>, C.E. Carey<sup>1,3</sup>, J. Smoller<sup>2,3</sup>, B. Neale<sup>1,2,3</sup>. 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, MA; 3) Broad Institute of MIT and Harvard.

The increasing amount of publicly available genome-wide association study (GWAS) summary results and biobanks that cover a wide range of human traits linked to genome-wide data have enabled us to comprehensively investigate the relationships between mental and physical health outcomes at an unprecedented scale. Here we aim to examine the impact of smoking, measured as average smoking pack-year over adult lifetime (ASP), on a wide range of health outcomes and traits using genome-wide data. We leverage data from existing large-scale GWAS summary statistics as well as individual level phenotype and genotype data from the UK Biobank. We performed genome-wide association analysis on ASP using 101,726 subjects from the UK Biobank with 10,889,592 imputed SNPs after QC. The ASP was derived as average number of smoking pack-years by an individual each year after age of 16. The association analysis was done with linear regression adjusted for sex and the first 10 PCs. The genome-wide association analysis identified 13 independent genome-wide significant loci, with  $\lambda_{GC}$  of 1.22 and LD score regression intercept of 1.017 (SE = 0.0081; ratio = 0.067 with SE = 0.0305) indicating high polygenicity with minimal inflation due to confounding. The SNP-based heritability of ASP was 0.124 (SE = 0.0083;  $p = 1.06E-50$ ). Using the association summary statistics, we first explored the genetic correlation ( $r_g$ ) between ASP and 230 phenotypes from publicly available GWAS summary statistics and 496 phenotypes from UK Biobank using LDhub. We identified 296 significant  $r_g$  after Bonferroni correction. The most significant results include self-reported poor health ( $r_g = 0.631$ ;  $p = 3.35E-118$ ) and years of schooling ( $r_g = -0.574$ ;  $p = 2.48E-92$ ). We further explored the causal effects of ASP on 40 health outcomes and traits using bidirectional 2-sample Mendelian randomization (MR). Multiple methods were used to detect and control for potential pleiotropic biases in the MR analysis, including MR-PRESSO, MR-Egger regression, and weighted median-based MR. The most significant result is that higher years of schooling decrease ASP, which also shows strong pleiotropic effects ( $\beta = -0.375$ ;  $p = 7.44E-10$ ; MR-PRESSO pleiotropy test  $p < 0.001$ ; N of SNP = 70). Our analyses highlighted that smoking has complex relationships with a wide range of mental and physical health outcomes and traits.

**2641T****Visualization of UK Biobank genetic association results in PheWeb.**

P. VandeHaar, S.A. Gagliano, G.R. Abecasis. Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI.

The UK Biobank cohort consists of >400,000 individuals, >2000 traits, and >39 million HRC-imputed or genotyped variants. Manually sifting through all of the resulting genetic association results, variable by variable, is neither an efficient nor comprehensive way to foster discoveries. Efficiently translating a massive amount of results into new understandings of health and disease requires making the information accessible to researchers in an easy-to-use manner. We use PheWeb, our web-based tool for visualizing and browsing through hundreds or thousands of genetic association results, to visualize the UK Biobank results. This instance of PheWeb provides a comprehensive view of association results for the largest genotyped population cohort. These results are based on the SAIGE generalized mixed model association test, which accounts for case-control imbalance and relatedness. PheWeb's visualization capabilities are particularly useful for studies with many phenotypes, and users can build a PheWeb of their own data by following instructions on GitHub (<https://github.com/statgen/pheweb>). We are continually implementing new features to aid in data analysis, such as the ability to conduct gene-burden tests on the fly, selection of customized panels for linkage-disequilibrium, and highlighting known GWAS loci. The UK Biobank PheWeb is freely available for all researchers at <http://pheweb.org/UKBiobank>.

**Does the *CPT1A* p.P479L variant increase risk for early neonatal hypoglycemia?** S. Collins<sup>1\*</sup>, E. Hildes Ripstein<sup>2\*</sup>, B. Thompson<sup>3</sup>, K. Barker<sup>4</sup>, C. Greenberg<sup>2</sup>, L. Arbour<sup>1</sup>, \* indicates shared first authorship. 1) Dept of Medical Genetics, University of British Columbia, Victoria BC Canada; 2) Dept of Pediatrics and Child Health, University of Manitoba, Winnipeg MB Canada; 3) Cadham Provincial Laboratory, Winnipeg MB Canada; 4) Dept of Health, Government of Nunavut, Canada.

**Background:** The *CPT1A* p.P479L variant, a possible risk factor for hypoglycemia, is overrepresented in Indigenous populations in the Arctic and coastal British Columbia. We assessed blood glucose (BG) levels to determine if full term Inuit neonates without other risk factors for hypoglycemia had an increased risk if either heterozygous or homozygous for the variant. **Methods:** Clinical charts were reviewed of 503 Inuit infants born to mothers residing in Kivalliq Nunavut between 2010 and 2014 (four years). BG levels in the first 12 hours of life were abstracted with additional variables (maternal diabetes mellitus, infant weight, gestation, feeding type and clinical course) and then linked to genotypes. We used standard neonatal BG thresholds to define hypoglycemia as per the Canadian Paediatric Society (<2.0 at 2hrs or <2.6mmol/L within 12hrs). Charts with missing genotypes (n=36) or risk factors for hypoglycemia (n=142) were excluded. **Results:** Genotype distribution was 4.9% wildtype (PP, n=16), 23.4% heterozygous (PL, n=76) and 71.7% homozygous (LL, n=233; total cohort=325). Mean BG was 2.63±0.07mmol/L and 26.5% had at least one hypoglycemic BG level within 12hrs of life. Infants with LL and PL genotypes had a higher proportion of documented hypoglycemia than infants with the PP genotype (29% and 22% vs 13%, respectively); however, the difference was not statistically significant (FET=0.266 and 2-wayANOVA F=0.28, p=0.753). Proportions of persistent hypoglycemia (2 or more consecutive hypoglycemic levels; 13% PP, 9% PL, 8% LL) and intravenous dextrose treatment (13% PP, 5% PL, 7% LL) did not significantly differ between genotypes (FET=0.579 and 0.420, respectively). Of note, approx. 14% of infants tested at 0-2hrs (n=238) had a BG level <2.0mmol/L, which was equally distributed within genotypes (FET=0.612). **Conclusion:** There was no statistical significant difference in documented early neonatal hypoglycaemia between genotypes of the *CPT1A* allele. Although not significant, it was notable that 29% of homozygotes and 22% of heterozygotes without other neonatal risk factors for hypoglycemia had documented hypoglycemia. Hypoglycemia in wildtypes was similar to that expected for a healthy newborn population (13%). However, there was no difference in persistent hypoglycemia or IV dextrose treatment between the genotypes. Further study into whether the *CPT1A* p.P479L variant influences the risk of neonatal hypoglycemia, and under what circumstance, is indicated.

**The common polymorphism of the *KISS1* gene promoter associated with endometriosis in Russian population.** T. Ivashchenko, A. Shagina, N. Ganbarli, M. Yarmolinskaya. Oott's institute of obstetrics and gynecology, St.Petersburg, st.Petersburg, Russian Federation.

Endometriosis is one of the most common gynecological diseases. Etiology and pathogenesis of endometriosis remain obscure so far. It is usually treated as a complex multifactorial disease with obvious genetic predisposition, immunology failure and possible noxious environmental factor involvement. Kisspeptins, the product of the *KISS1* gene, plays an essential role in the regulation of reproductive functions, acting primarily at the hypothalamic level of the gonadotropic axis. It was shown, that the *KISS1* expression in the ectopic glandular endometrium was significantly increased as compared with the eutopic glandular endometrium from patients with and without endometriosis. We examined the common polymorphism of the *KISS1* gene promoter (rs5780218 (c.-145insT); rs3924587 (c.-89G>A)) in women with and without endometriosis by PCR-RFLP analysis. We observed significantly higher frequencies of c.-145insT alleles in the patients group compared to the control group (20% versus 9%). There was no significant difference in frequency alleles for rs3924587 of the *KISS1* gene. The results suggest that polymorphism c.-145insT of the *KISS1* gene associated with endometriosis in Russian population.

**Genetic association of ER stress sensors IRE1 and XBP1 with cranial vault shape and nasal shape in humans.** S. Weinberg<sup>1</sup>, Y. Zhou<sup>1</sup>, J. Roosenboom<sup>1</sup>, M. Lee<sup>1</sup>, J. Hecht<sup>2</sup>, C. Heike<sup>3</sup>, G. Wehby<sup>4</sup>, K. Christensen<sup>5</sup>, L. Moreno<sup>6</sup>, E. Feingold<sup>6</sup>, M. Marazita<sup>7</sup>, P. Claes<sup>8</sup>, J. Shaffer<sup>8</sup>. 1) Department of Oral Biology, University of Pittsburgh, Pittsburgh, PA, 15219; 2) Department of Pediatrics, University of Texas McGovern Medical Center, Houston, TX; 3) Department of Pediatrics, Seattle Children's Craniofacial Center, University of Washington, Seattle, WA; 4) Department of Health Management and Policy, University of Iowa, Iowa City, IA; 5) Department of Epidemiology, Institute of Public Health, University of Southern Denmark, Odense, Denmark; 6) Department of Orthodontics, University of Iowa, Iowa City, IA; 7) Katholieke Universiteit Leuven, Belgium; 8) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA, 15261.

**Introduction** Endoplasmic reticulum (ER) unfolded protein response (UPR) pathway protein IRE1 (coded by the *ERN1* gene) and XBP1 play essential roles in bone formation and chondrogenesis, which are critical processes in craniofacial growth and development. For example, transgenic mice with heightened ER stress display pseudochondrodysplasia and cranial vault malformation. Whether genetic variants in *XBP1* and *ERN1* influence craniofacial variation in humans remains unknown. Therefore, we employed an *in silico* candidate gene approach testing the genetic association of common variants in *ERN1* and *XBP1*, with facial and cranial vault shape in a sample of healthy individuals. **Methods** 3D facial images were obtained from 2,329 participants in the 3D Facial Norms (3DFN) repository. Caliper measurements of the cranial vault were obtained from both the 3DFN study and the Pittsburgh Orofacial Cleft (POFC; N=2274) study. Whole-genome genotype data were collected for both studies using Illumina platforms, with imputation to the 1000 Genomes Study reference. 2259 single nucleotide polymorphisms (SNPs) with MAF > 1% at *ERN1* and 2562 SNPs on *XBP1* (+/- 200kb) were tested for genetic association with 63 multi-dimensional facial phenotypes in the 3DFN cohort and 3 cranial vault phenotypes in both 3DFN and POFC cohorts while adjusting for ancestry and pertinent covariates. **Results** We observed significant associations in the 5' flanking region of *XBP1* for Cephalic Index (rs35679096, p=0.00017). The associated SNP is in LD with several SNPs showing promoter and enhancer chromatin marks in many different cell types, including in bone-forming osteoblast lineage cells and mesenchyme stem cell-derived chondrocytes, which are cartilage-forming cells. We also detected associations between *ERN1* variant rs78885494 and several nasal shape phenotypes (p=5E-5 to 3E-6). This SNP is in strong LD with two other nose-associated SNPs, rs74940919 and rs8078549 (p=2E-5 to 9E-6), which are located in known promoter and enhancer regions in both chondrocyte and osteoblast lineage mesenchyme stem cells. **Conclusion** Although the mechanism remains unclear, our findings suggest that genetic variants at the *XBP1* and *ERN1* loci are associated with normal human cranial vault and nasal shape, respectively. Funding: R01-DE027023 U01-DE020078 R01-DE016148 .

**The genetic basis of social effects: Genome-wide association study of social genetic effects on 170 phenotypes in laboratory mice.** A. Baud<sup>1</sup>, F.P. Casale<sup>1,2</sup>, J. Nicod<sup>3,4</sup>, O. Stegle<sup>1,5</sup>. 1) European Molecular Biology Laboratory, European Bioinformatics Institute, Cambridge, UK; 2) Microsoft Research New England, Cambridge, Massachusetts, USA; 3) Wellcome Trust Centre for Human Genetics, Oxford, UK; 4) The Francis Crick Institute, London, UK; 5) European Molecular Biology Laboratory, Genome Biology Unit, Heidelberg, DE.

When two individuals such as peers or parent and offspring interact, heritable traits of one individual can influence the phenotype of the other, giving rise to associations between genotypes of one individual and phenotype of the other. Such associations are called social genetic effects (SGE), indirect genetic effects or "the nature of nurture". We previously demonstrated that SGE, in aggregate, affect a broad range of phenotypes in laboratory mice, and three studies of educational attainment in humans have shown that SGE are also at play in our species. In this study we took the next step and mapped SGE. Much like "traditional" direct genetic effects (DGE, effects of an individual's genotypes on their own phenotype), SGE are amenable to mapping and genome-wide association study of SGE (sgeGWAS) has the potential to greatly advance our understanding of how social partners influence each other's health. We carried out the first sgeGWAS in an outbred population, mapping SGE for 170 behavioral, physiological and morphological phenotypes in outbred laboratory mice. We developed a statistical framework for sgeGWAS that accounts for common confounding factors and identified 21 genome-wide significant SGE loci (FDR < 10%). In addition, for all 170 traits, we calculated the genetic correlation between DGE and SGE and mapped DGE (dgeGWAS). Our results provide the following insights into the mechanisms of social effects and their genetic architecture: first, SGE and DGE arise from partially different loci and/or loci with different effect sizes, which implies complex mechanisms for social effects going beyond "phenotypic contagion" or "spread" (e.g. my anxiety affects my partner's anxiety). Secondly, several genome-wide significant DGE associations but no SGE associations had large effect sizes, suggesting sgeGWAS is unlikely to uncover "low hanging fruits". Finally, our results suggest that a similar number of variants likely contribute to SGE and DGE. The framework we developed for sgeGWAS and the insights we gained from analysing 170 diverse phenotypes will inform the design, implementation and interpretation of sgeGWAS in humans. A better understanding of the role of the social environment could result in improved healthcare. Our study is available as a preprint: Baud, A., et al., *Genome-wide association study of social genetic effects on 170 phenotypes in laboratory mice*. *bioRxiv* (2018). Available from: <https://doi.org/10.1101/302349>.

**2646W****Deciphering sex-specific genetic architectures using Bayesian methods.**

S.A. Funkhouser<sup>1</sup>, G. de los Campos<sup>2</sup>. 1) Genetics Program, Michigan State University, East Lansing, MI; 2) Department of Epidemiology and Biostatistics, Michigan State University, East Lansing, MI.

Many human diseases, ranging from obesity-related conditions to psychiatric disorders, have a different prevalence in men than in women. These differences may be due to differential environmental exposures or differential genetic architectures (genetic sex differences). The existence of genetic sex differences is supported by heritability estimates and by genome-wide estimates of effect correlations. However, mapping loci possessing sex-specific effects remains elusive, in part because any causal locus generally explains a very small ( $R^2 < 1 \times 10^{-3}$ ) proportion of phenotypic variance. The methods commonly used in association analyses (single-marker regression, SMR) are severely underpowered to detect small effects, namely after multiple test correction. Bayesian multiple-marker regression techniques have been proposed for GWAS. These methods do not suffer the burden of multiple test correction and can provide better resolution in locating non-zero effects. In this study, we developed a Local Bayesian Multiple-Marker Regression (LBMMR) method, jointly fitting male and female SNP effects for overlapping chromosome segments spanning multiple LD blocks. This framework provides posterior probabilities of a SNP effect in either men or women as well as posterior probabilities of sex difference (PPDiff) for individual SNPs and chromosome segments. We use data from the UK-Biobank ( $N = 258,928$  unrelated white Caucasians) to evaluate these methods using simulations and using real human phenotypes. Our simulation (in which sex differences in SNP effects spanned  $R^2 = 7.9 \times 10^{-5}$  to  $R^2 = 1 \times 10^{-3}$ ) shows LBMMR has substantially higher power (LBMMR: 0.74; SMR: 0.51) and a lower false discovery rate (LBMMR: 0.02; SMR: 0.48) than SMR for finding sex-specific SNP effects. In applying the LBMMR method to real traits—height, heel bone mineral density (BMD), BMI, and waist-to-hip ratio (WHR)—correlations of effects between men and women are estimated to be 0.941, 0.901, 0.825, and 0.624, respectively. For height, we confirm previous findings that the cross-sex correlation of effects is near one, yet newly discover four SNPs with sex-specific effects (PPDiff  $\geq 0.9$ ). Likewise, we have discovered 30 SNPs with sex-specific effects for WHR, largely near previously implicated genes including *VEGFA* and *ADAMTS9*, but also in previously unreported loci. In summary, LBMMR can provide new insight into sex differences by enhancing the precision and power to detect loci with sex-specific effects.

The similarity of twins and relatives indicates that facial shape is under genetic control. Nonetheless, the number of replicated genetic variants showing associations with facial variation is small. In prior work, we used a novel data-driven approach to identify 15 loci involved in normal-range facial variation. Here, we report a substantial update and extension of that work. We meta-analyzed three large cohorts of European-ancestry with 3D facial shape data and genome-wide SNP data: PSU ( $N=1,743$ ), PITT ( $N=2,323$ ), and AL-SPAC ( $N=3,566$ ). To derive comparable sets of phenotypic data across studies, we established a dense correspondence among the 3D facial surfaces (~10,000 quasi-landmarks) and applied a hierarchical modular decomposition approach, previously reported by our group, on the entire dataset to construct phenotypes from the 3D facial surfaces. This data-driven process results in 63 distinct “global-to-local” facial modules identified based on pairwise spatially-dense landmark correlations. SNPs were tested for association with modular shape PCs via multivariate canonical correlation analysis (calculated separately in each dataset), controlling for sex, age, height, weight, and population stratification. To accommodate the unprescribed selection of facial traits, we utilized a round-robin approach, in which each of the three datasets is, in turn, used to discover and define the linear combination of phenotypic variables that is maximally correlated with the SNP. Subsequently, the two other datasets are projected onto this learned phenotype, creating univariate phenotypic variables which are then also tested for genotype-phenotype associations, unrestricted by the SNPs reaching significance in the discovery dataset. The p-values across a single discovery with follow-up replications were then combined using Fisher’s method, and only results with all three meta p-values (one for each dataset as discovery) reaching genome-wide significance ( $p < 5 \times 10^{-8}$ ) were retained. With this conservative approach, we identified 75 genome-wide significant loci associated with at least one facial module. By combining increased sample sizes and a novel approach for meta-analyzing multivariate 3D facial modules, we were able to quadruple the number of replicating loci involved in normal-range facial variation. This study provides new insights into the genetic basis of human facial shape and is both anthropologically and clinically relevant.

**The landscape of pervasive horizontal pleiotropy in human genetic variation is driven by extreme polygenicity of human traits and diseases.** *D.M. Jordan, M. Verbanck, R. Do.* Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY.

Understanding the nature and extent of horizontal pleiotropy, where one genetic variant has independent effects on multiple observable traits, is vitally important for our understanding of the genetic architecture of human phenotypes and for the field of human genetics. Undetected pleiotropy can bias genome-wide association studies (GWASs) and Mendelian randomization (MR) studies, and can cause unexpected effects when genetic evidence is used to select drug targets or in clinical applications of gene editing technology. Many recent studies have pointed to the existence of horizontal pleiotropy among human phenotypes, but the exact extent remains unknown, largely due to difficulty in disentangling the inherently correlated nature of observable traits. We have developed a statistical framework to isolate and quantify horizontal pleiotropy in human genetic variation, using a two-component pleiotropy score computed from summary statistic data derived from published GWASs. This score uses a statistical whitening procedure to remove correlations between observable traits and normalize effect sizes across all traits. When applied to simulated association summary statistics, our score successfully detects horizontal pleiotropy under a range of different models. When applied to real human phenotype data, using association statistics for 1,564 traits measured in 337,119 individuals from the UK Biobank, our score detects a significant excess of horizontal pleiotropy (genomic inflation factor  $\lambda_{GC} = 4.94 - 9.95$ ). We find that horizontal pleiotropy is pervasive throughout the human genome and across a wide range of phenotypes and biological functions, but is especially prominent in regions of high linkage disequilibrium and among phenotypes known to be highly polygenic and heterogeneous. We additionally identify 6,645 loci with extreme levels of horizontal pleiotropy, 4,234 of which have never been previously reported in any published GWAS. These loci represent an under-recognized class of genetic variation with weak effects on many distinct phenotypes, but no specific marked effect on any one phenotype. 42% of these loci replicate using independent datasets of GWAS summary statistics, where a permutation analysis shows only 15% expected to replicate by chance. These results highlight the central role horizontal pleiotropy plays in the genetic architecture of human phenotypes, and the importance of modeling horizontal pleiotropy in genomic medicine.

**2649W**

**Detailed annotation of genetic signals associated with human nose morphology.** *J. Roosenboom<sup>1</sup>, M.K. Lee<sup>1</sup>, E. Feingold<sup>2</sup>, M.L. Marazita<sup>1</sup>, M.D. Shriver<sup>3</sup>, J. Wysocka<sup>4</sup>, P. Claes<sup>5</sup>, J.R. Shaffer<sup>2</sup>, S.M. Weinberg<sup>1</sup>.* 1) University of Pittsburgh, Center for Craniofacial and Dental Genetics, Pittsburgh, PA, USA; 2) University of Pittsburgh, Department of Human Genetics, Pittsburgh, PA, USA; 3) Department of Anthropology, Penn State University, University Park, PA, USA; 4) Department of Developmental Biology, Stanford University School of Medicine, Stanford, CA, USA; 5) KU Leuven, Medical Imaging Research Center, ESAT-PSI, Leuven, Belgium.

The nose is one of the most heritable regions in the face and its development is under strong genetic control. This is in line with the results of a recently published GWAS on facial morphology, where the majority of significant signals were associated with nasal shape. In this study, we took a deeper look into these previously described GWAS signals using multiple bio-informatics tools, in an attempt to gain insights into the biological role nominated genes might be playing during facial development. All significant and suggestive SNPs from GWAS ( $p < 5E-06$ ) associated with nasal morphology were selected and 208 genes surrounding these variants ( $\pm 500$  kb) were identified. First, a Genomic Regions Enrichment of Associations (GREAT) analysis was performed, showing strong significant enrichment for biological processes involved in cartilage and bone formation, and neural crest cell differentiation. Furthermore, these signals were significantly associated with abnormal nose morphology in mice and humans. Second, using recently published large-scale transcriptome data, we investigated the tissue specificity of the implicated genes during craniofacial morphogenesis. Indeed, 16 of the genes surrounding the GWAS hits were strongly enriched in one of the facial prominences, with 15 of these genes showing differential expression in either the frontonasal (50%) or the maxillofacial (44%) prominence. Furthermore, the majority of these genes (69%) were strongly enriched in the ectodermal tissue during development. Thirdly, the SysFACE tool was used to identify six genes from the list of candidate genes that were strongly enriched in the frontonasal tissue. Finally, a STRING analysis was done to investigate the protein-protein interactions among these six candidates, in an attempt to unravel their mechanism of action. Based on this analysis, four genes (*SOX9*, *RUNX2*, *SMAD7* and *TWIST1*) showed strong experimental evidence of protein interactions and co-expression. These results provide strong biological validation of signals observed from GWAS of facial morphology and help us to focus our efforts in follow-up functional testing.

**Locally dependent screening: Strategies for developing an accurate genomic predictor using big data.** *M. Sun, G. de los Campos.* Michigan State University, East Lansing.

Modern genomic data sets include hundreds of thousands (even millions) of SNPs. However, even for highly complex traits the number of SNPs that are associated to disease risk and can contribute to prediction accuracy is considerably smaller than the number of genotyped SNPs. Therefore, SNP screening/selection is a critical step when building DNA-risk assessments. The standard approach for building risk assessments selects SNPs using summary statistics from single marker regressions (SMR). This approach has low power to detect small-effect variants and, by ignoring linkage disequilibrium, leads to redundant SNPs-sets and high rates of false discovery. To confront this problem, we propose a screening procedure based on Local-Regularized-Regression (LRR) methodology. The approach exploits the 'local' nature of linkage disequilibrium and applies sparsity-inducing penalized regressions (e.g., Lasso) within overlapping chromosome segments of the genome, each covering several LD-blocks (e.g., all the SNPs in a 10Mb region). The scanning procedure can be parallelized (one task per chromosome segment) allowing scanning the whole genome in reasonable computing time, even for very large sample size. The LRR is fitted over values of the sparsity-inducing parameter; this regularization path renders subsets of "active SNPs" and provides a natural approach for variable selection. Using simulations (based on real genotypes from ~270K (K=1000) unrelated white Caucasian individuals of the UK-Biobank) we show that the proposed methodology has substantially higher power and much lower false discovery rate than SMR (the method predominantly used in GWAS). We applied the proposed methodology to data from the UK-Biobank to identify relevant SNP sets for several complex human traits, including height, body mass index, body composition, bone mineral density and blood-biomarkers. The SNPs identified were then used to build a predictive model. The prediction accuracy (R-sq.) achieved by SNPs selected using LRR was compared with that of SNP-sets selected using p-values from SMR. Our empirical results show that the proposed screening method always yields better predictors than selection based on summary statistics from SMR for sets including up to 10-20K SNPs. This result aligns well with the simulation results. The improvement in prediction R-sq. achieved with the proposed screening procedure reached up to 8 percentage-point in the R-squared scale (a 76% relative gain).

**Inbreeding effects on damaging homozygote loads in gene-sets associated with 543 complex phenotypes.** *A. Blant<sup>1</sup>, Z.A. Szpiech<sup>2</sup>, T.J. Pemberton<sup>1</sup>.* 1) University of Manitoba, Winnipeg, Manitoba, Canada; 2) University of California San Francisco.

Genomic regions of autozygosity (ROA) reflect homozygosity for haplotypes inherited identical-by-descent from an ancestor common to both parents. They vary widely in length, density, and genomic distribution at both the individual- and population-level, where longer ROA arise from recent parental relatedness as a result of inbreeding or limited mate choice, while shorter ROA arise from baseline linkage disequilibrium patterns. Over the past two decades, the study of ROA patterns has provided key insights into the demographic and sociocultural processes that have shaped genomic variation patterns in the human genome. We have previously shown that longer ROA are enriched for damaging allele homozygotes, and strongly damaging allele homozygotes in particular, while the degree of enrichment in individual genomes varies appreciably across worldwide populations. Here, we explore the rates-of-gain in damaging allele homozygotes with increasing ROA coverage in gene-sets associated with 543 complex diseases and traits (relative to genes not associated with Mendelian and complex diseases and traits) in whole genome sequences available for 2,436 individuals included in Phase 3 of The 1000 Genomes Project. We find that the rate-of-gain in damaging allele homozygotes with increasing ROA coverage differs significantly from the rate-of-gain in non-damaging homozygotes in gene-sets associated with complex diseases and traits; and the magnitude of this difference increases as a function of ROA length. Notably, over half of all gene-sets acquire damaging allele homozygotes in longer ROA at a rate that significantly outpaces that of non-damaging homozygotes. Comparisons of the rate-of-gain in damaging allele homozygotes between gene-sets associated with complex diseases/traits versus unassociated genes highlights the gene-sets that acquire damaging allele homozygotes at either significantly higher or lower rates than the rest; which emphasizes that such patterns can vary both as a function of ROA length as well as across worldwide populations. These findings highlight the influence of cultural and demographic processes on the shaping of genetic risk for complex diseases as well as how variation in complex traits can arise through pattern modification of functionally important genetic variation in a population-specific manner.

**2652W**

**Improving SNP-based gene expression prediction.** *D. Zhou, E. Gamazon, N. Cox.* Vanderbilt Genetic Institute, Nashville, TN.

PrediXcan, a powerful gene-based complex trait mapping approach, leverages genetically determined gene expression level and associates it with phenotypes. Gene expression prediction is a fundamental step of PrediXcan. Currently, the selection criterion of input SNPs for expression prediction is fixed, i.e. 1 Mb both sides of the gene body or TSS (only considered local SNPs). While we supposed that gene specific local (or cis) window size and other parameters will bring some improvement for expression prediction. In the current study, we tried to improve the gene expression prediction using different parameters to build the model. The local window size (100kb, 500kb, 1Mb, and 5Mb), with or without distal (or trans) variant, and the alpha value of the model (0.5 for elastic net and 1 for LASSO) are considered for model training. In order to test the performance, we cut the GTEx whole blood sample data into three parts (223 samples for each part). Firstly, we built 20 models with different combinations of parameters using the first part of the data. Then, the second part of the data was used to find the best model according to the highest  $r^2$ . Meanwhile, we constructed the regular prediction model using the first two parts of the data together. At last, we compared the performance of the prediction model with best combinations to the regular way based on the third data set. Results show that, in global, the performance is no difference between the gene specific and uniform method. It indicated that using the additional data did bring some information like the suitable window size, but the improvement would be pulled back by the sample size. We noticed that most of the genes showed improvement using specific parameters are benefit from smaller local window size. So we used a modified SNP selection criterion (100kb as local size and the rest of the genome as distal) without cutting down the sample size to find out if it is better than the regular way. The result showed that the  $r^2$  is significantly higher using smaller window size when we have less than 200 samples for model training. When the sample size is greater than 300, the performance is almost the same. This study indicated that using some part of the samples to find the suitable input SNP list will bring benefits for model training, but it will also pay the price of loss of power. Smaller local window size will reduce the noise when the sample size is limited in the training set.

**2653T**

**Discovering genetically correlated variants in genome-wide association studies with multiple traits.** *K. Collins<sup>1</sup>, E. Eskin<sup>1,2</sup>.* 1) Computer Science, University of California, Los Angeles, Los Angeles, CA; 2) Human Genetics, University of California, Los Angeles, Los Angeles, CA.

Genetic correlations estimated from Genome-Wide Association Studies (GWAS) have been reported for dozens of pairs of traits over the past few years demonstrating a shared genetic basis for traits. These results show that many traits share both the same causal variants and that the variant effect sizes are correlated. However, the vast majority of methods for discovering genetic associations examine only one trait at a time, and virtually all reported genetic association studies utilize this single trait approach. It is natural to assume that by combining more than one trait in the association analysis, there would be more power to identify genetically correlated variants. In this project, we assume that the effect sizes of traits follow the Fisher polygenic model and are correlated according to genetic correlation estimates obtained from GWAS. We introduce a method that uses a likelihood ratio for summary statistics, an approach shown to be the most statistically powerful hypothesis test for any level of significance. Under the null hypothesis, summary statistics are derived from a set of variants with no genetic effect; therefore, any deviation in the summary statistics from zero is fully attributed to environmental effects. In the alternative model, however, there is at least one non-zero genetic effect and the distribution is according to the Fisher polygenic model. Using the distribution of genetic effects as a conjugate prior results in the alternative model being normally distributed such that the variance is a sum of the environmental effect and genetic effect. This approach results in substantial power increase for simulations where we assume the effect sizes follow the model. We also show that our method has a more moderate power increase in many scenarios where the simulations deviate from the model. We apply our model on real data from the UK Biobank and show that utilizing multiple traits increases power for detecting variants that affect more than one trait. We also examine how real data differs from the Fisher polygenic model which can give insights into the shared genetic basis of traits and into future methods for discovering variants affecting multiple traits.

**2654F****The search for quantitative iris pigmentation markers using automation in genome-wide association studies: From phenotype to genotype.** *R. Eller<sup>1</sup>, G. Zhu<sup>2</sup>, N. Herrick<sup>1</sup>, A. Wollstein<sup>4</sup>, M. Kayser<sup>3</sup>, N. Martin<sup>2</sup>, S. Walsh<sup>1</sup>.*

1) Biology, Indiana University Purdue University – Indianapolis, Indianapolis, IN; 2) Epidemiology, QIMR Berghofer Medical Research Institute, Herston, Queensland; 3) Department of Genetic Identification, Erasmus MC University Medical Center, Rotterdam, The Netherlands; 4) Woodmark Consulting AG, Grasbrunn, Bayern, Deutschland.

Iris pigmentation has often been classified in a categorical fashion despite being a complex trait that takes on a range of appearances. Grouping iris color into light, intermediate, and dark colors has proven useful in early Genome Wide Association Studies (GWAS) to elucidate some of the major genes that affect iris pigment production. However, here we apply a phenotyping strategy that has been previously published by the group (Wollstein et al. 2017). This approach tries to explain more of the intricate details of iris content such as the percentage of pre-defined color classes to identify variants that have a smaller effect size, and those associated with the yellow pigment type pheomelanin. In addition to moving toward a more quantitative color phenotyping method, we looked at iris morphological traits including heterochromia with differing colors and the presence of a concentric distribution with a similar pigment. After performing preliminary GWAS using the more quantitative range of phenotypes, we found hits in several known pigmentation genes and encouraging signals for several novel loci associated with our quantitative color classes. Additional GWAS including replication will need to be performed, though preliminary findings suggest moving to a more quantitative approach will lead to the elucidation of lower penetrance variants that may have been missed in previous searches. While performing GWAS is a standard in the field, its power of detection is often limited by sample size and delayed by data preparation. Finding additional subjects to increase power will remain a logistical challenge, however cleaning genetic and phenotypic data can be automated. Therefore, we produced Odyssey, an autonomous genetic preparation pipeline that can quickly organize genetic data from arrays to clean, phase, impute, perform quality control, convert into formats accepted by genetic analysis tools such as PLINK, and assist in the setup of GWAS analyses. Thus, researchers can minimize the time it takes to prepare data and/or eliminate the outsourcing of data preparation. Using Odyssey to prepare our genetic data in tandem with our in-house eye quantifier program, which automatically quantifies each image pixel into select quantitative color classes, we substantially decreased the time it took to go from data to analyses without issue. This can be seen in the preliminary findings where published signals for iris color association were observed for many loci.

**2655W****GWAS of 92 neurology-focused plasma proteins reveals over one hundred novel loci.** *B.P. Prins<sup>1</sup>, P.G. Bronson<sup>2</sup>, J.E. Peters<sup>1</sup>, D. Sangurdekar<sup>2</sup>, J. Danesh<sup>1</sup>, K. Estrada<sup>2</sup>, S. John<sup>3</sup>, A.S. Butterworth<sup>1</sup>.*

1) MRC/BHF Cardiovascular Epidemiology Unit, Department of Public Health and Primary Care, University of Cambridge, 2 Worts' Causeway, Cambridge CB1 8RN, UK; 2) Statistical Genetics and Genetic Epidemiology, Biogen, Cambridge, MA, 02142, USA; 3) Translational Biology, Biogen, Cambridge, MA, 02142, USA.

Many neurological and psychiatric diseases are substantially heritable and are often highly polygenic. For many of these disorders GWAS analyses have highlighted regions that are likely to harbour genes that are causally involved in disease pathogenesis. Identification of the causal genes and their protein products (the intermediate effectors), might permit development of therapeutics targeting these pathways. Furthermore, genetic variants that specifically influence protein levels can be utilised as instrumental variables to infer causality using Mendelian randomisation analyses. However, to date only a handful of powerful proteome association studies have been performed. Here we performed a proteome association study on a set of 92 neurologically relevant proteins using the Olink Proseek Multiplex Neurology I proteomics panel in plasma from 4,662 healthy individuals from the INTERVAL cohort. We found 67 proteins associated with nearby proteins (cis associations) ( $P < 5 \times 10^{-8}$ ) for which most sentinel SNPs were in genes (85%) and also had trans associations ( $N=54$ ). Furthermore, 12 pQTLs were cis-only, and 15 were trans-only. 69/178 of significantly associated cis-variants were previously identified using the SOMAscan platform (Sun et al, 2018); direction of effect was correlated between the two studies ( $r^2=0.89$ ,  $P=3.1 \times 10^{-16}$ ). Several loci overlap with those associated with relevant disorders, such as bipolar disorder, schizophrenia, and Alzheimer's disease, helping to pinpoint the causal pathways at these loci. Additionally, several variants highly correlated with our sentinel SNPs appear to affect methylation levels in relevant tissues (frontal- and temporal cortex). Finally, Mendelian randomisation analyses suggest several potential novel candidate therapeutic targets. Taken together, these results provide insights into the identification and interpretation of targetable causal intermediates for a wide range of relevant diseases.

***Alu* variants can affect gene expression or splicing and contribute to disease risk.** L.M. Payer<sup>1</sup>, J.P. Steranka<sup>1</sup>, D. Ardeljan<sup>1</sup>, T.A. Cooper<sup>2</sup>, K.H. Burns<sup>1</sup>.

1) Johns Hopkins University, Baltimore, MD; 2) Baylor College of Medicine, Houston, TX.

*Alu* elements are the most common mobile DNA in the human genome and the most polymorphic. *de novo* insertions of *Alu* sequence are known to underlie some Mendelian disorders. A handful of polymorphic *Alu* have been suggested to elicit functional effects and contribute to common disease risk. However, the potential functional repertoire of *Alu* polymorphisms has not been fully evaluated. Recent studies have yielded catalogs of common *Alu* variants; we wanted to systematically identify functional *Alu* variants and test their potential contribution to disease risk. We first identified 809 previously published *Alu* variants in linkage disequilibrium (LD) blocks ( $r^2 > 0.8$ ) with GWAS (Genome-Wide Association Studies) signals, a significant enrichment of *Alu* variants at GWAS loci ( $p = 0.013$ , permutation test). We propose that a subset of these variants modulate disease risk. We prioritized 44 *Alu* variants in strong LD ( $r^2 > 0.8$ ) with a GWAS trait-associated SNP and sought to determine the mechanism by which they may alter gene regulation. We hypothesized that polymorphic *Alu* elements may alter transcript level or structure. To evaluate the first model, we used standard luciferase assays to test 44 *Alu* polymorphisms for their potential to alter transcript levels, including ~300 bp of their genomic context. We observe a continuum of effects. Most notably, 4 *Alu* displaying significant effects were associated with breast cancer risk. To validate, we modified (CRISPR) the endogenous sequences in HEK293T cells establishing isogenic lines varying only in the *Alu* genotype. Consistent with our luciferase assays, these data reveal modulation of transcript levels (RT-qPCR) of adjacent genes, including *RANBP9* and *MYC*. To address the second model, evaluating the disruptive potential of intronic *Alu* variants, we used a minigene reporter assay to measure exon incorporation. We tested 5 polymorphic *Alu* elements that map near exon-intron boundaries ( $\leq 100$  bp), of which 3 alter exon incorporation rates (Genes *SLC2A9*, *NUP160*, *CD58*). The latter is of particular interest due to its hypothesized role in multiple sclerosis (MS) risk. This *Alu* element promotes skipping of *CD58* exon 3 leading to a frameshift and predicted nonsense mediated decay, consistent with the reduced *CD58* expression associated with MS risk. Collectively, these data demonstrate that, as a class, polymorphic *Alu* elements commonly alter transcript levels and content, highlighting their potential contribution to disease risk.

**The NHGRI genome sequencing program.** T. Matisse, NHGRI Genome Sequencing Program. Genetics, Rutgers University, Piscataway, NJ.

The NHGRI Genome Sequencing Program (GSP; <http://gsp-hg.org>) uses genome sequencing to identify genes and genomic variants underlying the full spectrum of human inherited disease from Mendelian diseases to common, genetically complex diseases. The GSP comprises four components: The Centers for Mendelian Genomics (CMG; Baylor-Hopkins, Broad, U Washington, Yale) use whole exome sequencing and other genomic approaches to discover the genetic basis underlying as many Mendelian traits as possible and accelerate discoveries by disseminating the new knowledge and effective approaches, by reaching out to individual investigators, and by coordinating with other rare disease programs. The CMG have studied over 22.7K families and have discovered over 1.2K novel unique gene-phenotype associations and 400 cases with phenotypic features that expand those previously reported for a Mendelian condition. The Centers for Common Disease Genomics (CCDG; Baylor, Broad, New York Genome Center, Washington U) collaborate to comprehensively identify rare risk and protective variants that contribute to multiple common disease phenotypes. The CCDG aim to improve understanding of the general principles of genomic architecture, to understand how best to design rare variant studies for common disease, and to develop resources, informatics tools, innovative approaches, technologies. They have so far produced over 56K WGS and 46K WES (using equivalent pipelines) from samples from over 90 common disease cohorts focused on immune-mediated disease (asthma, inflammatory bowel disease, type I diabetes), cardiovascular disease (early onset coronary disease, atrial fibrillation, hemorrhagic stroke), and neuropsychiatric disease (Alzheimer disease, autism, epilepsy). Where consents allow, these data are also being used for haplotype imputation, genome annotation, population genetics studies, and as common controls. Three GSP Analysis Centers are developing improved and novel analyses and methods to maximize the value of the CMG and CCDG studies, with a focus on genome annotation. The GSP Coordinating Center provides scientific leadership and expertise for specific cross-program objectives and coordination for administrative, logistical, and outreach activities. The GSP shares raw and processed data, analysis results, and novel methods and analysis pipelines. These products are available through dbGaP, ClinVar, GeneMatcher, MyGene2, Matchmaker Exchange, ClinVar, gnomAD, Bravo, and GitHub.

**Large scale implementation of clinical preemptive pharmacogenomic testing: The Mayo-Baylor RIGHT10K project.** S.E. Scherer<sup>1</sup>, S.J. Bielinski<sup>2</sup>, X. Qin<sup>1</sup>, J.L. Black<sup>2</sup>, E. Venner<sup>1</sup>, C. Kovar<sup>1</sup>, J. Hu<sup>1</sup>, K. Walker<sup>1</sup>, V. Korchina<sup>1</sup>, A. Moyer<sup>2</sup>, T. McAllister<sup>2</sup>, L. Jones<sup>2</sup>, C.R.R. Vitek<sup>2</sup>, J. St. Sauver<sup>2</sup>, J.E. Olson<sup>2</sup>, M.E. Karow<sup>2</sup>, A. Staj<sup>2</sup>, M. Wiepert<sup>2</sup>, W.T. Nicholson<sup>2</sup>, E. Matey<sup>2</sup>, J. Wright<sup>2</sup>, J. Giri<sup>2</sup>, P. Caraballo<sup>2</sup>, R. Sharp<sup>2</sup>, T.B. Curry<sup>2</sup>, D. Muzny<sup>2</sup>, E. Boerwinkle<sup>1</sup>, L. Wang<sup>2</sup>, R. Gibbs<sup>1</sup>, R. Weinshilbaum<sup>2</sup>. 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Center for Individualized Medicine, Mayo Clinic, Rochester, MN.

A major opportunity for the application of genome technologies for individualized therapies is informing drug prescribing practices by sequencing and analysis of variants found in genes encoding proteins involved in drug transport, metabolism and elimination. The Human Genome Sequencing Center at Baylor College of Medicine and Mayo Clinic's Center for Individualized Medicine have collaborated to institute clinical pharmacogenomic sequencing of 10,085 research participants as part of Mayo's RIGHT Study. The capture sequencing panel targets 77 genes and 2140 SNPs of pharmacogenomic relevance. Participant sequence generation was performed in a CAP/CLIA environment with results returned for an initial list of 13 genes and associated variants that correspond to clinically actionable drug interactions. To further assess the participant's relevant HLA genotypes, we incorporated Omixon's *HLA Explore* software. For *CYP2D6*, bam files were analyzed via local software to identify novel variants, including novel copy number/structural variations, for further analysis. Discrete clinical genotype and phenotype results were entered into the electronic health record to be utilized by electronic clinical decision support tools to inform future prescribing events. An annotated test report with genomic results and phenotype descriptions as well as clinical recommendations offered by pharmacists for results deemed clinically actionable were also added to the EHR for immediate and future use by providers. Additionally, test results and the test report were made available to participants by mail and through an electronic health portal. To support the use of results, an education and communication strategy was implemented specifically targeting 849 providers and 39 pharmacists as well as a broader awareness initiative for providers and allied health staff. In consultation with the Mayo-CIM community advisory board, the annotated report format was modified to increase patient comprehension and facilitate appropriate clinical response. Preliminary results within the 13 gene subset suggest an actionable variant rate of greater than 90%, a novel variant discovery rate of 13%, and a *CYP2D6* reflex rate of 2.3%. Further analyses are underway, including economic and overall changes to drug prescribing practices. This project represents the first large-scale comprehensive effort of this type and provides a model for broader implementation of precision medicine applied to drug response.

**Improving drug discovery with PheWAS across >400,000 UK Biobank participants.** E. Wong<sup>1</sup>, D. Ficenc<sup>2</sup>, M. Sabripour<sup>1</sup>, D. Merberg<sup>1</sup>, B. Li<sup>1</sup>, Y. Ge<sup>1</sup>, S. Szalma<sup>1</sup>. 1) Data Science Institute, Takeda Pharmaceuticals, USA; 2) Information Technology, Takeda Pharmaceuticals, USA.

As high-quality phenotype data becomes available, there is increasing interest to conduct phenome-wide association study (PheWAS) using those data, which assesses the impact of one or more genetic variants across multiple phenotypes. PheWAS enables us to better understand the landscape of associations across human diseases and traits. This would help validate disease-target association reported previously, identify pleiotropy, and thus help drug development through elucidating mechanisms of action, suggesting alternative indication hypotheses and predicting adverse drug events. UK Biobank collects vast amounts of phenotype data through electronic health records, online questionnaires, imaging, blood biomarker measurements, actigraphy, etc. This provides valuable resources to characterize the complex relationship between human genome and phenome. We therefore conducted a PheWAS using genotype data and extensively curated phenotype data from >400,000 UK Biobank participants with Caucasian ancestry. Variants of interest were identified based on three major therapeutic areas – gastroenterology, neuroscience and oncology. The phenotype data was pre-processed and harmonized to streamline subsequent analyses. We performed the PheWAS with a Spark and Hail framework on Amazon Databricks. The framework can be extended to the full exome sequencing dataset from UK Biobank when the data becomes available.

**Over the past several years, genome-wide association studies (GWAS) have come of age with sample sizes reaching the hundreds of thousands, providing unprecedented statistical power for discovery. However, the majority of this progress has taken place in European descent populations, exacerbating pre-existing disparities in genomic knowledge. The Population Architecture using Genomics and Epidemiology (PAGE) Study was developed to address the lack of non-European descent groups in large-scale genetic studies, comprising ~50,000 individuals self-identified as African American, Hispanic/Latino, Native American, Native Hawaiian, and Asian. While the focus of PAGE has been on discovery, it is important to consider its value within the context of the current state of the field. We empirically assessed the value of multi-ethnic studies by examining discovery, fine-mapping, and replication trends. To directly compare study findings of height to our multi-ethnic PAGE results, we subset a random sample of 50k 'White British' from UK Biobank (UKB50k) and meta-analyzed each stratified GWAS with GIANT, an existing large-scale study of anthropometric traits in European descent individuals. While UKB50k+GIANT yielded more novel significant loci, these signals explained a smaller proportion of variance in PAGE, reflecting differences in allele frequencies (AF) and exacerbating inequity. To assess the impact of linkage disequilibrium (LD), we compared the ability to finemap top GIANT loci. The mean 95% credible set size decreased with the addition of PAGE to GIANT ( $P=0.01$ ), while there was no decrease with UKB50k+GIANT ( $P>0.05$ ). Building on the unique multi-ethnic dataset in PAGE, we then interrogated the role of genetic ancestry to predict replication of known GWAS loci from the NCBI/EBI GWAS catalog across 26 traits. While there was no homogeneous relationship between African, European, or Native American ancestry and replication, we found several trait-specific trends ( $P<0.05$ ), reflecting both heterogeneity in genetic architecture and biases in existing literature. To further explore the role of heterogeneous LD and AF, we characterize genetic correlation between groups within PAGE. Together, these trends demonstrate the importance of leveraging ancestral diversity for both discovery and refinement of GWAS signals, as well as directly addressing the disparity in genomic knowledge between populations and the unique opportunities provided by multi-ethnic studies..**

**ease-associated rare loss of function variation.** S.A. Gagliano<sup>1</sup>, W. Zhou<sup>1</sup>, D. Taliun<sup>2</sup>, J. Nielsen<sup>2</sup>, J. LeFaive<sup>1</sup>, R. Dey<sup>1</sup>, S. Das<sup>1</sup>, G.R. Abecasis<sup>1</sup>, *The NHLBI Trans-Omics for Precision Medicine (TOPMed) Program.* 1) Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI; 2) Division of Cardiovascular Medicine, Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, MI.

Loss of function (LoF) variants, such as those that introduce a premature stop codon or shift the reading frame for translation machinery, alter protein structure to the extent of eliminating or greatly diminishing protein action. This biological interpretability makes LoF variants a particularly important subset of genetic variation to study. To pinpoint disease-associated LoF, we imputed additional variants into the UK Biobank cohort of half a million genotyped individuals using 60,039 deeply whole genome sequenced individuals from the multi-ethnic TOPMed project. This allowed us to expand the number of genotyped or imputed variants characterized in the UK Biobank from 39,131,578 to 177,895,992. The vast majority (94%; 167,502,731) of the imputed variants are rare (alternate allele frequency  $<0.5\%$ ), of which 0.03% (49,892) are high-confidence predicted LoF. This dramatic increase in the number of variants in a large well-characterized cohort provides an ideal setting to assess the impact of LoF variation. To identify disease-associated LoF variants, we conducted single-variant and gene-burden association tests for  $>1,400$  binary traits constructed from health record billing codes. In the single-variant analyses, we identified five rare LoF variants with frequency  $<0.5\%$  (not found in the 39M dataset) to be associated with disease. This included two variants associated with breast cancer: a frameshift indel in *CHEK2* (chr22:28695868:AG:A; build38;  $p=7.0E-22$ ) and a SNP resulting in a gained stop in *PALB2* (chr16:23621362:C:T;  $p=6.9E-14$ ). Both are present in the ClinVar database as potentially pathogenic for familial breast cancer, but this is the first time these variants have been identified by GWAS, and characterized in a population of generally healthy adults. Beyond single variant analyses, we found significant burden signals in genes previously implicated in familial disease, but for which no LoF variants were significantly associated in the single-variant analyses. This included an association between *USH2A* LoF and hereditary retinal dystrophies, *IFT140* LoF and kidney cysts, and *BRCA2* LoF and breast cancer. We demonstrate that association studies in large-scale biobanks, even with a relatively small number of cases, are capable of yielding pathogenic findings that previously were only detected in clinical cases or difficult-to-collect family cohorts, in which it can be challenging to obtain robust associations.

Prior studies suggest that human induced pluripotent stem cell (hiPSC) lines suffer from genomic instabilities (e.g. karyotypic abnormalities, chromosomal aberrations). Within the NHLBI sponsored NextGen program hiPSC lines were generated by 9 consortia to study the complex genetics of metabolic, cardiovascular and respiratory diseases. The objective of this work is to assess the genomic integrity of the NextGen hiPSCs. Genomic integrity of 1,226 hiPSC lines generated from a range of sources (PBMCs, fibroblasts and lung epithelium) was compared to their matched donor DNA from blood/PBMCs leveraging 1.3 million genetic variants from the Illumina Multiethnic Genotyping (MEGA) array. We investigated two levels of integrity; genotype discordance between parent donor DNA and hiPSC lines and structural variability using copy number variants (CNVs). CNVs were called using the automated *VanillaICE* package, and then subsequently manually validated by visual examination of all plotted data. We observed low rates of genotype discordance with average rates of 0.01% between the donor and hiPSC lines. There was a mean of 8 deletions and 4 amplifications per hiPSC line. Manual inspection of these CNVs was performed to identify which of these were acquired in the hiPSC (observed in the hiPSC but not the donor DNA). We found 151 hiPSC lines acquired 266 CNVs relative to the parent donor DNA. Out of 151 hiPSC lines, 91 hiPSC lines had 1 CNV, 33 lines had 2 CNVs and 27 had  $\geq 3$  CNVs. These CNVs were generally small (83% were less than 1Mb in size) and included 152 deletions and 114 amplifications. The cumulative impact per hiPSC line was small; 85% showing less than 2 Mb of cumulative CNV coverage. We observed a previously reported amplification on Chr20q in 15 hiPSC lines and the overlap (chr20:29,810,887-30,412,182) across these lines is limited to 15 genes including known cancer loci *ID1*, *BCL2L1* and *TPX2*. In conclusion, a low level of genomic instability was observed in the NextGen hiPSC lines compared to prior reports. The highest number of CNVs were observed in lines generated from fibroblasts, but it should be noted that these lines were compared to genomic DNA from blood/PBMC sources and not donor fibroblasts. Our results substantiate the importance of systematic evaluation of genetic variations in hiPSCs prior to their use as disease models and confirm the preferential amplification previously reported on Chr20q within hiPSCs.

**Overexpression of *RUNX2* in mesenchymal stem cells derived from fused cranial sutures of individuals with metopic non-syndromic craniosynostosis.** K. Bala<sup>1</sup>, M. Barba<sup>2</sup>, L. Di Pietro<sup>2</sup>, W. Lattanzi<sup>2</sup>, A. Cuellar<sup>1</sup>, S. Boyadjev<sup>1</sup>: 1) Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento, CA; 2) Institute of Anatomy and Cell Biology, Università Cattolica S. Cuore, Rome, Italy.

Craniosynostosis is a genetic birth defect occurring in 3–5 per 10,000 live births; causing the premature fusion of one or more cranial sutures. It presents as a feature of over 200 syndromes, but approximately 80% of cases are non-syndromic (NCS). The development and maintenance of cranial sutures is dependent on the activity of osteoblasts and osteocytes, which are controlled by several regulatory factors including those involved in the bone morphogenic protein (BMP)/transforming growth factor beta (TGF $\beta$ ), fibroblast growth factor (FGF), hedgehog (HH), eph-ephrin, and Wnt signaling pathways. These pathways all converge on the same downstream effector Runt-related transcription factor 2 (*RUNX2*), a major regulator of osteogenesis. In 2013, Lattanzi et al demonstrated overexpression of *RUNX2* in cells derived from fused sutures when compared to those from open sutures, but focused on the role of LMP (a target of *RUNX2*). The fused suture samples were derived from sagittal, coronal, and metopic sutures. Metopic NCS (mNCS), occurs between 1/7,000 and 1/15,000 births. To focus on *RUNX2* expression in mNCS patients, calvarial tissue fragments were collected from sixteen patients undergoing cranial surgery. Mesenchymal stem cells were isolated from both open and fused sutures of the same individual and RNA was isolated from these cells. qPCR was performed on these 16 pairs of samples to measure *RUNX2* mRNA expression. To evaluate statistical significance, a paired t-test on  $\Delta$ CT values with a p-value cut-off of 0.05 was used. When comparing within each pair, *RUNX2* was significantly upregulated in 62.5% of the cells derived from the fused suture. When comparing all cells derived from the fused sutures to those from the open sutures, *RUNX2* was significantly upregulated in cells derived from the fused suture. Also, differential expression patterns for the different splice variants of the gene were found. *RUNX2* overexpression may cause accelerated differentiation of the mesenchymal stem cells present in the fused sutures, leading to the premature suture ossification.

**USF1 modulates chronotype and consolidates sleep.** *H.M. Ollila*<sup>1,2,3</sup>, *N. Sinnott-Armstrong*<sup>4</sup>, *K. Zitting*<sup>5</sup>, *T. Paunio*<sup>3</sup>, *R. Saxena*<sup>1</sup>, *T. Porkka-Heiskanen*<sup>6</sup>, *J.K. Pritchard*<sup>4</sup>. 1) Department of Medical Genetics, Massachusetts General Hospital, Boston USA; 2) Department of Psychiatry and Behavioral Sciences, Stanford University, Palo Alto CA, USA; 3) Institute for Molecular Medicine Finland, FIMM, University of Helsinki, Helsinki, Finland; 4) Department of Genetics, Stanford University, Stanford, CA 94305, USA; 5) Division of Sleep Medicine, Harvard Medical School, 221 Longwood Avenue, BLI438, Boston, MA, USA; 6) Department of Physiology, Faculty of Medicine, University of Helsinki Helsinki, Finland.

Timing and amount of sleep are controlled by a set of master regulators in the brain. *USF1* has been shown to modify sleep traits in mammals. Here we aimed to understand how *USF1* affects sleep. We show that *Usf1* knock-out mice have lower activity, frequent napping, extreme sleepiness and severe fragmentation of sleep. The sleep defects were compensated by increase in total sleep amount, which was specific for NREM sleep. To understand the effect on human sleep we then examined whether *USF1* transcription factors affect sleep traits in a sample of 453,000 European individuals from the UK Biobank. While modest association was seen at *USF1* locus itself ( $p=3.7E-7$  with insomnia), we saw a strong enrichment of *USF1* and *USF2* binding sites, which explained up to 20% of SNP-based heritability for morningness-eveningness, insomnia, excessive daytime sleepiness and napping ( $p$ -value  $< 0.0001$ ). These findings replicated the phenotypes seen with *Usf1* knock-out mice. Furthermore, 28 sites at *USF1* binding sites were both GWAS-significant for sleep traits and showed a statistically significant allele specific DNase directly on *USF1* binding site ( $p<0.05$ ) including an allele specific expression at *USF1* binding site near a key circadian pace maker *PER1* ( $p<0.05$ ). These findings suggest that *USF1* transcription factor is a crucial master regulator in shaping sleep. These effects of *USF1* are likely conveyed through small cumulative effects on a number of circadian downstream targets.

## 3250T

**Genetic associations between obesity and asthma: A genome-wide cross trait analysis of 450,000 individuals from UK Biobank.** Z. Zhu<sup>1,2</sup>, Y. Guo<sup>1</sup>, R. Pangniban<sup>3</sup>, W. Chung<sup>1</sup>, L. O'Connor<sup>1</sup>, B. Himes<sup>4</sup>, S. Gazal<sup>1</sup>, K. Hasegawa<sup>5</sup>, C. Camargo Jr.<sup>5</sup>, L. Qi<sup>6</sup>, M. Moffatt<sup>7</sup>, Q. Lu<sup>3</sup>, W. Cookson<sup>7</sup>, L. Liang<sup>1,8</sup>. 1) Epidemiology, Harvard University T H Chan School of Public Health, Boston, MA; 2) Environmental Health, Harvard University T H Chan School of Public Health, Boston, MA; 3) Program in Molecular and Integrative Physiological Sciences, Departments of Environmental Health and Genetics & Complex Diseases, Harvard T.H. Chan School of Public Health, Boston, MA; 4) Department of Biostatistics, Epidemiology and Informatics, University of Pennsylvania, Philadelphia, PA; 5) Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA; 6) Department of Epidemiology, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA; 7) Section of Genomic Medicine, National Heart and Lung Institute, London, UK; 8) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA.

Clinical and epidemiological studies showed that obesity and other metabolic disorders are associated with asthma. Recent observational studies suggest that these associations may differ by asthma phenotype. In the current study, we investigated the shared genetic components between metabolic traits and asthma, and specifically examined whether these shared genetic components differ among childhood-onset, later-onset, atopic and non-atopic asthma. We conducted a large-scale GWAS cross-trait analysis between asthma (childhood-onset, later-onset, atopic, and non-atopic asthma) and body mass index (BMI) in UK Biobank (N=459,306) and publically available GWAS data for 8 obesity related metabolic traits. We found a strong positive genetic correlation of obesity (evaluated by body mass index [BMI] and waist to hip ratio [WHR]) with later-onset asthma ( $r_g=0.25$ ,  $P=4.21 \times 10^{-22}$  for BMI; and  $r_g=0.23$ ,  $P=3.29 \times 10^{-10}$  for WHR), and non-atopic asthma ( $r_g=0.23$ ,  $P=1.32 \times 10^{-10}$  for BMI; and  $r_g=0.17$ ,  $P=5.03 \times 10^{-5}$  for WHR). Cross phenotype meta-analysis identified 11 independent loci that reached genome-wide level of significances ( $P_{meta} < 5 \times 10^{-8}$ ) for BMI and later-onset asthma, 9 loci for BMI and non-atopic asthma. Colocalization analysis found that most of these loci were colocalized between BMI and asthma either at a single causal variant or with different causal variants. Additionally, we found causal relationship between the association of BMI with later-onset asthma and eQTLs of 10 relevant GTEx tissues. Pathway analysis highlighted immune and antigen related pathways shared by BMI and asthma. Finally, we conducted RNA-seq gene expression experiment of lung tissues from two sets of obese mouse and identified 8 out of the 17 independent loci from GWAS analysis were enriched in mouse data. Our work identifies shared genetic components between specific types of obesity and asthma, and will help to advance our understanding of the molecular mechanisms underlying co-morbid obesity and asthma.

## 3251F

**Polygenic risk stratified by eQTL influence for obesity and related comorbidities for patients from the Geisinger MyCode Community Health Initiative.** M. Butkiewicz, S.A. Pendergrass. Department of Biomedical and Translational Informatics, Geisinger, Rockville, MD.

**Background:** Obesity is a major public health burden in the United States and is associated with other conditions, such as coronary artery disease, stroke, diabetes, and sleep apnea. There is substantial heritability of many obesity related comorbidities, and quantitative measures of genetic risk may be useful towards this end. Polygenic risk scores (PRS), in particular, can be calculated well before illness onset and have the potential for clinical use in health care. **Methods:** We used summary genetic association statistics for multiple obesity-comorbidity diagnoses available across individuals from the MyCode Community Health Initiative of Geisinger, and calculated PRS for 59,499 individuals of European-American ancestry from MyCode using all genetic variants with minor allele frequency > 1%. We also calculated PRS using the software PRSice (v2.1.2.beta) after filtering genetic variants only for those identified as expression quantitative trait loci (eQTLs) from The Genotype-Tissue Expression (GTEx) project. Next, associations between these PRS and comprehensive patient diagnoses were assessed using univariate logistic regression in a phenome-wide association study (PheWAS). Diagnoses were defined using 'phecodes': a hierarchical grouping of ICD-9 diagnostic codes. Cases for a given phecode had three or more relevant ICD-9 codes, and phecodes with 100 cases or fewer were excluded. Further, we created an obesity-based comorbidity network, linking obesity related ICD-9 codes to associated phecodes. **Results:** As expected, the obesity co-morbidity based PRS were associated with Type-1 ( $p < 1 \times 10^{-35}$ ) and Type-2 diabetes ( $p < 1 \times 10^{-10}$ ). However, when excluding SNPs that are eQTLs in the PRS calculations, we see an increase in statistical signal for obesity related PRS associations, like hypothyroidism (resultant  $p = 1 \times 10^{-7}$ ) as well as a selection of known severe diabetes related comorbidities, such as foot and leg ulcers (resultant  $p = 2 \times 10^{-6}$ ). The resulting network is an undirected graph representing disease traits as nodes and their associations as edges. **Discussion:** This study suggests a substantial difference in significance when using eQTLs for PRS calculation, showing the importance of filtering on functionally impactful SNPs. Next, we will investigate the impact of tissue specificity on PRS. In general, such scores could be applied in a hospital setting, elevating their potential for risk stratification efforts in the future.

## 3252W

**Genome-wide analyses of secondary outcomes with electronic health records.** C. Gao<sup>1</sup>, A. Li<sup>1</sup>, A. Marcketta<sup>1</sup>, B. Ye<sup>1</sup>, D. Carey<sup>2</sup>, D. Ledbetter<sup>2</sup>, M. Ritchie<sup>2</sup>, C. O'Dushlaine<sup>1</sup>, J. Overton<sup>1</sup>, J. Reid<sup>1</sup>, A. Baras<sup>1</sup>, A. Shuldiner<sup>1</sup>, T. Teslovich<sup>1</sup>, F. Dewey<sup>1</sup>, S. McCarthy<sup>1</sup>. 1) Regeneron Genetics Center, Tarrytown, NY; 2) Geisinger Health System, Danville, PA.

Many insights into the genetic risk of disease have been gleaned through genome-wide association studies (GWAS), shedding light on novel biological mechanisms and opening avenues for therapeutic development. By extending GWAS to longitudinal electronic health records (EHR), new questions about disease risk and therapeutic outcomes can be assessed e.g. what are the genetic risks for disease co-morbidities, are treatment side-effects predictable, and can existing drugs be repurposed? In this study, we aim to investigate the genetic basis of secondary outcomes (co-morbidities, side-effects, repurposing) in DiscovEHR. Exomes from 88,584 European individuals were analyzed for genetic factors that impact the risk of Coronary Artery Disease (CAD) in patients with Type 2 Diabetes (T2D) using two-degree-of-freedom (2DF) joint analysis, 1DF interaction tests and sample-stratified analyses. The genetic risk for CAD and effects on four serum lipids measures were evaluated given T2D status and serum glycated hemoglobin (HbA1C) as interaction variables. Overall, 505 variants from 184 genes were significantly associated ( $P < 5 \times 10^{-8}$ ) with serum lipid levels in 2DF joint test (156 variants and 47 genes located in HLA region). The E40K loss-of-function (LOF) variant (rs116843064) in Angiopoietin-like 4 (*ANGPTL4*) was strongly associated with reduced triglycerides (TG) and elevated high-density lipoprotein cholesterol (HDL-c) including potential interaction effects with HbA1C ( $P_{2DF\_TG} = 1.32 \times 10^{-31}$ ,  $P_{1DF\_TG} = 3.35 \times 10^{-03}$ ,  $P_{2DF\_HDL} = 1.59 \times 10^{-26}$ ,  $P_{1DF\_HDL} = 6.40 \times 10^{-04}$ ). On average, carriers of the LOF allele had 15.78mg/dl lower TG compared to non-carriers in the normal HbA1C group ( $\leq 5.6\%$ ). However, in the high HbA1C group ( $> 8\%$ ), the LOF allele had twice of the effect size (-37.56mg/dl per allele). Similar pattern was also observed for HDL-c (2.76mg/dl and 5.03mg/dl change per allele in normal and high HbA1C group, respectively). Consistently, a LOF variant (rs268) in the *ANGPTL4* target gene, lipoprotein lipase (*LPL*), also showed a moderate HbA1C dependent effect on TG and HDL ( $P_{1DF\_TG} = 3.54 \times 10^{-03}$ ,  $P_{1DF\_HDL} = 2.97 \times 10^{-02}$ ). In summary, exome-wide stratified and interaction analyses were performed and *ANGPTL4*-*LPL* pathway was identified as a potential target to reduce the risk of CAD in diabetics. Results from the secondary effect analysis may shed light on novel biological mechanisms underlying disease risk and inform drug discovery to develop medications for specific diseases complications.

**Effect of adiponectin level and genetic variation of *ADIPOQ* and *CDH13* on diabetic retinopathy.** W.L. Liao<sup>1,2</sup>, Y.C. Huang<sup>3,4</sup>, C.C. Chen<sup>2,5</sup>, Y.H. Chen<sup>1,6,7,8</sup>, Y.T. Chen<sup>9</sup>, C.M. Wu<sup>4</sup>, Y.W. Chang<sup>4</sup>, F.J. Tsai<sup>2,4,10</sup>. 1) Graduate Institute of Integrated Medicine, China Medical University, Taichung, Taiwan; 2) Center for Personalized Medicine, China Medical University Hospital, Taichung, Taiwan; 3) School of Chinese Medicine, China Medical University, Taichung, Taiwan; 4) Human Genetic Center, Department of Medical Research, China Medical University Hospital, China Medical University, Taichung, Taiwan; 5) Division of Endocrinology and Metabolism, Department of Medicine, China Medical University Hospital, Taichung, Taiwan; 6) Departments of Chinese Medicine, China Medical University Hospital, Taichung, Taiwan; 7) Chinese Medicine Research Center, Research Center for Chinese Medicine & Acupuncture, China Medical University, Taichung, Taiwan; 8) Department of Psychology, College of Medical and Health Science, Asia University, Taichung, Taiwan; 9) Graduate Institute of Food Safety, National Chung Hsing University, Taichung, Taiwan; 10) Division of Pediatrics Genetics, China Medical University Children's Hospital, Taichung, Taiwan.

**Background/Objective:** The effects of adiponectin (APN) level and related APN receptors on diabetic retinopathy (DR) have been raised but the results were not consistence. In present study, we investigate the association between the plasma ANP level and variations in APN-related genes, including *ADIPOQ* and *CDH13*, individually and in combination, and DR. We also investigated the effect of genetic polymorphism and epigenetic modification on the expression of APN receptors. **Subjects/Methods:** Type 2 diabetes (T2D) patients (N = 1,604), above 20 years of age in Taiwanese population. Demographic information was collected from questionnaires, and blood pressure and serological markers were measured at enrollment. Genomic DNA was isolated from blood and genotyping. The relative mRNA levels were measured by qPCR and the DNA methylation level was examined using methylation-specific PCR method. The plasma APN level was assessed by enzyme-linked immunosorbent assay. **Results:** T2D patients with DR (N = 632) had diabetes for a longer duration, and had higher HbA1c, and systolic and diastolic blood pressure compared to those without DR (N = 972) ( $P < 0.001$ , for all the parameters). Overall, 10 SNPs in *ADIPOQ* and *CDH13* susceptibility loci were associated with DR. Furthermore, the genetic risk score (GRS) was calculated based on these 10 SNPs for each subject and the cumulative effect of genes was observed. Among the subjects with plasma APN level (N = 518), *natural logarithm (LN)* [APN] [OR was 1.63 (95% C.I. = 1.19–2.25)] and GRS [ORs (95% CI) for those in the middle and high range of GRS were 1.90 (1.11–3.26) and 2.61 (1.48–4.59) compared to those in the bottom range of GRS, respectively] were independent risk factors for DR after adjustment for age, duration of diabetes, HbA1c, and SBP in multivariate logistic regression model. Compared to non-DR subjects in the lowest range of GRS, the mRNA levels of T cadherin which encoded by *CDH13* were higher in non-DR subjects with middle/high GRS, DR subjects with low GRS, and DR subjects with middle/high. **Conclusions:** The plasma APN level and the genetic variations in adiponectin receptors were associated with DR. And the higher expression mRNA level of T cadherin among DR subjects with high GRS was observed.

**Genome-transcriptome-wide association of renal and morphometric traits across glomerular and tubular tissues in diabetic Pima Native Americans.** A. Liu<sup>1</sup>, V. Nair<sup>1</sup>, R. Nelson<sup>2</sup>, R. Hanson<sup>2</sup>, H. Looker<sup>3</sup>, C. Boustany<sup>3</sup>, P. Guarnieri<sup>3</sup>, J. Hill<sup>3</sup>, M. Mauer<sup>4</sup>, M. Kretzler<sup>4</sup>, H.M. Kang<sup>1</sup>. 1) University of Michigan, Ann Arbor, MI; 2) National Institute of Diabetes and Digestive and Kidney Diseases, Phoenix, AZ; 3) Boehringer Ingelheim, Ridgefield, CT; 4) University of Minnesota, Minneapolis, MN.

Diabetic kidney disease (DKD) is a global health concern and a leading cause of chronic kidney disease (CKD) and end-stage kidney disease. Understanding the etiology of DKD is challenging due to the lack of high quality and population-scale omics data from glomerular and tubular tissues from persons with type 2 diabetes (T2D). We deeply sequenced genomes of 97 diabetic Pima Indians with >10 years of exposures to T2D and assayed their transcriptomic profiles (using expression arrays and/or RNA-seq) from micro-dissected kidney biopsies [NR([1] collected at two time points 7-10 years apart. We then performed systems genetic analysis with clinical and morphometric phenotypes. We detected and genotyped 10.2 million high quality genetic variants from WGS and performed eQTL association analysis with glomerular and tubular transcriptomic profiles using linear mixed models, after accounting for reference bias by removing variant-overlapping probes and correcting for systematic confounding factors using Singular Value Decomposition. We identified 2,018 eGenes that contain cis-eQTLs in at least one pair of biopsy-tissues, revealing numerous tissue-specific cis-eQTL genes, including *VPS33B* from glomerular tissue and *FERMT1* from tubular tissue. We identified 5-fold larger cis-eQTL genes with RNA-seq than with expression arrays. These eQTL variants are highly enriched for significant previously reported GWAS associations relevant to CKD and ESRD. We then developed and applied methods that integrate information from external transcriptome association studies (e.g. GTEx) into GWAS, providing further insights and combined p-values for top GWAS signals. Genome-wide and transcriptome-wide association analysis identified significant associations with clinically important kidney phenotypes, including albuminuria (urine albumin-creatinine ratio) and measured glomerular filtration rate (iothalamate). Associations with quantitative morphometric traits identified many significantly associated genes that are also implicated as clinically relevant from independent studies. [NR([1] Consider specifying the number of paired kidney biopsies here.

**Genome-wide association study identifies susceptibility loci for proliferative diabetic retinopathy in Africans.** C. Liu<sup>1,2</sup>, G.J. Chen<sup>1</sup>, A.R. Bentley<sup>1</sup>, D. Shriner<sup>1</sup>, A.P. Doumatey<sup>1</sup>, J. Zhou<sup>1</sup>, J.K. Yang<sup>2</sup>, A. Adeyemo<sup>2</sup>, C.N. Rotimi<sup>2</sup>. 1) Center for Research on Genomics and Global Health, National Human Genome Research Institute, Bethesda, MD. Bethesda, Maryland 20892 USA; 2) Beijing Key Laboratory of Diabetes Research and Care, Beijing Diabetes Institute, Beijing Tongren Hospital, Capital Medical University, Beijing 10730, China.

Proliferative diabetic retinopathy (PDR) is a sight-threatening complication of diabetes that is associated with longer duration of diabetes and poor glycemic control under a genetic susceptibility background. Although genome-wide association studies (GWAS) of PDR have been conducted in European and Asian ancestry individuals, none have been conducted in Africans, a population of interest given higher burden of undiagnosed and untreated type 2 diabetes (T2D), which may increase PDR risk. Here, we conduct a GWAS of PDR among Africans drawn from the AADM study. PDR cases (n = 44) were T2D patients with new vessel growth in the retina and/or retinal detachment. Controls (n = 138) were T2D patients without listed eye complications despite high risk (T2D duration ≥ 10 years and fasting blood glucose > 169 mg/dl; i.e., A1C > 7.5). Participants were genotyped on the MEGA array and imputation was performed using the African Genome Resources Panel through Sanger Imputation Service. EPACTs was used to perform association testing with adjustment for covariates (sex, age, and three significant PCs) and a random effect for cryptic relatedness. We identified 4 significant loci: *WDR72*, *TMEM132B*, *KLHL3*, and *AMFR*. The T allele for rs12906891 (*WDR72*) was associated with increased risk of PDR (freq = 0.08, p = 1.1 × 10<sup>-8</sup>, OR = 1.60, 95%CI [1.38, 1.84]); variants in this gene have been associated with glycemic control. At *TMEM132B*, the lowest p-value was for rs4073534 (T allele freq = 0.04; p = 2.6 × 10<sup>-8</sup>, OR = 0.48, 95%CI [0.38, 0.6]). *KLHL3* variant rs72800063 was associated with increased PDR risk (G allele freq = 0.03, p = 1.2 × 10<sup>-8</sup>, OR = 2.0, 95%CI [1.6, 2.5]); *KLHL3* is a known risk variant for hypertension, a condition that increases PDR risk. African ancestry-specific variant rs148177825 (*AMFR*) was associated with increased PDR risk (G allele freq = 0.03, p = 2.7 × 10<sup>-8</sup>, OR = 2.1, 95%CI [1.63, 2.69]). *AMFR* has been associated with traits relevant for PDR, including insulin resistance, vascular endothelial growth factor, hypoxia, and cell proliferation. Despite the small sample size, this first GWAS of PDR in Africans identified 4 susceptibility loci, perhaps reflecting our strict definition of controls to include only those at high risk but did not develop PDR, thus minimizing inclusion as controls those who would eventually progress to PDR. Known associations of these loci with relevant traits highlight expected pathways, including glycemic control, hypertension, and revascularization.

## 3256T

**Rare variants in *SLC5A10* are associated with serum 1,5-anhydroglucitol (1,5-AG) in the Atherosclerosis Risk in Communities (ARIC) Study.** S. Loomis<sup>1</sup>, A. Köttgen<sup>1,2</sup>, M. Li<sup>1,3</sup>, A. Tin<sup>1</sup>, J. Coresh<sup>1,4</sup>, E. Boerwinkle<sup>5</sup>, R. Gibbs<sup>6</sup>, D. Muzny<sup>6</sup>, J. Pankow<sup>7</sup>, E. Selvin<sup>1,4</sup>, P. Duggal<sup>1</sup>. 1) Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Institute of Genetic Epidemiology, Medical Center and Faculty of Medicine - University of Freiburg, Freiburg, Germany; 3) Division of Nephrology and Department of Human Genetics, University of Utah, Salt Lake City, Utah; 4) Welch Center for Prevention, Epidemiology, & Clinical Research, The Johns Hopkins University, Baltimore MD; 5) Department of Epidemiology, The University of Texas Health Science Center at Houston School of Public Health at Houston, Houston, TX; 6) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 7) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN.

**Introduction:** Serum 1,5-anhydroglucitol (1,5-AG) is a measure of hyperglycemic excursions that is available as a clinical test to aid monitoring of glycemic control in persons with diabetes. Recent genome-wide association studies (GWAS) have identified several 1,5-AG associated common variants. Rare genetic variants may have large effects on the concentrations of biomarkers that are in clinical use. The association between rare coding variants and 1,5-AG concentrations measured with a targeted assay of 1,5-AG was investigated in individuals of European and African ancestries. **Methods:** Whole exome sequencing association analysis was performed on 1,5-AG among European ancestry (N=6,589) and African ancestry (N=2,309) participants without diagnosed diabetes in the Atherosclerosis Risk in Communities (ARIC) Study. Both single variant and gene-based tests were conducted. **Results:** Five variants representing 3 independent signals on chromosome 17 in *SLC5A10* were associated with lower 1,5-AG levels of up to 10.38 µg/mL per allele (1,5-AG range 3.4-32.8 µg/mL). Two of these variants (rs61741107, p=8.85E-56, amino acid change: G>E; rs148178887, p=1.13E-36, amino acid change: N>I) with similar allele frequencies in the European (MAF=0.002 to 0.007) and African (MAF=0.0005 to 0.004) ancestry samples were rare, nonsynonymous, and predicted to be damaging or deleterious by multiple algorithms that predict deleteriousness. Taken together, these three signals explained 6% of the variance in 1,5-AG. Gene-based SKAT-O tests were significant for *SLC5A10* in the European ancestry (p=5.13x10<sup>-64</sup>) and validated in the African ancestry (p=0.006) samples. Significant common and low frequency variants were identified at five other loci in or near *MUC1*, *LCT*, *SI*, *MGAM*, and *SLC5A1* that also contain common 1,5-AG associated variants. **Conclusions:** Several rare, protein-altering variants in individuals of European ancestry were associated with 1,5-AG concentrations and were validated in an African ancestry sample. The large effect sizes for *SLC5A10* variants and similar allele frequencies across populations without diabetes, along with the multiple independent signals are evidence of the important impact of *SLC5A10* on serum 1,5-AG concentrations, and suggest *SLC5A10* may code for an important transporter of 1,5-AG in the kidney. This study helps to characterize the genetic architecture of 1,5-AG, an emerging diabetes biomarker, and may have implications for its clinical utility.

## 3257F

**Undiscovered novel polymorphisms in the SOWAHC-RGPD5 intergenic region on chromosome 2q are associated with diabetic retinopathy.** S. Y. Rhee<sup>1</sup>, J. Y. Lee<sup>2</sup>, D. W. Lee<sup>2</sup>, S. Chon<sup>1</sup>, J. T. Woo<sup>2</sup>, S. J. Kim<sup>2</sup>. 1) Endocrinology and Metabolism, Kyung Hee University School of Medicine, Seoul, Korea, Republic of; 2) Theragen Etx, Inc., Suwon, Korea, Republic of.

Diabetic retinopathy (DR) is a significant diabetic microvascular complication that causes visual disturbance and blindness in adults. We conducted a genome-wide association study of 426,593 single nucleotide polymorphisms (SNPs) in 1,456 subjects (741 cases and 715 controls). We followed up with an imputation analysis using approximately 6,198,263 SNPs and then validated the results with an independent cohort that included 974 subjects (553 cases and 421 controls). We identified significant genome-wide novel variants, such as imputed rs34229733 ( $P = 3.62 \times 10^{-9}$ ) and genotyped rs17197569 ( $P = 7.32 \times 10^{-6}$ ), in the intergenic region of *SOWAHC-RGPD5* (Sosondowah Ankyrin Repeat Domain Family Member C, RANBP2-Like and GRIP Domain Containing 5) on chromosome 2. Furthermore, we observed marginally associated rs17741348 and rs8077896 (*STX8*,  $P = 1.45 \times 10^{-7}$  and  $P = 4.40 \times 10^{-6}$ ), rs35774187 (*SASH1*,  $P = 2.52 \times 10^{-6}$ ), rs2734363 (*FHIT*,  $P = 9.56 \times 10^{-6}$ ), rs7730344 (*ANKRD31-HMGCR*,  $P = 9.66 \times 10^{-6}$ ), and 26 loci with statistical significance. Further imputation and validation analyses revealed that *AREL1* (rs9671386,  $P = 1.42 \times 10^{-5}$ ), *MED13L* (rs8181760,  $P = 4.52 \times 10^{-5}$ ), *PLCB1* (rs6108152,  $P = 1.36 \times 10^{-5}$ ), *SASH1* (rs35774187,  $P = 4.03 \times 10^{-5}$ ), and *SLC24A3* (rs6035258,  $P = 6.79 \times 10^{-5}$ ) were associated with DR. Moreover, after a comparison to previously reported genes, the matched SNPs did not show statistical significance; however, *GLIS1*, *MCPH1*, *PLXDC2*, and *VEGFA* were associated with DR. These findings suggest that genetic variation in the *SOWAHC-RGPD5* intergenic region plays an important role in the pathogenesis and development of severe DR, and may explain why some patients with type 2 diabetes are less susceptible to microvascular complications than patients with DR.

**Genome-wide association study of type 2 diabetes phenotypes in**

**Sāmoans.** *E.M. Russell<sup>1</sup>, J.C. Carlson<sup>1</sup>, N.L. Hawley<sup>2</sup>, G. Sun<sup>3</sup>, H. Cheng<sup>3</sup>, T. Naseri<sup>4</sup>, M. Sefuiva Reupena<sup>5</sup>, R. Deka<sup>6</sup>, D.E. Weeks<sup>1,6</sup>, S.T. McGarvey<sup>7,8</sup>, R.L. Minster<sup>1</sup>, TOPMed Diabetes Working Group.* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Epidemiology (Chronic Disease), School of Public Health, Yale University, New Haven, CT; 3) Department of Environmental Health, College of Medicine, University of Cincinnati, Cincinnati, OH; 4) Ministry of Health, Government of Samoa, Apia, Samoa; 5) Bureau of Statistics, Government of Samoa, Apia, Samoa; 6) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 7) International Health Institute, Department of Epidemiology, School of Public Health, Brown University, Providence, RI; 8) Department of Anthropology, Brown University, Providence, RI.

Type 2 diabetes (T2D) is prevalent in the Independent State of Sāmoa in Polynesia with an age-standardized prevalence of 22.7% for men and 26.6% for women. Unique genetic factors may exist that contribute to this high prevalence. In addition, the effect of genes on susceptibility to T2D can differ between obese and lean cases. The Sāmoan population is genetically isolated, making it a prime candidate for genetics studies. We used whole-genome sequence data generated through NHLBI's TOPMed Program for 1,195 Sāmoans to create a Sāmoan-specific reference panel to impute genotypes for an additional 1,897 Sāmoans. To identify genes and variants associated with T2D phenotypes, we completed genome-wide association studies (GWAS) of (1) T2D, (2) T2D in obese (Polynesian cutoff of BMI $\geq$ 32 kg/m<sup>2</sup>) and (3) T2D in non-obese with 9,609,170 sequenced and imputed variants, adjusting for age, sex, principal components of ancestry and empirical kinship (model 1). We also adjusted for BMI in model 2. In the T2D GWAS ( $n=478$  cases,  $n=2,389$  controls), a variant in a known T2D gene, *PPARG-C1A*, was genome-wide significant in both models 1 and 2 ( $p=1.30\times 10^{-9}$  and  $p=8.32\times 10^{-9}$ , respectively). This variant is common both in other TOPMed populations (minor allele frequency (MAF)=0.376) and in Sāmoans (MAF=0.250). In the non-obese T2D GWAS ( $n=148$  cases,  $n=1,119$  controls), variants in or near three BMI-associated genes were significantly associated with T2D in models 1 and 2 (in *ADAM23*,  $p=6.67\times 10^{-11}$  and  $p=2.08\times 10^{-11}$ , respectively; near *SATB2*,  $p=1.37\times 10^{-10}$  and  $p=6.68\times 10^{-10}$ ; and near *CREB1*,  $p=1.17\times 10^{-9}$  and  $p=7.02\times 10^{-10}$ ), and a variant in *MAP2*, which has not been previously associated with T2D or related traits, was genome-wide significant in models 1 and 2 ( $p=4.80\times 10^{-10}$  and  $p=5.22\times 10^{-11}$ , respectively). These four variants are common in other TOPMed populations (MAF:0.094–0.179), but rare in Sāmoans (MAF<0.009). In the obese T2D GWAS ( $n=330$  cases,  $n=1,270$  controls), no variants were genome-wide significant. However, a suggestive (model 1:  $p=5.38\times 10^{-6}$ ) variant near known BMI gene *TMEM182* is notable because this variant is rare in other TOPMed populations (MAF=0.0003), but common in Sāmoans (MAF=0.151). Additional exploration is necessary to further replicate these novel associations and characterize these variants. This highlights the importance of including diverse populations in genetics research to further characterize a map of disease-associated variation.

## 3259T

**Genome-wide association study identifies novel associations with serum cytokine levels in southwestern native americans.** *L.E. Wedekind<sup>1</sup>, M.F. Walter<sup>2</sup>, S. Kobes<sup>1</sup>, P. Chen<sup>1</sup>, W.C. Hsueh<sup>1</sup>, R.G. Nelson<sup>1</sup>, L.J. Baier<sup>1</sup>, W.C. Knowler<sup>1</sup>, R.L. Hanson<sup>1</sup>.* 1) National Institute of Diabetes and Digestive and Kidney Disorders; Phoenix, AZ; 2) National Institute of Diabetes and Digestive and Kidney Disorders; Bethesda, MD.

Circulating cytokine levels may reflect important molecular processes leading to type 2 diabetes, but there is limited information about genetic associations with levels of circulating cytokines. We performed a genome-wide association study (GWAS) of serum cytokine levels in 1061 non-diabetic Southwestern Native Americans (500 female; 561 male). We measured fasting levels of 6 traits—adiponectin, adipsin, amylin, glucose-dependent insulinotropic peptide (GIP), leptin and resistin—using EMD Millipore assays (Sigma-Aldrich, St Louis, MO). We conducted a GWAS involving 496,190 single-nucleotide polymorphisms (SNPs) with minor allele frequency >1% on a custom Axiom array designed to capture common variation in Pima Indians (Affymetrix, Santa Clara, CA). Imputation was performed based on whole-genome sequence data from 266 Pima Indians; a total of 4.8M variants were analyzed. Data were normalized by inverse Gaussian transformation and analyzed for association using a mixed model accounting for familial relationships; adjusted for age, sex and genetic principal components 1-5. A genomic control procedure was performed to account for residual population stratification. The strongest genetic associations with respect to serum levels of each trait were as follows: adiponectin with rs188692736 near *KDR* on chromosome 4 ( $\beta=0.32$  SD per copy of the A allele,  $p=6.21\times 10^{-7}$ ), adipsin with rs146930006 near *LOC105372762* on chromosome 21 ( $\beta=0.26$  SD per G allele,  $p=1.47\times 10^{-6}$ ), amylin with rs117681391 in *LINC00290* on chromosome 4 ( $\beta=0.53$  SD,  $p=2.05\times 10^{-6}$ ), GIP with rs1975618 in *MCPH1* on chromosome 8 ( $\beta=0.22$  SD per A allele,  $p=1.03\times 10^{-6}$ ), leptin with rs61801876 on chromosome 1 ( $p=1.08\times 10^{-6}$ ), and resistin with rs190461045 in *B3GALT1* on chromosome 2 ( $\beta=0.30$  SD,  $p=1.60\times 10^{-6}$ ). In summary, these studies have identified several variants with suggestive genetic associations with each of six different cytokine levels. For some of these variants minor allele frequencies are low for populations outside of Native Americans—suggesting possibly unique signals. These associations need to be confirmed in additional cohorts, but may yield important information about molecular processes contributing to complex traits.

**3260F**

**Rare variation in and near *CREBRF* and association with fasting glucose in non-Polynesian participants in the TOPMed Program.** R.L. Minster<sup>1</sup>, E.M. Russell<sup>1</sup>, N.L. Hawley<sup>2</sup>, G. Sun<sup>3</sup>, H. Cheng<sup>3</sup>, T. Naseri<sup>4</sup>, M.S. Reupena<sup>5</sup>, R. Deka<sup>3</sup>, D.E. Weeks<sup>1,6</sup>, S.T. McGarvey<sup>7,8</sup>, TOPMed Diabetes Working Group. 1) Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 2) Epidemiology (Chronic Disease), School of Public Health, Yale University, New Haven, CT, USA; 3) Environmental Health, College of Medicine, University of Cincinnati, Cincinnati, OH, USA; 4) Ministry of Health, Government of Samoa, Apia, Samoa; 5) Bureau of Statistics, Government of Samoa, Apia, Samoa; 6) Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 7) International Health Institute, Epidemiology, School of Public Health, Brown University, Providence, RI, USA; 8) Anthropology, Brown University, Providence, RI, USA.

The minor allele of rs373863828, a missense variant in *CREBRF*, has been associated with lower fasting glucose (FG) in Samoans. This variant is common in Polynesians (reported minor allele frequency [MAF] range: 0.096–0.259) but very rare in non-Polynesian populations (MAF < 0.001). Other variation in the region may affect FG in other populations. We explore here whether rare variation in the *CREBRF* region is associated with FG in non-Polynesians in NHLBI's TOPMed Program. We used whole-genome sequencing data from 11 TOPMed studies with reported FG and excluded individuals with type 2 diabetes. We divided the sample into four groups based on self-reported ancestry (African,  $n = 6,551$ ; Asian,  $n = 2,309$ ; European,  $n = 18,013$ ; and Hispanic,  $n = 1,054$ ). We used SKAT-O to test rare variation for association with FG, adjusting for age, sex, BMI, and ancestry. We selected rare SNPs in the *CREBRF* region (gene boundaries  $\pm 50$  bp) with a TOPMed-wide minor allele count  $\leq 10$ . Within each ancestry group, we excluded SNPs with a MAF > 0.05. First, we used a sliding window approach covering the region with 41 windows (4 kbp with 2 kbp overlap) with 28 to 348 variants per window and a median of 106. We set a conservative significance threshold of  $p < 6 \times 10^{-4}$  based on the number of non-overlapping windows and ancestry groups ( $0.05 / (21 \times 4)$ ). We found a significant association between a European window of 263 variants and FG ( $p = 2.9 \times 10^{-4}$ ). The window comprises the last 3.3 kbp of intron 8 and the first 0.7 kbp of exon 9, including the stop codon. However, we did not see significant evidence of association in other ancestries, and the location of the peak association was not consistent between ancestry groups (African:  $p = 0.014$ , 185 variants; Asian:  $p = 0.023$ , 76 variants; Hispanic:  $p = 1.7 \times 10^{-3}$ , 62 variants). Second, we completed a gene-based analysis of the same *CREBRF* region. Our significance threshold was  $p < 0.013$  given the number of ancestry groups tested ( $0.05 / 4$ ). In this analysis, we did not see significant evidence of association of *CREBRF* with FG in any ancestry (African:  $p = 0.097$ , 3,319 variants; Asian:  $p = 0.261$ , 1,671 variants; European:  $p = 0.027$ , 4,643 variants; Hispanic:  $p = 0.018$ , 1,336 variants). These results suggest that rare variation in the *CREBRF* region could be affecting the variance of FG in Europeans. It is possible that with more power association between rare variation and FG could be detected in other ancestries.

**3261W**

**Rare variants explain a substantial portion of the missing heritability of the uric acid level.** K. Misawa<sup>1,2</sup>, E. Mishima<sup>3</sup>, M. Ouchi<sup>4</sup>, T. Hasegawa<sup>5</sup>, K. Kojima<sup>1,2</sup>, Y. Kawai<sup>6</sup>, M. Nagasaki<sup>1,2</sup>, N. Anzai<sup>7</sup>, T. Abe<sup>8</sup>, M. Yamamoto<sup>1,2</sup>. 1) Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 2) Graduate School of Medicine, Tohoku University, Sendai, Miyagi, Japan; 3) Division of Nephrology, Endocrinology and Vascular Medicine, Tohoku University Hospital, Sendai, Miyagi, Japan; 4) Department of Pharmacology and Toxicology, Dokkyo Medical University School of Medicine, Tochigi, Japan; 5) The Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 6) Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 7) Department of Pharmacology, Chiba University Graduate School of Medicine, Chiba, Japan.

Gout is one of the most common inflammatory arthritides, caused by hyperuricemia. Hyperuricemia is an abnormally high level of uric acid in the blood. The prevalence of hyperuricemia in Japanese adult men is estimated to be nearly 30%. A twin study showed that the heritability of urate levels is estimated to be approximately 60%. However, the proportion of variance in urate levels explained by common genetic variants detected in the previous GWAS was about 6.0%, accounting for only a small proportion of the genetic component. This problem has been known as the "missing heritability". In this study, we focused on the rare variants as the causes of the missing heritability of SUL. We compared the serum uric acid level (SUL) of 2,049 participants of ToMMo cohort study to their whole genome sequences. By using SKAT, we detected one transporter gene whose rare variants might be associated with SUL. Then we conducted the functional analyses the variants identified the rare-variant analysis experimentally on splicing by using Human Embryonic Kidney cells 293 (HEK293) as well as on uric acid uptake by using the *Xenopus* oocytes. These experimental studies showed that the rare variants are affecting on urate uptake. We estimated the effects of the rare variants found in this study on SUL by using the regression analyses that include age, gender, BMI, drug, and food intake as covariates of SUL. We also used eGFR as the measure of the level of kidney function and HbA1s as the measure of diabetic status. The regression analyses showed that they account for more than 10% of the variation of SUL. The result suggests that rare variants explain a substantial portion of the missing heritability of the uric acid level.

**Replicating type 2 diabetes GWAS results using self-reported data.** A. Annis, A. Pandit, S. Gagliano, G. Abecasis. University of Michigan, Ann Arbor, MI.

The efficacy of physician- vs. self-diagnosed phenotypes in GWAS is disputable, particularly for Type 2 Diabetes (T2D) where much of the affected population is undiagnosed. Some researchers fear that self-diagnosis leads to underreporting and failure to replicate associated SNPs, while others hold that self-diagnosis is an effective means of data collection. We address this issue by comparing T2D GWAS results from a primarily physician-diagnosed meta-analysis (DIAGRAM) with results from a smaller, self-reported dataset (Genes for Good). DIAGRAM's most recent publication, Mahajan et al (2018), gives a meta-analysis of 74,124 T2D cases and 824,006 controls, largely drawn from physician-diagnosed studies. Genes for Good (GfG), a University of Michigan study, relies on questionnaires administered through a social-media-based web application to gather individuals' self-reported phenotypes. GfG currently has 848 self-reported T2D cases and 16,898 controls. We identified the ten most strongly associated independent SNPs from DIAGRAM's (BMI-unadjusted) GWAS and then found the same SNPs in the GfG dataset for comparison. For our analysis, we first used the online GAS Power Calculator to find GfG's statistical power for replicating the DIAGRAM associations at a 0.05 significance level. We then compared p-values, odds ratios (ORs), and confidence intervals (CIs) from DIAGRAM with those calculated in GfG at the same SNPs. Using DIAGRAM's disease prevalence (10%), disease allele frequencies, and genotype relative risks, we found that GfG averaged 45% power for replicating the DIAGRAM associations at the 0.05 significance level. Five of these 10 SNPs had p-values below the 0.05 significance level in GfG, which is consistent with our power calculation. We also found all ten effect sizes in GfG and DIAGRAM to have consistent direction, and nine out of the ten ORs from DIAGRAM fell within the GfG CIs. As we would expect our CIs to contain the true effect size 95% of the time, our results coincide with our expectations. The consistency of our GfG findings with the DIAGRAM results suggests that self-reported T2D diagnoses are an effective means of collecting data for GWAS. Although GfG remains underpowered due to sample size, we were able to replicate five of the ten associations identified in the much larger DIAGRAM meta-analysis. This shows that GWAS with self-reported data has potential to produce meaningful results and contribute to our understanding of human genetics.

Body mass index (BMI), a commonly used estimate of obesity, is highly heritable and a leading risk factor for type 2 diabetes, cardiovascular disease, some cancers, and premature death. Genome-wide association studies (GWAS) have identified many genetic variants that influence BMI mostly in populations of European descent, but only a few loci have been established in populations of African ancestry. We performed a large GWAS of BMI in up to 98,277 individuals of African ancestry. The discovery GWAS of BMI was conducted among 55,525 non-Hispanic African American participants in the Million Veteran Program (MVP) with over 47 million 1000 Genome phase 3 imputed SNPs. BMI-associated SNPs ( $p < 5 \times 10^{-8}$ ) from the MVP were replicated among 42,752 participants from the African Ancestry Anthropometry Genetics Consortium (AAAGC). Genome-wide significant ( $p < 5 \times 10^{-8}$ ) SNPs were identified in a fixed effect meta-analysis combining all participants from the MVP and the AAAGC, followed by functional annotation and bioinformatic analyses. In the phenome-wide association study (PheWAS), two BMI-polygenic risk scores (PRS) were developed based on: 1. Ten variants from established BMI loci of African ancestry by the AAAGC; 2. 100 variants from 41 BMI loci identified by current meta-analysis. We tested associations of BMI-PRS with >1,800 ICD-9 diagnosis codes from 16 disease groups among non-Hispanic African American participants in the MVP. Among 19 BMI loci identified in the MVP, 12 were replicated in the AAAGC (consistent direction and  $p < 0.05$ ). In the combined meta-analysis, 985 SNPs from 41 loci reached genome-wide significance, of which 63 SNPs were analyzed only in the MVP. By comparing to all previous GWAS findings from populations of European or African ancestry, 10 loci were novel (distance to lead SNP of published loci >500 kb). Genes mapped by the novel BMI loci include *MOB1B*, *KCNQ5*, *SMCR5* and *CCDC85A*. PheWAS using established BMI loci from AAAGC identified associations with type 2 diabetes and heart disease, while the expanded BMI-PRS identified further associations with sleep apnea and orthopnea. Using the largest sample of African ancestry, we identified 41 BMI loci, including 10 novel loci not reported in previous GWAS in populations predominantly of European ancestry. PheWAS of BMI-PRS can explore novel associations between BMI and disease outcomes, and generate hypotheses for causal role of BMI for testing in future Mendelian Randomization analysis.

**Evidence for bidirectionally-causal relationships between dental disease and metabolic health.** S. Haworth<sup>1</sup>, I. Johansson<sup>2</sup>, P.W. Franks<sup>3,4,5</sup>, E. Ingelsson<sup>6,7</sup>, N.J. Timpson<sup>1</sup>, *GLIDE consortium*. 1) MRC Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom; 2) Department of Odontology, Umeå University, Umeå, Sweden; 3) Department of Clinical Sciences, Genetic and Molecular Epidemiology Unit, Lund University, Malmö, Sweden; 4) Department of Public Health and Clinical Medicine, Umeå University, Umeå, Sweden; 5) Department of Nutrition, Harvard T. H. Chan School of Public Health, Boston, MA; 6) Department of Medicine, Stanford University School of Medicine, Stanford, CA; 7) Stanford Cardiovascular Institute, Stanford University, Stanford, CA.

**Background.** Dental caries and periodontal disease are associated with many systemic diseases in epidemiological studies, potentially through metabolic effects. It has been argued that dental diseases increase risk of systemic metabolic disturbances through systemic spread of oral bacteria or inflammatory by-products. Conversely, it is also believed that systemic metabolic changes affect homeostasis of the oral environment, leading to increased risk of dental disease. Recent analysis within the Gene Lifestyle Interactions and Dental Endpoints (GLIDE) consortium identified genetic correlation between dental disease and metabolic health traits. The aim of the study was to test these relationships for causal effects. **Methods.** All analyses were undertaken using generalized summary Mendelian randomization (GSMR), implemented in GCTA. HEIDI-outlier analysis was used to assess for horizontal pleiotropy. Summary statistics for 6 metabolic disease traits were taken from published consortia. Summary statistics for dental disease (n=487,898) were taken from combined analysis of a dental disease index in GLIDE and a dental disease proxy endpoint in UK Biobank (dentures). **Results.** In GSMR analyses, dental disease was seen to have bidirectional causal relationships with metabolic traits. Dental disease increased risk of type 2 diabetes (OR 1.37 per 20 diseased tooth surfaces, p=0.00086), increased body mass index (BMI, p=1.4e-12) and decreased HDL-cholesterol (p=2.2e-05). In reciprocal analysis, metabolic traits were seen to influence dental disease. Each 1 mM increase in fasting glucose resulted in approximately 1.2 additional diseased tooth surfaces (p=0.012) and increasing BMI also had detrimental effects on dental disease (p=6.5e-11). There was evidence for pleiotropic genetic effects. **Discussion.** This study supports prior observational studies and clinical belief that dental and metabolic disease are closely intertwined, through a combination of forward-causal, reverse-causal and pleiotropic mechanisms. Analyses are therefore planned to characterize these relationships further and investigate whether dental diseases causally influence health outcomes including cardiovascular disease endpoints.

**Mendelian randomization analysis provides evidence for a casual role of serum triglyceride leads to increased glycated hemoglobin in the population of Taiwan.** C. Hsiung, C. Lin, C. Chang, C. Shen. Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

The relationships between elevated circulating triglyceride (TG) levels and elevated glucose level/HbA1c/type 2 diabetes (T2D) have been reported in many studies. However, the causal relationship of these associations is ambiguous. This is because complex interactions among fat, muscle, liver, pancreas, and the intestine. Furthermore, these interactions may not be the same among populations because differences in diet, dietary habits, and more importantly genetic predisposition. Mechanistically, both sides of relationships are possible. To clarify this relationship, we used a Mendelian randomization (MR) analysis to test the hypothesis that elevated circulating TG levels causally results in elevated circulating HbA1c level. To employ a two-sample MR approach, we used summary results from GWAS catalog database, and seven SNPs reaching the GWAS significant ( $P < 5 \times 10^{-8}$ ) specially in East-Asian population, being genomically independent to each other, and without pleiotropic effect were selected as instrumental variable (IV) to represent TG. We used Taiwan Biobank database in order to identify the casual effects between serum TG and HbA1c in the population of Taiwan. The Taiwan biobank database has completed whole-genome genotyping typing in more than 16,000 individuals. Associations using the MR estimate and the MR-inverse variance weighted method analysis show a unit increase in TG (measured by a log-transformed unit, mg/dl) was associated with a significant increase of 10.86 units of HbA1c (indicated by the beta value of regression model, 95% CI, 1.16-20.56;  $P=0.028$ ). Sensitivity analysis, including MR-egger regression and the weighted-median approach provides no evidence to pleiotropic effect of IV. To confirm our results, we performed bidirectional MR analysis. Our results show that the genetic determinants of HbA1c don't contribute to TG, suggested by a non-significant beta value. (beta: 1.75, 95% CI: -11.50-14.90). These results suggest that elevated circulating triglyceride level causally affects circulating elevated level of glycated hemoglobin.

**Non-alcoholic Fatty Liver Disease (NAFLD) increases risk for Type 2 Diabetes (T2D) but decreases susceptibility to obesity: A Mendelian randomization study.** Z. Liu<sup>1</sup>, R. Pique-Regi<sup>2,3</sup>, W. Liu<sup>1,4,5,6</sup>. 1) Department of Medicinal Chemistry and Molecular Pharmacology, College of Pharmacy, Purdue University, West Lafayette, IN; 2) Center for Molecular Medicine and Genetics, School of Medicine, Wayne State University, 540 E. Canfield, Detroit, MI; 3) Department of Obstetrics and Gynecology, School of Medicine, Wayne State University, Detroit, MI; 4) Department of Pharmaceutical Sciences, Eugene Applebaum College of Pharmacy and Health Sciences, Wayne State University, Detroit, MI; 5) Department of Pharmacology, School of Medicine, Wayne State University, Detroit, MI; 6) Integrative Biosciences Center, Detroit, MI.

**Background** Non-alcoholic fatty liver disease (NAFLD) is highly correlated with type 2 diabetes (T2D) and obesity in many observational studies. However, the causal relationship between them has not been completely investigated yet. **Aim** We aim to test whether genetic factors conferring risks to NAFLD increase the susceptibility to T2D and obesity. **Design** Two-sample Mendelian Randomization using published data **Methods** The genome-wide associated variants for computerized tomography (CT) measured hepatic steatosis were searched in a meta-analysis of 7,176 individuals of European descent from the GOLD (Genetics of Obesity-related Liver Disease) consortium. We considered two of the top associated variants, *PNPLA3* rs738409 and *NCAN* rs2228603, and tested their associations with T2D and Obesity in individuals from the DIAGRAM (Diabetes Genetics Replication And Meta-analysis) consortium, MAGIC (the Meta-Analyses of Glucose and Insulin-related traits) consortium, and the Genetic Investigation of Anthropometric Traits (GIANT) consortium. We conducted the two-sample MR analysis using each of the two variants as instrumental variable (IV). We also performed the MR analysis using the combined effects of the two variants and compared the results. **Results** MR analysis using either *PNPLA3* rs738409 or *NCAN* rs2228603 as instrumental variable gave similar results. In a cohort consists of 12,171 T2D cases and 56,862 controls of European descent, we found that genetically instrumented NAFLD was significantly associated with a higher risk of T2D (odds ratio [OR] per 1-SD higher fatty liver, 1.29, 95%CI [1.12, 1.49],  $p = 0.001$ ). Statistically significant associations were also found for genetically instrumented hepatic steatosis and increased insulin resistance ( $p = 0.016$ ), fasting glucose ( $p = 0.027$ ) and fasting insulin ( $p = 0.02$ ) levels. With regards to the relationship between NAFLD and obesity, surprisingly, we also found a moderate, but significant correlation between genetically increased hepatic steatosis and decreased BMI ( $b = -0.046$  kg/m<sup>2</sup>, 95%CI [-0.078, -0.014] kg/m<sup>2</sup>,  $p = 0.005$ ) in a cohort consists of 209,895 individuals of European descent. Similar negative relationship ( $b = -0.028$  kg/m<sup>2</sup>, 95%CI [-0.046, -0.011] kg/m<sup>2</sup>,  $p = 0.002$ ) was estimated using another sample of GWAS for BMI with a larger sample size of 420,805 participants. **Conclusion** Lifelong, genetically contributed NAFLD is a causal risk factor of T2D, but plays a protective role for obesity.

**The human gut microbiome and obesity – causal or confounded companionship?** K.H. Wade<sup>1</sup>, D. Hughes<sup>1</sup>, L. Corbin<sup>1</sup>, J. Wang<sup>2</sup>, R. Bacigalupe<sup>3</sup>, N.J. Timpson<sup>1</sup>, J. Raes<sup>3</sup>. 1) MRC Integrative Epidemiology Unit, Population Health Sciences, Bristol Medical School, Bristol, United Kingdom, BS8 2BN; 2) Institute of Microbiology, Chinese Academy of Sciences, Chaoyang District, Beijing, 100101; 3) VIB-KU Leuven Center for Microbiology, Gasthuisberg Campus, Rega Instituut, 3000 Leuven.

Despite the exceptional growth in studies implicating the gut microbiome in health, there has been very little causal assessment within humans. We aimed to assess causality in the association between gut microbial taxa abundance and body mass index (BMI) using bi-directional, two-sample Mendelian randomization (MR). This work is based on data from the Flemish Gut Flora Project (FGFP), a population-level microbiome collection in Flanders, Belgium (primary analysis, N=2259). Microbiome phylogenetic profiling was characterised with 16S ribosomal RNA gene amplicon sequencing of the V4 hypervariable region. Given the equilibrated range of age, sex, health and lifestyle, FGFP is likely to represent the average gut microbiota composition in a Western European population. Observational associations between BMI and microbial taxa abundance were assessed using Spearman's correlation. Of the microbial taxa with evidence supporting an observational relationship, MR analyses were conducted to assess causality in a bi-directional framework. For MR analyses assessing the impact of the microbiome on BMI, the best proxies for specific bacterial taxa were obtained from the genome-wide association study (GWAS) of the rank-normalised raw counts of microbial taxa abundance conducted in FGFP. For MR analyses assessing the reverse direction (i.e., impact of BMI on the microbiome), 97 genetic variants robustly associated with BMI from the GIANT GWAS were used as instruments. All analyses were conducted using the MR-Base platform ([www.mrbase.org](http://www.mrbase.org)), a large-scale database of GWAS summary-level data, enabling automated and efficient MR analyses. The inverse-variance weighted (IVW), weighted median, weighted mode and MR-Egger methods were applied. Observational analyses provided evidence that multiple taxa were correlated with BMI to a varying degree (range of correlation coefficients=-0.16, 0.14;  $P < 1 \times 10^{-06}$ ). Follow-up MR analyses provided evidence that a higher abundance of certain microbial taxa may influence BMI (e.g., maximum effect=-0.02kg/m<sup>2</sup>;  $P=0.05$  per SD higher level of count-derived abundance). In contrast, greater BMI may lead to a variation in the count-derived abundance of gut microbial taxa (e.g., maximum effect=0.33SD;  $P=0.02$  per kg/m<sup>2</sup> higher BMI). Refinement of the current GWAS of microbiome taxa abundance within the FGFP and consortium expansion will allow systematic MR analyses to improve causal inference within the relationship between the human gut microbiome and BMI.

**3268T**

**Modeling with semi-continuous predictors: Testing and effect estimation in the presence of zero-inflated metabolites.** *S.H. Chu<sup>1,2</sup>, J. Lasky-Su<sup>1,2</sup>, P. Kraft<sup>3,4</sup>*. 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA; 3) Department of Epidemiology, Harvard T. H. Chan School of Public Health, Boston, MA; 4) Department of Biostatistics, Harvard T. H. Chan School of Public Health, Boston, MA.

Zero-inflated metabolite levels are very common when analyzing metabolomic data, whether due to true absence of the metabolite (such as in the case of xenobiotics), or due to measurements falling below the limit of detection. While a great deal of statistical literature has explored best practices for modeling zero-inflated outcomes, less attention has been paid to the context in which the exposure of interest is semi-continuous. We conducted simulation studies to compare power and bias of effect estimates for three methods: two typical approaches in case-control study designs, naïve logistic regression (n-LR) and logistic regression with log-transformed metabolite levels (ln-LR); and a new and simple alternative employing logistic regression with interaction terms (2df-LR). Using a factorial design, we explored the effect of altering limit of detection thresholds, mean and SD of distributions for observed metabolite levels, metabolite effect size, and population proportion of xenobiotic ingestion across 7 different distributions of metabolite sampling probabilities, with 1000 iterations each. Simulations were further conducted to investigate differences in power and bias estimates with respect to chronicity of the metabolite-disease association (i.e. acute vs chronic outcomes). All approaches demonstrated appropriate Type-I error rates across all 7 sampling probability simulations for the chronic ( $\alpha_{n-LR}$ : 0.043-0.063,  $\alpha_{ln-LR}$ : 0.035-0.060,  $\alpha_{2df-LR}$ : 0.047-0.063) and acute ( $\alpha_{n-LR}$ : 0.034-0.059,  $\alpha_{ln-LR}$ : 0.033-0.058,  $\alpha_{2df-LR}$ : 0.044-0.061) association settings. In general, n-LR demonstrated good power performance across a wide range of simulation settings. However, 2df-LR performed best in simulations with higher population proportions of xenobiotic ingestion in acute outcome settings. Overall, all methods were biased toward the null in terms of effect estimates, but best performance with respect to the variability and degree of bias varied by specific simulation settings.

**Metabolite-GWAS of obesity in the Atherosclerosis Risk in Communities (ARIC) study.** *K.L. Young<sup>1</sup>, H.M. Highland<sup>1</sup>, B. Yu<sup>2</sup>, M. Grove-Gaona<sup>2</sup>, C. Avery<sup>1</sup>, P. Gordon-Larsen<sup>1</sup>, E. Boerwinkle<sup>2</sup>, K.E. North<sup>1</sup>*. 1) University of North Carolina, Chapel Hill, NC; 2) University of Texas Health Science Center at Houston, Houston, TX.

Over the past 30 years, the US prevalence of obesity (measured as body mass index (BMI) >30) has more than doubled. However, not all obese individuals have the same risk for adverse health consequences. As obesity can be considered a dysregulation of energy balance, metabolites are a logical means to refine obesity phenotypes and may provide insights into mechanisms leading to disease. GWAS with metabolomics (mGWAS) can identify SNP-metabolite associations that can often be linked to metabolic transporters, regulators, or enzyme coding genes, providing an excellent opportunity to discover the best biological candidates in known GWAS regions, as well as identify novel regions associated with obesity. Our study leverages existing data in the Atherosclerosis Risk in Communities (ARIC) Study (N=4,032), a prospective, longitudinal cohort study of cardiovascular disease in African and European Americans, to identify metabolic signatures of obesity. We estimated associations between baseline natural log transformed BMI (lnBMI) and 245 baseline standardized plasma metabolites, using ancestry and sex-stratified additive linear models adjusting for age, center, smoking status, estimated glomerular filtration rate, and batch. The top 10 metabolites positively associated with lnBMI in at least one stratum ( $p=2.04E-4$  (0.05/245)) were carried forward for mGWAS (n=21). Ancestry and sex-stratified mGWAS were conducted using additive linear models adjusted for prior covariates plus PCs in EFACTS, followed by meta-analysis in METAL. Sixty-two percent of metabolites positively associated with lnBMI in this preliminary analysis were involved in amino acid/peptide pathways, replicating previous findings implicating amino acid catabolism in adipose tissue formation. We replicated mGWAS signals for kynurenine, urate, tyrosine, and mannose, and found interesting novel signals for dihomolinolenate. An intronic variant in *MYRF15* is associated with metabolite level in all strata ( $\beta=0.32$ ,  $SE=0.04$ ,  $p=3.20E-13$ ,  $MAF=0.14$ ); this gene was previously associated with plasma fatty acid levels. A variant near *CDKAL1* is associated with dihomolinolenate levels in African Americans only ( $\beta=0.65$ ,  $SE=0.12$ ,  $p=1.33E-8$ ,  $MAF=0.03$ ); the gene was previously associated with BMI and T2D. These results highlight the potential for metabolomics to refine obesity signals in GWAS. Future studies will examine causal inference and improved obesity risk prediction using metabolomics.

McCarthy*<sup>1,2,7</sup>, *Life Lines Deep*. 1) Wellcome Centre Human Genetics, University of Oxford, Oxford, UK; 2) Oxford Centre for Diabetes Endocrinology and Metabolism, Churchill Hospital, University of Oxford, Oxford, UK; 3) University of Groningen, University Medical Center Groningen, Department of Genetics, 9700 RB Groningen, the Netherlands; 4) Department of Internal Medicine and Radboud Center for Infectious Diseases, Radboud University Medical Center, 6525 HP Nijmegen, the Netherlands; 5) University of Groningen, University Medical Center Groningen; 6) Department of Pediatrics, Groningen, 9700 RB Groningen, the Netherlands; 7) Oxford NIHR Biomedical Research Centre, Oxford University Hospitals Trust, Churchill Hospital, Oxford, UK.

Microbiome-wide association studies on large population cohorts have highlighted hundreds of correlations between gut microbiome features, obesity and type 2 diabetes (T2D). However, the causal relationships between microbiome and metabolic traits remain unresolved. We conducted a bidirectional Mendelian Randomisation (MR) study to identify causal relationships between gut microbiome features and metabolic traits. We leveraged information from Life Lines Deep (LLD), a cohort of 952 normo-glycaemic individuals for whom genetics, gut metagenomics and faecal short chain fatty acid (SCFA) levels, to construct genetic risk scores (GRS) for microbiome features that were correlated with metabolic traits in LLD. The GRS for these microbiome features were tested for association with metabolic traits in published summary statistics from large genome-wide association studies in an MR analysis. We found that a GRS for increased abundance of gut microbiota involved in SCFA butyrate anabolism (MetaCyc acronym: PWY-5022) was associated with increased insulin response after an oral glucose test ( $P=9.8 \times 10^{-5}$ ). Studies of butyrate supplementation, an SCFA solely produced by the gut microbiome, in humans have shown improvement in insulin response. A GRS of increased faecal SCFA propionate levels was causally related to increased body mass index (BMI,  $p=0.007$ ) and risk of T2D ( $p=0.004$ ). The causal relationships between increased faecal propionate increased and risk of T2D were replicated in individual level data from an independent sample in the UK Biobank. We also conducted a PheWAS analysis in the UK Biobank for the two significant microbiome feature GRS. We found that the GRS for PWY-5022 was nominally associated with increased waist-hip ratio (WHR) ( $p=0.01$ ) and risk of obesity ( $p=0.02$ ). The GRS for increased faecal propionate was associated with increased body fat % ( $p=2 \times 10^{-4}$ ), increased WHR ( $p=4.3 \times 10^{-3}$ ) and lower visceral adipose tissue ( $p=0.01$ ). This study demonstrates how MR can be used to study causal relationships between the gut microbiome and disease traits. The data from this study demonstrate a causal role for gut microbiome produced SCFAs butyrate and propionate in energy metabolism and glucose homeostasis in man.

**Estimating carrier frequency of newborn screening disorders by using the 3.5KJPN whole-genome reference panel.** *Y. Yamaguchi-Kabata*<sup>1</sup>, *J. Yasuda*<sup>1</sup>, *S. Koshiba*<sup>1</sup>, *A. Uruno*<sup>1</sup>, *Y. Suzuki*<sup>1,2</sup>, *N. Fuse*<sup>1</sup>, *F. Katsuoka*<sup>1</sup>, *H. Kawame*<sup>1</sup>, *K. Kojima*<sup>1</sup>, *M. Nagasaki*<sup>1</sup>, *T. Mimori*<sup>1</sup>, *S. Tadaka*<sup>1</sup>, *G. Tamiya*<sup>1</sup>, *O. Tanabe*<sup>1</sup>, *N. Yaegashi*<sup>1</sup>, *S. Kure*<sup>1</sup>, *K. Kinoshita*<sup>1</sup>, *M. Yamamoto*<sup>1</sup>, *ToMMo Study Group*. 1) Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 2) Ageo Central General Hospital, Ageo, Japan.

Incidence rates of Mendelian diseases vary among ethnic groups, and variant types and their frequencies of causative genes also vary among human populations. To estimate frequency of potential patients in a population, it is important to clarify frequency of causative variants of genetic diseases in a general population. In this study, we 1) examine to what extent we can predict population frequency of recessive disorders from genomic data, and 2) explore better strategies of variant interpretation and classification. We used the 3.5KJPN whole genome reference panel from a general population of Japanese, which was constructed by the Tohoku Medical Megabank Organization (ToMMo). By focusing on 32 genes for 17 congenital metabolic disorders for newborn screening in Japan, we identified reported and predicted pathogenic variants through variant annotation, interpretation and multiple ways of classifications. Then the estimated carrier frequencies were compared with those from the newborn screening data in Japan based on 1,949,987 individuals. As an example of the *PAH* gene for hyperphenylalaninaemia (HPA) and phenylketonuria (PKU), the incidence rate of HPA/PKU in Japan was known to be about 1/70,000. The carrier frequency of the *PAH* variants by using the ACMG guideline of variant interpretation (2015) showed the closest estimate to that by the incidence than the other methods did. On the other hand, using only reported pathogenic variants in ClinVar resulted in a lower estimate, and including all of HGMD disease-causing (DM) variants resulted in a much higher estimate. However, there is a common missense variant, *PAH*:p.Arg53His, which has been previously reported among the patients in East Asia as heterozygous with another *PAH* variant. This type of common variant with mild effect is often discarded by conventional filtering for pathogenic variants. Our results showed that estimation of carrier frequency based on genomic data with recent guidelines of variant interpretation gave us a closer estimate to that by the observed incidence than the other methods did. However, taking other evidences and knowledge into consideration, we should be aware of that 1) the number of pathogenic variants may increase by including additional evidences, 2) common variants with mild effects also contribute to the actual frequency of the patients, 3) penetrance of each variant is not clear yet, and 4) there may exist causative indels, not detected by whole-genome sequencing.

**Clinical intervention study: Assessing the effect of genomic data-guided individualized lifestyle coaching platform for body fat loss.** H. Kim, J. Kang, H. Oh, W. Park, J. Kim. Samsung Genome Institute, Samsung Medical Center, Gangnam-gu, Seoul, South Korea.

The burden of obesity is increasing worldwide due to high-calorie diets and low activity level. Given the high failure rate of uniformed weight loss methods, expectations for the individual genome-guided approach are growing. However, the interaction between environmental and genetic factors on obesity is not clear. Here, we aimed to identify interactions of genetic and environmental effect on obesity and assess the effect of genome-guided individualized life-style coaching on body fat loss using genetic risk score, GRS and lifelog data including dietary habit and physical activity. Two cohorts of a total of 274 obese and non-obese adults were studied during 15 weeks in an interventional study, which include three weeks observational period and following 12 weeks interventional period. We collected genotype data before the observational period, self-reported questionnaires, anthropometric measures, blood chemistry tests and blood pressure data before and after study periods, and lifelog data using wearable device throughout both periods. The two independent cohorts were studied from June to Sep. 2017 and from Oct. 2017 to Feb 2018. To diversity lifestyle changes, the participants were engaged in different activity groups, such as control (n = 9), high intensity exercise (n = 89), moderate intensity exercise (n = 101), low carbohydrate diet (n = 39) and low fat diet (n = 36) groups, and were advised to change their dietary habits and amount of physical activities. We assessed GRS for previously reported models for four categories (carbohydrate intake, fat intake, total calorie intake, and exercise). We divided the participants into two groups as high and low GRS for each of these four categories. During the study periods, BMI, body fat mass, weight were significantly reduced in the participants enrolled from June (all p values <0.001) but there were no significant reduction in the participants from Oct. (p=0.85, p=0.91, and p=0.80 respectively). Comparing the high GRS group with the low GRS group in those who have reduced the amount of carbohydrates intake, there was a greater loss of body fat percentage in people with high GRS (p=0.02). However, there were no significant differences in the other three categories (p for fat intake=0.51, p for total calories intake=0.77, p for exercise=0.99). The results of this study show that high GRS for carbohydrates increases the effect of low carbohydrates diet.

**FTO in the Polynesians: Association of FTO-rs9939609 with body mass index in a fixed-effect meta-analysis in people of Polynesian ancestry living in Aotearoa/New Zealand and other Pacific nations.** M. Krishnan<sup>1</sup>, A. Phipps-Green<sup>2</sup>, S. Altaf<sup>3</sup>, T.J. Major<sup>4</sup>, M. Cadzow<sup>5</sup>, L. Stamp<sup>3</sup>, N. Dalbeth<sup>1</sup>, E.M. Russell<sup>6</sup>, R.L. Minster<sup>1</sup>, N.L. Hawley<sup>6</sup>, T. Naseri<sup>6</sup>, M.S. Reupena<sup>7</sup>, R. Deka<sup>8</sup>, D.E. Weeks<sup>4,9</sup>, S.T. McGarvey<sup>10,11</sup>, T.R. Merriman<sup>2</sup>, R. Murphy<sup>1</sup>. 1) Department of Medicine, University of Auckland, Auckland, Auckland, New Zealand; 2) Department of Biochemistry, University of Otago, Dunedin, New Zealand; 3) Department of Medicine, University of Otago, Christchurch, New Zealand; 4) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pennsylvania, USA; 5) Department of Epidemiology (Chronic Disease), School of Public Health, Yale University, New Haven, Connecticut, USA; 6) Ministry of Health, Government of Sāmoa, Apia, Sāmoa; 7) Bureau of Statistics, Government of Sāmoa, Apia, Sāmoa; 8) Department of Environmental Health, College of Medicine, University of Cincinnati, Cincinnati, Ohio, USA; 9) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 10) International Health Institute, Department of Epidemiology, School of Public Health, Brown University, Providence, Rhode Island, USA; 11) Department of Anthropology, Brown University, Providence, Rhode Island, USA.

The fat mass and obesity associated (*FTO*) locus consistently associates with obesity and increased body mass index (BMI) in most ancestral groups with *rs9939609* being the most commonly described variant associated with anthropometric measures of adiposity. Yet, previous small studies have failed to replicate the association of *FTO* with obesity among people of Polynesian ancestry. In this study, we tested for association of *rs9939609* with BMI in (1) 1,239 people of East Polynesian ancestry (indigenous NZ Māori, Cook Island Māori and Tahitian) living in Aotearoa/New Zealand and (2) 711 people of West Polynesian ancestry (Sāmoan, Tongan, Niuēan, Pukapukan, Tokelauan and Tuvaluan) living in Aotearoa/New Zealand, and in (3) 3,072 indigenous Sāmoans living in the Independent State of Sāmoa. Published statistics of three small sample sets of Polynesian (Tongan,  $n=116$ ), Melanesian (Solomon Islander  $n=129$ ) and Micronesian (Kiribatian living in the Solomon Islands  $n=75$ ) peoples were meta-analysed with the three study groups for association of *rs9939609* with BMI. The minor allele frequencies (MAF) for the East Polynesians, West Polynesians and Sāmoans were 0.25, 0.19 and 0.20 respectively. Significant evidence of association was not found ( $P \geq 0.05$ ) between *rs9939609* and BMI in the East ( $\beta=0.55 \text{ kg/m}^2$ ), West ( $\beta=0.51 \text{ kg/m}^2$ ), or Combined East and West Polynesian ancestry groups ( $\beta=0.50 \text{ kg/m}^2$ ) or in the Sāmoan group ( $\beta=0.35 \text{ kg/m}^2$ ). Meta-analysis of these groups along with the small Tongan group, did show association of the *rs9939609* minor (A) allele with higher BMI in Polynesian peoples ( $\beta=0.38 \text{ kg/m}^2$ ,  $P=0.023$ ,  $n=5,404$ ) but not with the wider Oceanic ( $\beta=0.28 \text{ kg/m}^2$ ,  $P=0.064$ ,  $n=5,608$ ) samples using a Bonferroni adjusted  $P$ -value of 0.025. These data demonstrate that *rs9939609* is associated with BMI in Polynesian peoples. Previous studies investigating the association of *FTO* with BMI among people of Polynesian ancestry may have been limited by low statistical power.

## 3274T

**Multi-omics of BMI in Hispanics by sparse canonical correlation analysis: IRAS family study.** K.D. Taylor<sup>1</sup>, N.D. Palmer<sup>2</sup>, X. Guo<sup>1</sup>, D.W. Bowden<sup>2</sup>, Y.-I.I. Chen<sup>1</sup>, M.O. Goodarzi<sup>3</sup>, K.L.S. Lam<sup>1</sup>, C.D. Langefeld<sup>2</sup>, L.E. Wagenknecht<sup>2</sup>, J.I. Rotter<sup>1</sup>, *Insulin Resistance & Atherosclerosis Family Study.* 1) Inst. Translational Genomics, Los Angeles Biomedical Institute, Torrance, CA., USA; 2) Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC, USA; 3) Division of Endocrinology, Cedars-Sinai Medical Center, Los Angeles, CA, USA.

**Introduction.** Penalized matrix decomposition methods such as sparse canonical correlation analysis (SCCA) are promising for multi-omics studies that require methods appropriate for high dimensional data, for integration of different data types, and for feature-selection, or finding correlations across a multi-omics landscape. **Aim.** Perform SCCA of BMI in Hispanics with metabolomic/genomic data in the Insulin Resistance & Atherosclerosis Family Study (IRASFS). **Methods.** SCCA was performed in three steps using R packages bestNormalize and PMA: (a) *Datasets.* BMI was adjusted for age and sex. 865 metabolomic features by Metabolon were transformed and features with a Shapiro-Wilks test >0.9 were retained. GWAS SNPs (Illumina) passing stringent QC and minor allele frequency > 0.01 were retained. The final dataset consisted of 904 subjects, 644 metabolomic features, and 1,074,639 SNPs. (b) *Penalty Selection* was performed using permutation; at the penalty set used, the correlation (0.63) was greater than the highest correlation obtained with 1000 permutations (0.38). (c) SCCA was applied using the penalty set and 4 "result clusters" (RC) extracted in succession; an RC consists of a "short list" of metabolites and SNPs which together correlate with BMI. **Results.** The 4 RCs were combinations of 24 metabolites and 169 SNPs, with 26 SNPs near loci expressed in adipose tissue (GTEx), 5 SNPs near genes for mitochondrial function (MitoCarta), and 16 SNPs associated with obesity-related traits (GWAS Catalog). RC correlations across metabolites, SNPs, and BMI were 0.62, 0.58, 0.42, 0.48, respectively. RC1 correlates increased BMI, increased branched-chain and urea-cycle amino acids, and obesity loci *LRP1B*, *KIAA1217* & *HAS2* together; RC2 & RC3 correlate BMI, lysolipid increases (RC2) and decreases (RC3), and obesity loci *ATXN1*, *CRB1*, *MYT1L*, *NRXN2*, *SLC52A3*; RC4 correlates phospholipids with obesity loci *BCAT2*, *Chr1orf94*, *GBE1*, *RORA*, *TRIP11*, and *ZMIZ1*. **Discussion.** The association of branched-chain amino acids and adiposity is well-known and many known loci for the regulation of obesity, metabolism, and insulin resistance were correlated with a modest number of metabolites. In addition to confirmation of method, these correlations provide clues to metabolic consequences of SNPs leading to BMI. We conclude that SCCA is a promising tool for integration of multi-omics datasets into a single analysis and for finding major features across a large data landscape. .

## 3275F

**Polymorphism rs822396 (-3971 A/G) of ADIPOQ gene as a risk factor to develop metabolic syndrome in Mexican population: Preliminary results.** L. Rubio Chavez<sup>1</sup>, R. Rosales Gómez<sup>2</sup>, J. Ramos Núñez<sup>1</sup>, D. Rubio Chavez<sup>1</sup>, T. Garcia Cobian<sup>1</sup>, J. Sánchez Corona<sup>3</sup>, S. Gutiérrez Rubio<sup>1</sup>. 1) Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Universidad de Guadalajara, Tonalá, Jalisco, Mexico; 3) Centro de Investigación Biomédica del Occidente, Guadalajara, México.

**Introduction:** The adiponectin (ApN) has a role in metabolic process and immunological effects. ApN is encoded by *ADIPOQ* gene located in 3q27. The polymorphism rs822396 in this gene has been associated with components of metabolic syndrome (MS) in Caucasian and Asiatic populations. High serum ApN levels have a protector effect to develop chronic and metabolic diseases. **Aim:** to evaluate the association of rs822396 polymorphism and serum ApN levels with metabolic syndrome development in Mexican population.

**Materia and Methods:** The clinical, biochemical and anthropometric data of 74 MS cases, 35 controls and 115 individuals of general population (GP) were achieved. The polymorphism detection was made by PCR-RFLP from DNA. The serum ApN levels were determinates by ELISA. **Results:** The 33% of recruited individuals have MS. The frequency of the GG genotype is 8.12%, 2.86% and 2.6% and the G allele is 30.4%, 17.1% and 21.7% in the Cases, Controls and GP respectively. The association analysis showed that dominant model (GA/GG) in carriers with MS has an OR of 2.431 (p= 0.037, CI: 1.04-5.67) regard to controls. Another hand, allelic analysis indicated that G allele carriers with MS and an OR 2.112 (p= 0.037, CI: 1.035-4.310) regard to controls. The serum ApN levels were higher (p> 0.001) in control group (9.49 ±3.8 µg/mL) regard to MS (6.03 ±2.2 µg/mL). The GP serum ApN levels (6.875 ±2.6 µg/mL) were no different compared to cases **Conclusions:** There was found an association of twice fold risk of G allele of rs822396 polymorphisms carries to develop MS. A lower serum ApN levels was found in cases with MS related with develop MS.

**3276W****Transethnic meta-analysis of adiposity traits: Use of large population biobanks reveals multiple ancestry-specific association signals.** Z. Fairhurst-Hunter<sup>1</sup>, K. Lin<sup>1</sup>, W. Gan<sup>1</sup>, M. Arnold<sup>2</sup>, A. Mahajan<sup>1</sup>, I.Y. Millwood<sup>1</sup>, Z. Chen<sup>1</sup>, M.I. McCarthy<sup>1</sup>, M.V. Holmes<sup>1</sup>, R. Walters<sup>1</sup>.

1) University of Oxford, Oxford, United Kingdom; 2) University of Cambridge, Cambridge, United Kingdom.

The prevalence of obesity and overweight is increasing worldwide. However, for a given body mass index (BMI), adipose tissue distribution varies considerably between ethnic groups, resulting in different relationships between measures of adiposity and disease. Association signals from previous adiposity GWAS, which predominately used European (EUR) cohorts, account for less variation in East Asians (EAS) than is explained in EUR populations. This limits the utility of EUR identified SNPs for investigating the causal influence of adiposity on disease risk in EAS. To identify novel loci useful for translational genetic studies in EAS, and to explore differences in the genetic architecture of adiposity measures between ancestries, we used data from 96K EAS individuals from China Kadoorie Biobank (CKB) and 430K EUR individuals from UK Biobank (UKB). We performed ancestry-specific GWAS for 8 adiposity measures, including BMI, waist-hip ratio (WHR) and body fat percentage. Ancestry-specific GWAS were then meta-analysed using the Han-Eskin random effects model. GWAS in UKB yielded 100s of independent loci ( $p < 5 \times 10^{-8}$ ) for all traits assessed. Trans-ethnic meta-analysis of the GWAS data identified on average a further 15% of additional loci. While the use of two ethnically diverse biobanks increased the number of loci identified for each adiposity trait, on average 14% of lead variants displayed significant effect size heterogeneity (5% FDR) between the two ethnicities. Differences in linkage disequilibrium account for some of these instances of trans-ethnic heterogeneity, but often the divergence appears to be due to an absence of effect in one or other ethnicity. This was most evident for WHR, with 83% of heterogeneous loci showing evidence of association in only one ancestry. In addition, genetic risk scores (GRS) constructed using GWAS results from one ancestry performed poorly when applied to the other, highlighting the consistent differences in effect size between the two ethnicities. In the extreme, a GRS for WHR constructed using CKB lead SNPs, with an overall effect size in CKB of 1.00 SD [95% CI: 0.92-1.08] per weighted allele, had a quarter of the effect when applied to UKB (0.24 SD [0.21-0.28]). These findings may relate to previously characterised differences in body-fat distribution between EAS and EUR populations and may provide insights into underlying differences in genetic architecture.

**3277T****Addressing the missing data issue in multi-phenotype genome-wide association studies.** M.D. Anasanti<sup>1</sup>, M. Kaakinen<sup>1,2</sup>, H. Draisma<sup>1</sup>, Z. Balkhiyarova<sup>1</sup>, M. Jarvelin<sup>3,4,5,6,7</sup>, I. Prokopenko<sup>1</sup>.

1) Section of Genomics and Common Disease, Department of Medicine, Imperial College London, United Kingdom; 2) Division of Experimental Medicine and Toxicology, Department of Medicine, Imperial College London, United Kingdom; 3) Department of Epidemiology and Biostatistics, School of Public Health, Imperial College London, United Kingdom; 4) Department of Epidemiology and Biostatistics, MRC-PHE Centre for Environment and Health, School of Public Health, Imperial College London, London, UK; 5) Center for Life Course Health Research, University of Oulu, Oulu, Finland; 6) Unit of Primary Care, Oulu University Hospital, Oulu, Finland; 7) Biocenter Oulu, University of Oulu, Oulu, Finland.

Joint analysis of multiple phenotypes in genome-wide association studies (MP-GWAS) increases power for locus discovery but suffers from missingness in phenotype values, especially with high-dimensional data. This leads to inefficiency of the standardly implemented complete case (CC) analysis and loss of power. We investigated properties of missing data imputation methods within MP-GWAS and implemented a user-friendly extension to the multi-phenotype analysis software tool SCOPA. We focussed on single and multiple-imputation (SI/MI) using Bayesian approach and expectation-maximisation bootstrapping (EMB), k-nearest neighbour (kNN), left-censored imputation method (QRILC) and random forest (RF). We simulated genetic data for 5,000/50,000/500,000 individuals using Hapgen2, and highly ( $r=0.64$ ) and moderately correlated ( $r=0.33$ ) phenotypes (three/nine/30/120) for these individuals in R. We randomly selected common, low-frequency and rare variants to be significantly ( $P < 5 \times 10^{-8}$ ) associated with the simulated phenotypes. We considered different proportions of missing data (1/5/20/50%) under three mechanisms: missing completely at random (MCAR), missing at random (MAR), and missing not at random (MNAR). The Root Mean Squared Error (RMSE) was calculated by contrasting the regression coefficients from the analyses regressing each SNP on the linear combination of the phenotypes, after applying the selected missing data methods, to those resulting from the full data analysis. The evaluations of the RMSEs were done using one-way Analysis of Variance (ANOVA) with CC vs. full data RMSE as the reference level. The best performing methods were applied to real data from the Northern Finland Birth Cohorts (NFBC) 1966 and 1986 (4,955 and 2,687 individuals, respectively) for the imputation of anthropometric, fasting blood glucose/insulin measurements and 149 serum metabolite levels and MP-GWAS of 31 amino acids. RF and MI-EMB showed RMSE levels closest to zero and diverged the most from the reference under MCAR ( $P_{RF}=7.18 \times 10^{-4}$ ,  $P_{MI-EMB}=6.27 \times 10^{-4}$ ). RF also outperformed under MAR ( $P=6.22 \times 10^{-4}$ ), whereas QRILC outperformed under MNAR ( $P=7.45 \times 10^{-4}$ ). With the MP-GWAS of the NFBCs after imputation with RF and QRILC we observed a number of additional loci as compared to CC analysis. We propose new user-friendly high-performing solutions for phenotype imputation in high-dimensional omics data analyses and have implemented these into imputeSCOPA software tool.

**Using short identical-by-descent (IBD) segments to map disease genes in unrelated case-control studies.** *W.-M. Chen<sup>1</sup>, A. Manichaikul<sup>1</sup>, J. Nguyen<sup>1</sup>, Z. Zhu<sup>1</sup>, C. Robertson<sup>1</sup>, J.R.J. Inshaw<sup>2</sup>, S. Onegut-Gumuscu<sup>1</sup>, J.A. Todd<sup>2</sup>, S.S. Rich<sup>1</sup>, Type 1 Diabetes Genetics Consortium.* 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) JDRF/Wellcome Trust Diabetes and Inflammation Laboratory, Wellcome Trust Centre for Human Genetics, University of Oxford.

While it is known that long stretches of genomes are shared identical-by-descent (IBD) between a pair of relatives, it is less well-known that unrelated individuals can also share noticeable IBD segments that are short, say < 1Mb. For example, in the 1000 Genomes Project, the total length of IBD segments between a random pair of individuals from east Asia or Europe is estimated to be >6% of the genome (*i.e.*, 5<sup>th</sup>-degree relatedness). Similarly, while inbreeding is characterized by existence of long chromosomal regions consisting of homozygotes only, an outbred individual that does not have any recent family history of inbreeding can also carry many Runs of Homozygosity (ROHs) that are short. The widely-spread short IBD segments and ROHs in human populations can be utilized for disease gene mapping in unrelated case-control studies. Built upon a computationally efficient tool KING which is mostly known for its fast and accurate inference of relatedness by estimating kinship coefficients and recently by inferring IBD segments, we developed two IBD-based gene mapping methods, IBD mapping and homozygosity mapping. The IBD mapping method compares average IBD sharing at a position in affected pairs with that in discordant pairs, with P values being assessed by a permutation test. The homozygosity mapping method tests association between the disease status and ROH status at any position in outbred individuals using contingency tables. We applied these two IBD-based gene mapping methods to three case-control cohorts where study participants were densely genotyped at 186 immune-related loci using the ImmunoChip array and type 1 diabetes (T1D) was of primary interest. The IBD mapping scan in a case-control study in European population identified loci (with  $P < 0.0001$ ) at *MHC*, *IKZF4*, and *SH2B3*. The IBD mapping scan in a case-control study in African Americans identified loci (with  $P < 0.0001$ ) at *C1orf106*, *IL10*, *MHC*, *CENPW*, *IKZF4* and *SH2B3*, in contrast to 3 genes only identified using the standard logistic regression method. The Homozygosity mapping scan in a large dataset identified loci at *PTPN22*, *CTLA4*, *MHC*, *BACH2*, *CENPW*, *IKZF4*, *DEXI*, *TYK2*, and *FUT2* with  $LOD > 3$ . The successful identification of known T1D loci without false positives provides proof of concept of the utility of our newly developed IBD-based gene mapping methods. As WGS becomes more available, genetic loci for diseases and complex traits can be mapped alternatively using IBD-based gene mapping methods. .

**3279W**

**Machine learning in multi-omics data to assess longitudinal predictors of glycaemic trait levels.** *M. Kaakinen<sup>1,2</sup>, L. Prelot<sup>1</sup>, H. Draisma<sup>1</sup>, M.D. Anasanti<sup>1</sup>, Z. Balkhiyarova<sup>1</sup>, M.-R. Jarvelin<sup>3,4</sup>, I. Prokopenko<sup>1</sup>.* 1) Section of Genomics of Common Disease, Department of Medicine, Imperial College London, London, United Kingdom; 2) Centre for Pharmacology and Therapeutics, Department of Medicine, Imperial College London, London, United Kingdom; 3) Department of Epidemiology and Biostatistics, School of Public Health, Imperial College London, London, United Kingdom; 4) Center for Life Course Health Research, University of Oulu, Oulu, Finland.

Multi-omics data hold enormous potential for personalised medicine; however, analysis of high-dimensional data poses computational and statistical challenges. Type 2 diabetes (T2D) is a global health burden that will benefit from personalised risk prediction and tracking of disease progression. We aimed to identify longitudinal predictors of the levels of glycaemic traits relevant for T2D by applying machine learning (ML) approaches to multi-omics, including epigenetic and metabolomic data, from the Northern Finland Birth Cohort 1966 at 31 (T1) and 46 (T2) years of age. We predicted fasting glucose/insulin (FG/FI), glycated haemoglobin (HbA1c) and 2-hour glucose/insulin (2hGlu/2hIns) at T2 in 595 individuals using a total of 1,010 variables from T1 and T2: body-mass-index (BMI), waist-hip-ratio, sex; 10 blood plasma measurements; 453 NMR-based metabolites; 542 methylation probes established for BMI/FG/FI/HbA1c/T2D/2hGlu/2hIns and measured with Illumina InfiniumHumanMethylation450 BeadChip (T1)/EPIC (T2) arrays. Metabolic and methylation data were used in their raw form (Mb-R, Mh-R) or transformed into scores (Mb-S, Mh-S) and we tested different input data combinations. We used six ML approaches: random forest (RF), boosted trees (BT) and support vector machine (SVM) with the kernels of linear/linear with L2 regularization/polynomial/radial basis function. Data were split with a nested cross validation. The outer and the inner cross validation had both 5-folds, corresponding to 20% testing and 80% training data. RF and BT showed consistent performance while SVMs struggled with higher-dimensional data. The predictions worked best for FG and FI, with the average  $R^2$  values from the six ML models reaching values of up to 0.47 and 0.30, respectively, using Mb-S data. Both with Mb-R and Mb-S data, T2 branched-chain and aromatic amino acids, HDL-cholesterol, VLDL, glycoprotein acetyls, glycerol, ketone bodies, and measurements of obesity already at T1 were amongst the most important predictors. Addition of methylation data, either raw or score, did not improve the predictions ( $P > 0.3$  for model comparison); however, BMI-associated methylation probes T1\_cg26361535 at *ZC3H3/T1\_cg00634542* at *SLC11A1* were within the top 25 predictors of FI/FG variability when using Mb-S+Mh-R as input data. With ML we could narrow down hundreds of variables into a clinically relevant set of predictors and demonstrate the importance of longitudinal traits in prediction. .

**Joint proteomic quantitative trait locus analysis sheds light on the genetic architecture of proteins involved in obesity.** *H. Ruffieux*<sup>1,2</sup>, *W.H.M. Saris*<sup>3</sup>, *A. Astrup*<sup>4</sup>, *M.E. Harper*<sup>5</sup>, *R. Dent*<sup>6</sup>, *A.C. Davison*<sup>1</sup>, *J. Hager*<sup>2</sup>, *A. Valsecchia*<sup>2</sup>. 1) Chair of Statistics, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Vaud, Switzerland; 2) Metabolic Health Unit, Nestlé Institute of Health Sciences SA, Lausanne, Switzerland; 3) Department of Human Biology, NUTRIM, School of Nutrition and Translational Research in Metabolism, Maastricht University Medical Centre, Maastricht, Netherlands; 4) Department of Nutrition, Exercise and Sports, Faculty of Science, University of Copenhagen, Copenhagen, Denmark; 5) Bioenergetics Laboratory, University of Ottawa, Ottawa, Ontario, Canada; 6) Weight Management Clinic, The Ottawa Hospital, Ottawa, Ontario, Canada.

Hundreds of genome-wide association studies have investigated the role of thousands of loci on obesity susceptibility, yet the mechanistic consequences of genetic variation on metabolic states remain elusive. This has prompted analysis of endophenotypes via quantitative trait locus (QTL) studies which assess how genetic variants affect intermediate molecular traits, such as gene or protein expression phenotypes. Owing to the number of tests that they entail, however, conventional single-SNP approaches often fail to detect weak effects, as may exist between a genetic variant and products from remote genes. We considered two obesity clinical cohorts ( $n = 1644, 789$ ), each involving two proteomic QTL datasets with plasma samples quantified by mass spectrometry and SomaLogic assays. To bypass the multiplicity burden and increase statistical power, we performed joint analyses of these data using our molecular QTL method LOCUS (Ruffieux et al., *Biostatistics*, 2017). LOCUS implements fast variational inference for a Bayesian hierarchical regression model that leverages shared association patterns across all genetic variants and expression outcomes; we reassessed its statistical and computational efficacy on genetic variants from our cohorts and on simulated outcomes emulating the proteomic data. We took a two-stage approach, using the Optifast Canadian cohort for discovery and the DiOGenes cohort for replication. We analyzed the mass-spectrometry and SomaLogic pQTL data in two separate LOCUS runs; these data involved 130 and 1,100 proteins respectively, and 275,000 common tag variants capturing information from Illumina Exome arrays. LOCUS uncovered 18 (respectively 118) associations, of which 83% could be replicated at false discovery rate 5%. The hits significantly co-localized with many epigenomic marks and known eQTL effects. Our analyses identified 20 *trans* associations with significant evidence for functional roles. Taking advantage of the comprehensive clinical data available for both cohorts, we studied the links between our pQTL signals and measures of insulin sensitivity and total lipid levels. These analyses indicated that most proteins under genetic control act on low-grade inflammation, insulin resistance, and dyslipidemia. Our methods and results may help to better understand obesity and associated co-morbidities. In particular, we identified novel candidate biomarkers, whose roles merit further investigation, at both clinical and pre-clinical levels.

**High dimensional mediation for causal gene screening.** *Q. Zhang*. Statistics, University of Nebraska Lincoln, Lincoln, NE.

QTL and eQTL study the genetic regulation of the complex traits and the gene expression. The two have also been analyzed jointly, with the hope of identifying the potential causal genes of complex diseases. Such problems can be translated as selecting the gene set that mediates the genetic effect. Conventional mediation analysis typically focuses on one mediator and one predictor at a time. Even though there have been a few mediation models for multi-variate predictors and/or mediators, statistical methods for multivariate mediation with both high dimensional predictors and mediators are still rare. In this project, we developed a high dimensional mediation framework based on penalized linear mixed model for causal gene screening. We applied the proposed method to study the mechanism of insulin secretion using an f2 cross mouse data, and found that a dozen genes could block a large proportion of the genotype-phenotype causal flow, including many interesting genes with known association to pancreas function and Type 2 Diabetes.

**3282W****Association of Glucose-6-phosphate dehydrogenase (G6PD) variants with non-glycemic lowering of Hemoglobin A1c (HbA1c) in East Asians.**

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked disorder caused by mutations in the *G6PD* gene. Prevalences of G6PD deficiency are 7.1% globally and 4.7% in Asia. A common African-American specific *G6PD* variant has been reported to be associated with non-glycemic lowering of HbA1c, a commonly used diagnostic test for diabetes (rs1050828, MAF=11%,  $P=8.23 \times 10^{-135}$ ). HbA1c in male carriers of the *G6PD* variant was 0.81% lower than non-carriers. To identify Asian-specific *G6PD* variants associated with HbA1c, we performed imputation with the 1000 Genomes reference panel in seven Asian studies and tested the variants for association with HbA1c. We performed sex-stratified association analyses before combining by meta-analysis [9,773 East Asians (4,850 men, 4,923 women) and 1,486 South Asians (732 men, 754 women)]. No significant association was observed in South Asians. In East Asian men, 35 variants were associated with HbA1c at the *G6PD* locus ( $P < 5 \times 10^{-6}$ ). The strongest association was a low-frequency missense mutation known as *G6PD*-Canton (rs72554665, Arg489Leu, MAF=2.2%,  $P=1.25 \times 10^{-27}$ ,  $n=2,844$ , variance explained in men=6.9%). HbA1c in male carriers was 0.76% lower than non-carriers. Conditioning on this variant, 10 variants at the locus remained significant. These associations were driven by another low-frequency missense variant, *G6PD*-Kaiping (rs72554664, Arg493His, MAF=1.1%,  $P=9.59 \times 10^{-11}$ ,  $n=612$ , effect size =-1.11%,  $r^2=0.0$  with *G6PD*-Canton in 1000G EAS). Further conditioning on both variants, the conditional  $P$ -values at the locus was  $>0.1$ . Imputed genotypes had good concordance with exome sequencing data (*G6PD*-Kaiping: 98.6% and *G6PD*-Canton: 100%). To determine whether genetic effects on HbA1c were mediated by glycemia, we tested whether *G6PD*-Canton and *G6PD*-Kaiping were associated with glucose measures. Both variants were not associated with fasting glucose (rs72554664,  $P=0.915$ ,  $n=548$ ; rs72554665,  $P=0.533$ ,  $n=1134$ ) or random glucose (rs72554665,  $P=0.485$ ,  $n=791$ ), and conditioning on these glucose measures did not attenuate their effect on HbA1c. In summary, we identified 2 *G6PD* variants in East Asian men associated with non-glycemic lowering of HbA1c. Diabetes diagnosis may be missed in carriers of these *G6PD* variants when screening Asian populations for diabetes with HbA1c, highlighting the importance of investigations in diverse ancestries to uncover ancestry-specific variants that influence the accuracy of clinically useful diagnostic tests.

**3283T****Causal effects of blood lipids on breast cancer risk: A Mendelian randomization study.**

C. Nowak<sup>1</sup>, J. Ärnlöv<sup>1,2</sup>. 1) Division of Family Medicine and Primary Care, Department of Neurobiology, Care Sciences and Society (NVS), Karolinska Institutet, Huddinge, Sweden; 2) Dalarna University, Falun, Sweden.

Observational studies have reported associations between circulating lipids and risk of breast cancer, but whether low-density lipoprotein-cholesterol (LDL-cholesterol), high-density lipoprotein-cholesterol (HDL-cholesterol) and triglycerides causally affect breast cancer risk is unclear. We used summary genetic datasets for breast cancer and blood lipids in two-sample Mendelian randomization to assess whether lipids affect breast cancer risk. Mendelian randomization uses exposure-associated genetic variants as instruments to avoid bias from reverse causation and confounding. We constructed instruments of genome-wide significant variants for lipids and used inverse variance-weighted, Egger, weighted median and multivariable Mendelian randomization. To approximate effects of lipid-modifying drugs, we instrumentalised lipid-associated variants in the genes encoding the targets of statins, PCSK9 inhibitors, CETP inhibitors and ezetimibe. Genetically raised HDL-cholesterol was associated with higher risk of breast cancer (odds ratio, OR, per standard deviation, 1.10, 95% confidence interval, CI, 1.04, 1.16,  $p = 0.001$ ) and ER-positive breast cancer (OR 1.10, 95% CI 1.03, 1.17,  $p = 0.003$ ). There were no clear effects of LDL-cholesterol or triglycerides. We detected evidence that HDL-cholesterol-raising variants in *CETP* could be associated with higher risk of breast cancer (OR 1.04, 95% CI 1.01, 1.07,  $p = 0.002$ ) and ER-positive breast cancer (OR 1.03, 95% CI 1.00, 1.07,  $p = 0.025$ ), and that LDL-cholesterol-lowering variants in genes encoding the targets of statins, PCSK9 inhibitors and ezetimibe may have protective associations. We found evidence that genetically raised HDL-cholesterol levels may be associated with a small increase in the risk of breast cancer in women. Genetic effects may differ from pharmacologic interventions and bias from unaccounted-for pleiotropy cannot be excluded.

**Genomewide association for high-density lipoprotein change levels over time in three large combined studies.** M.F. Feitosa<sup>1</sup>, K.L. Lunetta<sup>2,3</sup>, L. Wang<sup>4</sup>, M.K. Wojczynski<sup>5</sup>, C.M. Kammerer<sup>6</sup>, T. Perls<sup>5</sup>, N. Schupf<sup>6</sup>, K. Christensen<sup>7</sup>, J.M. Murabito<sup>3</sup>, M.A. Province<sup>1</sup>. 1) Division of Statistical Genomics, Department of Genetics, Washington University School of Medicine, St Louis, MO; 2) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 3) Framingham Heart Study, MA; 4) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, PA; 5) Department of Medicine, Geriatrics Section, Boston Medical Center, Boston University School of Medicine, Boston, MA; 6) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Department of Neurology, Columbia University Medical Center, New York, NY; 7) Department of Public Health, The Danish Aging Research Center, University of Southern Denmark, Odense, Denmark.

Elevated HDL-C levels contribute to atheroprotection, and HDL-C levels are higher among healthy elderly and exceptional aging than in younger adults. However, extreme HDL-C levels are associated with increased all-cause mortality risk. Although several genetic factors are known to contribute to levels and metabolism of HDL-C, their protective effects in cardiovascular disease (CVD) and healthy aging-longevity are complex and poorly understood. We hypothesized that a genome-wide association study (GWAS) of HDL-C longitudinal change, accounting for harmonization of HDL-C and imputed genotype in 3 family-based studies recruited for exceptional survival (Long Life Family Study, LLFS), CVD risk factors (Family Heart Study, FamHS) and community based sample (Framingham Heart Study, FHS), might identify additional loci for HDL-C. We examined fasting HDL-C change in 7738 subjects with 2-visits for LLFS (N=2002, interval=5.5–11.2 years) and FamHS (N=1895, interval=6.3–9.6 years), and 2-to-28 visits for FHS (N=3841, interval=1–36 years). All HDL measures (N=25146) from the FHS were adjusted for age, sex, and standardized (0,1). Age and sex regression coefficients from FHS were applied to adjust HDL by age-sex in LLFS (N=4004) and FamHS (N=2790). We performed imputation on 1K-Genome in each study. For genotyping harmonization, we included imputed SNPs present in all 3 studies with imputation quality $\geq$ 0.3 and allele frequency differences $<$ 0.2 from 1K-Genome. We employed growth curves using linear mixed models to estimate random effects of slope of interval for each person to derive the best linear HDL-C change. We performed GWAS using a linear regression model with additive variant effects on HDL-C change accounting for family relationships. To adjust for genotype batches, changes in assays, across years and data, we corrected HDL-C for study (LLFS, FHS, FamHS) and population structure using principal components. We identified a novel association for HDL-C change with *GRID1* (1.43E-9), which encodes a subunit of glutamate receptor channels involved in synaptic plasticity. Suggestive novel associations ( $<$ 1.0E-5) for HDL-C change were with *MBOAT2* (role in lipid-metabolism pathway), *CYSLTR2* (role in cardiovascular systems), *NTNG2* (role in neurite outgrowth) and *LINC01314*. Modeling HDL-C levels over time in prospective studies, with difference in healthy-longevity and CVD risk, contributed to gene discovery and provides novel insights into mechanisms of HDL-C regulation. .

**Genome-wide association study of FADS1  $\omega$ -6 activity in a homogeneous island population.** M. Daya<sup>1</sup>, T.M. Brunetti<sup>1</sup>, N. Rafaels<sup>1</sup>, M. Boorgula<sup>1</sup>, A. Shetty<sup>2</sup>, S. Chavan<sup>1</sup>, M. Campbell<sup>1</sup>, S. Sergeant<sup>2</sup>, C.R. Gignoux<sup>1</sup>, T.H. Beaty<sup>3</sup>, F.H. Chilton<sup>2</sup>, K.C. Barnes<sup>1</sup>, R.A. Mathias<sup>3</sup>. 1) Department of Medicine, University of Colorado, Aurora, CO; 2) Wake Forest University Health Sciences, Wake Forest Center for Botanical Lipids, Winston-Salem, NC; 3) Department of Epidemiology, Bloomberg School of Public Health, JHU, Baltimore, MD, USA.

**RATIONALE:** Tangier Island, Virginia, is a small island located in Chesapeake Bay. The majority of its inhabitants trace their ancestry to three original founders who settled the island in 1722. The population has a homogeneous island-wide diet high in saturated and  $\omega$ -6 fatty acids, due in part to limited access to fresh produce on the island. The unique homogeneous genetic and dietary environment of this population is well suited to detecting and interpreting the effects of genetic variants in the formation of long-chain polyunsaturated fatty acids (PUFAs), which play an important role in immunity and inflammation. In a previous candidate gene association study, we identified a cluster of SNPs in the *FADS1* gene with minor alleles that are strongly associated with a decrease in ratio of  $\omega$ -6 PUFAs reflecting *FADS1* activity ( $P<$ 1E-12). Subsequently we performed genome-wide genotyping, and now have the opportunity to test for additional associations at the genome-wide level. **METHODS:** Samples were genotyped on Illumina's MEGA and genotype imputation was performed on the Michigan Imputation Server (using the HRC reference panel). After quality control, 220 samples with fasting serum PUFA concentrations were available for analysis. Linear mixed effect models implemented in the R Bioconductor package GENESIS were used to test for association between imputed allele dose and the ratio of  $\omega$ -6 PUFAs reflecting *FADS1* activity. Age at serum collection, sex and PC1 were included as fixed effect covariates in the statistical model, and a kinship matrix estimated from genome-wide data was included as random effect to account for relatedness between individuals. **RESULTS:** Even with the high degree of relatedness across this study, test statistic inflation was not observed ( $\lambda=0.99$  for  $MAF \geq 5\%$ ,  $\lambda=0.96$  for  $MAF < 5\%$ ). Two loci reached genome-wide significance ( $P<$ 5E-8): the *FADS1* gene on chr11q12-q13.1 (most significant  $P=1.9E-13$ ), as well as a region on chr1p36 including 13 SNPs (all in complete LD,  $MAF 7\%$ ,  $Rsq=0.99$ ,  $P=1.2E-8$ ). These SNPs in chr1p36 are intronic to the *ALPL* gene, which plays a role in vitamin B6 catabolism, and the significant minor alleles were associated with an increase in the *FADS1* activity ratio. **CONCLUSION:** We identified genetic variants that may increase the formation of  $\omega$ -6 PUFAs through the vitamin B6 pathway. This is biochemically plausible as vitamin B6 pathway components are cofactors in fatty acid metabolism.

## 3286T

**A powerful and adaptive gene based method to identify multiple traits associated genes using GWAS summary data.** X. Guo<sup>1</sup>, J. Zhang<sup>2</sup>, Z. Zhao<sup>3</sup>, B. Guo<sup>4</sup>, B. Wu<sup>4</sup>. 1) Department of Computer Science and Engineering, UNIVERSITY OF NORTH TEXAS, DENTON, TX; 2) Department of Mathematics, University of North Texas, Denton, TX, USA; 3) Texas Academy of Mathematics & Science, University of North Texas, Denton, TX, USA; 4) School of Public Health, University of Minnesota, Minneapolis, MN, USA.

Genome-wide association studies (GWAS) have been routinely used for discovering disease susceptible genes. They have successfully identified tens of thousands of disease related variants; however, significant missing heritability remain for many traits and there remain many more variants with small effects to be discovered. Recent research has suggested that integrating multiple related traits and multiple variants can significantly boost our power to detect novel genetic variants. This has been partly motivated by the polygenic nature of most complex human traits and the widespread pleiotropy observed in many traits. For example, accumulating evidence show that pleiotropic loci affect more than one blood lipid trait and it is also the case in Alzheimer's disease, which is highly related to disrupted brain networks represented as a set of multiple traits. Despite its promise, testing for multivariate trait/locus associations is challenging. In this study, we propose a general adaptive p-value combination method (GPC) that integrate multiple correlated traits and multiple variants in a gene region or pathway to improve the power to detect disease susceptible genes in GWAS. Our method needs only publicly available GWAS summary data, avoiding the privacy and logistic issue of obtaining raw data. We conducted extensive simulation studies to check that GPC properly controls the type I errors at the genome-wide significance level. We compared the power of GPC to several popular existing tests, using real GWAS summary data for lipids and glyceic traits. GPC showed dramatically improved statistical power and identified many novel genetic variants missed by the individual trait based GWAS analysis. Many of these newly identified variants have been reported strongly related to the lipids and glyceic traits in the literature.

Proprotein convertase subtilisin/kexin type 9 (PCSK9) enzyme inhibitors reduce serum low-density lipoprotein cholesterol (LDL-C) and subsequent risk of cardiovascular disease. While some long-term trials have evaluated the safety of such inhibitors, a broad investigation of potential outcomes over the life-time, has not been conducted. We investigated genetic variants associated with serum PCSK9, and examined effects of PCSK9-lowering genetic variants on a range of potential outcomes to inform about possible unanticipated effects of long-term PCSK9 inhibition. We linked genotype and phenotype data from 69,422 participants in the population-based Nord-Trøndelag Health Study (HUNT) with hospital-recorded ICD codes. We performed a genome-wide association study of serum PCSK9 measured in 3,697 adults. In the total sample, we defined a new genetic risk score for serum PCSK9, and regressed both this and an existing score on a broad range of outcomes. For comparison, we estimated the corresponding associations for variants associated with LDL-C on *HMGCR*, the target of statins. We further performed two-sample Mendelian randomization on 48 outcomes using large biobanks. Finally, we assessed the genetic correlation between serum PCSK9 and 229 diseases or traits using LD-score regression. Three independent genetic variants were associated with serum PCSK9 at genome-wide significance: two variants in *PCSK9* (rs11591147,  $P=2.9 \times 10^{-37}$ ; rs499883,  $P=2.3 \times 10^{-16}$ ) and one in *PCSK2* (rs192265866,  $P=2.8 \times 10^{-68}$ ), of which the two variants in *PCSK9* were replicated in an independent cohort. Using an existing PCSK9 genetic risk score, we demonstrated probable causal associations between lower serum PCSK9 and both lower serum LDL-C ( $P=2.8 \times 10^{-43}$ ) and lower risk of coronary heart disease ( $P=8.9 \times 10^{-24}$ ). Similar associations were observed using a new genetic risk score for serum PCSK9 using the two *PCSK9* variants identified in our GWAS. We did not observe any other convincing adverse or beneficial associations of the PCSK9 genetic risk scores across a range of cardiovascular, respiratory, mental, diabetes, or pain related outcomes. The lack of association between the PCSK9 genetic risk scores and a range of potential adverse outcomes is reassuring for the long-term use of PCSK9 inhibitors. However, further studies are warranted to confirm our findings, follow-up on the functional influences of the variants identified, and extend our investigations to other outcomes.

**3288W**

**Large-scale genetic analysis identifies 17 novel loci for asthma.** *Y. Han<sup>1,2</sup>, J.A. Hartiala<sup>1,2</sup>, P. Huang<sup>1,2</sup>, Q. Jia<sup>1,2</sup>, N.C. Woodward<sup>1,2</sup>, J. Gukasyan<sup>1,2</sup>, F.D. Gilliland<sup>1</sup>, H. Allayee<sup>1,2</sup>.* 1) Departments of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 2) Biochemistry & Molecular Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA.

To date, genome-wide association studies (GWAS), primarily in subjects of European ancestry, have identified 51 loci associated with asthma. To further understand the contribution of genetic factors to asthma, we conducted a meta-analysis of GWAS data with ~2.0 million SNPs in 62,739 asthma cases and 416,529 controls from the Trans-National Asthma Genetic Consortium (TAGC) and UK Biobank. In analyses with multi-ancestry populations, we identified 17 novel associated regions, bringing the total number of asthma susceptibility loci to 68. The risk alleles at eight of the novel loci were also associated with reduced lung function. By comparison, only two loci were associated with hay fever or eczema, indicating that the majority of the regions may be involved in adult non-allergic asthma. Bioinformatics and expression quantitative locus (eQTL) analyses identified candidate causal genes at nearly all 17 novel loci, including *CD52*, *PRDM11*, and *FADS1/2*, and provided evidence for enrichment of associated variants at all 68 asthma loci colocalizing to enhancer marks and DNase I hypersensitive sites specifically in blood and immune cells. Collectively, the results of our analyses shed additional light on the genetic architecture of asthma.

**3289T**

**Utilizing epistasis to investigate bronchodilator response in African American youth.** *J. Magana<sup>1</sup>, M. White<sup>1</sup>, M. Contreras<sup>1,2,3</sup>, O. Risse-Adams<sup>1,4</sup>, P. Goddard<sup>1</sup>, A. Zeiger<sup>1,5</sup>, A. Mak<sup>1</sup>, S. Salazar<sup>1</sup>, J. Liberto<sup>1</sup>, S. Oh<sup>1</sup>, D. Hur<sup>1</sup>, C. Eng<sup>1</sup>, S. Huntsman<sup>1</sup>, E. Burchard<sup>1,6</sup>.* 1) Department of Medicine, University of California, San Francisco, CA; 2) SF BUILD, San Francisco State University, San Francisco, CA; 3) MARC, San Francisco State University, San Francisco, CA; 4) Lowell Science Research Program, Lowell High School, San Francisco, CA; 5) Department of Biology, University of Washington, Seattle, WA; 6) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, CA.

In the U.S. asthma is one of the leading chronic illnesses among children. Bronchodilator medications are the standard of care for asthma, yet Bronchodilator Drug Response (BDR) is a complex phenotype that is highly variable among different racial/ethnic groups. As we attempt to deepen our understanding of complex phenotypes that impact disparate health outcomes, it is important to consider interactions between environmental, psycho-social, demographic, genetic, and clinical variables that may inform BDR. We evaluated the impact of pairwise and higher-order interactions (known as epistasis) on BDR in African American youth with asthma. Our study population consisted of 688 individuals with asthma from the Study of African Americans, Asthma, Genes, & Environments (SAGE II) population with detailed measures of BDR, perceived discrimination, environmental exposures, genetic ancestry, and more. We conducted epistatic interaction analysis using ViSEN, a non-parametric entropy-based program which has been shown to be as or more powerful than standard regression-based methods in identifying interaction effects. We identified 6 significant epistatic interactions associated with BDR in the full dataset. The strongest interaction models were: Prenatal Smoke Exposure + Age (IG: 2.05%,  $p=0.002$ ), and Sex + Experience of Discrimination + Global African Ancestry (IG: 0.81%,  $p=0.015$ ). Having identified the interaction effects that have the greatest impact of BDR within our cohort, future studies can focus on further investigating these interaction models to characterize the nature of the relationship between these interactions and BDR. This novel methodology may contribute to the understanding of how epistasis between genetic and other health related factors impacts health disparities.

**3290F**

***TBC1D29* is associated with response to inhaled corticosteroids in adult asthmatics.** A.L. Wang, A.A. Dahlin, M.J. McGeachie, A.C. Wu, K.G. Tantisi-*ra*. Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA.

Up to one-third of asthmatics have poor response to inhaled corticosteroids (ICS), the primary therapy for asthma control. The influence of genetics on ICS treatment response has been described in small genomic studies. In a larger population of 3,542 adult Caucasian asthmatics on ICS therapy, we aimed to replicate and identify novel genetic loci associated with ICS treatment response. Within the 16,274 Caucasian asthmatics in the Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort, 3,542 were on inhaled corticosteroids with or without the use of long-acting bronchodilators. Subjects with respiratory co-morbidities and use of other asthma medications were excluded. In total, 1,225 (34.5%) of subjects responded to ICS treatment, as defined by the absence of asthma-related oral corticosteroid bursts, emergency department visits, and hospitalizations. Genome-wide multivariate logistic regression was performed using PLINK2. One SNP, rs216454, in the intronic region of *TBC1D29* on chromosome 17q11.2 was associated with ICS treatment response (OR 1.43, FDR-adjusted  $P = 2.035 \times 10^{-6}$ ). Homozygotes for the major allele (G/G) had 6% less asthma exacerbations and heterozygotes had 3% less asthma exacerbations than homozygotes for the minor allele (T/T) ( $P = 0.035$ ). In the largest ICS pharmacogenomic study, we identified a novel genetic locus associated with ICS treatment response in adult Caucasian asthmatics. *TBC1D29* has not previously been associated with ICS treatment or asthma but has been implicated in another type 2 inflammatory disease, eosinophilic esophagitis. Replication of this study is underway in 2,125 asthmatics on ICS therapy in the Partners Biobank.

**3291W**

**Whole-blood eQTL analysis of multiple sclerosis patients from Puerto Rico.** H. Bai<sup>1,2</sup>, A.H. Beecham<sup>3,4</sup>, K.L. Miskimen<sup>2</sup>, C.P. Manrique<sup>3</sup>, W. Hulme<sup>3</sup>, J.L. McCauley<sup>3,4</sup>, W.S. Bush<sup>2</sup>. 1) Department of Nutrition, Case Western Reserve University, Cleveland, OH, USA; 2) Institute for Computational Biology, Department of Population and Quantities Health Sciences, Case Western Reserve University, Cleveland, OH, USA; 3) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 4) Dr. John T. Macdonald Department of Human Genetics, Miller School of Medicine, University of Miami, Miami, FL, USA.

Multiple Sclerosis (MS) is an autoimmune disease that causes chronic progressive disability in patients accompanied by the formation of plaques in the central nervous system. MS has multiple established genetic factors, however, the majority of genetic studies of MS to date have been performed in European-descent populations. This is due in part to the higher prevalence of MS in European populations, specifically those at higher latitudes. However, studies of MS in Latin American countries suggest either a rising prevalence or under-diagnosis of MS in Hispanic populations, and many Latin American countries have moderate influence of European genetic admixture. In this work, we performed a small pilot eQTL analysis of six Hispanic MS cases ascertained from Puerto Rico. RNA was extracted from whole-blood and was characterized using RNA-seq. Gene expression profiles for each case were matched to available genotype data generated from the MegaEx chip and MS chip. Due to the limited sample size, we restricted this analysis to established whole-blood eQTL signals found in the GTEx project, composed of predominantly European-descent samples. We further filtered these eQTL variants to identify 1559 variants that had both available genotypes and high allele frequency within the Puerto Rican population based on the 1000 Genomes dataset. These variants (with expected minor allele frequency  $> 0.4$ ) were evaluated using additive linear regression models. 731/1559 (46%) of genes with strong eQTLs from GTEx also had eQTL effects detected in our analyses of the MegaEx chip data, and 175/1559 (11.2%) were detected by analyses of the MS chip data ( $p < 0.05$ ). Three of these variants have been previously associated to MS in European-descent samples, and in our study appear to alter expression of the GSDMB, MCM9, and PLEC genes. While this study is small in scope, we illustrate the power of eQTL analysis given the strong effects alleles have on gene expression, and the relative proportion of European-derived eQTL effects we see generalizing in the Puerto Rican population.

**Developing an efficient method for identifying gene-gene interaction via random forest and least absolute shrinkage and selection operator.** S. Wu<sup>1</sup>, C. Chang<sup>1</sup>, C. Lee<sup>2</sup>, J. Lian<sup>2</sup>, C. Fann<sup>2</sup>. 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Department of Mathematics, National Changhua University of Education, Changhua, Taiwan.

Gene-gene interaction has been identified as a potential factor that contributes to heritability in complex traits. Multifactor Dimensionality Reduction method (MDR) is often used to test for genetic interaction<sup>1</sup>. Another popular tool is the epistasis module of PLINK<sup>2</sup>. A recent available procedure is Matrix-Epistasis<sup>3</sup> that could adjust for covariates and detect putative epistasis with a short time. Despite the advancement, dimensionality particularly for NGS data remains a challenge. The issues encompass the problem of handling higher order interactions (> 2-way) where the number of possible marker combinations is manifold for a large number of SNPs. To circumvent, we propose a method that combine Random Forest Algorithm and Least Absolute Shrinkage and Selection Operator (LASSO) to detect gene-gene interactions. Firstly, Random Forest is used to select important variants by pre-determined criteria. Secondly, by using results from Random Forest, LASSO screens out most explanatory variants and two-way interactions. The above two procedures are repeated 1000 times; those appear most frequently are retained. Lastly, LASSO is used to select the most potential ones for a logistic regression model. The HierNet function with LASSO algorithm and randomForest in R package were implemented for our proposed method. A GAW16 dataset which consisted of 868 Rheumatoid Arthritis patients and 1194 controls was used to test feasibility. Only 84609 marginal significant SNPs were analyzed ( $p < 0.1$ ). Aside from HLA markers, the results showed that the interaction between *GRIN2A* and *PLXDC2* were most significant ( $p = 0.000529$ ) while the  $p$  value for *GRIN2A* (rs1448258) is 0.001301 and *PLXDC2* (rs7919778) is 0.06147 ( $p = 0.06147$ ). By using IPA, we found that *GRIN2A*, *PLXDC2* and *PSEN1* are in a network, however, only one SNP in *PSEN1* was typed and the  $p$ -value was higher than 0.1 therefore, not included in the study. In conclusion, our proposed method provides a new way to look at gene-gene interaction that can help to uncover epistasis effects in gene mapping studies. 1. **GWAS of six red blood cell traits identifies multiple associations with ancestry-specific lead variants: The PAGE study.** C.J. Hodonsky<sup>1</sup>, K. Nishimura<sup>2</sup>, M. Graff<sup>3</sup>, R. Tao<sup>3</sup>, S. Buyske<sup>4</sup>, L.A. Hindorf<sup>5</sup>, Y. Li<sup>1,6</sup>, D. Lin<sup>1</sup>, R.J.F. Loos<sup>7</sup>, A.P. Reiner<sup>2</sup>, K.E. North<sup>1,6</sup>, C.L. Kooperberg<sup>2</sup>, C.L. Avery<sup>1</sup>. 1) University of North Carolina Gillings School of Public Health, Chapel Hill, NC; 2) Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Vanderbilt University, Nashville, TN; 4) Rutgers University, Piscataway, NJ; 5) National Human Genome Research Institute, Bethesda, MD; 6) University of North Carolina Chapel Hill, Chapel Hill, NC; 7) Icahn School of Medicine at Mount Sinai, New York, NY.

**Background:** Red blood cell (RBC) traits—including hematocrit, hemoglobin, RBC count, mean cell hemoglobin (MCH), MCH concentration, and mean corpuscular volume—are heritable and associated with a wide array of cardiovascular- and inflammatory diseases. Recent large-scale genotype analyses suggest that genetic associations with RBC traits remain to be identified. We thus conducted a GWAS of six RBC traits in Population Architecture using Genomics and Epidemiology (PAGE II) participants genotyped on the Multiethnic Genotyping Array (MEGA). **Methods:** The Illumina MEGA platform was designed to improve common and low frequency variant discovery and fine mapping in global populations. A maximum of 29,223 PAGE participants (30% African American, 65% Hispanic/Latino, 75% female) with phenotype and MEGA genotype data were available for one or more traits. We conducted a GWAS of inverse-normal-transformed RBC traits and ~30 million genotyped and 1000 Genomes Phase 3-imputed autosomal variants in PAGE II participants. We defined a discovery association signal as a lead variant >500kb from any published lead variant. Inverse-normalized residuals were adjusted for age, sex, study, study center, self-reported race/ancestry, family structure, and ten ancestral principal components. **Results:** We identified 23 association signals that exceeded genome-wide significance ( $p < 5 \times 10^{-8}$ ) for one or more RBC traits. Sixteen association signals had been previously reported for at least one trait; seven qualified as discoveries (proximal genes: *SLC26A*, *KHDRBS3*, *LINC00550*, *SEL1L*, *CATSPERB*, *ERCC4*, and *COX4I2*). Three discovery lead variants had a rare allele frequency (MAF < 1%). Two of these and one additional discovery lead variant were specific to African- or Amerindian 1000 Genomes populations. Replication analysis will be performed in study populations representing African, Amerindian, East Asian, and European ancestries. **Discussion:** The identification of seven discovery association signals at a stringent significance threshold emphasizes the need for ancestrally diverse study populations in genomic analyses, particularly for highly polygenic complex traits. Ancestry specificity of multiple discovery signals reinforces the benefits of a genotyping array that allows high-quality imputation outside of European-ancestry populations. Bioinformatic characterization of discovery lead variants is ongoing, including prioritization of candidate functional variants at each association signal.

## 3294W

**Violence exposure, stress biomarkers and gender differences in buccal telomere length among African American young adults.** L. Jackson<sup>1,2</sup>, F. Saadatmand<sup>1</sup>. 1) Pediatrics and Child Health, Howard University, Adelphi, DC; 2) W. Montague Cobb Research Lab, Howard University, Washington, DC.

Violence exposure has long-lasting social and biological impacts on African American (AA) health and can lead to physiological changes, including shorter telomere length (TL). While studies have investigated the relationship between TL and life stress, few focus on African American young adults and their direct nexus to violence. This study examines the effect of violence and gender on both stress biomarkers and TL in AA young adults. We examine the relationship between violence exposure, seven stress biomarkers (IgA/G/E/M, C Reactive Protein, Cortisol, Epstein Barr Virus Antigen) and TL in a cross sectional analysis of 50 buccal samples (N=50 males & 50 females) of AA 18-25 years old in Washington DC who experience differential violence exposure (physical, threat, witnessed, and sexual). Average TL was measured by qPCR. Mann-Whitney tests identified differences between males and females in exposure to violence, stress biomarkers, and the measures of TL. Correlations were calculated between TLs, biomarker levels, and violence measures. Elevated sexual violence exposure was positively correlated (RRANGE= 0.22 to 0.55) with all elevated stress biomarkers except IgE. TL in the high violence exposure group was negatively correlated to all stress biomarker levels (RRANGE= -0.09 to -0.31) except for IgG. There was no significant difference in TL among females exposed and not exposed to violence. Violence exposed females had a longer TL than men (MeanF:M=1.87 v 1.62, p<.05). Male sexual violence exposure was correlated to TL (R=0.575, p< 0.03). High violence levels correlate to shorter TLs and higher stress biomarker levels in AA young adults. These findings suggest that additional focus should be placed on African American young men who have experienced sexual violence.

## 3295T

**GWAS of iron traits in Chilean children of the Santiago Longitudinal Study (SLS).** G. Chittoor<sup>1,2</sup>, E. Blanco<sup>3</sup>, M. Graff<sup>4</sup>, Y. Wang<sup>5</sup>, PE. Melton<sup>6</sup>, C. Albala<sup>7</sup>, JL. Santos<sup>8</sup>, B. Angel<sup>9</sup>, B. Lozoff<sup>8</sup>, VS. Voruganti<sup>8</sup>, KE. North<sup>2</sup>, S. Gahagan<sup>3</sup>, AE. Justice<sup>1,2</sup>. 1) Biomedical and Translational Informatics Institute, Geisinger, Danville, PA, USA; 2) Department of Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 3) Division of Academic General Pediatrics, Child Development and Community Health at the Center for Community Health, University of California at San Diego, San Diego, CA, USA; 4) Curtin/UWA Center for Genetics Origins of Health and Disease, School of Pharmacy and Biomedical Science, Faculty of Health Science, Curtin University, Perth, Australia; 5) Department of Public Health Nutrition, Institute of Nutrition and Food Technology, University of Chile, Santiago, Chile; 6) Department of Nutrition, Diabetes and Metabolism, School of Medicine, Pontificia Universidad Católica de Chile, Santiago, Chile; 7) Pediatrics and Communicable Diseases, University of Michigan, Ann Arbor, MI, USA; 8) Department of Nutrition and UNC Nutrition Research Institute, University of North Carolina at Chapel Hill, Kannapolis, NC, USA.

**Background:** Genetic predisposition may contribute to iron deficiency and its negative health outcomes. Despite its high world-wide prevalence, investigations of genetic contribution to iron phenotypes are limited in pediatric and ethnically diverse populations, especially those of Hispanic/Latino descent. Estimating the genetic effects of iron biomarkers in an ancestrally diverse and admixed Chilean pediatric cohort is important to gain a comprehensive understanding of these traits and their health consequences. Thus, we aim to identify genetic risk factors for seven iron-related measures (ferritin, free erythrocyte protoporphyrin (FEP), hemoglobin (Hgb), serum iron, mean corpuscular volume (MCV), total iron binding capacity (TIBC), and transferrin saturation (SAT)) in the Santiago Longitudinal Study (SLS) of Chilean children at age 10 (N=770; 52% boys). **Methods:** The Illumina MEGA array was imputed using the 1000 Genomes Phase III AMR reference panel for all participants. We conducted linear regression, assuming an additive genetic model, adjusted for sex, population substructure, and random clinical trial arm of the parent infant study based on iron supplementation. Quality control included individual call rate>90%, SNP call rate>95%, imputation quality>0.3, effective N>10, gender mismatch, and ancestry outliers. **Results:** In total, we identified 22 significant loci (P<5x10<sup>-8</sup>, MAF: 0.01-0.43, +/- 500kb) across the 7 traits. Of these 22 loci, 19 were novel associations, including one locus near *ARHGAP8* associated with Hgb, *HMGB1* and *MYLK* with Ferritin, and *SVIL* with MCV (MAF<0.02). Moreover, one locus associated with TIBC was *TF* (P=6x10<sup>-16</sup>, MAF=0.08), and a variant of *TST* associated with both SAT and iron. We generalized several previous SNP-trait associations published, notably, *TF* and *TST* variant associations in these Chilean children were also observed in adult participants from Hispanic Community Health Study/Study of Latinos. **Conclusion:** We demonstrated association of both common and low-frequency variants with iron phenotypes in Chilean children, generalized some loci and reported concordant direction of effects with published findings. Importantly, we observed novel associations indicating possible age- and/or population-specific genetic effects on iron traits. Our findings support the importance of conducting GWAS studies in ancestrally diverse populations and across life stages to better understand the inherent genetic architecture of iron traits.

**Characterisation and somatic mosaicism of the human glycoporphin DUP4 structural variant, and association with haemoglobin levels in a malaria-endemic village.** *W. Algady<sup>1</sup>, S. Gomes<sup>2</sup>, D. Carpenter<sup>1</sup>, P. Brajer<sup>1</sup>, A. Färnert<sup>3</sup>, I. Rooth<sup>4</sup>, M. Shaw<sup>5</sup>, F. Yang<sup>2</sup>, E. Hollox<sup>1</sup>.* 1) University of Leicester, Department of Genetics, United Kingdom; 2) Wellcome Sanger Institute, Cambridge, United Kingdom; 3) Infectious Disease Unit, Department of Medicine Solna, Karolinska Institutet, Stockholm, Sweden; 4) Nyamisati Malaria Research, Rufiji, National Institute for Medical Research, Dar-es-Salaam, Tanzania; 5) School of Medicine, University of Leeds, Leeds, United Kingdom.

Human glycoporphins A and B are proteins expressed on the surface of erythrocytes, and are receptors for invasion of the *Plasmodium falciparum* parasite, which causes malaria in sub-Saharan Africa. The proteins are encoded by the genes GYPA and GYPB which, together with GYPE, reside on a tandemly-duplicated repeat region on chromosome 4q31.21. Previous genome-wide analysis has shown that a structural variant within this region (DUP4), is identical to the blood group antigen Dantu NE+, and confers a clinically-important protective effect, is common in East Africans and is strongly protective against severe malaria, reducing the risk of severe malaria by up to 40%. DUP4 is a complex structural genomic variant that carries hybrid (GYPA/GYPB) fusion genes. Using fibre-FISH, we validate the structural arrangement of the glycoporphin locus in the DUP4 variant, and provide evidence of somatic variation in the number of GYPA/GYPB fusion genes. Subsequently, we have developed a paralogue-specific junction fragment PCR to genotype DUP4. We demonstrate association of DUP4 variant with hemoglobin levels - a phenotype related to malaria - in 348 unrelated DNA samples from a Tanzanian village holoendemic for malaria using a family-based association test. Using the family-based association approach implemented in (QTD), we have found a statistically significant association of the DUP4 variant with hemoglobin levels ( $p=0.0054$ ). Our study confirms the importance of the DUP4 variant in malaria protection, and raises the intriguing possibility of heightened somatic instability and somatic mosaicism at this locus in DUP4 carriers, which might confer added protection against malaria.

As part of an ongoing IBD sequencing program, we have to date sequenced 7,915 whole genomes (3,347 IBD cases) with African American and Hispanic/Latino ancestry. While the sample size is yet relatively small for new locus discovery, we employ this data for use in several ways that aim to elucidate the largely unexplored contribution of non-European populations in rare variant studies of IBD. First, we utilize these data as a source of replication for results from an exome analysis of more than 15,000 IBD cases from four distinct European-derived populations. Here we can explore both effect and frequency distribution seen at many known IBD variants and are able to assess the utility of diverse populations to replicate new associations at different frequencies. We can further detect the existence of variants in known genes that are previously undetected because they are rare or absent in Europeans. For example, several variants in the NOD2 gene have higher effect sizes in European populations, but do not seem to contribute as much in African Americans. Nevertheless, we find NOD2 to have a similar importance in African-Americans through identification of a strongly associated missense variant not observed in Europeans. Beyond providing us with additional association and enrichment results, these genomes serve to reinforce the importance of Quality Control-related decisions in restricting and aligning whole genomes to an exome-based analysis. Preliminary results show that in both exomes and genomes, full-coverage filtering based on the GnomAD QC metrics have had the most significant impact on otherwise difficult to address noise in single-variant analysis.

**3298T****Retrospective epidemiological study of Venezuelan patients with Haemoglobinopathies. Haematological characteristics, most frequent mutations, comprehensive clinical care and genetic counselling programs.**

A.B. Falcon de Vargas. Clinical Genetics Unit, Hospital Vargas Caracas.

Escuela Vargas. UCV. San Jose . Caracas. 1061.

A HVP-GG2020 Challenge protocol for Haemoglobinopathies in Developing Countries was used. Researchers and international publications were consulted. Major haemoglobinopathies in Venezuela are Sickle cell disease, beta thal minor, HbS, variants C, D. In 80400 haemolytic anaemia Venezuelan patients; 9% haemoglobinopathy, HbS, variants C and D. Frequency haplotypes bs gen in 272 with drepanocytosis (SCA) , heterocytotes for HbS was 50, 8%; Benin, 32,2%; CAR, 14; Senegal 2 and 2,3% Camerun. In homocytous HbS patients, 8% was Ben haplotype, 82% double heterocytote for haplotypes Ben/CAR, 8,8% haplotypes Ben, Senegal, CAR/Senegal y Ben/Camerun, one patient homocytos for haplotype CA (A Arends et al, Science and Technology,2007, 32;8:516521). Sickle Cell Disease SCD , frequency from zero in Indians up to 5% in Mestizo and Afro-American population; 12% in the NC costal Region (Arends,1971; Arends et al 1982). Seven polymorphic sites in b-globin gene cluster (State Aragua). Benin haplotype 0.479, Bantu haplotype 0.406; atypical Bantu A2 0.042; Senegal 0.031; atypical Bantu A7; 0.021 Saudi Arabia\_Indian (0.021). (N Moreno et al, Genet. Mol. Biol. 25,1:2002). Sudanese, Bantu origins. 101.301 newborns were analysed (HPLC-CE; VBRS SC Short program ; Betathak program for family studies). 127 unrelated subjects suspicion  $\beta$ -thalassemia trait or clinically  $\beta$ -thal syndrome had DNA studies (PCR-bases reverse dot-blot method or amplification refractory mutation system (ARMS). 15 different mutations were identified , 92% of the mutant alleles studied, revealing genetic heterogeneity at the  $\beta$ - globin gene locus ( M Bravo-Urquiola, Hemoglobin, 2012;36(3):209-18). Most frequent mutations: Codon 39 (C >T) 34.1%, IVS-I-(G >A) 11.1%, IVS-I-6(T >C=6.6%, -29 (A >G) 5.2%. Less common mutations IVS-I-5 (G >A) 3.7%; 1,393 bp deletion 3.0%: IVSII-1 (G >A) 3.0%, -86 (C >G) 2.2% , IVSII-1 (G >T) 1.5%; (C >T) codons 41/42 (-TCTT) 1.5%, IVSS-II745 (C >G) 0.7% and deletion at  $\beta$ - thal 0.7%.The major sources of  $\beta$  - thal-alleles in Venezuela are of Mediterranean and African origins. Diversity of haplotypes associated with some of the  $\beta$ -thal mutations explained by in situ recombination events in Venezuela.

**3299F****Investigating the burden of nonsynonymous variation in PI3Kdelta pathway genes of individuals affected with idiopathic bronchiectasis.**

Bronchiectasis (BE) is a respiratory condition characterized by dilated bronchi, mucus hypersecretion, and chronic respiratory infection. Non-cystic fibrosis (CF) BE currently affects 300-650 in 100,000 people in the US and UK, with 35-50% of affected individuals having no obvious or easily definable disease origin (idiopathic). BE can also be caused by defined genetic disorders such as cystic fibrosis, primary ciliary dyskinesias, and immunodeficiencies (e.g. Activated PI3Kinase Delta Syndrome (APDS)). Currently, there are no specific licensed medicines for BE patients, presenting a clear need for deeper exploration into the genetic etiology of this disease. We performed whole exome sequencing of blood samples from 400 cases with idiopathic BE, and obtained whole exome sequence data generated for 4,300 healthy controls from the INTERVAL cohort (Cambridge, UK) at ~50x coverage. Variants were jointly called in the case and control cohorts followed by call set refinement, sample kinship estimation, and principal component ancestry analysis. Exome-wide association scans were carried out using both single variant (minor allele frequency (MAF) > 1%) and gene-based tests to evaluate the aggregate burden of low frequency (MAF < 5%) protein-truncating, protein-altering, and silent coding variants in a subset of 4,387 unrelated samples of recent European ancestry (373 cases and 4,014 controls). We also evaluated the burden of pathogenic variants present in curated gene sets of relevant pathways (e.g. PI3Kdelta signaling, ciliopathy) in BE cases versus controls. Of the 623,507 high quality variant sites identified in protein-coding regions, 8,505 were loss-of-function (LoF) variants (stop-gained, splice site disrupting, or frameshift; Loss-Of-Function Transcript Effect Estimator (LOFTEE) high confidence), and 155,880 were missense variants with CADD score > 21. As a first analysis, we evaluated the combined burden of LoF and missense variants in PI3Kdelta pathway genes (SKAT-O) including *AKT2* ( $P=4 \times 10^{-4}$ ), *PIK3R1* ( $P=0.02$ ), *FOXO1* ( $P=0.02$ ), and *INPP5D* ( $P=0.03$ ). We identified one affected heterozygous carrier of the APDS-causing E81K amino acid substitution in *PIK3CD*, subsequently confirmed by Sanger sequencing. Case-enrichment of pathogenic variants in genes of immune and airway-related pathways suggests potential mechanisms for disease susceptibility. Further sub-phenotyping will help identify patient subgroups that may benefit from specific therapeutic interventions.

**Whole transcriptome cis-eQTL analysis of the nasal airway epithelium in childhood asthmatics reveals functional asthma risk variants.** S.P. Sajuthi, B.A. Saefi, M.T. Montgomery, J.L. Everman<sup>1</sup>, A.C. Mak<sup>2</sup>, M. White<sup>2</sup>, C. Eng<sup>2</sup>, S. Oh<sup>2</sup>, J. Rodriguez-Santana<sup>3</sup>, E.G. Burchard<sup>2,4</sup>, M.A. Seibold<sup>1,5,6</sup>. 1) Center for Genes, Environment, and Health, National Jewish Health, Denver, CO; 2) Department of Medicine, University of California San Francisco, San Francisco, CA; 3) Centro de Neumología Pediátrica, San Juan, Puerto Rico; 4) Department of Bioengineering and Therapeutic Sciences, University of California San Francisco, San Francisco, CA; 5) Department of Pediatrics, National Jewish Health, Denver, CO; 6) Division of Pulmonary Sciences and Critical Care Medicine, Department of Medicine, University of Colorado-AMC, Aurora, CO.

Genetic association studies of asthma have found most risk variants are non-coding, suggesting that these variants affect gene expression regulatory regions. Therefore, expression quantitative trait loci (eQTL) variants identified in asthma disease-involved tissues will likely be enriched for risk variants. The bronchial airway epithelium is central to asthma pathogenesis through the production of mucus, which causes airway obstruction and immune signaling leading to airway inflammation. The expense and safety concerns of performing bronchoscopies on children to collect bronchial airway epithelial brushings have impeded airway epithelial eQTL studies in children with asthma. Previously, we verified the use of minimally-invasive nasal airway epithelial brushings collected from children as an effective proxy of the bronchial airway epithelium. Therefore, we recruited a cohort of 698 children from the Genes-Environments, and Admixture in Latino Americans (GALA II) Study with nasal airway epithelial brushings to perform a cis-eQTL study. Whole transcriptome expression data was generated on nasal brushings from all subjects and paired with subject whole genome genotyping data. We found over 70% of expressed genes contained a significant cis-eQTL (eGenes=13,638). Stepwise regression analysis identified 24,737 independent eQTL variants, with 29.2%, 30.8%, and 40% of eGenes harboring 1, 2, or 3+ independent cis-eQTLs, respectively. Examining the 45 genes contained across the 18 validated asthma genomic loci identified in the largest asthma meta-analysis performed to date, we found 24 genes exhibiting a significant cis-eQTL. For example, we identified several strong independent eQTLs for both the GSDMB and PGAP3 genes at the 17q21 asthma locus. We next examined whether asthma eQTLs differed based on the airway inflammation exhibited by subjects. Specifically, we found 47% of subjects exhibited excessive airway inflammation triggered by type 2 cytokines (type 2-high disease) through gene expression clustering analyses. Meta-analysis of eQTL results for the two groups identified eGenes unique to type 2-high (n=1,547) and type 2-low (n=1,595) subjects. We are currently testing these eQTLs for association with type 2-high and -low asthma in >10,000 minority children. These results reveal the wide-spread nature of genetic regulation of airway epithelial gene expression including asthma genes, as well as the dependence of genetic effects on airway inflammation.

**Novel strategies for gene-environment-wide interaction scans in family-based studies of admixed individuals.** Y. Chen<sup>1,2</sup>, I. Adrianto<sup>1,2</sup>, M. Lanuzzi<sup>3</sup>, C. Montgomery<sup>4</sup>, B. Rybicki<sup>1</sup>, A. Levin<sup>1,2</sup>, J. Li<sup>1,2</sup>. 1) Department of Public Health Science, Henry Ford Health System, Detroit, Michigan; 2) Center for Bioinformatics, Henry Ford Health System, Detroit, Michigan; 3) Department of Internal Medicine, State University of New York, Upstate Medical University Hospital, Syracuse, NY; 4) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma.

Etiology of many complex diseases involves both environmental exposures and inherited genetic pre-disposition, and interactions between them. Genome-environment-wide interaction scans (GEWIS) provide a means to identify the interactions between genetic variation and environmental exposures that underlie disease risk. However, current GEWIS methods lack the capability to adjust for the potentially complex correlations in family based study designs carried out in admixed populations. Here, we developed novel methods based on generalized estimating equation (GEE) -- GEE-adaptive and GEE-joint to account for phenotypic correlations due to kinship while accounting for covariates, including measures of genome-wide ancestry. In two simulated family study designs of admixed individuals, both methods demonstrated higher power than traditional case-control method and controlled the family-wise error rate (FWER), an advantage over the case-only approach. Applying the proposed method to a real data analysis of insecticide exposure and risk of sarcoidosis in African American, we identified 19 potential SNPs interacting with insecticide exposure at a p-value threshold < 1\*10<sup>-5</sup>.

## 3302F

**Genome-wide scan identifies loci for white blood cell and platelet traits in a multi-ethnic study from population architecture using genetic epidemiology (PAGE).** S.A. Bien<sup>1</sup>, K.K. Kooperberg<sup>1</sup>, *Population Architecture using Genetic Epidemiology (PAGE)*.

1) Cancer Prevention, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Epidemiology, University of North Carolina Chapel Hill, Chapel Hill, NC; 3) Vanderbilt University Medical Center, Nashville, TN; 4) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 5) Department of Statistics and Bio-statistics, Rutgers University, New Brunswick, NJ; 6) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 7) Cancer Research Center, University of Hawaii, Honolulu, HI; 8) Department of Genetics, Rutgers University, New Brunswick, NJ.

Circulating White Blood Cell (WBC) and platelet counts are moderately heritable and vary in healthy individuals by race/ethnicity. Importantly, circulating WBC and platelet counts are used to alert clinicians to possible undiagnosed conditions, such as autoimmune diseases, immune deficiencies and blood disorders. We conducted a large, multi-ethnic GWAS in the Population Architecture using Genomics and Epidemiology (PAGE) Study to gain a deeper understanding of how ancestry-specific genetic variants may influence 8 indices of WBC and platelet counts. Transethnic meta-analysis was performed for 70,428 individuals of African American (AFR), Hispanic/Latino (H/L), Native American, or European (EUR) ancestry with WBC and platelet measurements and genotyped on either the multiethnic genotyping array (n=23,907) or another GWAS platform. These data were imputed into the 1000 Genomes Phase 3 data. Those with measurement +/- 4 standard deviations were excluded. SUGEN software was used to perform linear regression for each trait stratified by race/ethnicity and adjusting for age and age<sup>2</sup> at WBC measurement, sex, body mass index, current smoking status, self-identified race/ethnicity, study center, family/household membership, and 10 ancestral principal components (PCs). Variants were then tested for association using rank-based inverse normal transformation of the residuals from these models and results were combined using fixed effects meta-analysis. We identified 100 regions independently associated at  $p < 5 \times 10^{-8}$  across 8 blood cell indices. Signals were detected in 7 regions not previously associated with any of the blood cell indices analyzed (1q25.1-*RC3H1*, 1q25.1-*RABGAP1L*, 2p23.3-*HADHB*, 7q21.3-*GNG11*, 7q36.2-*INSIG1*, 12q32.2-*IGF1*, and 8q24.22-*SLA*), and 5 known regions associated blood cell trait differing from the trait previously reported, (1p34.2-*MPL*, 2q21.3-*CXCR4*, 3p22.2-*CX3CR1*, 9q34.11, and 12q24.21-*MED13L*). Additional independent associations were detected in 11 known loci, which remained genome-wide significant after conditioning on previously reported associations. As clinical practice begins to move towards precision medicine, it is critically important to perform GWAS in ancestrally diverse study populations in order to gain better understanding of genetic influences on biomarkers that should be accounted for when interpreting their circulating concentrations. Additional analyses including gene burden tests, and finemapping are ongoing.

## 3303W

**Association between the risk of monoclonal B-cell lymphocytosis (MBL) and the chronic lymphocytic leukemia (CLL) polygenic risk score (PRS).** G. Kleinstern<sup>1</sup>, S.J. Achenbach<sup>1</sup>, D.P. Robinson<sup>1</sup>, A.D. Norman<sup>1</sup>, K.G. Chaffee<sup>1</sup>, C.E. Lesnick<sup>1</sup>, S.A. Parikh<sup>2</sup>, T.G. Call<sup>3</sup>, J.E. Olson<sup>1</sup>, J.R. Cerhan<sup>1</sup>, N.E. Kay<sup>4</sup>, C.R. Hanson<sup>2</sup>, T.D. Shanafelt<sup>4</sup>, S.L. Slager<sup>1</sup>. 1) Department of Health Sciences Research, Mayo Clinic, Rochester MN, United States; 2) Division of Hematology, Mayo Clinic, Rochester, MN, United States; 3) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN, United States; 4) Department of Medicine, Division of Hematology, Stanford University, Stanford, CA, United States.

**Background** MBL is a precursor state to CLL, with a prevalence of ~5-8% in the general population and 15-18% in CLL families. To date, 41 single nucleotide polymorphisms (SNPs) have been found to be associated with CLL. We previously showed that a PRS of the weighted average of the number of risk alleles of these SNPs is associated with CLL risk using cases and controls from the International Lymphoma Epidemiology (InterLymph) Consortium. We validated this score in an independent sample of CLL cases and controls from the Genetic Epidemiology of CLL (GEC) Consortium, a cohort of families with  $\geq 2$  members with CLL. In the CLL families we also reported an association between the PRS and MBL risk. Here we evaluate the PRS in an independent sample ascertained from the Mayo Clinic Biobank. **Methods** The Mayo Clinic Biobank is a large-scale bio-repository of adult patients assembled to provide a wide array of health-related research studies. Biobank participants were screened for MBL using a highly-sensitive, 8-color flow-cytometry assay on stored cryopreserved peripheral blood mononucleotide cells. Low-count MBL was defined as those individuals who had  $< 85\%$  clonal B-cells out of total B-cells. Individuals without MBL ("controls") were frequency matched to MBLs based on age and sex. Participants were genotyped using the Illumina OmniExpress array. Standard genotyping quality-control metrics were applied. We computed the PRS as previously published and categorized it by quintiles based on values previously used with InterLymph controls. The middle quintile served as the reference category. We used logistic regression to estimate odds ratios (ORs) and 95% confidence intervals (CI), adjusting for age at consent, sex, and socioeconomic status. **Results** We identified 276 MBLs and 844 controls; 97% of MBLs had low-count MBL. Family history of leukemia/lymphoma was 11.3% among MBLs and 8.8% among controls. The continuous PRS had a 1.75-fold increased risk for MBL (CI:1.5-2.1,  $P=2.65 \times 10^{-12}$ ). Compared to the middle quintile, the highest quintile had 2.2-fold increased risk for MBL (CI:1.5-3.3,  $P=1.46 \times 10^{-4}$ ) and the lowest quintile had 0.6-fold decreased risk (CI:0.4-0.96,  $P=0.03$ ). **Conclusion** In this independent sample, we validated our previous findings that the CLL PRS is associated with MBL risk. These results may help identify individuals at higher risk of MBL (especially low-count MBL) beyond the risk associated with age and family history of CLL.

## 3304T

**Whole genome sequences association with E-selectin levels reveals loss-of-function variant in African Americans.** L.M. Polfus<sup>1</sup>, L.M. Raffield<sup>2</sup>, R.P. Tracy<sup>3,4</sup>, L.A. E-selectin is highly expressed on endothelial cells when activated by cytokines or chemokines, and is specifically involved in the tether and rolling phases of the leukocyte-endothelial adhesion during various inflammatory and immune responses. Previous genome-wide association studies (GWAS) have identified the *ABO* locus associated with E-Selectin levels in European and Asian individuals. Using whole-genome sequencing (WGS) data in 2,458 African Americans (AAs) from the Jackson Heart Study (JHS) in the Trans-Omics for Precision Medicine (TOPMed) Program, we examined genome-wide associations with soluble E-Selectin levels. We performed discovery analyses for 30,016,534 single nucleotide variants and small indels with minor allele frequency (MAF)  $\geq 0.001$ . Three loci surpassed a genome-wide significance threshold: 9q24 (85 variants, sentinel: *ABO* rs532436,  $P=2 \times 10^{-83}$ ), 1q24 (70 variants, sentinel *SELL-SELE* rs139825795,  $P=7 \times 10^{-48}$ ), and 19p13 (31 variants, sentinel: *FUT6* rs17855739,  $P=7 \times 10^{-24}$ ). Because the *FUT6* rs17855739 (p.Glu274Lys) loss-of-function variant is considerably more common in populations of African ancestry (MAF=0.28-0.29) compared to non-African ancestry populations (MAF=0.03-0.06), we performed targeted replication and phenotypic association studies in another African-American population. We replicated the association of *FUT6* (rs17855739) with higher soluble E-selectin in an independent population of 748 AAs from the Women's Health Initiative ( $P=4 \times 10^{-5}$ ) and identified a pleiotropic association with vitamin B12 levels. We also conducted electronic medical record (EMR)-based phenome-wide association scan of these loci in over 9,000 African Americans from the BioVU and BioMe EMR-based biobanks. Despite the broad role of both selectins and fucosyltransferases in various inflammatory, immune and cancer-related processes, we were unable to identify any additional disease associations of the *FUT6* rs17855739 variant in an EMR-based phenome-wide association scan. The African *FUT6* rs17855739 is associated with plasma alpha(1,3)-fucosyltransferase deficiency, and should be further investigated for association with chronic disease outcomes in African Americans, particularly given the potential importance of E-selectin-interactions as a therapeutic target for various chronic inflammatory conditions.

## 3305F

**Understanding the genetic determinants of peanut-specific IgG4 in the learning early about peanut allergy (LEAP) study.** A.H. Winters<sup>1</sup>, M. Boorgula<sup>2</sup>, H.T. Bahnson<sup>3,7</sup>, S. Chavaan<sup>2</sup>, G. Du Toit<sup>4,5</sup>, I. Ruczinski<sup>1</sup>, P.H. Sayre<sup>3,6</sup>, K.C. Barnes<sup>2</sup>, G.T. Nepom<sup>7</sup>, G. Lack<sup>4,5</sup>, R.A. Mathias<sup>1</sup>, the Immune Tolerance Network Learning Early About Peanut Allergy study team. 1) Johns Hopkins University, Baltimore, MD; 2) University of Colorado, Anschutz, CO; 3) Immune Tolerance Network, San Francisco, CA; 4) Department of Paediatric Allergy, Division of Asthma, Allergy and Lung Biology, King's College London, UK; 5) Guy's and St. Thomas' NHS Foundation Trust, London, UK; 6) Department of Medicine, University of California, San Francisco, CA; 7) Benaroya Research Institute, Seattle, WA.

The LEAP study showed a protective effect of early oral peanut exposure for infants at high risk of developing peanut allergy, with an 81% reduction in peanut allergy incidence in the peanut consumption group compared to the peanut avoidance group. We have now performed whole genome sequencing (WGS) to understand the genetic determinants of clinical outcomes and biomarker correlates of peanut allergy in the LEAP Study. It has been shown that peanut-specific IgG4 increased more in the peanut consumption group as compared to the peanut avoidance group and showed the largest difference between the two groups amongst the biomarkers measured in LEAP. In this report, we leverage array data from the Illumina Omni 2.5 bead chip, generated as part of our WGS quality control pipeline, to begin to understand the genetic determinants of peanut-specific IgG4. Single SNP tests for association for peanut-specific IgG4 at 60 months of age (the conclusion of the LEAP trial) were performed on 267 participants in the peanut consumption group. The peak association identified was with the variants rs75590598 and rs11681497 ( $p=5.79E-07$  and  $9.33E-07$ , respectively). These are located on chromosome 2 in the *HDLBP*, *SEPT2*, and *FARP2* gene cluster. Both the SNPs are common intronic variants with minor allele frequencies  $>10\%$ . While rs75590598 maps to *HDLBP* and rs11681497 to *FARP2*, both are reported to be expression quantitative trait loci (eQTLs) for the *SEPT2* gene in a number of tissues in GTEx. A second signal was seen on chromosome 6 for rs17612852 ( $p=5.80E-07$ ) which maps to the region between *HLA-DQA1* and *HLA-DQB1*. rs17612852 is an eQTL for *HLA-DQB1* in multiple tissues in GTEx. *SEPT2* has previously been shown to regulate airway epithelial barrier function, and deficiencies in the epithelial barrier are known to be associated with allergy. Additionally, previous work has shown association with variants in *HLA-DQB1* and increased risk of peanut allergy independent of asthma, implicating this locus in peanut allergy-specific risk and not just general atopic risk. We are currently analyzing all sequence-identified variants from the WGS to follow up on these results from the GWAS array and to identify additional rare and novel variants associated with peanut-specific IgG4. We are also extending these analyses to other biomarkers associated with peanut allergy as measured in the LEAP subjects.

**3306W**

**Genetic modifiers of IgE response in AD.** C. Polymeropoulos, S. Smieszek, M. Polymeropoulos. Vanda Pharmaceuticals, DC.

Immunoglobulin E (IgE) mediated allergy to environmental allergens plays a central role in the pathophysiology of asthma, atopic dermatitis, and food allergy. Atopy and plasma IgE concentration are genetically complex traits, and the specific genetic risk factors that lead to IgE dysregulation and clinical atopy are an area of active investigation. To ascertain the genetic risk factors which lead to IgE dysregulation we conducted a genome-wide association analysis using 117 whole genome sequencing atopic dermatitis samples. Using linear regression, we have directly tested the association between 14,322,979 SNPs and log transformed IgE response, correcting for covariates including sex and principal components. We detected 24 loci at  $P < 9.5 \times 10^{-8}$ . Interestingly there was a strong signal within 6q23 region containing immune response genes such as Interleukin 20 Receptor Subunit Alpha (*IL20RA*) and Interleukin 20 Receptor Subunit Alpha (*IL22RA2*). The *IL20RA* gene encodes the IL-20 receptor  $\alpha$  subunit, which can form a heterodimeric receptor with either IL-20RB to bind IL-19, IL-20 and IL-24, or with IL-10RB to bind IL-26. Evidence suggests that this family of cytokines have a pro-inflammatory effect and involvement in skin inflammation. This gene and interleukin 20 receptor beta are highly expressed in the skin, and are upregulated in psoriasis. Top loci were enriched in cytokine receptor activity and interleukin-20 binding (GO:0042018, GO:0042020). Haploreg v4.1 was used to investigate the regulatory potential, showing that rs276571 demonstrates a number of lines of evidence to support a function in disease causality, including mapping to an enhancer in B-lymphoblastoid cell lines, primary and T-regulatory cells. It also maps to a region of open chromatin, characterised by DNase hypersensitivity, shows evidence of binding of STAT3. Furthermore the locus has been shown to be a significant (0.000004) eQTL for *IL20RA* in GTEX. The risk allele is effectively correlated with higher expression of *IL20RA*. We can explain a high proportion of variance (GCTA) in IgE within the AD samples ( $p$  val 8.882e-16, SE 0.09). Moreover top hits include some other interesting associations such as a missense variant rs2280090 within a disintegrin and metalloprotease 33 gene *ADAM33*. Interestingly, our analysis led to functional and actionable results of relevance to the greater understanding of AD and IgE responses that could aid in therapeutics with genetic support.

**A genome-wide association study of intracellular phenotypes reveals novel haematological biology.** P. Akbari<sup>1</sup>, T. Jiang<sup>1</sup>, D. Vuckovic<sup>2</sup>, D.J. Roberts<sup>2,3</sup>, E. Di Angelantonio<sup>1</sup>, J. Danesh<sup>1</sup>, W.H. Ouwehand<sup>4</sup>, A.S. Butterworth<sup>1</sup>, N. Soranzo<sup>2</sup>, W.J. Astle<sup>1,3</sup>. 1) Cardiovascular Epidemiology Unit, Department of Public Health and Primary Care, University of Cambridge, Strangeways Research Laboratory; 2) Department of Human Genetics, The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge; 3) Department of Haematology, Churchill Hospital, Headington, Oxford; 4) Department of Haematology, University of Cambridge, Cambridge Biomedical Campus, Long Road, Cambridge.

An adult human synthesises approximately 1012 blood cells per day. These cells have crucial functions in respiration, immunity and wound healing, and have been implicated in the aetiology of many common diseases, ranging from asthma to stroke. However, our understanding of the regulation of the production, clearance and activation of blood cells is limited. Up to now, population genetic studies of quantitative cellular blood phenotypes have focused on cell count/volume (CBC) traits, which are largely insensitive to intracellular functional mechanisms. We used the Sysmex XN advanced haematology analyser to assay ~80 novel cellular traits in ~40,000 blood donors participating in the INTERVAL study. These traits include measures of nucleic acid-content, membrane lipid content, granularity, neutrophil activation and lymphocyte reactivity, previously unstudied by human geneticists. We conducted a GWAS of ~30 million imputed variants, identifying 929 loci associated with at least one phenotype. Comparisons with a recent GWAS of CBC traits measured in ~170,000 participants (Astle et al, Cell, 2016) showed that just 54% of the intracellular trait associated loci had been detected by the previous study despite its 4 fold larger sample, demonstrating that the new phenotypes detect a novel spectrum of biological variation. Functionally relevant ontology terms such as 'defense response to bacterium' and 'T cell differentiation' were respectively enriched in genes associated with neutrophil and lymphocyte traits. Neutrophil granularity was significantly associated ( $p=4.2 \times 10^{-313}$ ) with the azurophilic granule residing antimicrobial defensin locus (*DEFA4*, *DEFA6*, *DEFA8P* &c) and Mendelian randomisation implicated defensins in the aetiology of coronary artery disease. Platelet granularity was associated with a common variant linked to *NBEAL2* ( $p=4.1 \times 10^{-12}$ ), rare mutations in which cause gray platelet syndrome, a disorder with bleeding symptoms caused by the dysfunction of alpha-granules. We identified associations with a number of alleles implicated in rare recessive disorders, such as those in *SPTA1* ( $p=5.4 \times 10^{-47}$ ) known to cause hereditary pyropoikilocytosis, a form of hemolytic anemia characterized by an abnormal sensitivity of red blood cells to heat. Our analysis, which is the first large scale investigation of flow cytometry derived intracellular phenotypes, reveals novel haematological biology with implications for understanding the aetiology of rare and complex diseases.

**Optimizing chronic hepatitis C treatment in a Canadian cohort using precision medicine based methods.** J.J. Lin<sup>1</sup>, C.M. Loucks<sup>2</sup>, J.N. Trueman<sup>2</sup>, E.M. Yoshida<sup>3</sup>, J. Ford<sup>3</sup>, S.S. Lee<sup>4</sup>, E. Tam<sup>5</sup>, A. Ramji<sup>5</sup>, B.I. Drogemoller<sup>2,6</sup>, G.E.B. Wright<sup>1,2</sup>, C.J. Ross<sup>6</sup>, B.C. Carleton<sup>1,2,6</sup>. 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Pediatrics, University of British Columbia, Vancouver, BC, Canada; 3) Division of Gastroenterology, University of British Columbia, Vancouver, BC, Canada; 4) Division of Gastroenterology and Hepatology, University of Calgary Liver Unit, Calgary, AB; 5) LAIR Centre, Vancouver, BC, Canada; 6) Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, BC, Canada.

**Background:** Chronic Hepatitis C virus (HCV) infection is a major cause of cirrhosis and liver disease, making it a leading indicator for liver transplantation. In the era of direct acting antiviral therapy for HCV with impressive cure rates over 95%, ribavirin (RBV) is still used to improve outcomes for difficult to treat patients and shorten therapy length. However, RBV can cause serious anemia in up to 50% of patients, requiring dose reductions to prevent further harm. This can compromise treatment success, resulting in longer treatment periods and higher costs. We aim to validate previously identified genomic variants, and discover novel variants associated with RBV-induced anemia in Canadian patients and develop a pharmacogenomic prediction model identifying patients most likely to develop anemia due to RBV-containing treatments. **Methods:** We have recruited patients treated with RBV-containing regimens from five sites in three cities across Canada. A genome-wide association study will then be conducted to (i) validate the role that previously associated variants (e.g. rs1127354 and rs7270101 in *ITPA*) play in current RBV treatment regimens and (ii) uncover novel genomic predictors of RBV-induced anemia. **Results:** 191 patients treated with RBV-containing regimens were recruited. Of these, 50 cases were identified and defined as those with serious anemia that warranted a change in treatment in the form of dose reductions in RBV or erythropoietin supplementation. These patients had a median hemoglobin decline of 38 g/L during treatment. The case cohort is comprised of a higher proportion of viral genotype 1 infected patients and lower proportion of viral genotype 3. We are currently assessing recruited patients for ~700,000 variants across the genome for genomic analyses which will be completed by September 2018. **Conclusions:** Downstream genomic analyses will need to take into account the differences in HCV genotype distribution in the studied cohort. Knowing in whom serious anemia to RBV is likely to occur, based on precision medicine, will allow for tailoring of therapy to individual patients to increase the probability of treatment success and minimize the likelihood of developing serious anemia. This will be particularly interesting in our Canadian cohort, as it is composed of patients of various ancestries that may have unique predispositions to anemia. Together, this will help decrease both economic and psychological burdens on affected families.

**3309W**

**Identifying transcriptional and epigenetic mechanisms associated with genetic risk for inflammatory bowel disease using causal mediation analysis.** K.T. Nguyen<sup>1,2</sup>, Y. Park<sup>1,2</sup>, L. Hou<sup>1,2</sup>, C. Boix<sup>1,2</sup>, L. He<sup>1,2</sup>, M. Kellis<sup>1,2</sup>. 1) Massachusetts Institute of Technology, Cambridge, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA.

Identifying the mechanisms by which genetic variants influence risk of complex disease is a fundamental problem in human genetics. Summary-based transcriptome-wide association studies (sTWAS) have helped address this problem, identifying genes associated with human disease by aggregating cis-regulatory effects on gene expression learned in expression quantitative trait loci (QTL) studies. Our contribution to this problem, Causal Multivariate Mediation within Extended Linkage disequilibrium (CaMMEL) is a Bayesian inference framework that jointly models multiple mediated and unmediated effects of GWAS risk variants. We showed that this method addresses limitations of other methods of detecting causal mediation by allowing for horizontal pleiotropy and other unmediated effects, and jointly modeling mediators in order to select a sparse set of mediators in LD regions. In addition to expression QTLs, the availability of QTL data for other types of molecular phenotypes has been rapidly increasing, allowing us to investigate additional mechanisms of disease etiology. Recently, the BLUEPRINT consortium generated a rich dataset of QTLs for a wide variety of molecular phenotypes, including gene expression (eQTL), histone modifications H3K27ac and H3K4me1 (hQTL), splicing (sQTL), and DNA methylation (meQTL), generated in purified samples of monocytes, T-cells, and neutrophils. We applied CaMMEL to this data to investigate the mediation effect of these molecular phenotypes on inflammatory bowel disease (IBD), a complex autoimmune disease. This has allowed us to identify regulatory regions whose activity is predicted to mediate IBD risk. These regions are enriched in motifs of transcription factors such as LXR and KLF4, which have both been experimentally linked to protection against induced colitis in mice. We also determined that those regions are associated with GO pathways such as negative regulation of developmental growth and regulation of T cell mediated cytotoxicity. This work allows us to gain specific insights into the mechanisms of action of risk variants and to identify therapeutic targets for IBD. More generally, we will also be able to evaluate the contribution of the various types of molecular QTL and the importance of cell type-specific information to disease etiology.

## 3310T

**Whole-genome sequencing identifies *CRISPLD2* as a candidate gene for lung function in children with airway hyperresponsive asthma.** P. Kachroo<sup>1</sup>, J. Hecker<sup>2,3</sup>, B. Chawes<sup>1,4</sup>, C. Lange<sup>1,3</sup>, S.T. Weiss<sup>1</sup>, J. Lasky-Su<sup>1</sup>. 1) Channing Division of Network Medicine, Department of Medicine, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 2) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA; 3) Department of Genomic Mathematics, University of Bonn, Bonn, GE; 4) COP-SAC, Copenhagen Prospective Studies on Asthma in Childhood, Herlev and Gentofte Hospital, University of Copenhagen, Copenhagen, DK.

**Background:** Resequencing of common asthma candidate genes discovered by genome-wide association studies has shown that uncommon and rare variants contribute to asthma susceptibility. This implies the need for high-coverage sequencing to unravel the genetic basis of asthma. **Objective:** To identify regions of genetic variation contributing to airway hyperresponsive asthma affection status and lung function utilizing whole-genome sequencing (WGS) data from Costa Rican children with asthma. **Methods:** WGS data were generated on 1,053 individuals from trios and extended pedigrees participating in the family-based 'Genetic Epidemiology of Asthma in Costa Rica' cohort. Asthma affection status was defined by asthma plus bronchial hyper-responsiveness to methacholine, and lung function (FEV<sub>1</sub>, FEV<sub>1</sub>/FVC-ratio) was measured at baseline and post-bronchodilator. Analyses were done with family-based association test (FBAT) methods for both single-variant and region-based tests. P-values were combined for meta-analysis in two other independent cohorts that defined asthma similarly: CAMP and Hartford-Puerto Rico using metaP package in R. **Results:** After data cleaning, 25.76 million autosomal SNPs remained for single-variant FBAT, showing a genome-wide significant association with baseline FEV<sub>1</sub>/FVC-ratio for a SNP in *CRISPLD2* (rs12051168,  $p=3.6 \times 10^{-8}$ ). This SNP also had nominally significant associations for asthma affection status ( $p=0.025$ ), baseline FEV<sub>1</sub> ( $p=0.044$ ) and post-bronchodilator FEV<sub>1</sub>/FVC-ratio ( $p=2.6 \times 10^{-3}$ ). Additionally, rs12051168 could be replicated across two independent cohorts (Puerto Rico and CAMP) for baseline FEV<sub>1</sub> ( $p=0.048$ ). Combined P value for rs12051168 was significant across all cohorts for baseline FEV<sub>1</sub> ( $p=0.002$ ) and FEV<sub>1</sub>/FVC ratio ( $p=1.47 \times 10^{-4}$ ) and post-bronchodilator FEV<sub>1</sub> ( $p=0.006$ ) and FEV<sub>1</sub>/FVC ratio ( $p=0.016$ ). A total of 327,761 regions with at least 6 SNPs were constructed for the region-based FBAT analysis, which identified several regions with association p-value below  $10^{-5}$  that supports the single-variant findings. **Conclusions:** This WGS analysis of asthma defined utilizing airway hyperresponsiveness identified *CRISPLD2* as a lung function candidate gene. It has previously been shown that *CRISPLD2* regulates anti-inflammatory effects of glucocorticoids in the airway smooth muscle cells, whereas these WGS findings suggest that *CRISPLD2* may play a larger role in asthma pathogenesis.

## 3311F

**Identifying modifying genes to explain the variation in severity of fragile X-associated primary ovarian insufficiency.** C.E. Trevino, E.G. Allen, P. Jin, H.R. Johnston, D.J. Cutler, M.E. Zwick, S.T. Warren, S.L. Sherman. Emory University, Atlanta, GA.

Primary ovarian insufficiency (POI) is a condition characterized by symptoms of early menopause and infertility that affects 1% of the general population, making it a leading cause of infertility in women. Patients with this condition also display elevated follicle stimulating hormone, low anti-Müllerian hormone levels and early estrogen deficiency. Women who carry the *FMR1* premutation, a CGG repeat expansion in the range of 55-200 repeats in the 5'UTR of the X-linked *FMR1* gene, are at a significantly increased risk for POI: about 20% of carriers are diagnosed with fragile X-associated POI (FXPOI). Although the risk for FXPOI is significant, not all carriers experience the disorder, and among those who do, the range of severity is broad. We hypothesize that there are other genetic variants, in addition to premutation repeat number, that modify the age of onset and severity of FXPOI. To test this hypothesis, we are conducting a whole genome sequencing (WGS), case/control study among women who carry the premutation. For this study, cases are defined as women with the premutation who experience secondary amenorrhea before the age of 35 and controls are women with the premutation who experience natural menopause after the age of 50. For the first 65 cases and 55 controls, variants were called using a well-established pipeline of WGS analyses and candidate genes were prioritized using burden testing of rare variants, expression in ovaries, and presence of a fly ortholog. The top candidate genes (*DCP2*, *TIA1*, *SUMO1*, *STAT1*, and *KRR1*) are currently being screened using the *Drosophila* model as a high-throughput, whole organism functional screen. This intermediate screen points to the next set of experiments to identify a set of genes that influence ovarian dysfunction in a cost effective way. The overall goal of this project is to elucidate novel molecular mechanisms for FXPOI to facilitate early risk assessment and diagnosis, allowing more informed choices about family planning and fertility options. In addition, the identified genes may also play a role in idiopathic POI and lead to a new understanding of possible treatment targets.

## 3312W

**Kidney Genome Atlas: A whole-genome landscape of more than 2,000 kidney disease patients.**

W. Zhang<sup>1</sup>, T. Soare<sup>1</sup>, A. Tebbe<sup>1</sup>, L. Walsh<sup>1</sup>, M. Kretzler<sup>2</sup>, G.N. Nadkarni<sup>3</sup>, R.A. Gbadegesin<sup>4</sup>, J.L. Wenke<sup>5</sup>, P.H. Mundel<sup>1</sup>, T.T. Tibbitts<sup>1</sup>. 1) Goldfinch Bio, Cambridge, MA; 2) U.Michigan, Ann Arbor, MI; 3) Ichan School of Medicine, New York, NY; 4) Duke University Medical Center, Durham, NC; 5) Nashville Biosciences, Nashville, TN.

Chronic kidney disease (CKD) is a heterogeneous disease affecting more than 30 million people in the US, which is about 10% of the US population. Despite the urgent need for targeted therapeutics, the understanding of the mechanistic basis of CKD including the genetic variants that potentially drive it has lagged other diseases (e.g. cancer) for decades. Here we report the generation and initial analysis of the Kidney Genome Atlas (KGA), the world's largest whole-genome landscape of individuals with molecularly defined kidney diseases. Focusing initially on focal segmental glomerulosclerosis (FSGS), related disorders, and diabetic kidney disease (DKD), KGA contains whole genome sequences (>30X coverage) from more than 2,000 patients and 2,500 matched healthy controls. Each genome is linked to longitudinal clinical records and for a subset of 500 patients, the atlas also includes matched transcriptomic data from microdissected glomerular and tubulointerstitial samples. The KGA has enabled the discovery of genetic variants associated with kidney disease and the integration of genomic and transcriptomic data to identify kidney disease-specific expression quantitative trait loci (eQTLs). The atlas also provides the foundation for establishing the relationships between genetic variants, histologic diagnoses, and quantitative clinical phenotypes of kidney function and disease progression. Computational integration of these datasets will enable the prioritization of candidate variants with putative disease modulating effect. Investigating and validating biological pathways derived from these analyses can also be used to stratify patients into subtypes most likely to respond to specific targeted therapies. The KGA is a valuable resource fueling our understanding of the molecular mechanisms of kidney diseases at the whole genome scale.

Idiopathic pulmonary fibrosis (IPF) is a rare complex lung disease of unknown cause characterised by scarring of the lung. There are few effective treatments and half of patients die within three years of diagnosis. Previous genome-wide association studies (GWAS) have identified 17 genetic signals of association with IPF susceptibility, implicating genes involved in host defence, cell-cell adhesion, regulation of growth factors and telomere maintenance. The strongest genetic association is in the promoter of *MUC5B* where individuals have around 5 times the risk of disease for each copy of the risk allele. Using polygenic risk scores we were able to show IPF is highly polygenic with possibly hundreds of variants associated with the disease. Therefore, we performed a genome-wide meta-analysis on three IPF studies to identify additional genetic variants associated with susceptibility to IPF. In total 2,769 IPF cases and 8,591 controls were included in the meta-analysis. Each study was imputed to the HRC reference panel and GWAS were performed adjusting for 10 principal components to account for population structure. There were 10,768,131 variants measured in at least two of the studies and included in the final meta-analysis. Variants were deemed to show an association with IPF if they reached genome-wide significance (meta-analysis  $p < 5 \times 10^{-8}$ ), were nominally significant ( $p < 0.05$ ) in each study, and had consistent direction of effects across studies. Association with gene expression was investigated using the NESDA-NTR (blood) and GTEx (multiple tissues) eQTL databases. Three common novel association signals met the significance criteria and all had supporting evidence from directly genotyped variants in all three studies. Additional replication is in progress. The top variants of these three signals were found in introns of *KIF15* (rs78238620, GWAS  $p = 8.85 \times 10^{-10}$ , OR = 1.57 (95% CI [1.36, 1.82]), eQTL for *KIF15* in brain tissue), *MAD1L1* (rs12699415, GWAS  $p = 2.95 \times 10^{-13}$ , OR = 0.78 (95% CI [0.73, 0.83]), eQTL for *MAD1L1* in heart tissue) and *DEPTOR* (rs6469878, GWAS  $p = 5.20 \times 10^{-10}$ , OR = 0.81 (95% CI [0.76, 0.87]), eQTL for *DEPTOR* in multiple tissues including lung). In addition, low frequency variants in *RTEL1* (a telomere regulating gene previously implicated in familial pulmonary fibrosis), and rare variants in *HECTD2* and at 5p14.1 were identified and require further investigation. This is the largest GWAS of IPF performed to date and provides new insight into disease risk.

**Gene prioritization in kidney function associated loci through systematic colocalization with gene expression.** K.B. Sieber, CKDGen Consortium. Target Sciences, GlaxoSmithKline, Collegeville, PA.

Genome-wide association studies (GWAS) have successfully identified genetic loci associated with complex traits; however, identification of effector genes is an ongoing challenge. One promising method to prioritize effector genes is to perform colocalization of GWAS and expression quantitative trait loci (eQTL) data to identify shared genetic variants that implicate effector genes. We applied GWAS-eQTL colocalization analysis to GWAS meta-analyses of estimated glomerular filtration rate (eGFR, n=560K) and urinary albumin-to-creatinine ratio (UACR, n=540K) based on European ancestry individuals within the CKDGen Consortium. For eQTL data, we used all GTEx v6p tissues and the first publicly available kidney eQTLs (NephQTLs) with glomerular and tubular data derived from nephrotic syndrome patients. In addition, we introduce a novel method to calculate the direction of effect across the eQTL and GWAS results using a posterior probability weighted average of the effect ratios. Colocalization testing identified genetic evidence for 367 genes with >80% posterior probability of colocalization across 314 GWAS loci. Across the 314 GWAS loci, we identified at least one colocalized gene in 55% (140/253) of the eGFR loci and 52% (32/61) of the UACR loci. Of the GWAS loci with at least one colocalized gene, 48% (67/140) of the eGFR loci and 38% (12/32) of UACR loci had a single effector gene. Focusing on the positive kidney tissue eQTL colocalizations, UACR had six genes colocalizing in the kidney tissues, of which two were unique to the NephQTL dataset. In contrast, fourteen of the twenty eGFR genes that colocalized within the kidney tissue were unique to the NephQTLs. For example, an eGFR locus colocalizes with the *KNG1* eQTL exclusively in the NephQTL tubular data. Along with the systematic colocalization, we evaluated the effect direction to assess consistency across tissues. For example, *METTL10* colocalized with an eGFR locus in 34 tissues, all of which support that higher expression of *MTTL10* is associated with higher eGFR. In contrast, *SH3YL1* colocalized with an eGFR locus in 24 tissues; however, only 13 of the 24 positive colocalization tissue eQTLs support that higher *SH3YL1* expression associates with higher eGFR. Together, our findings support the utility of using a large data source such as GTEx for colocalization testing, but also emphasize the need for additional tissue-specific open access eQTLs datasets such as the NephQTL data.

**Using human genetics to identify a novel biomarker for idiopathic pulmonary fibrosis.** A. Cerani<sup>1,2</sup>, S. Ross<sup>1,2</sup>, D. Assayag<sup>3</sup>, D.A. Schwartz<sup>3</sup>, M. Lathrop<sup>7</sup>, P. Wolters<sup>4</sup>, J.B. Richards<sup>1,2,5,6</sup>. 1) Department of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, QC, Canada; 2) Lady Davis Institute for Medical Research, Jewish General Hospital, Montreal, QC, Canada; 3) Department of Medicine, University of Colorado, Denver, CO; 4) Department of Medicine, University of California, San Francisco, San Francisco, CA; 5) Department of Human Genetics, McGill University, Montreal, QC, Canada; 6) Department of Medicine, McGill University, Montreal, Canada; 7) McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada.

**Introduction:** Idiopathic pulmonary fibrosis (IPF) is a lethal disease with limited effective treatments. There is, therefore, an urgent need to find and validate biomarkers for diagnosis, prognosis, as to serve as potential drug targets. We undertook combined genetic epidemiology and metabolomics studies to identify a metabolic biomarker for idiopathic pulmonary fibrosis. **Methods and Results:** To identify potential metabolites associated with idiopathic pulmonary fibrosis, we combined GWAS for IPF and blood metabolites and identified a shared genetic determinant at isovaleryl dehydrogenase (*IVD*). The product of this gene is an enzyme whose inhibition is known to increase its substrate, the metabolite isovalerylcarnitine (IVC). Through two-sample Mendelian randomization (MR), we observed that genetically decreased IVC levels were strongly associated with increased risk of IPF ( $p = 9.8 \times 10^{-4}$ ). We confirmed this result by using another blood metabolomics GWAS in a second MR study ( $p = 5.5 \times 10^{-7}$ ). We next found that the non-coding alleles from the two metabolite GWAS that were associated to decreased IVC blood levels increased *IVD* expression ( $p = 2.10 \times 10^{-20}$ ). We therefore tested whether low IVC levels were associated with IPF risk in a study of 382 cases and 217 control. We found that decreased IVC blood concentration was associated with a 26% increase in IPF risk (OR: 1.26 per 50 nM decrease; 95% CI: 1.00 -1.60,  $p = 0.048$ ). **Conclusion:** IPF presents important unmet clinical needs. Building on strong orthogonal evidence from genetics and metabolomics data, we found evidence that low IVC levels were associated with higher risk of IPF. IVC represents a clinically relevant biomarker and its enzyme, *IVD*, could represent an entirely novel IPF drug target.

## 3316T

**Towards precision medicine management of vitamin D inadequacy.** *K.E. Hatchell, C.D. Engelman.* Department of Population Health Sciences, University of Wisconsin-Madison, MADISON, WI.

Vitamin D inadequacy affects more than 50% of adults in the United States and is associated with numerous adverse health outcomes. Vitamin D concentrations are influenced by genetic factors which may determine how much vitamin D intake is required to reach optimal vitamin D blood concentration (25(OH)D). Therefore, knowledge of the genetic factors of 25(OH)D could be useful for the prevention of vitamin D associated morbidity and mortality. To date, only a small portion of the genetic factors of 25(OH)D is understood. Understanding the complete set of genetic factors that contribute to 25(OH)D could allow for personalized treatment of vitamin D inadequacy. Participants (European ancestry  $n=9,569$ , African ancestry  $n=2,761$ ) come from dbGaP studies: ARIC, MESA and WHI. In an ancestry specific manner, using PRSice and published GWAS summary statistics, polygenic risk scores (PRSs) were created to capture a more complete set of genetic factors. PRSs were iteratively calculated, using p-value thresholds from  $5 \times 10^{-5}$  to 0.5, incrementing the threshold by  $5 \times 10^{-2}$  each iteration. SNPs were clumped ( $r^2 < 0.5$ ) for independence in the PRS. The relationship between 25(OH)D and PRS was tested, selecting the PRS with the highest coefficient of determination ( $R^2$ ) as the most optimal. Additionally, using ancestry-specific estimates from GCTA, heritability of the PRS was quantified and compared to SNP heritability and heritability of published GWAS findings. The most optimal PRS for African ancestry was derived using a p-value cut-off of 0.013, includes 32,269 SNPs and has an  $R^2$  of 4.4%; for European ancestry, the PRS was derived using a p-value cut-off of  $3.5 \times 10^{-4}$ , includes 341 SNPs and has an  $R^2$  of 1.4%. Results show that the PRS is associated with 25(OH)D in training and validation cohorts. For example, in the validation cohort, those with lowest genetic risk had 25(OH)D concentrations 2.7 ng/mL higher than those of median risk ( $p < 0.0001$ ) in European ancestry, and concentrations 1 ng/mL higher (NS) in African ancestry. Additionally, where sample size allowed for analysis (European ancestry), the PRS explains more of the heritability of 25(OH)D than do published GWAS findings (3.7% vs 1.5%). However, the PRS only explains 17.1% of the total SNP heritability (21.6%). Given that much of the heritability remains unexplained, further genetic exploration of 25(OH)D concentrations is needed to leverage genetic information for personalized vitamin D dosing.

**Introduction:** Chronic obstructive pulmonary disease (COPD) is a condition with high global morbidity. It is characterised by reduced lung function, quantified by the ratio of the forced expiratory volume in 1 second to forced vital capacity (FEV<sub>1</sub>/FVC). We have shown that constructing genetic risk scores for reduced FEV<sub>1</sub>/FVC (as an endophenotype for COPD) is a well-powered method of predicting COPD in people of European descent. However to date, scores defined in European-ancestry individuals have not shown strong associations with lung function in other ancestries. Here, we construct a new, *weighted* genetic risk score of FEV<sub>1</sub>/FVC from 279 signals (139 novel), and test its association with FEV<sub>1</sub>/FVC and COPD in multiple ancestries from the UK and China Kadoorie Biobanks, and the COPDgene study. **Methods:** The European-derived weighted genetic risk score comprised 140 known lung function signals, and 139 novel signals discovered in over 400,000 individuals from UK Biobank and the SpiroMeta consortium. Unbiased weights were derived from the largest cohort of UK Biobank or SpiroMeta not included in signal discovery. The score was tested for association with FEV<sub>1</sub>/FVC in UK Biobank participants of South Asian, Chinese and African ancestry, and the China Kadoorie Biobank. Associations with COPD (defined as FEV<sub>1</sub>/FVC < 0.7, FEV<sub>1</sub> < 80% predicted) were tested in China Kadoorie Biobank, African American participants of COPDgene, and UK Biobank ancestries with >100 COPD cases. Associations were adjusted for age, age<sup>2</sup>, sex, height, smoking status, and population structure. **Results:** The weighted risk score was associated with FEV<sub>1</sub>/FVC in all ancestries, with a 1-SD increase in score corresponding to a decrease in ~0.1-0.2 SDs in FEV<sub>1</sub>/FVC. In non-European ancestry participants, effect sizes were largest in 6,358 UK Biobank individuals of South Asian descent ( $\beta = -0.18$  [95%CI -0.21, -0.16]  $p = 3.7 \times 10^{-47}$ ), and smallest in 4,225 UK Biobank individuals of African descent ( $\beta = -0.09$  [95%CI -0.12, -0.06]  $p = 2.1 \times 10^{-9}$ ), and 72,796 individuals within China Kadoorie Biobank ( $\beta = -0.08$  [95%CI -0.09, -0.07]  $p = 5.1 \times 10^{-99}$ ). The score predicted COPD in all ancestries tested. **Conclusion:** For the first time, we show that a weighted genetic risk score constructed from signals discovered in European individuals is predictive of lung function and COPD across global ancestries. This work provides evidence of shared genetic architecture of COPD across ancestries.

**Defining phenotypes with non-ignorable missingness on the basis of heritability: Application to lung disease in cystic fibrosis.** S.O. Kim<sup>1,4</sup>, B. Xiao<sup>1</sup>, N. Panjwani<sup>1</sup>, G. He<sup>1</sup>, J. Gong<sup>1</sup>, E. Corfield<sup>2</sup>, L.J. Strug<sup>1,2,4</sup>. 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 3) Department of Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada; 4) Biostatistics Division, Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada.

Heritability is the proportion of phenotypic variance attributable to genetic variation. Although heritability provides little information on the genetic architecture, it offers a meaningful comparison of traits within a population and can help define phenotypes to improve gene-mapping studies. Quantitative measurements are often used as an indirect measure of a trait, such as forced expiratory volume in 1 sec (FEV1) as a measure of lung disease in cystic fibrosis (CF). Since FEV1 changes with factors including age, sex and height, it needs to be standardized to population norms (CF-specific reference equations). This standardization reduces the phenotypic variation due to environmental factors and results in a more heritable trait. However, the progressive mortality due to lung disease in CF results in cohort and sex-specific non-ignorable missingness and left truncation; this mortality limits the utility of standardized FEV1 phenotypes in genetic studies. Here, we propose several comprehensive, alternative model-based solutions. To facilitate modelling choices of phenotypes, we use heritability comparisons. We propose the use of non-parametric quantile regression with pattern-mixture modeling (PMM) for a variety of imputation choices that directly incorporates both mortality and CF-specific reference equations into a single phenotype calculation. We used SNP-based heritability by Yang *et al.* (2010) to discriminate between the imputation choices including complete, neighboring and available case missing values in PMM. To estimate the heritability, we included unrelated individuals aged between 6 and 40 years from the Canadian CF Gene Modifier Study (n=1,233). We used a parametric bootstrapping approach by Schweiger *et al.* (2016) to construct 95% confidence intervals (CI) and to test the difference in heritability between phenotypes. The highest estimated heritability across phenotypic modeling choices was  $h^2=0.446$  (CI: 0 - 0.632). It was more than 2-fold greater than the heritability estimate ignoring the missingness ( $h^2=0.207$ ; CI: 0 - 0.367) and an improvement of 11% over previously defined phenotypes used by the International CF Gene Modifier Consortium (Taylor *et al.*, 2011) ( $h^2=0.401$ ; CI: 0 - 0.575). Tests of the differences, however, did not reach statistical significance. Phenotypes defined using quantile regression and PMM would be useful for other progressive diseases with mortality, and heritability comparisons facilitate modeling choices.

**3319T**

**Copy number polymorphism on Y chromosome and adult height: The gr/gr deletion does not contain the Y-specific growth gene.** A. Hattori<sup>1,2</sup>, K. Saito<sup>1</sup>, M. Fukami<sup>1</sup>. 1) Department of Molecular Endocrinology, National Research Institute for Child Health and Development, Tokyo, Japan; 2) Department of Advanced Pediatric Medicine, Tohoku University School of Medicine, Tokyo, Japan.

In the 1990s, Ogata *et al.* proposed a hypothesis that the Y-specific growth gene, which is termed GCY (growth control, Y chromosome influenced), accounts for about two-thirds of the sexual difference in human adult height. Thus far, the genomic position of GCY has been investigated by case-based phenotype-genotype correlation studies. However, it is difficult to set an appropriate adult height cut-off value because GCY abnormality does not always cause an adult height below -2.0 standard deviations. Here, we performed a group-based statistical analysis focusing on the 1.6 Mb gr/gr deletion, which is a common polymorphism in Japanese populations. A total of 315 healthy Japanese men were enrolled in this study. We performed PCR amplification analysis of two sequence-tagged site markers (sY1291 and sY1191) to examine the presence of the gr/gr region. The participants were classified into two groups with and without gr/gr deletion. Then, we compared the mean adult height of the two groups. The statistical difference was examined by student's t-test. Of the 315 men, 127 and 188 were classified into the deletion-positive and -negative groups. There was no significant difference in the mean adult height between the two groups (170.3 cm vs. 170.1 cm,  $P = 0.833$ ). The present study statistically demonstrated for the first time that the gr/gr region does not encompass growth control genes. The group-based study focusing on a common polymorphism enabled effective statistical analysis. We may further narrow candidate regions for GCY by applying this method to rarer recurrent variants.

**Identification of CpG sites as mediators for genetic influence on osteoporosis by Mendelian randomization.** *F.T. Yu, C. Qiu, C. Xu, H.W. Deng, H. Shen.* Center for Bioinformatics and Genomics, Department of Global Biostatistics and Data Science, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA, USA.

Osteoporosis is one of the most serious public health concern that affect more than 200 million people worldwide. It can be characterized by low bone mineral density (BMD), which is primarily caused by excessive bone resorption by osteoclasts. Peripheral blood monocytes (PBMs) serve as an important source of precursors of osteoclasts and produce cytokines affecting the differentiation, activation, and apoptosis of osteoclast. Due to the biological relevance of PBM with bone metabolism and disorders, it has been determined as a working cell model for genomic and epigenomic studies of osteoporosis and other-bone related disease. Recent studies have assessed the cell-type-specific correlation between diverse genetic, epigenetic and transcriptomic factors of PBMs and evaluated the impact of these factors on immune disease. However, the higher-resolution epigenetic profile of PBMs measured by Illumina Human Methylation 450K array and the mediation effects of DNA methylation on the pathway of genetic factors to disease has not been examined. In this study, we performed a comprehensive analysis of DNA methylation data measured from PBMs of 105 Caucasian women with extreme BMD phenotype. By testing the association between each pair of SNP and CpG, we identified a large amount of methylation quantitative loci (mQTLs). For the mQTLs that show significance in GWAS, we perform Mendelian Randomization (MR) analysis and reverse MR to further evaluate the mediation role of the corresponding CpGs in the causal pathway of SNP and BMD. A novel SNP (rs12811331) has been identified as a mediator of the genetic effect on BMD. We will also check the colocalization between the mQTL signals and the GWAS signals of BMD trait, which would allow us to detect more precisely the common causal variant of DNA methylation and BMD trait. This work is supported by grants from the NIH (R01AR059781, P20GM109036) and Edward G. Schlieder Endowment as well as the Drs. W. C. Tsai and P. T. Kung Professorship in Biostatistics from Tulane University.

**A genome-wide association study of bone mineral content and bone mineral density of multiple skeletal sites in Hispanic children.** *R. Hou<sup>1</sup>, S.A Cole<sup>2</sup>, K. Haack<sup>3</sup>, S. Laston<sup>3</sup>, N.R Mehta<sup>4</sup>, R. Shypailo<sup>4</sup>, A.G Comuzzie<sup>5</sup>, N.F Butte<sup>1</sup>, V.S. Voruganti<sup>1</sup>.* 1) Department of Nutrition and Nutrition Research Institute, University of North Carolina at Chapel Hill, Kannapolis, NC; 2) Texas Biomedical Research Institute, San Antonio, TX; 3) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley, Brownsville, TX; 4) Pediatrics and USDA/ARS Children Nutrition Research Center, Baylor College of Medicine, Houston, TX; 5) The Obesity Society, Silver Spring, MD.

Background: Peak bone mass attained in early life is a significant predictor of bone mass in later life and is known to be highly heritable. Aim: To identify genetic variants affecting bone mineral content (BMC) and bone mineral density (BMD) of multiple skeletal sites in Hispanic Children from the Viva La Familia Study. Methods: We performed a genome-wide association study of bone outcomes with 1.1 million single nucleotide polymorphisms (SNPs) genotyped using the Illumina Human Omni-Quad v1.0 BeadChip marker panel in 815 Hispanic children. BMC and BMD were determined by dual-energy X-ray absorptiometry with a Hologic Delphi-A whole-body scanner (Version 11.2). Measured genotype analysis was performed between SNPs and BMC and BMD of multiple skeletal sites after accounting for kinships. Empirical thresholds for genome-wide significant and suggestive associations were defined as  $p < 1 \times 10^{-7}$ , and  $p < 1 \times 10^{-6}$ , respectively. Results: The heritabilities for BMC and BMD across different skeletal sites ranged from 42-76% ( $p < 3.1 \times 10^{-9}$ ). Evidence for statistical significant association ( $p < 1 \times 10^{-7}$ ) was observed for several SNPs with BMC, including BMC of right arm with rs762920 in *PVALB* ( $p = 4.6 \times 10^{-8}$ ), BMC of right leg with rs4871750 in *LOC105375751* ( $p = 7.3 \times 10^{-8}$ ) and with rs142813632 in *PVT1* ( $p = 7.6 \times 10^{-8}$ ) and association with BMD pelvis was observed for rs7000615 in *PTK2B* ( $p = 7.4 \times 10^{-8}$ ). Suggestive evidence ( $p < 1 \times 10^{-6}$ ) for association was found for BMC and BMD on different skeletal sites with genes relevant to bone metabolism (*USP12*, *RSU1*, *DGKB*, *ROBO2*, *IGF2R* and *PRLR*) and novel genes with unknown relationship with bone metabolism (*LRIF1*, *METTL10*, *STMN4*, *DSCAM*, *VSIG10*, *LOC105378516* and *ZDHHC1*). Conclusion: These findings shed light on the genetic structure underlying BMC and BMD variation and osteoporosis susceptibility. .

**Identification of putative causal genes regulating hip bone mineral density using tree-based methods.** X. Meng<sup>1</sup>, L. Tan<sup>1</sup>, H. Xiao<sup>1,2,3</sup>, H. Deng<sup>2</sup>. 1) Hunan Normal University, Changsha, China; 2) Tulane University, New Orleans, USA; 3) Central South University, Changsha, China.

**Objective:** Osteoporosis is a complex disease characterized by low bone mineral density (BMD) and an increased susceptibility to fractures. Several studies have identified dozens of genes associated with BMD from gene expression profiles using the linear regression model. However, this approach cannot distinguish those genes whose expression levels have a non-linear correlation with BMD or determine whether these genes causally regulate BMD. **Method:** We analyzed gene expression profiles from bone biopsies in 84 postmenopausal women using a tree-based method known as Gene Network Inference with Ensemble of trees (GENIE3). The inferred regulation network was used to identify putative genes which may regulate hip BMD. Enrichment analysis was performed to identify transcription factors whose binding sites are significantly enriched in femoral neck BMD (FN-BMD) genome-wide association studies (GWAS) signals. **Results:** In the gene regulatory network we successfully identified six genes which were previously identified using the standard linear regression model, and another 14 novel predictive genes. Among 161 transcription factors, FN-BMD GWAS signals were significantly enriched within JUN binding sites (fold enrichment = 5.45,  $p$  value =  $1.51 \times 10^{-4}$ ). Three predictive genes (*PLIN5*, *CLIP4* and *LINC00312*) were significantly enriched in JUN regulation network (fold enrichment = 4.44,  $p$  value = 0.045). **Conclusion:** We identified three putative causal genes and one transcription factor that may be involved in the regulation of FN-BMD. The transcription factor JUN interacts with NFAT and is crucial for RANKL-regulated osteoclast differentiation. Our results suggest that while the traditional linear regression model is useful to identify some trait associated genes, the tree-based method may identify more putative causal genes. These novel insights into the transcription factor regulation network are helpful to understand the biological mechanisms of these predictive genes regulating BMD.

**HLA-DQB1\*03:01 as a biomarker for genetic susceptibility to bullous pemphigoid induced by DPP-4 inhibitors.** T. Ozeki<sup>1</sup>, H. Ujiie<sup>2</sup>, K. Muramatsu<sup>2</sup>, T. Mushiroda<sup>1</sup>, H. Miyoshi<sup>3</sup>, H. Iwata<sup>2</sup>, T. Ito<sup>2</sup>, K. Izumi<sup>2</sup>, W. Nishie<sup>2</sup>, H. Shimizu<sup>2</sup>. 1) Laboratory for Pharmacogenomics, RIKEN Center for Integrative Medical Sciences, Yokohama, Kanagawa, Japan; 2) Department of Dermatology, Hokkaido University Graduate School of Medicine, Sapporo, Japan; 3) Department of Rheumatology, Endocrinology and Nephrology, Faculty of Medicine, Graduate School of Medicine, Hokkaido University, Sapporo, Japan.

Dipeptidyl peptidase-4 inhibitor (DPP-4i) has been widely used to treat type 2 diabetes. DPP-4i has been known as a safe drug; however, an increased risk of bullous pemphigoid (BP), which is an autoimmune subepidermal blistering disease, during DPP-4i exposure has been reported in diabetic patients administered with DPP-4i. Although the exact mechanism behind the association of DPP-4i exposure and BP has not been elucidated, several studies have reported an association between human leukocyte antigens (HLA) and drug-induced reactions. Thus, we examined HLA genotypes in Japanese patients with BP who had been taking DPP-4i for type 2 diabetes for at least 3 months before the BP onset (DPP-4i-BP). It was reported that DPP-4i-BP tends to show a "noninflammatory" phenotype with few erythematous lesions, in sharp contrast to conventional BP unrelated to DPP-4i intake. We encountered 30 patients with DPP-4i-BP in the last 3 years and found that the majority of cases (21/30) showed the noninflammatory phenotype. We compared the 6 HLA alleles in noninflammatory DPP-4i-BP with those in Japanese general population controls or in DPP-4i-tolerant patients with type 2 diabetes and found that 86% (18/21) of noninflammatory DPP-4i-BP patients, 18% (156/873) of general population controls and 31% (19/61) of the tolerant patients carry *HLA-DQB1\*03:01*. The frequency was significantly higher in DPP-4i-BP patients than in general population controls ( $P = 5.86 \times 10^{-11}$ ; OR = 27.6, 95% CI = 8.0-94.8) and in the tolerant patients ( $P = 2.13 \times 10^{-2}$ ; OR = 13.3, 95% CI = 3.5-50.5). This work was supported by JSPS Core-to-Core Program, A. Advanced Research Networks.

**Background:** Caribbean Hispanic (CHI) populations have a higher prevalence and incidence of late-onset Alzheimer disease (LOAD) than non-Hispanic white (NHW) individuals. However, CHI populations are understudied compared to NHW. Moreover, the ancestral heterogeneity of CHI makes studies of this population critical in discovery ancestry-specific genetic factors in AD. To identify novel genetic variation influencing AD, to test generalization of the NHW findings and to better understanding AD in the CHI we performed genome-wide association analysis in CHI Puerto Rican (PR) population. **Methods:** Through PR Alzheimer Disease Initiative we have ascertained a family-based dataset consisting of 412 individuals of PR ancestry. The dataset includes 231 AD cases and 181 cognitively intact individuals matched for age and sex. Genome-wide genotyping was performed on two platforms: MEGA and GSA. Single variant association analysis was performed by using the GWAF geepack package in R. Logistic model was adjusted for principal components, age, and sex. We assessed the ancestral background of the candidate genes ("local" ancestry) by using RFMix. Variants were annotated with Ensemble VEP annotation. A gene-wise adjusted *p*-value was calculated to correct for multiple markers within the gene. **Results:** Our results showed that 15 GWAS candidate AD loci significantly associated with AD in PR population, (e.g. ABCA7, BIN1). The top SNP among the candidate genes was observed in the exonic region of the ABCA7 gene (rs3752240, *p*=2e-4). By stratifying the dataset according to the local ancestral backgrounds, we observed that the European and African genetic ancestry contributed risk in ABCA7 gene. We also found that APOE  $\epsilon$ 4 risk allele was associated with the LOAD (OR=1.96, *p*=6e-4), but the effect size was much less than in NHW. By using the local ancestry we found that African ancestral background mitigate the effect of  $\epsilon$ 4 allele. Genome-wide the most significant association was observed in the SYNDIG1 gene (rs2892216, *p*=9.1e06). SYNDIG1 gene plays a critical role during synapse development, and associated with a mental and behavioral disorder. **Conclusions:** Our findings support the hypothesis that there may be an interaction between the genetic factors and the ancestral backgrounds located around the genomic region of interest. Results on PRs demonstrated the risk in ABCA7 was contributed by AF and EU ancestry. Further, we will apply genome-wide ancestry-aware approach.

**Development of a polygenic risk score for Alzheimer's disease using a Bayesian hierarchical model.** S.P. Dickson<sup>1</sup>, S.B. Hendrix<sup>1</sup>, B.L. Brown<sup>2</sup>, P.G. Ridge<sup>2</sup>, S.B. Booth<sup>2</sup>, R.R. Fortna<sup>2</sup>, J.S.K. Kauwe<sup>2</sup>, NIAGADS. 1) Pentara, 2261 E. 3300 S. Millcreek, UT; 2) Brigham Young University, Provo, UT; 3) Affirmativ Group 3614 Meridian Street, Suite 100 Bellingham, WA.

Our knowledge of the genes associated with Alzheimer's disease has grown steadily over the past three decades. While the effect of the APOE gene still remains the single largest genetic risk factor, dozens of other genes have been implicated over the years. Summary results from published studies based on large, well-curated datasets were combined with data from multiple genetic studies to incorporate the most important genetic risk factors identified to date with age, sex and their interaction into a single polygenic risk score. This combined information represents the best information available about the genetic risk of Alzheimer's disease. We explored a range of techniques for combining past results, including additive and multiplicative risk models, regularization techniques like LASSO and elastic nets, as well as Bayesian models, and use cross validation to select the best performing method. A Bayesian hierarchical model is reported and used to demonstrate the calculation of the unconditional lifetime risk of developing Alzheimer's disease, as well as the lifetime risk of developing Alzheimer's disease conditional on the current absence of disease.

**3326F****Shared causal paths underlying Alzheimer's disease and type 2 diabetes.**

Z. Hu<sup>1</sup>, R. Jiao<sup>4</sup>, Y. Zhu<sup>3</sup>, J. Zhao<sup>3</sup>, D. Bennett<sup>4</sup>, L. Jin<sup>1</sup>, M. Xiong<sup>1</sup>. 1) School of Life Science, Fudan University, Shanghai, China; 2) Rush Alzheimer's Disease Center, Rush University Medical Center; 3) Department of Epidemiology, University of Florida; 4) University of Texas School of Public Health.

Although Alzheimer's disease (AD) is a central nervous system disease and type 2 diabetes MELLITUS (T2DM) is a metabolic disorder, an increasing number of epidemiological and genetic epidemiological studies show clear link between AD and T2DM. AD with great economic, political and social consequences is a progressive, irreversible degenerative disease of the brain and is the most common cause of dementia due to the gradual accumulation of accumulation of amyloid-beta (A $\beta$ ) and twisting of tau protein. AD is also involved in inflammation and oxidative stress and exhibits memory loss and cognitive dysfunction. The current approaches to identifying several shared pathophysiology processes between AD and T2DM have several limitations. Firstly, the pathophysiological links between AD and T2DM have been assessed mostly through literature review. Secondly, the most previous works have focused on identifying biological pathways underlying AD and T2DM. Few attempts to discover the role of dysregulated SNPs, gene expressions and methylations have been carried out. Thirdly, the conventional evidences for linking AD and T2DM purely depend on the statistical association. It is time to develop a new generation of genetic analysis for shifting the current paradigm of genetic analysis from shallow association analysis to deep causal inference and from genetic analysis alone to integrated causal genomic, epigenomic, and phenotypic data analysis for unraveling the mechanistic link between AD and T2DM. We develop novel causal inference methods for genetic studies of AD and T2DM and unified frameworks for systematic causal analysis of integrated genomic, epigenomic, and clinical phenotype data and to infer multilevel omics causal networks for the discovery of common paths from genetic variants to AD and T2DM via methylations, gene expressions and multiple phenotypes.

**3327W****Constrained instruments and their application to Mendelian randomization with pleiotropy.**

L. Jiang<sup>1,2</sup>, K. Oualkacha<sup>3</sup>, D. Didelez<sup>4</sup>, A. Ciampini<sup>1,2</sup>, P. Rosa<sup>5,6</sup>, A. Benedet<sup>6</sup>, S. Mathotaarachchi<sup>6</sup>, B. Richards<sup>7</sup>, C. Greenwood<sup>1,2</sup>. 1) Department of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, Quebec, Canada; 2) Lady Davis Institute, Jewish General Hospital, Montreal, QC, Canada; 3) University of Quebec at Montreal, Montreal, Quebec, Canada; 4) Leibniz Institute for Prevention Research and Epidemiology, University of Bremen, Germany; 5) Department of Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada; 6) Translational Neuroimaging Laboratory, McGill University Research Centre for Studies in Aging, Douglas Hospital, McGill University, Montreal, Quebec, Canada; 7) Department of Medicine, McGill University, Montreal, Quebec, Canada.

**Introduction:** In Mendelian randomization (MR), genetic variants are used to construct instrumental variables, which enable inference about the causal effect of a phenotype of interest on a response or disease outcome. Conventional estimation methods depend on a set of prior assumptions regarding the validity of instrumental variables, such as the genetic variants only influence the response through the phenotype of interest. In practice, these assumptions are violated when pleiotropy occurs, in which genetic variants influence the response through multiple phenotypes and render conventional MR analysis invalid. **Methods:** We present a set of intuitive methods (Constrained Instrumental Variable methods [CIV]) to construct valid instrumental variables and perform adjusted causal effect estimation when pleiotropy exists, given that pleiotropic phenotypes have been measured. One of the methods in this set, CIV\_smooth, implement an automatic and valid selection of genetic variants when building the instrumental variables. Despite the fact that the variable selection problem is NP-hard, we implement an approximate solution that is computationally efficient. **Results:** The performance of the proposed methods, compared to competitor methods, is demonstrated on data simulated under different types of pleiotropy. We also analyzed data from the Alzheimer's Disease Neuroimaging Initiative (ADNI) Mueller et al. (2005) to disentangle causal relationships of several biomarkers with AD progression. A list of valid genetic instrument for each of these biomarkers of interest are identified, and adjusted estimation of their causal effect on AD progression are implemented. CIV\_smooth found only one significant causal effect, that of Amyloid beta 1-42 on AD progression; this indicates that the previously known association of this biomarker with AD progression may be causal. However, due to the limitation of the ADNI study design, additional analysis are still needed to validate our results.

## 3328T

**Searching for the causal effects of genetic variants for Alzheimer's disease in UK Biobank.** R. Korologou-Linden<sup>1</sup>, L.A.C. Millard<sup>1,2</sup>, W. Spiller<sup>1</sup>, G. Davey-Smith<sup>1</sup>, L.D. Howe<sup>1</sup>, E.L. Anderson<sup>1</sup>, E. Stergiakouli<sup>1,3</sup>. 1) MRC Integrative Epidemiology Unit (IEU), Bristol Medical School (Population Health Sciences), University of Bristol, Bristol, UK; 2) Intelligent Systems Laboratory, Department of Computer Science, University of Bristol, Bristol, UK; 3) School of Oral and Dental Sciences, University of Bristol, UK.

**Introduction:** Observational studies for Alzheimer's disease have reported conflicting evidence for most potential modifiable risk factors. This may be due to bias from confounding and reverse causation that can be problematic in observational studies. Furthermore, the hypothesis-driven nature of previous work biases research on Alzheimer's disease to hypotheses with a prior. Alzheimer's disease is highly heritable with estimates as high as 79%. Genetic studies have identified 21 single nucleotide polymorphisms associated with late-onset Alzheimer's disease, all exerting low to modest effects (except for those in the apolipoprotein E gene). We perform a phenome-wide association analysis to investigate the causal effects of a polygenic risk score (PRS) for Alzheimer's disease on a large and diverse array of phenotypes, without a prior and without the biases present in most observational studies. **Methods:** We used a sample of 334,968 participants from UK Biobank, and generated a PRS calculated as the weighted sum of the risk-increasing alleles identified in a genome-wide association study of Alzheimers disease. We performed a phenome-wide association analysis of this PRS on 21,868 traits, using the PHEnome Scan Analysis tool (PHESANT). We also examined whether findings varied by age categories (39 to 53, 53 to 62 and 62 to 72 years). **Results:** We identified associations of the PRS for Alzheimer's disease with family history of dementia, own diagnosis of dementia, death from dementia, and brain related-measures (e.g. lower mean intra-cellular volume in parahippocampal part of cingulum, lower cognitive function). Other factors associated with the PRS included lifestyle (eg. more days of moderate/vigorous activity), biological measures (e.g. lower monocyte percentage), higher risk of diseases (e.g. atherosclerotic disease, delirium), and physical measures (e.g. lower body mass index). The associations observed for the entire sample appear to be driven by the older age groups. For the youngest sample with mean age 47 years (39-53), we only identified associations with biological measures (e.g. reticulocyte percentage), hypercholesterolaemia and family history of dementia. **Conclusion:** The novel factors identified by our phenome-scan may either lie on the causal pathway from genetic predisposition to Alzheimer's disease or may be a consequence of a higher genetic risk for Alzheimer's disease. These novel associations should be replicated in independent cohorts.

**Genome-wide association analysis identifies novel Alzheimer disease candidate risk loci for African-Americans.** B.W. Kunkle<sup>1</sup>, K.L. Hamilton-Nelson<sup>1</sup>, M. Jean-Francois<sup>1</sup>, M. Schmidt<sup>1</sup>, E.R. Martin<sup>1</sup>, L.A. Farrar<sup>2</sup>, J.L. Haines<sup>3</sup>, G.S. Byrd<sup>4</sup>, G.D. Schellenberg<sup>5</sup>, R. Mayeux<sup>6</sup>, M.A. Pericak-Vance<sup>1</sup>, C. Reitz<sup>2</sup>, Alzheimer's Disease Genetics Consortium. 1) University of Miami, Miami, FL, USA; 2) Columbia University, New York, NY, USA; 3) Boston University, Boston, MA, USA; 4) Case Western Reserve University, Cleveland, OH, USA; 5) North Carolina A&T State University, Greensboro, NC, USA; 6) University of Pennsylvania, Philadelphia, PA, USA.

**Background:** The largest Alzheimer disease (AD) genome-wide association study (GWAS) to date in African-Americans (AA), conducted by the Alzheimer's Disease Genetics Consortium (ADGC) in 2013, identified in addition to *APOE*, two susceptibility loci for Late-onset Alzheimer disease (LOAD), *ABCA7* and an intergenic locus at 5q15. This analysis used the 1000 Genomes (1000G) 2011 panel for imputation, a panel based on haplotypes of 1,094 individuals (246 with African ancestry). Following up these analyses, we conducted a GWAS using two reference panels: the African Genome Resource (AGR) panel, constructed from 4,956 individuals (~2,650 with African ancestry), and the latest 1000G panel, used for indel imputation. We increase our analysis sample by 37 percent (2,845 cases and 5,271 controls). **Methods:** All datasets were imputed to the AGR (~93 million variants) and 1000G panels (~85 million variants) using the Sanger imputation server. Single-variant association analysis was conducted adjusting for age, sex, and principal components (PCs). Additional models adjusted for *APOE*. Individual datasets were analyzed applying logistic regression for case-control datasets and general estimating equations for family-based datasets. Within-study results were meta-analyzed using METAL. **Results:** Following quality control, approximately 35.8 million variants were analyzed. In addition to the previously reported AA risk loci (*APOE*, *ABCA7*, and 5q15), we identified several novel candidate loci ( $P < 5 \times 10^{-6}$ ) for LOAD in AA. These include signals centered at 15q26.1 ( $P = 7.89 \times 10^{-7}$ ), 14q23.3 ( $P = 9.75 \times 10^{-7}$ ), 15q13.3 ( $P = 1.11 \times 10^{-6}$ ), 4p15.32 ( $P = 1.72 \times 10^{-6}$ ), and 6q26 ( $P = 2.69 \times 10^{-6}$ ). Of the 18 other known non-Hispanic white GWAS loci besides *APOE* and *ABCA7*, only *BIN1* showed suggestive association in AA ( $P = 0.005$ ). Gene-based results for these loci are pending however. **Conclusions:** We identified several novel candidate loci for LOAD in AA. These loci contain genes with functions relevant to Alzheimer disease and neurodegeneration including: *CHD2* (highly expressed in microglia) and *RGMA* (synapse formation/accumulated in amyloid plaques) at 15q26.1, *FMN1* (highly expressed in microglia) at 15q13.3, *LDB2* (associated with coronary artery disease) at 4p15.32, and the Parkinson's disease risk gene *PARK2* in 6q26. While overlap between AD risk genes exists between AA and NHW, there are also ethnic specific loci for AA in AD.

Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 10) Department of Epidemiology, Erasmus Medical Center, Rotterdam, the Netherlands; 11) Alzheimer Center, VU University Medical Center, Amsterdam, the Netherlands; 12) Centre for Neuropsychiatric Genetics and Genomics, Cardiff University, Wales, UK; 13) Department of Biostatistics, School of Public Health, Boston University, Boston, MA, USA; 14) Department of Neurology, School of Medicine, Boston University, Boston, MA, USA; 15) Department of Population & Quantitative Health Sciences, School of Medicine, Case Western Reserve University, Cleveland, OH, USA; 16) Dr. John T. Macdonald Foundation, Department of Human Genetics, Miller School of Medicine, University of Miami, Miami, FL, USA; 17) Alzheimer's Institute, UT Health San Antonio, San Antonio, TX, USA.

IGAP meta-analyses of genome-wide association studies (GWAS) have previously identified 19 LOAD susceptibility loci in addition to *APOE*, however the majority of these were common (minor allele frequency (MAF)>0.05); only recently have rare variant associations with LOAD such as *TREM2* been observed in these meta-analyses. The Haplotype Reference Consortium (HRC) released a dense reference panel (~65K haplotypes/~39.2M SNPs) allowing imputation of rare variants (MAF>0.0008) for discovery association testing. IGAP consortia imputed 42 GWAS datasets to HRC to identify novel rare variant associations. We imputed 22,847 cases and 36,889 controls to the HRC r1.1 reference panel using Minimac3 on the University of Michigan Imputation Server. Logistic regression on individual variants with MAF>0.01 was performed in PLINKv1.9 (generalized linear mixed model in R for family-based variants) using imputed genotype probabilities, while variants with MAF≤0.01 were analyzed using score-based tests with the program SNPTEST; both analyses adjusted for age, sex, and population substructure. Fixed-effects meta-analysis across datasets was performed in METAL. Gene-based association was also performed using SKAT-O. Preliminary analyses of ~39.2M genotyped or imputed SNVs identified single variant associations of  $P<5\times 10^{-8}$  in 10 known IGAP LOAD candidate loci (*APOE*, *BIN1*, *MS4A* region, *PICALM*, *CR1*, *CD2AP*, *CLU*, *SPI1*, *SORL1*, and *ABCA7*), including some in more recent IGAP analyses (*LILRA5*, *ADAMTS1*) and multiple suggestive associations ( $P<10^{-6}$ ) at each of an additional 14 loci (including known IGAP loci), rs13155750 in *MEF2C* (OR(95% CI): 1.13(1.08,1.20);  $P=5.09\times 10^{-6}$ ) and rs755951 in *PTK2B* (OR 1.11(1.06,1.16);  $P=5.61\times 10^{-6}$ ). Novel associations include signals at *LILRA5* (19:54821819; OR 1.14(1.08,1.20);  $P=4.84\times 10^{-7}$ ), involved in innate immunity pathways; and at *ADAMTS1* (rs2830500; OR 1.11(1.06,1.17);  $P=5.17\times 10^{-6}$ ), which is downregulated in Down Syndrome with AD/neurodegeneration. Rare variant and gene-based analyses demonstrated significant *APOE*  $\epsilon$ 2 and *TREM2* associations, and a novel association in *STK32C* ( $P=6.96\times 10^{-7}$ ) previously associated with cognitive decline, while gene-based testing identified strong but marginal association for *SORL1* ( $P=5.55\times 10^{-6}$ ). Several novel candidate loci for LOAD have been identified using high-quality imputation of rare and low-frequency variants in the ADGC, reinforcing the utility of high-density imputation panels in whole genome studies.

**3331T****A new powerful co-localization test.** W. Pan, Y. Deng. University of Minnesota Twin Cities, Minneapolis, MN.

Recently some integrative methods like transcriptome-wide association study (TWAS) have been proposed to detect genetic association between a gene's expression (or another molecular trait) and a GWAS trait, which may suggest, however does not directly determine, co-localization of GWAS causal variants and eQTL (or other molecular trait) causal variants, in spite of their causal inference frameworks of instrumental variable analysis or Mendelian randomization due to likely violations of their imposed assumptions. Nevertheless, co-localization testing can move statistical inference closer to establishing causal relationships: for example, if it can be established that a causal variant for a GWAS trait and that for an eQTL are the same, then it may suggest a regulatory role of the causal SNP on the GWAS trait through gene expression. Accordingly, there have been extensive efforts in developing and applying various co-localization testing approaches. However, they all have some severe limitations as briefly discussed below. First, the null hypothesis of the popular *coloc* and *HEIDI* specifies a co-localization, which will not be rejected if the sample size is too small and/or the significance level is stringent, clearly a downside. Second, many (e.g. *coloc*, *HEIDI* and *JLIM*) assume the presence of no more than one causal SNP in a locus, contradicting the recently discovered widespread allelic heterogeneity; when the assumption is violated, they may have substantial power loss. Third, although *eCAVIAR* does not impose such an assumption, it requires specifying an upper bound on the number of causal SNPs in a locus, typically at 6, to be computationally feasible. Fourth, some (e.g. *JLIM*) require the availability of individual-level genotypic and gene expression data. Fifth, at least with their current implementations, none of the existing methods can handle more than two traits with dependent samples with only genome-wide association summary statistics for all the traits, which is important to identify pleiotropy and/or for multi-trait analysis. We develop a novel and powerful test overcoming the above shortcomings of the existing methods. We demonstrate its power advantages over the existing methods using both simulated and real data, including a large-scale Alzheimer's disease GWAS and a gene expression datasets, and a large-scale blood lipids GWAS summary association dataset.

Seshadri<sup>2,3,9</sup>. 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA, USA; 2) Boston University and the NHLBI Framingham Heart Study, Boston, MA, USA; 3) Department of Neurology, Boston University School of Medicine, Boston, MA, USA; 4) Lille University, Inserm, CHU Lille, Institut Pasteur de Lille, U1167 - RID-AGE - Risk factors and molecular determinants of aging-related diseases; Lille, France; Labex Distalz; 5) Centre for Human Psychopharmacology, Swinburne University of Technology, Hawthorn, Australia; 6) Melbourne Dementia Research Centre, The Florey Institute for Neuroscience and Mental Health and the University of Melbourne, Australia; 7) Department of Neurology and Center for Neuroscience, University of California at Davis, CA, USA; 8) Preventive Medicine & Epidemiology, Boston University School of Medicine, Boston, MA, USA; 9) Glenn Biggs Institute for Alzheimer's & Neurodegenerative Diseases, University of Texas Health Sciences Center, San Antonio, TX, USA.

**Background:** Amyloid beta (A $\beta$ ) and tau levels are two biomarkers of Alzheimer Disease (AD). Few genome-wide association studies (GWAS) were conducted on A $\beta$  or tau levels and these studies were limited by their sample sizes and their inability to explore less common genetic variants. **Methods:** We performed a GWAS of plasma tau levels measured using an ultrasensitive assay in 6,018 Framingham Heart Study participants. We used mixed-effect linear regression models to examine the association between tau levels and imputed genetic variants from the Haplotype Reference Consortium, while accounting for familial relatedness and adjusting for age, sex and principal components. We conducted bivariate analyses to explore potential pleiotropy between tau and three measures of A $\beta$  levels (A $\beta_{42}$  or A $\beta_{40}$  dosages and A $\beta_{42}$ /A $\beta_{40}$ ) in plasma. Finally, we performed pathway analyses based on results from single-variant association analyses. **Findings:** We detected, at the genome-wide level ( $P < 5 \times 10^{-8}$ ), a new locus on 1p36 (rs34683021, MAF=0.26,  $P = 2.8 \times 10^{-9}$ ) in the intron of *PANK4*, a gene overexpressed in the brain that belongs to a family of proteins associated with neurodegeneration. We also confirmed the association of the 17q21 locus and identified two distinct signals (*MAPT*, rs242557, MAF=0.36,  $P = 9.9 \times 10^{-89}$  and *ARL17A*, rs4630592, MAF=0.35,  $P = 1.3 \times 10^{-50}$ ). We found associations ( $P \leq 0.05$ ) in loci associated with tau (CSF p-tau and t-tau and plasma t-tau), AD, and AD-related traits (AD age of onset, accelerated cognitive decline, total ventricular volume, hippocampal atrophy, whole-brain volume and small vessel stroke). Bivariate analyses of tau and A $\beta$  levels uncovered pleiotropic effects for variants located in the AD gene *C10orf11*, the neurological disorder gene *GOSR2*, the tau and AD gene *GLIS1* and the neuromuscular disease gene *PKD1L2*. Finally, we found enrichment for pathways linked to synaptic function and immunity. **Interpretation:** Our GWAS of plasma tau levels reveals new variants, genes and pathways associated with tau levels and identifies potential pleiotropic effects with A $\beta$  in brain-related genes. Studying relevant AD biomarkers in genetic analyses can help to uncover new genes and pathways that may contribute to AD-related processes and be promising targets for developing new drugs and preventive medicines for AD.

## 3333W

**African American whole exome sequencing suggests risk coding variants in IDH1 gene.**

P. Whitehead<sup>1</sup>, F. Rajabli<sup>1</sup>, K. Hamilton<sup>1</sup>, J.M. Vance<sup>1</sup>, E.R. Martin<sup>1</sup>, G.D. Schellenberg<sup>2</sup>, L. Wang<sup>3</sup>, L.A. Farrer<sup>3</sup>, J.L. Haines<sup>4</sup>, R. Mayeux<sup>5</sup>, G.S. Byrd<sup>6</sup>, G.W. Beecham<sup>1</sup>, M.A. Pericak-Vance<sup>1</sup>, Alzheimer Disease Genetics Consortium. 1) John P. Hussman Inst for Human Genomics, University of Miami, Miami, FL; 2) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Departments of Medicine (Biomedical Genetics), Neurology, Ophthalmology, Epidemiology, and Biostatistics, Boston University Schools of Medicine and Public Health, Boston, MA; 4) Inst for Computational Biology, Case Western Reserve University, Cleveland, OH; 5) Department of Neurology, College of Physicians and Surgeons, Columbia University, New York, NY; 6) Department of Biology, North Carolina A & T State University, Greensboro, NC.

African Americans (AA) have a higher prevalence and incidence of AD than non-Hispanic white (NHW) individuals. However, AA populations are understudied, and genomics successes in AD have primarily arisen from studying NHW participants. To identify novel genetic variation influencing AD, and to better understand AD in the AA population we performed whole-exome sequencing (WES) in a set of AA individuals. Our study is the largest to date WES sample for genetic studies of AD in AA individuals. Exome was captured using the Agilent's SureSelect Human All Exon V6 kit. WES was performed on the Illumina's HiSeq 3000 System at average sequencing depth 101. General alignment was performed using BWA algorithm. Genotyping calling was done with GATK and ATLAS calling pipelines. Sequencing was performed on 2,998 unrelated individuals (1,680 cognitively intact controls and 1,318 AD cases). Samples were matched for sex (65.6% vs 73.7%, case vs control) and age (74.8(8.1) vs 74.7(8.7), case vs control). Single variant association and gene-based analysis were performed by using SeqMeta score test analysis and SKAT-O respectively by adjusting for age, sex, PC1 and PC2. Variants were annotated with Ensemble VEP annotation, and were given a high priority if they have a functional impact by a high CADD score. WES confirmed the association of APOE with LOAD (rs741780,  $p$ value=1.2e-55; gene-based test,  $p$ value=1.1e-16). The IDH1 synonymous variant (rs552214533,  $p$ value=5.4e-6) on chromosome 2 did not fully reach genome-wide significance, but was observed as one of the top significant variants. We observed nominal association at 8 variants in AKAP9 gene (rs190545859,  $p$ value=2.6e-3). Similarly, 15 variants in ABCA7 were nominally significant (rs73505232,  $p$ value=6.8e-5). Our results confirm that variants in ABCA7 and AKAP9 genes are the risk factors in AA, and suggest the presence of AD risk variants in IDH1 gene. The IDH1 gene is expressed in brain tissue and related to the immune system pathways, an important pathway in AD. Identification of population-specific variation that influences disease is important to understand the genetic basis of health disparities.

**Correcting for confounding from batch effects and genotype imputation with whole genome sequence data: Application to the ADSP family sample.** *E.M. Wijsman<sup>1,2</sup>, T.R.C. Day<sup>1</sup>, T.A. Thornton<sup>2</sup>, E.E. Blue<sup>1</sup>, Alzheimer's Disease Sequencing Project.* 1) Division of Medical Genetics/Department of Medicine, University of Washington, Seattle, WA; 2) Department of Biostatistics, University of Washington, Seattle, WA.

Disease-gene identification often employs whole genome sequence (WGS) data. Evaluation of WGS variants may be carried out with association methods used in GWAS studies, including adjustment for related subjects, if necessary. Costs and time required to generate WGS data introduce practical complications. High cost induces incentives to limit the number of subjects with newly-generated WGS. Limiting sample size may include sequencing cases while using previously sequenced shared controls, or sequencing only some subjects, with genotype imputation into the rest. The time needed to generate WGS data in large samples also leads to temporal and/or spatial batch-effects. We show in analysis of the Alzheimer's Disease Sequencing Project (ADSP) family sample that these issues lead to confounding, requiring correction to avoid spurious results in association analyses. We carried out association analysis of Alzheimer's disease (AD) with genotype dose from WGS data in 110 ADSP families with GWAS SNP data from the initial discovery sample, using a linear mixed model in GENESIS, principal components as covariates, and adjustment for relatedness via a kinship matrix. WGS was initially generated for an ~8:1 AD case-control ratio. A second extension round of WGS, providing 854 subjects with WGS in total, emphasized controls in the same families, but still yielded an overall case-control ratio of ~2:1. WGS data and AD status was therefore confounded. Only p-values obtained from the initial WGS conformed to the expected null distribution. Analysis of the joint WGS from both rounds of sequencing lead to a large genomic inflation factor,  $\lambda=1.25$ , for  $-\log_{10}p$ . Family-based genotype imputation led to a severe ( $\lambda > 3$ ) inflation factor, which was worse in the presence of sequencing batch effects. Inflation in  $\lambda$  was reasonably controlled by adding several covariates: 1) sequence batch, 2) GWAS status, 3) a measure of imputation quality (imputation deviance) that is a function of family size and proximity to subjects with observed data, and 4) functions of family-based WGS fractions from each batch. Our results provide approaches to adjust for issues in WGS data that are likely to be widespread. They also show that care is needed to capture multiple sources of confounding, both qualitative and quantitative, to avoid spurious conclusions to be drawn from the WGS data.

**Genetically-informed association analysis identifies risk factors for late-onset Alzheimer's disease.** *D. Yan<sup>1</sup>, B. Hu<sup>2</sup>, Y. Wang<sup>1</sup>, Q. Lu<sup>2,3</sup>.* 1) University of Wisconsin-Madison, Madison, WI, USA; 2) Department of Statistics, University of Wisconsin-Madison, Madison, WI, USA; 3) Department of Biostatistics and Medical Informatics, University of Wisconsin-Madison, Madison, WI, USA.

Genome-wide association studies (GWAS) have provided insights into the genetic basis of numerous complex traits. Increasingly accessible GWAS summary statistics and biobank data have made it possible to further dissect the complex relationship between traits. Here, we introduce GAACT (Genetically-informed Association Analysis for Complex Traits), an efficient method to identify associations between a disease of interest and thousands of genetically-imputed traits using GWAS summary statistics. Compared to traditional association analysis, GAACT does not require traits to be measured on the same individuals and effectively reduces reverse causation from associations. We demonstrated the effectiveness of GAACT through extensive simulations and application to more than 2,000 traits from the UK Biobank (N~337,000) and summary statistics of 30 complex diseases. Our results confirmed many classic causal risk factors including smoking behavior for lung cancer ( $p=3.9e-55$ ). Additionally, we performed detailed analyses to identify risk factors for late-onset Alzheimer's disease (LOAD) using UK biobank traits and GWAS summary statistics from the International Genomics of Alzheimer's Project (IGAP; N=54,162). We further replicated our findings in an independent summary dataset (N=7,050) and results from two stages were meta-analyzed. We identified a total of 58 LOAD-associated traits with Bonferroni-corrected significance and consistent effect directions in two independent analyses. Unsurprisingly, family history of dementia ( $p=1.3e-71$  and  $2.1e-34$  for illnesses of mother and father, respectively) and cognitive impairment ( $p=6.4e-07$ ) were strongly associated with higher LOAD risk. In addition, various intelligence and education traits, e.g. fluid intelligence score ( $p=1.1e-16$ ) and age completed full time education ( $p=6.4e-08$ ), showed consistent associations with lower risk of LOAD. In contrast, not having any education specified in the survey were associated with a higher risk ( $p=3.4e-09$ ). Further, a few traits with previously mixed results in the literature showed strong and consistent associations with LOAD in our analysis, including high cholesterol ( $p=1.8e-14$ ) and leukemia ( $p=4.2e-09$ ). Finally, we demonstrated that multivariate conditional analysis can be performed in the GAACT framework and suggested a number of traits with independent effects on LOAD risk. GAACT has the potential to be widely used in future studies to screen risk factors for complex diseases.

**3336W****A genetic epidemiological study for rare spinocerebellar degeneration based on whole exome sequencing analysis in the Japanese population.**

Y. Hama<sup>1</sup>, H. Date<sup>1</sup>, S. Watanabe<sup>1</sup>, H. Ishiura<sup>2</sup>, J. Mitsui<sup>2</sup>, J. Yoshimura<sup>3</sup>, K. Doi<sup>3</sup>, S. Morishira<sup>3</sup>, S. Tsuji<sup>2</sup>, M. Murata<sup>1</sup>, H. Mizusawa<sup>1</sup>, Y. Takahashi<sup>1</sup>. 1) Department of neurology, national center hospital, national center of neurology and psychiatry, Japan; 2) Department of neurology, graduate school of medicine, the university of Tokyo, Japan; 3) Department of computational biology, graduate school of frontier sciences, the university of Tokyo, Chiba, Japan.

Background Hereditary spinocerebellar degeneration (hSCD) is genetically heterogeneous group of disorders with more than 50 causative genes. Common disease types of hSCD include triplet repeat expansion diseases and SCA31 in the Japanese population, which collectively account for ~80% of hSCD. However, genetic epidemiology of the remaining SCD, which is considered to be aggregation of rare disease types, has not been fully delineated. Purpose The purpose of our study was to elucidate the genetic epidemiology of rare SCD in the Japanese population. Methods Seventy subjects diagnosed as SCD were enrolled in this study with informed consent, in whom mutations in triplet repeat expansion diseases, EAOH/AOA1, AOA2, AR-SACS and ataxia telangiectasia were excluded. Whole exome sequencing analysis was conducted and nonsynonymous variants were filtered with the allele frequency <0.002. The present analyses compared age, sex, family history, and clinical findings between patients with mutation and without mutation. This study was approved by the Institutional Review Board of National Center of Neurology and Psychiatry. Results Twenty-seven (39%) subjects harbored likely pathogenic mutations in 16 genes including *AARS2*, *B4GALNT1*, *CACNA1A* (3 subjects), *FGF14*, *GCH1*, *ITPR1*, *KIF1A* (2 subjects), *LYST*, *NPC1*, *PLA2G6* (2 subjects), *SCYL1*, *SETX*, *SPTBN2* (2 subjects), *SYNE1* (5 subjects), *TGM6* (2 subjects), *TTBK2*, and *ZFYVE26*. Nine (33%) genes were causative for diseases not classified as SCD including *AARS*, *B4GALNT1*, *GCH1*, *ITPR1*, *KIF1A*, *LYST*, *NPC1*, *PLA2G6*, and *ZFYVE26*. Pathogenic mutations were more likely to be identified in female patients (female vs. male, 29% vs. 16%,  $p=0.046$ ) or patients with mental retardation ( $p=0.048$ ). There was a tendency towards enrichment of pathogenic mutations in patients with peripheral neuropathy ( $p=0.074$ ). There was no significant difference in age and presence of family history, pure cerebellar symptom, pyramidal sign, parkinsonism, autonomic disturbance, and cognitive dysfunction between the two groups. Conclusion This study demonstrated the advantage of exome-first approach for rare hSCDs, particularly for female patients or the disease subtypes complicated with mental retardation or peripheral neuropathy. Broad categories of genes should be taken into consideration in molecular diagnosis of this entity.

**3337T****A third linear association between Olduvai (DUF1220) copy number and the severity of the classic symptoms of inherited autism.** *J.M. Davis<sup>1</sup>, I. Heft<sup>1</sup>, S.W. Scherer<sup>2,3</sup>, J.M. Sikela<sup>1</sup>.*

1) University of Colorado Denver, Anschutz Medical Campus, Department of Biochemistry and Molecular Genetics, Aurora, CO; 2) McLaughlin Centre and Department of Molecular Genetics, University of Toronto; 3) The Centre for Applied Genomics and Program in Genetics and Genome Biology, Hospital for Sick Children.

Autism is a highly heritable condition which typically involves social deficits, communication impairments and repetitive behavior. We previously have reported, and subsequently confirmed, that the copy number of sequences encoding the Olduvai protein domain (formerly DUF1220) shows a linear association with the severity of the primary symptoms of autism (social deficits and communication impairment). Here, using another independent population ( $n = 215$ ) and a new higher resolution measurement method that uses whole genome sequence data, we show, for the third time, that as the copy number of the CON1 Olduvai subtype increases autism symptoms become incrementally worse. Specifically, in male multiplex children a linear association between CON1 copy number and Social Diagnostic Score (SDS) ( $b = 0.24$ ,  $se = 0.12$ ,  $p = 0.041$ ) and Communication Diagnostic Score (CDS) ( $b = 0.23$ ,  $se = 0.08$ ,  $p = 0.007$ ) was confirmed. Combining data from the three studies ( $n = 524$ ) identified linear associations of CON1 dosage with SDS ( $b = 0.18$ ,  $se = 0.05$ ,  $p = 0.0008$ ) and CDS ( $b = 0.13$ ,  $se = 0.04$ ,  $p = 0.0009$ ), further supporting a role for Olduvai sequences in the classic symptoms of autism. In addition, the enhanced discriminatory power of our sequence read depth method allowed us to implicate Olduvai subtypes specifically found in two of the 23 Olduvai-encoding genes (*NBPF1* and *NBPF14*) as primary contributors to this association. The variability of a latent genotype constructed using the copy number of *NBPF1 CON1* and *NBPF14 HLS1* subtypes explained 6.1% of the variability of a latent social phenotype ( $R^2 = 6.1\%$ ,  $p = 0.002$ ). We also note that our associations with these core autism phenotypes are consistently found in multiplex but not simplex families, and thus may be particularly important in inherited forms of autism. Finally, Olduvai sequences are hyper-amplified specifically in humans and have been implicated in human brain evolution and cognitive function. Such findings, taken together with our autism findings, lend further support to the proposal that Olduvai domains may constitute a genomic trade-off in which the same sequences, depending on how they vary, can produce either evolutionary benefit or neurological disease.

**Analysis of APOE and known depression SNPs in patients with multiple sclerosis.** S.W. Brugger<sup>1</sup>, J.C. Denny<sup>2</sup>, M.F. Davis<sup>1</sup>. 1) Microbiology and Molecular Biology, Brigham Young University, Provo, UT; 2) Departments of Biomedical Informatics and Medicine, Vanderbilt University Medical Center, Nashville, Tennessee, USA.

Multiple Sclerosis (MS) is a debilitating disease characterized by the demyelination of the axons of the central nervous system. Although symptomatic manifestations of MS are unique to each patient, previous studies have demonstrated that up to 50% of MS patients will experience clinically significant depression at some point in their life. This correspondence warranted an investigation into a potential genetic link between MS and depression. Certain APOE variants have been reported to be linked to depressive affect in MS patients, which this study aimed to replicate. We also examined the relationship between MS and a collection of SNPs recently identified as being significantly associated with depression in the general population. This study was performed by dividing an EHR population of MS patients into three groups: MS patients with billing codes for depression at any point in their medical record (n=270), at least one year before their MS diagnosis (n=31), and at least one year after their MS diagnosis (n=154). Controls were defined as patients with MS but no billing codes for depression (n=968). Genome-wide association analyses did not identify any significant SNPs within each of these categories. Logistic regression analyses with both APOE and other depressive SNPs failed to reach statistical significance for association between MS and depression, although moderate significance was discovered with one known depression SNP on chromosome 1 (rs1432639, p = 0.058). We were unable to replicate the results linking known APOE SNPs to depression in MS patients, nor were we able to identify any associations between reported depression SNPs in the general population and MS in our patients.

**3339W**

**Transcriptomic analysis in multiple system atrophy (MSA).** C. Bleuh<sup>1,2</sup>, I.S. Piras<sup>1,2</sup>, J.S. Talboom<sup>1,2</sup>, M.A. Naymik<sup>1,2</sup>, I. Schrauwen<sup>3</sup>, M.D. De Both<sup>1,2</sup>, M.J. Huentelman<sup>1,2</sup>. 1) Translational Genomics Research Institute, Phoenix, AZ; 2) Arizona Alzheimer's Consortium, Phoenix, AZ; 3) Baylor College of Medicine, Houston, TX.

Multiple System Atrophy (MSA) is a rare neurodegenerative disorder characterized by ataxia, autonomic dysfunction, parkinsonism and aggregation of  $\alpha$ -synuclein in oligodendrocytes. Here we present the RNA-sequencing profiling results of post-mortem brains (cerebellum white matter) from MSA patients (n = 67) and healthy controls (HC; n = 66), also stratifying for MSA subtype (MSA-P and MSA-C). This is the largest known RNA profiling study conducted on MSA post-mortem brains. Samples are from Banner Sun Health (Sun City, AZ), New South Wales (Sydney, AU) (Cohort1; C1) and Queen Square (London, UK) (Cohort 2; C2) brain banks. RNA was prepared using Illumina's Truseq kit (C1) and TempO-Seq protocol (BioSpyder) (C2) and sequenced using Illumina HiSeq 2500 and NextSeq. Differentially expressed genes (DEGs) were detected using DESeq2 including age, sex, and PMI as covariates. We conducted Gene Ontology (GO) and protein-protein interaction (PPI) network analysis on DEGs lists. We detected 33 DEGs in C1 (mostly upregulated), and 3 genes in C2 associated with MSA. In the MSA-P group, we detected 20 DEGs in C1 (mostly upregulated) and 3 DEGs in C2. No overlap between the cohorts were detected. In MSA-C, we detected 519 DEGs in C1 and 304 DEGs in C2 with a slight prevalence of upregulated genes (55.3% in C1 and 52.3% in C2). 30 genes were detected in both cohorts and not detected in MSA-P. GO analysis highlighted the enrichment of genes associated with "Negative regulation of phosphate metabolic processes" (C1) and "Astrocytes and glial cell projection" (C2). We generated a PPI network using the 30 candidate genes, detecting a sub-network including 9 DEGs, with 5 directly connected with APP. In conclusion, we show the presence of 30 candidate genes associated with MSA-C, the subtype characterized by olivopontocerebellar ataxia. The PPI network analysis showed a potential direct interaction of five of them (IL1RL1, TLL7, GAS2, PCYT1B, and MTURN) with APP. It is known that  $\beta$ -amyloid may drive  $\alpha$ -synuclein pathology through different mechanisms (e.g impairment of protein clearance, enhancing inflammation and phosphorylation). At this time,  $\beta$ -amyloid pathology has been detected only in one case of MSA-C. However, it has been suggested that  $\beta$ -amyloid plaques may contribute to cognitive impairment related to MSA and decreased levels of Ab42 were observed in MSA CSF, similarly to AD. Finally, GO processes detected could be related to the  $\alpha$ -synuclein phosphorylation.

**3340T**

**Genome-wide association studies of brain structure and function in the ~20,000 UK Biobank participants.** *K.J. Sharp<sup>1</sup>, L.T. Elliott<sup>1</sup>, F. Alfaro-Almagro<sup>2</sup>, S. Shi<sup>1</sup>, K. Miller<sup>2</sup>, G. Douaud<sup>2</sup>, J. Marchini<sup>1,3</sup>, S. Smith<sup>2</sup>.* 1) Dept. of Statistics, University of Oxford, Oxford, Oxford, United Kingdom; 2) FMRIB, Wellcome Centre for Integrative Neuroimaging, University of Oxford, Oxford, UK; 3) The Wellcome Centre for Human Genetics, University of Oxford, Oxford, UK.

Genome-wide association studies of brain imaging derived phenotypes (IDPs) have great potential to shed light on the genetic basis of many neurodegenerative and psychological traits. UK Biobank is in the process of brain imaging 100,000 participants. We recently analyzed the first tranche of ~8,500 subjects for over 3,000 IDPs and identified 148 clusters of SNP-imaging associations with lead SNPs that replicate at  $p < 0.05$  in an additional set of 3,456 samples (consistent with a post-hoc winner's curse corrected power analysis). Notable significant and interpretable associations include: iron transport and storage genes, related to changes in T2\* in subcortical regions; extracellular matrix and the epidermal growth factor genes, associated with white matter micro-structure and lesion volume; and genes regulating mid-line axon guidance development associated with pontine crossing tract organization. We will report an expanded set of results from an analysis of ~20,000 participants and highlight the role of computationally efficient methods for tests using multi-trait mixed models. These complement individual IDP tests by utilising estimates of genetic correlation to boost power, while needing to correct for a much smaller number of tests. In our multi-trait analysis of 23 groups of IDPs for ~8,500 subjects with up to 243 IDPs per group, we found 170 associations that survived a correction for 23 scans with  $-\log_{10}$  p-value  $> 8.86$ . 138 of these replicated at  $p < 0.05$  including 25 loci that showed no genome-wide significance in the flanking region for any individual IDP in the corresponding group. Notable examples were rs62073157 ( $P=4.07E-11$ ) associated with diffusion MRI measures of mode of anisotropy (dMRI MO) and rs12928124 ( $P=1.31E-10$ ) associated with FreeSurfer measures of brain volume. rs62073157 is an eQTL of *MAPT* which has been associated with several neurodegenerative disorders, while rs12928124 is located in *IL-34* which has been shown to protect against oligomeric amyloid- $\beta$  mediated synaptic dysfunction and neuronal damage in Alzheimer's disease. We also report results from a new Sparse Bayesian Multitrait Testing method (SBAT) which can identify the most probable IDPs within a group with greater precision than a full model test. By analysing a group of 15 subcortical volumes, we demonstrate markedly greater power to identify known associations than a recently published approach based on summary statistics from single phenotype GWAS of the same data.

**3341F**

**Replication of the *SCFD1* associated locus in ALS using linear mixed models.** *A. Nicolas<sup>1</sup>, M. Nalls<sup>2,3</sup>, B. Traynor<sup>1</sup>, International ALS Genomic Consortium.* 1) Neuromuscular Diseases Research Section, Laboratory of Neurogenetics, National Institute on Aging, NIH, Porter Neuroscience Research Center, Bethesda, MD 20892, USA; 2) Molecular Genetics Section, Laboratory of Neurogenetics, National Institute on Aging, NIH, Porter Neuroscience Research Center, Bethesda, MD 20892, USA; 3) Data Tecnica International, Glen Echo, MD, USA.

ALS is a progressive and fatal neurodegenerative disease causing muscle weakness and atrophy and leading to death within 2 to 5 years of symptom onset, due to respiratory failure. This disease kills approximately 7,000 Americans annually and no effective treatments currently exist. A genome-wide association study published in 2016 (Van rheenen *et al.*, 2016) nominated five novel loci as being associated with ALS, based on linear mixed modeling: rs616147 in *MOBP*; rs7813314 in *LOC101927815*; rs10139154 in *SCFD1*; rs35714695 in *SARM1*, and rs75087725 (*C21orf2*). We have previously replicated the association of rs75087725 (*C21orf2*) and ALS (Nicolas *et al.*, 2018). Here, we attempted to replicate the remaining four loci in an independent dataset of 8,229 ALS cases and 36,329 controls. To do this, we performed standard quality control of genotyping data using PLINK software package (version 1.9). Haplotypes were estimated with SHAPEIT (version 2.r790). Variants were imputed using Minimac3 software (version 1.0.11) and using the reference panel of 1000 Genomes Project dataset (phase 3, version 5a, release 2013-05-02). Post-imputation quality control was performed to filter out variants with a  $R^2 < 0.3$  and a  $MAF < 0.01$ . Joint association analysis was run using the MLMA-LOCO linear mixed models algorithm as implemented in GCTA and corrected for 5 principal components, age and gender. Within our data, the *SCFD1* locus only is replicated with a  $p=2.89 \times 10^{-8}$ , in the Van rheenen's study,  $p=4.95 \times 10^{-8}$  and in the combined dataset,  $p=5.342 \times 10^{-11}$  ( $OR=1.014$ , 95%  $CI=1.010-1.018$ ). We did not find definitive evidence of association for *MOBP*, *LOC101927815* or *SARM1*. Another GWAS of 1,234 ALS cases and 2,850 controls did not replicate any of the 5 loci (Benyamin *et al.*, 2017), in a Chinese population. *SCFD1*, for Sec1 Family Domain Containing 1, is involved in the Golgi-to-ER retrograde transport and interacts with syntaxin, for the docking of synaptic vesicles.

**3342W**

**A factor analysis of early stressful life events identifies evidence for G-E interaction in multiple sclerosis.** *M.K. Horton<sup>1</sup>, X. Shao<sup>1</sup>, H. Quach<sup>1</sup>, D. Quach<sup>1</sup>, K.H. Bellesis<sup>2</sup>, T. Chinn<sup>2</sup>, C. Schaefer<sup>2</sup>, L.F. Barcellos<sup>1,3</sup>.* 1) Genetic Epidemiology and Genomics Laboratory, Division of Epidemiology, School of Public Health, University of California, Berkeley, Berkeley, CA; 2) Kaiser Permanente Division of Research, Oakland, CA; 3) Computational Biology Graduate Group, University of California, Berkeley, Berkeley, California.

Causes of multiple sclerosis (MS [MIM 126200]), a chronic inflammatory and autoimmune disease, remain largely unexplained, but evidence suggests gene-environment interactions (G-E) account for part of its etiologic complexity. Childhood stress is implicated in pathogenesis of adult disease, and because stress is mechanistically related to inflammation, it may play a role in MS etiology. Prior studies reported an association between childhood stress and MS; however, none have tested whether SNPs associated with MS or stress interact with childhood stress to modify MS risk. We hypothesize that individuals who experienced childhood stressful life events and carry MS- or stress-related SNPs will have an increased risk of MS compared to individuals with one or neither exposure. We analyzed 1,500 MS cases and 12,000 controls from Kaiser Permanente Northern California. Ten stressful life events during ages 0-10 and 11-20 years were retrospectively measured using a modified version of the Life Event Record. Factor analysis was used to combine events into fewer latent factors and derive factor scores. Genotyping was performed using Illumina microarrays on saliva or blood samples. We selected *a priori* established MS risk variants, including those in the major histocompatibility complex (MHC) and 200 non-MHC variants, and SNPs within 30 candidate stress-related genes involved in hypothalamic-pituitary-adrenal axis regulation, such as *CYP21A1*, *CRHR1*, and *HSD11B2*. To test for G-E interaction and risk of MS, we used logistic regression with interaction-terms for latent factor scores and SNPs. We adjusted for genetic ancestry, gender, year of birth, and mother's educational attainment. Factor analysis revealed four latent factors of childhood stressful life events: "crime/abuse", "left home", "death/ illness" of immediate family member, and "divorce/remarry" of parents. Results identified 18 significant G-E interactions ( $p < 0.05$ ). The top interaction was rs1177228X"left home" ( $p < 0.01$ ). Stratified results by genotype showed that as the latent factor "left home" increased, the odds of MS increased among rs1177228 AA and AG genotypes but not GG genotypes [OR<sub>AA</sub>= 1.42 (95% CI: 1.20, 1.71); OR<sub>AG</sub>=1.40 (95% CI: 1.02, 2.10); OR<sub>GG</sub>=1.04 (95% CI: 0.94, 1.14)]. Although further studies with larger sample sizes are needed to increase power, our results suggest there is evidence for interaction between MS- and stress-related SNPs and childhood stressful life events in MS.

**3343T**

**Analysis of predicted loss of function variants in MSSNG identifies potentially causative variants in autism spectrum disorder.** *B. Przychodzen<sup>1</sup>, S. Smieszek<sup>2</sup>.* 1) Cleveland Clinic, Cleveland, OH; 2) Case Western Reserve University.

The complex genetic architecture of ASD encompasses profound clinical heterogeneity, which poses huge challenges in understanding its pathophysiology. We conducted a large scale analysis of the loss of function variants in the MSSNG whole genome sequencing data encompassing 7231 individuals to elucidate variants potentially relevant to ASD. We focused on rare LOF (MAF<0.01, frameshift/stopgain/splicing), inherited variants within this data. We then calculated the cumulative frequency among patients. As a control group we processed GnomAD database to extract similar variants among normal population. We then focused on statistically relevant genes that is single gene level over-represented, group/family of genes over-represented. Altogether we used X predicted LOF variants We identified interesting variants including KCNU1 and FBN2, amongst others, a missense variant rs168885577 (6.18E-08), eQTL, that has been shown to be implicated in schizophrenia. Enrichment analysis led us to calcium ion binding (GO:0005509). In addition we have conducted TDT meta-analysis of the MSSNG data. Less than 3% of protein coding genetic variants are predicted to result in loss of protein function through the introduction of stop codon for example, frameshift, disruption of splice site however such predicted variants provide insights regarding the direction of effect. We focus on such as such can lead us to actionable targets providing insights about pathophysiology of ASD.

Excessive daytime sleepiness (EDS) affects 10-20% of the population and is associated with substantial functional deficits and a wide variety of adverse health outcomes. EDS results from chronic insufficient sleep duration or poor sleep quality related to suboptimal sleep behaviors or underlying primary sleep disorders. However, there is significant individual variation in susceptibility to EDS as well as evidence for heritability of this trait. To improve our understanding of the genetic basis of EDS and related sleep disorders, we performed a genome-wide association analysis (GWAS) of self-reported EDS using 452,071 individuals of European ancestry in the UK Biobank. We identified 42 significant loci ( $P < 5 \times 10^{-8}$ ) associated with EDS, many of which also associate with other sleep traits, including self-reported short sleep duration, insomnia, chronotype, and accelerometer-derived sleep efficiency and daytime inactivity. Novel EDS loci include genes previously associated with primary sleep disorders, psychiatric and metabolic traits (e.g. *BTBD7*, *CACNA1C*, *GABRA2*, *HCRTR2*, *HTR7*, *KSR2*, *PCLC1*, and *RAI1*) as well as other loci. Identified signals were enriched for genes expressed in multiple brain tissues and central nervous pathways. Experimental analysis further showed knock out of *CG8916* (an ortholog of *GABRA2*) results in sleep alteration in *Drosophila melanogaster*. Mendelian randomization analyses were consistent with a causal association between BMI with EDS. Shared genetic basis were suggested between EDS and coronary artery disease, psychiatric diseases, cognitive traits, and reproductive aging. This largest GWAS for EDS identified multiple genetic loci and phenotypic associations that offer biological clues into pathways that contribute to EDS and chronic health disorders. .

**lateral sclerosis.** MQ. Zhang<sup>1,2,3</sup>, A.S. Allen<sup>1,2,3</sup>. 1) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC; 2) Center for Genomic and Computational Biology, Duke University, Durham, NC; 3) Center for Statistical Genetics and Genomics, Duke University, Durham, NC.

Gene-set-based analyses are often used to identify pathways where pathogenic variants may lead to disease. These analyses combine information across the genes in a pathway and attempt to identify any evidence of non-null effects within. For example, Higher Criticism (HC) statistics can be used to detect the weak-sparse signal within a pathway by looking for the largest scaled departure of ordered p-values from expectation. Here we investigate HC-like statistics that are based on integrating the scaled departure of ordered p-values from expectation instead of taking the max. We can show that this approach improves signal detection of certain alternatives over the traditional HC test. We illustrate our approach with a pathway analysis using data from a whole-exome sequencing data of amyotrophic lateral sclerosis (ALS) and show that our approach prioritizes ALS related pathways.

**The influence of puberty on risk of multiple sclerosis: A Mendelian randomization study.** A. Harroud<sup>1,2</sup>, J.A. Morris<sup>2,3</sup>, V. Forgetta<sup>2,3</sup>, R. Mitchell<sup>4</sup>, G.D. Smith<sup>4</sup>, S. Sawcer<sup>5</sup>, J.B. Richards<sup>2,3,6,7,8</sup>. 1) Department of Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada; 2) Centre for Clinical Epidemiology, Department of Epidemiology, Lady Davis Institute for Medical Research, Jewish General Hospital, Montreal, Quebec, Canada; 3) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 4) MRC Integrative Epidemiology Unit, School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 5) Department of Clinical Neurosciences, Cambridge Biomedical Campus, University of Cambridge, Cambridge, United Kingdom; 6) Department of Medicine, McGill University Montreal, Quebec, Canada; 7) Department of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, Quebec, Canada; 8) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom.

Several observational studies have reported an increased risk of multiple sclerosis (MS) with earlier age at puberty, although others found no relationship. In addition, these studies are susceptible to bias from confounding, further limiting causal inference. Therefore, we performed a Mendelian randomization (MR) study to investigate the potential for a causal effect of age at puberty on MS susceptibility. We also explored how body mass index (BMI) might influence this association, as weight status relates to both puberty timing and risk of MS. We used 375 genome-wide significant variants associated with age at menarche in a genome wide association study (GWAS) involving 329,245 women from the ReproGen consortium. The genetic architecture of puberty timing across both sexes is highly correlated ( $r_g=0.75$ ,  $p=1.2 \times 10^{-79}$ ), allowing these variants to provide reliable insight into puberty timing in males as well. Of the 375 variants, 372 were ascertained either directly ( $n=345$ ) or through proxies ( $n=27$ , median  $r^2=1.00$ ) in the latest International MS Genetics Consortium GWAS, including 14,802 MS cases and 26,703 controls. The effect of each variant on MS was weighted by its association with age at puberty. Estimates were combined using an inverse-variance weighted meta-analysis. To test whether puberty effects on MS were dependent on BMI, we performed multivariable MR controlling separately for the effects of adult and childhood BMI. For this, we used summary statistics from the ENGAGE (87,048 individuals) and EGG (35,668 individuals) consortia, respectively. The inverse-variance weighted MR revealed that a 1-year increase in age at puberty decreased odds of MS by 8% (OR=0.92, 95% CI 0.86-0.99,  $p=0.03$ ). However, multivariable MR analysis showed that after accounting for effects on adult BMI, the association of age at puberty with MS susceptibility attenuated significantly (OR=0.96, 95% CI 0.89-1.02,  $p=0.36$ ). Similar results were obtained when adjusting for childhood BMI (OR=0.97, 95% CI 0.89-1.05,  $p=0.40$ ). Sensitivity analyses, including multivariable MR-Egger regression, provided no evidence of directional pleiotropy or reverse causation. This study found support for an inverse association between age at puberty and risk of MS with a magnitude comparable to that reported in observation studies. This effect is largely mediated by the strong association between age at puberty and obesity, and a large causal effect of puberty timing independent of BMI is unlikely.

**Regional collapsing of rare variation implicates specific regions in known and novel ALS genes.** S. Gelfman<sup>1</sup>, S. Dugger<sup>1</sup>, C. De Araujo Martins Mo<sup>1</sup>, Z. Ren<sup>1</sup>, C. Wolock<sup>1</sup>, N.A. Shneider<sup>1</sup>, H. Phatnani<sup>2</sup>, E.T. Cirulli<sup>3</sup>, B.N. Lasseigne<sup>4</sup>, T. Harris<sup>5</sup>, T. Maniatis<sup>1</sup>, G.A. Rouleau<sup>6</sup>, JrR.H. Brown<sup>7</sup>, A.D. Gitler<sup>8</sup>, R.M. Myers<sup>4</sup>, S. Petrovsk<sup>9</sup>, A. Allen<sup>10</sup>, M.B. Harms<sup>1</sup>, D.B. Goldstein<sup>1</sup>. 1) Columbia University Medical Center, New York, NY, 10032 USA; 2) New York Genome Center, New York, NY, 10013 USA; 3) Human Longevity INC, San Diego, CA 92121 USA; 4) HudsonAlpha Institute for Biotechnology, Huntsville, AL 35806 USA; 5) SV Health Investors, Boston, MA 02108 USA; 6) McGill University, Montreal, H3A 2B4 Canada; 7) University of Massachusetts Medical School, Worcester, MA 01655 USA; 8) Stanford University School of Medicine, Stanford, CA 94305 USA; 9) Austin Health and Royal Melbourne Hospital, University of Melbourne, Melbourne, Australia; 10) Duke University, Durham, NC, USA.

Large-scale sequencing efforts in amyotrophic lateral sclerosis (ALS) have implicated novel genes using gene-based collapsing methods. However, pathogenic mutations may be concentrated in specific genic regions. To address this, we developed two collapsing strategies, one focuses rare variation collapsing on homology-based protein domains as the unit for collapsing and another gene-level approach that, unlike standard methods, leverages existing evidence of purifying selection against missense variation on said domains. The application of these two collapsing methods to 3,093 ALS cases and 8,186 controls of European ancestry, and also 3,239 cases and 11,808 controls of diversified populations, pinpoints risk regions of ALS genes including *SOD1*, *NEK1*, *TARDBP* and *FUS*. We identify *LGALS1* as a novel ALS gene that is also associated with early age-at-onset and implicate *PKP4* as a novel candidate gene. This work establishes a paradigm for identifying genic regions contributing to ALS occurrence in both known and novel candidate genes.

**Associations between hematologic laboratory values and multiple sclerosis subtypes.** *J.M. Miller<sup>a</sup>, J.C. Denny<sup>a</sup>, M.F. Davis<sup>a</sup>.* 1) Department of Microbiology and Molecular Biology, Brigham Young University, Provo, Utah, USA; 2) Departments of Biomedical Informatics and Medicine, Vanderbilt University Medical Center, Nashville, Tennessee, USA.

Multiple Sclerosis (MS) is a complex disease of the central nervous system in which the myelin sheaths of the nerve cells in the brain and spinal cord are damaged. Because expression of the disease varies widely between patients, four subtypes of MS have been defined based on patterns of its progression. Two of these subtypes are the focus of this study: Primary Progressive Multiple Sclerosis (PPMS), and Relapsing Remitting Multiple Sclerosis (RRMS). PPMS is the gradual progression of the disease with no relapses or remissions, while RRMS is characterized by unpredictable attacks (with potential permanent deficits) followed by periods of disease quiescence. Patients are classified into a subtype after monitoring of the disease over time. There are no known risk factors that vary significantly between PPMS and RRMS. In this study, we evaluated common laboratory tests to see if there are differences between the two populations without monitoring disease activity. We identified 5,416 people from the Vanderbilt Synthetic Derivative matching a case definition of MS, and then identified MS subtypes using previously developed natural language processing algorithms. We then took laboratory tests comprising the Complete Blood Count (CBC) from 2,440 patients with either PPMS ( $n=352$ ) or RRMS ( $n=2,088$ ) and compared them to see if there was a correlation between each specific lab value and MS subtype. Logistic regression was performed on the highest laboratory value for each patient, using patient's age at the date of the laboratory test as a covariate. This analysis showed that hemoglobin, PCV, platelet count, red blood cell count, and white blood cell count (.024, .0207, .0186, .00484, and .0102, respectively) were significantly different between the two subtypes of MS. We will look for genetic associations with the significant CBC and Comprehensive Metabolic Panel (CMP) lab values.

**Optimal and data-adaptive p-value combination tests with applications in omics data analysis.** *Z. Wu<sup>a</sup>, H. Zhang<sup>a</sup>.* 1) Worcester Polytechnic Institute, Worcester, MA; 2) Merck & Co., Inc., Kenilworth, NJ.

P-value combination is an important statistical approach for information-aggregated decision making. It is foundational to a lot of applications such as meta-analysis, data integration, signal detection, and others. We propose two generic statistic families for combining p-values: gGOF, a general family of goodness-of-fit type statistics, and tFisher, a family of Fisher type p-value combination with a general weighting-and-truncation scheme. The two families unify many optimal statistics over a wide spectrum of signal patterns, including both sparse and dense signals. We provide efficient solutions for analytical calculations of p-value and statistical power, as well as studies of asymptotic efficiencies, while emphasizing the conditions of realistic data analysis: small or moderate group size, Gaussian and non-Gaussian distributions, correlated data, generalized linear model based alternative hypotheses, etc. Based on these two families of statistics, omnibus tests are also designed for adapting the family-retained advantages to unknown signal patterns. Applications of these methods are illustrated in integrative analyses of large-scale omics data.

**3350F****Bivariate causal discovery and its applications to gene expression and imaging data analysis.**

*R. Jiao<sup>1</sup>, N. Lin<sup>1</sup>, Z. Hu<sup>2</sup>, D.A. Bennett<sup>3</sup>, L. Jin<sup>2</sup>, M. Xiong<sup>1,2</sup>.* 1) The University of Texas School of Public Health, Houston, TX; 2) School of Life Sciences, Fudan University; 3) Rush University.

Genetic data analysis has experienced significant progress on statistical association, but it remains elusive to understand the etiology and mechanism of complex phenotypes. As a major analytical platform, association analysis may hamper the theoretic development of genomic science and its application. Thus, many researchers suggest making the transition from association to causation. To explore bivariate causal discovery, we introduced independence of cause and mechanism (ICM) as a basic principle, using additive noise model (ANM) as a major tool for bivariate causal discovery. Large-scale simulations were performed to evaluate the feasibility of the ANM for bivariate causal discovery. To further evaluate its performance, ANM was applied to the gene regulatory network construction of Wnt signaling pathway with RNA-Seq of 145 genes measured in 447 tissue samples. Around fifty most significant causal relations were selected to test detection accuracy. For comparison, the score-based linear structural equation model (SEM), causal additive model (CAM), PC algorithm and random network were also included in analysis. Results showed that 38% of ANM-detected paths agreed with the KEGG, while SEM only reached 20% accuracy, CAM 16%, PC 21.57% and random network 25.41%. The ANM outperformed the other three causal algorithms. Also, ANM was applied to the Alzheimer's Disease Neuroimaging Initiative (ADNI) data with 91 individuals with Diffusion Tensor Imaging measured at four time points: baseline, 6 months, 12 months and 24 months. We identified causal relationships between working memory and activities of the temporal R (hippocampus) at 24 months with  $P = 0.00014$  (image working memory), but found no association ( $P = 0.59$ ). Corresponding images showed that the decreased neural activities in the temporal R region deteriorated AD patients' working memory. This result provided evidence that causation may be identified in the absence of association signals. We also observed only association between cholesterol and imaging signal variation at 12 and 24 months in the Occipital\_Mid brain region ( $P = 0.0003$  at 12m,  $P = 0.00004$  at 24m), but no causation ( $P = 0.68$  at 12m,  $P = 0.19$  at 24m), which was consistent to the fact of no significant imaging signal variation in the occipital lobe region. It infers that association may not provide enough information on mechanism of complex phenotypes.

**3351W****Polygenic risk score analysis of antidepressant response in major depressive disorder in the STAR\*D study.**

*W. Guo<sup>1</sup>, A. Rush<sup>2</sup>, L. Hou<sup>3</sup>, I. Henter<sup>4</sup>, M. Ritter<sup>1</sup>, S. Kang<sup>1</sup>, N. Akula<sup>3</sup>, F. McMahon<sup>3</sup>, Y. Shugart<sup>1</sup>.* 1) Statistical Genomics and Data Analysis Core, National Institute of Mental Health, National Institutes of Health, Bethesda, MD; 2) Duke – National University of Singapore, Singapore; 3) Human Genetics Branch, National Institute of Mental Health, National Institutes of Health, Bethesda, MD; 4) Section on PET Neuroimaging Sciences, National Institute of Mental Health, National Institutes of Health, Bethesda, MD.

Major depressive disorder (MDD) is one of the most common mental disorders in the United States, affecting about 6.7% of the population in a given year. The Sequenced Treatment Alternatives to Relieve Depression (STAR\*D) study provided the largest cohort and was designed to assess effectiveness of treatments in patients with nonpsychotic major depressive disorder. In the STAR\*D data, four levels of the study were designed to assess the effectiveness of depression medication in patients with major depressive disorder. Antidepressant response has been shown as a polygenic trait and involves a large number of SNPs with small effect sizes, and approximately 42% of phenotypic variance in antidepressant response was explained by common SNPs across the human genome. The STAR\*D Study aimed to assess the effectiveness of depression treatments in 4,041 outpatients with major depression, recruited in 18 primary care and 23 psychiatric clinical sites across the United States. Of the initial 4,041 participants, 1,165 were extracted because they either were not qualified to have "at least moderate" depression or they chose not to participate. Then as entering level 1, 2,876 participants were treated with the antidepressant citalopram, a selective serotonin reuptake inhibitor (SSRI) from 2 to 14 weeks. In this study, QIDS-SR<sub>16</sub> was used as the primary measure to report citalopram's efficacy. First, the most stringent quality control (QC) was carried out for the STAR\*D data at both SNP-level and sample-level before imputation. The STAR\*D samples were genotyped on Affy 5.0 platform. Second, the imputation of genotypes was conducted using the IMPUTE2 software program using the 1000 Genomes Phase 3 dataset as reference. Furthermore, as a comparison, we re-genotyped a subset of STAR\*D-Omni1S samples by Illumina Omni1S BeadChip to inspect the imputation concordance within this replication samples to evaluate the quality of imputation. To detect single-nucleotide polymorphisms (SNPs) associated with antidepressant response, we re-analyzed the antidepressant efficacy in MDD patients of STAR\*D data using well-imputed dosage data. Finally, a polygenic risk score analysis was carried on the antidepressant response at all four levels in Major Depressive Disorder in the STAR\*D samples. .

**3352T**

**Selecting best polygenic risk scoring method based on the features of a study.** A.A. Shabalin<sup>1</sup>, J.S. Anderson<sup>1</sup>, A.R. Docherty<sup>1,2</sup>. 1) Psychiatry, University of Utah, Salt Lake City, UT; 2) Virginia Institute for Psychiatric & Behavioral Genetics, Virginia Commonwealth University, Richmond, VA.

Polygenic risk scoring (PRS) is a new approach for phenotype prediction designed for highly polygenic outcomes. The predictive power is achieved by integrating millions of effects across the entire genome into a single metric. Due to the success of PRS paradigm, multiple PRS calculation methods have been proposed, each with individual strengths and weaknesses and a distinct set of parameters (or priors for Bayesian methods). The choice of the method and parameters can strongly affect the performance of calculated PRS and there is no single best method / set of parameters. All of the following features affect polygenic risk score calculation: 1) polygenicity of the phenotype, 2) heritability of the phenotype, 3) reliability/validity of the phenotype measurement, 4) whether the outcome is binary or continuous, 5) prevalence of binary outcomes / distribution of continuous outcomes, 6) sample size of the training data and the test cohort, 7) number of SNPs tested in original GWAS and test cohort. These features can be used to select a PRS method and its parameters. Here we present empirically derived guidelines for selection of PRS calculation methods and for the choice of the parameters based on the aforementioned features. The assessment is conducted using both real and simulated data with a variety of clinical phenotypes and psychiatric diagnoses.

**3353F**

Huckins<sup>1</sup>, W. Wang<sup>1</sup>, D. Ruderfer<sup>4</sup>, X. Xu<sup>5</sup>, J. Buxbaum<sup>6</sup>, D. Pinto<sup>5,6,7</sup>, X. He<sup>8</sup>, P. Sullivan<sup>9</sup>, E. Stahl<sup>1</sup>. 1) Division of Psychiatric Genomics, Department of Genetics and Genomic Sciences, Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 2) Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 3) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 4) Division of Genetic Medicine, Departments of Medicine, Psychiatry and Biomedical Informatics, Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville, TN, USA; 5) Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 6) The Mindich Child Health & Development Institute, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 7) Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 8) Department of Human Genetics, University of Chicago, Chicago, IL, USA; 9) Departments of Genetics and Psychiatry, University of North Carolina, Chapel Hill, North Carolina, USA.

Gene-set enrichment analysis has contributed to the understanding of the genetic architectures of complex diseases. In current de novo and rare case-control sequencing studies, either gene set analyses or individual gene analyses are conducted, but typically results of gene set enrichment analysis are not used to better identify individual risk genes. Here, we have developed a Bayesian method-based pipeline, termed gTADA, which identifies enrichment in gene sets or gene-expression levels through their direct incorporation into models of de novo (DN) and rare inherited/case-control (rCC) gene burden data. With this pipeline, arbitrary significance thresholds can be circumvented. Our method can leverage external gene-level information to prioritize risk genes. Applying gTADA to available whole exome sequence data sets including developmental disorder (DD), intellectual disability (ID), autism spectrum disorder (ASD), epilepsy (EPI), and congenital heart disease (CHD) phenotypes, gTADA is able to replicate previously reported gene-set enrichments and identify novel risk genes. For EPI, gTADA prioritized multiple significant genes of which 25 are novel significant genes (posterior probabilities > 0.95) in a meta-analysis of multiple types of EPI (356 trios, 5704 cases and controls). Several of our novel EPI risk genes replicate in a recent whole genome sequencing study using independent samples. Top prioritized EPI genes have high protein-protein interaction network connectivity, and their expression during human brain development correlates with subnetwork functional annotations. Finally, we also saw more enriched drug-target gene sets for EPI than for other disorders.

**Methods for estimating covariate effects on 5hmC methylation: A proposed method and a comparison.** C.M.T. Greenwood<sup>1,2</sup>, K. Greenlaw<sup>1</sup>, J. Gross<sup>3</sup>, A. Canty<sup>4</sup>, A. Ciampi<sup>1</sup>, G. Tureck<sup>1,2,3</sup>. 1) Lady Davis Institute for Medical Research, Montreal, Quebec, Canada; 2) McGill University, Montreal, QC, Canada; 3) Douglas Mental Health University Institute, Montreal, QC, Canada; 4) McMaster University, Hamilton, ON, Canada.

**Introduction:** 5hydroxymethylcytosine (5hmC) methylation levels in DNA can be estimated by applying both an oxidative treatment and a bisulfite treatment to DNA samples, and then comparing the resulting signal distributions. This possibly transitory methylation state is more commonly detected in brain tissues than in other tissues, and may be associated with psychiatric and behavioural phenotypes. Although methods have been developed to estimate 5hmC methylation levels, little attention has been paid to estimating the effects of covariates on 5hmC methylation. This could be important, for example to assess whether 5hmC methylation, at particular CpG sites, is associated with a disease state. Hence, we propose 2 new approaches and compare performance in a simulation study. **Methods:** A set of 38 postmortem brain samples were assayed with the Illumina 450K platform, measuring methylated and unmethylated signals with and without additional oxidative treatment. We carefully selected a few CpG sites showing signature signal patterns across the samples. These signatures include high overall methylation with and without strong apparent 5hmC methylation, and low overall methylation with and without apparent 5hmC methylation. From these raw data distributions, we designed a rich simulation study to detect covariate effects on 5hmC methylation. We simulated presence or absence of covariate effects on either 5hmC methylation, 5methylcytosine (5mC) methylation, both, or neither. We then compared the type 1 error and power for detection of covariate influences on 5hmC methylation across a published method (Houseman et al. 2016), and two proposed approaches built on generalized linear models with contrasts, with and without random effects. **Results:** Both our approaches control type 1 error and show adequate power for detection of 5hmC methylation. The previously published approach yielded strongly inflated type 1 error for detection of covariate effects on 5hmC methylation when covariate effects on 5mC methylation were present. In contrast, one of our approaches, using random effects, controls the type 1 error well in this situation. **Conclusion:** Care must be taken to choose an appropriate analytic method when looking for factors influencing 5hmC methylation levels. Our proposed approach with random effects takes the signal intensity into account, as well as the inherent pairing between signals before and after oxidative treatment, and performs well.

**3355T**

**Environmental factors are often heritable. Does this bias polygenic gene-by-environment interaction analyses?** W.J. Peyrot<sup>1</sup>, M.C. Keller<sup>2</sup>, W. van Rheenen<sup>3</sup>, N.R. Wray<sup>3</sup>, B.W.J.H. Penninx<sup>1</sup>. 1) VU medical center, Noord-Holland, Netherlands; 2) University of Colorado, Boulder, US; 3) University of Queensland, Brisbane, Australia.

**Background** In the era of genome-wide genotype data, research in gene-by-environment interaction (GxE) has shifted its focus from candidate genes to polygenic methods, such as analyses of polygenic risk scores (PRS) and the genetic relatedness matrix (GRM). This progress acknowledges the highly polygenic nature of psychiatric disorders, but also introduces new challenges. In particular, most environmental factors tested in GxE analyses have a genetic component, such as smoking, cannabis use and even exposure to childhood trauma (CT). We hypothesize that commonly used polygenic GxE analyses may be biased when analyzing heritable environmental factors. **Methods** Polygenic data were simulated using population parameters representative of Major Depressive Disorder (MDD), i.e., heritability of 35% and lifetime risk 15%. In addition, we simulated CT for the same individuals, assuming a cumulative CT risk of 20%, and an odds ratio for MDD of 2.5 for exposed individuals (CT=1) compared to unexposed individuals (CT=0). We simulated 5 scenarios: (1) no interaction & CT not heritable (CT-h2I=0), (2) different direction of genetic effect on MDD in CT=1 compared to CT=0, CT-h2I=0, (3) larger genetic effects on MDD in CT=1 compared to CT=0 & CT-h2I=0, (4) no interaction & CT-h2I=50% with no genetic correlation with MDD (other than via the causal effect of CT on MDD), and (5) no interaction & CT-h2I=50% with genetic correlation with MDD. On these simulated data, we performed PRS analyses (logistic regression of MDD on PRSxCT) and GRM-based analyses (cross-product Haseman-Elston regression to estimate (1) the genetic correlation between MDD in CT=1 and MDD in CT=0, and (2) the difference in magnitude of the liability-scale heritability of MDD in CT=1 compared to CT=0). **Results** The PRS- and GRM-based analyses provided non-biased results for scenarios 1-4. For scenario 5, a slight bias was introduced when simulating a relatively strong genetic correlation between MDD and CT of 0.53 (MDD-h2I of 0.31 in CT=1 and 0.33 in CT=0). **Discussion** Contrary to our hypothesis, these simulations suggest that polygenic GxE analyses generally provide reliable results. However, GxE results should be interpreted with caution when a heritable environmental factor is studied with a strong genetic correlation with the disorder. A limitation of our work is that we cannot rule out potential bias from other genetic architectures or polygenic methods than those studied here.

**3356F****Genome-wide association study of amphetamine related stimulant**

**dependence risk variants.** *J.W. Cox*<sup>1,2</sup>, *R. Sherva*<sup>1</sup>, *L. Wetherill*<sup>6</sup>, *T. Foroud*<sup>6</sup>, *H. Edenberg*<sup>7</sup>, *H. Kranzler*<sup>3</sup>, *J. Amphetamine dependence is an understudied disorder of public health significance. Studies have consistently found it to have a genetic basis, but to date there has not been an adequately-powered genome-wide association study (GWAS) to identify genetic risk factors for stimulant dependence. We performed a GWAS for DSM-IV stimulant dependence in the Yale-Penn study sample, composed of small families and unrelated African Americans (AA, 149 cases, 5243 controls) and European Americans (EA, 368 cases, 3951 controls) ascertained for dependence on no/other substances. Dependence diagnosis was regressed on imputed SNP dosage adjusted for sex, age and the first 5 ancestry PCs in a logistic regression solved with generalized estimating equations to adjust for relatedness. All included subjects reported lifetime exposure to stimulants. Association tests were performed within each array with AA, EA separately. Summary statistics were analyzed via inverse variance meta-analysis. We attempted to replicate SNPs with  $p < 1 \times 10^{-6}$  in 2 independent datasets of AAs (N=445) and EAs (N=2333) groups. In the discovery cohort, 10 genomic regions passed a  $p < 1 \times 10^{-6}$  threshold for replication. The most significant association in discovery AAs was rs55670624 ( $p = 7.1 \times 10^{-9}$ , OR=0.46) located 91 kb upstream of *KYNU*, intergenic between *KYNU* and *LRP1B*. We had a genome-wide significant (GWS) finding for rs73000123 after combining with replication AAs (meta  $p = 4.66 \times 10^{-9}$ , OR=0.3), located 44 kb upstream of rs55670624 ( $r^2 = 0.178$ ,  $D' = 0.955$ ). An intergenic SNP (rs76036414) between *ISL1* and *PELO* showed marginal association in discovery AAs ( $p = 3.91 \times 10^{-7}$ , OR=0.38) with the same (non-significant) effect direction in replication AAs (OR= 0.74) and EAs (OR=0.95). To date, this is the first GWAS for non-cocaine stimulant dependence to identify GWS results. *KYNU* encodes kynureninase, an enzyme that has been implicated in cannabis dependence in AAs. *LRP1B* encodes a low-density lipoprotein family receptor, whose expression is down-regulated in chronic cocaine-treated mouse brain. *ISL1* encodes a protein that regulates insulin gene expression, and has been reported to be differentially methylated in sperm of cocaine-preferring mice and differentially translated in motor neurons. *PELO* encodes a protein with a conserved nuclear localization signal. These findings include both previously identified and novel genes and pathways involved in substance dependence which may contribute to stimulant dependence risk.

**3357W****Identifying sub-phenotypes from hidden structure in polygenic SNP**

**scores.** *J. Yuan*, *B. Lai*, *H. Xing*, *A. Lamy*, *I. Pe'er*. Computer Science, Columbia University, New York, NY.

While genome-wide association studies have in recent years discovered numerous associations between genetic variants and increased risk for disease phenotypes, GWAS analysis methods typically assume that phenotypic labels are homogeneous, with no underlying sub-structure arising from distinct disease etiologies. This assumption may not be true for diseases such as schizophrenia, which has been suggested to comprise multiple hidden genetic disorders despite presenting outwardly as a single disease. We propose to discover hidden sub-phenotypes from polygenic SNP scores by applying a logistic regression method in which the labels are not provided. Instead, the labels are inferred along with effect sizes distinguishing the sub-phenotypes, by taking advantage of the underlying heterogeneity in individual genotype data of cases. We demonstrate through simulation the robustness of this method in comparison to traditional clustering methods, which are more easily confounded by the numerous small effects characteristic of polygenic traits. For simulations of 30,000 genotypes of cases and a per-SNP heritability of .04 percent, our method discovers SNP effects and associates them with the correct sub-phenotypes with a consistently greater than 95 percent accuracy. We also present preliminary results on GWAS data of schizophrenia obtained from the Psychiatric Genomics Consortium. We further extend the scenario of heterogeneity to quantitative traits, showing the presence of heterogeneous cases to be detectable when evaluating the likelihood of correlations between associated SNPs. Finally, we combine a layer of quantitative phenotypes with a dichotomous outcome through hierarchical models. We demonstrate by simulation that with samples of at least 50,000 genotypes, this method recovers associations at both the hidden and observed phenotype layers with an R-squared of greater than 0.60. When heterogeneity of the dichotomous phenotype arises at the quantitative layer, we show it is also detectable under such parameters. We believe these methods may be applied widely across existing GWAS summary statistics to enhance understanding of the genetic etiology of these associations.

**3358T**

**Inferring association between trait and single protein/protein pathways based only on GWAS summary statistics.** S. Bacanu, C. Chatzinakos, B. Webb, B. Riley, V. Vladimirov, K. Kendler. Virginia Commonwealth University, Richmond, VA.

Lately, much attention was paid to “imputed” transcriptomic methods, i.e. using summary statistics to infer association between the trait and gene expression (GE) of gene/pathway of genes. However, there are various levels of RNA degradation between transcription and protein synthesis, which is assumed to greatly influence downstream cellular processes. Thus, proteomics is a more biologically informative measure for trait analysis and, thus, more powerful when available. We thus propose JEPEGMIX2-P, a proteomics software that is based on our already developed Gene-level Joint Analysis of functional SNPs in Cosmopolitan Cohorts 2 Pathway (JEPEGMIX2) transcriptomic software. The proposed method is an  $O(n)$  procedure, uses only summary statistics to test the association between trait and protein concentration (PC) of single proteins or protein pathways, as estimated from protein Quantitative Trait Loci (pQTLs). Due to its practical use of predicted PCs, the test is practically a Mendelian Randomization statistic, which avoids the counter-causation and confounders encountered by most of the higher powered observational studies. Being written in C++, JEPEGMIX2-P takes less than 5 days to compute all proteins, protein pathways statistics. We applied JEPEGMIX2-P to summary statistics from Psychiatric Genetics Consortium data sets. This application suggests a big role for protein pathways with PCs that are regulated by several microRNA. .

**3359F**

**Significance testing for allelic heterogeneity.** Y. Deng, W. Pan. University of Minnesota Twin Cities, Minneapolis, MN.

It is useful to detect allelic heterogeneity (AH), i.e. the presence of multiple causal SNPs in a locus, which for example may guide developing new methods for fine mapping and may determine how to interpret an appearing epistasis. In contrast to Mendelian traits, the existence and extent of AH for complex traits had been largely unknown until the recent publication of Hormozdiari et al. (2017, *AJHG* 100: 789–802.). Hormozdiari et al. (2017) proposed a Bayesian method, called causal variants identification in associated regions (CAVIAR), and uncovered wide-spread AH in complex traits. However, there are several limitations with CAVIAR. First, it assumes a maximum number of causal SNPs in a locus, typically up to 6, to save computing time; this assumption, as to be shown, may influence the outcome. Second, its computational time can be too demanding to be feasible since it examines all possible combinations of causal SNPs (under the assumed upper bound). Finally, it outputs a posterior probability of AH, which may be difficult to calibrate with a commonly used nominal significance level. Here we introduce an intersection-union test (IUT) based on a joint/conditional regression model with all the SNPs in a locus to infer AH. We also propose two sequential IUT-based testing procedures to estimate the number of causal SNPs. Our proposed methods are applicable to not only individual-level genotypic and phenotypic data, but also GWAS summary statistics. We provide numerical examples based on both simulated and real data, including a large-scale schizophrenia (SCZ) and a high-density lipoprotein (HDL) GWAS summary datasets, to demonstrate the effectiveness of the new methods. In particular, for both the SCZ and HDL data, our proposed IUT not only was faster, but also detected more AH loci than CAVIAR. Our proposed methods are expected to be useful in further uncovering the extent of AH in complex traits.

**GAMBITS: An improved method for genetic association testing of symptom and questionnaire data in psychiatric genetic studies.** A.M. Holleman<sup>1,2</sup>, K.A. Broadaway<sup>3</sup>, R. Duncan<sup>3</sup>, L.M. Almlj<sup>4</sup>, B. Bradley<sup>4,5</sup>, K.J. Ressler<sup>6</sup>, D. Ghosh<sup>7</sup>, J.G. Mulle<sup>2,3</sup>, M.P. Epstein<sup>2,3</sup>. 1) Department of Epidemiology, Emory University, Atlanta, GA; 2) Center for Computational and Quantitative Genetics, Emory University, Atlanta, GA; 3) Department of Human Genetics, Emory University, Atlanta, GA; 4) Department of Psychiatry and Behavioral Sciences, Emory University, Atlanta, GA; 5) Mental Health Service Line, Department of Veterans Affairs Medical Center, Atlanta, GA; 6) Department of Psychiatry, McLean Hospital, Harvard Medical School, Belmont, MA; 7) Department of Biostatistics and Informatics, Colorado School of Public Health, Aurora, CO.

Genetic studies of psychiatric disorders often deal with phenotypes that are not directly measurable. Instead, researchers rely on multivariate symptom data from questionnaires and surveys like the PTSD Symptom Scale (PSS) and Beck Depression Inventory (BDI) to indirectly assess a latent phenotype of interest. Researchers subsequently collapse such multivariate questionnaire data into a univariate outcome to represent a surrogate for the latent phenotype. However, when a causal variant is only associated with a subset of collapsed symptoms (which is a likely phenomenon for phenotypically heterogeneous psychiatric disorders), the effect will be challenging to detect using the univariate outcome. We propose a more powerful method to analyze multivariate symptom data called Gene Association Method for Broader Integration of Tests and Scores (GAMBITS). GAMBITS compares similarity in multivariate symptom-scale data from questionnaires to similarity in common genetic variants across a gene. We use simulated data to demonstrate that GAMBITS provides substantially increased power over standard approaches that collapse questionnaire data into a single surrogate outcome (i.e., univariate linear regression and kernel machine regression), while properly controlling Type I error. GAMBITS is also computationally efficient and can scale easily to large-scale psychiatric GWAS projects. We illustrate our approach using GWAS data from the Grady Trauma Project, and identify two study-wise significant genes; one gene (*SIRPA*) associated with PSS and another gene (*ZHX2*) associated with BDI. Both genes were not identified using standard univariate techniques.

**3361T**

**Life is pain: Fibromyalgia as a nexus of multiple liability distributions.**

A. Moscati<sup>1</sup>, L.K. Davis<sup>2</sup>, C. Arnaiz<sup>2</sup>, G.N. Nadkarni<sup>1</sup>, J.H. Cho<sup>1</sup>, R.J.F. Loos<sup>1</sup>, K.S. Kendler<sup>3</sup>. 1) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, New York 10029, USA; 2) Division of Genetic Medicine, Department of Medicine, Vanderbilt University, Nashville, TN, USA; 3) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA, 23298, USA.

**Background:** Fibromyalgia syndrome (FMS) is a condition characterized by widespread pain, tiredness, concentration problems, and other ailments. This diffuse complex of symptoms overlaps with other disorders, which can make diagnosis challenging. FMS also displays pronounced comorbidity with a number of diagnoses, but little research has focused on shared etiology between them. This study aims to identify and estimate phenotypic and genetic relationships that FMS may have with other diseases. **Methods:** Using data from the BioMe and BioVU biobanks (N = 19,558 and 64,208, respectively), ICD-10-defined FMS (M79.7, which had a PPV of 0.92 based on a clinician-validated subset of cases) was used to predict an extensive array of other ICD-defined conditions (1,814 phenotypes in BioMe) in a phenome-wide association analyses (PheWAS). GWAS summary statistics for depressive symptoms (DEP), neuroticism (NEU), and subjective well-being (SWB) were used to construct polygenic scores, which were correlated with FMS to estimate the genetic relationships in an initial European subset of BioMe (N = 2026). **Results:** PheWAS showed that FMS was robustly associated (all reported results having p-values < 1e-15) with psychiatric diagnoses, with odds ratio (OR) for major depressive disorder > 7 (OR<sub>anxiety disorder</sub> > 7), autoimmune conditions (OR<sub>rheumatoid arthritis</sub> > 20, OR<sub>lupus</sub> > 10), and joint degeneration (OR<sub>spondylosis</sub> > 14, OR<sub>osteoarthritis</sub> = 6). Shared etiology between FMS and psychiatric traits was weakly suggested using polygenic scores; FMS was positively correlated with the polygenic scores for DEP and NEU, and negatively correlated with the score for SWB at all thresholds (p-values ranged from 0.02 to 0.77, due to limited N in the subset). **Conclusions:** Our findings suggest that FMS has a phenotypic relationship with internalizing disorders, with autoimmune conditions, and with joint degeneration. The polygenic score results are slightly suggestive of a genetic relationship with DEP & NEU (negative with SWB) as well, though further refinement of this analysis in the full sample of both biobanks, while incorporating autoimmune and joint degeneration polygenic scores, is underway. The results also indicate, due to the extent of sharing, that FMS should be treated as seriously as arthritis or major depression, and should not be dismissed as malingering. Progress in research on the condition could, indeed, benefit multiple branches of medicine.

## 3362F

**Describing the genetic architecture of psychiatric disorders from population scale genealogies.** A.J. Schork<sup>1,2</sup>, W.K. Thompson<sup>3</sup>, T.M. Werge<sup>1,2</sup>, A. Buil<sup>1,2</sup>, . . . for the iPSYCH Consortium<sup>2</sup>. 1) Institute for Biological Psychiatry, Roskilde, Denmark; 2) The Lundbeck Foundation Initiative for Integrative Psychiatric Research, iPSYCH, Copenhagen, Denmark; 3) Department of Family Medicine and Public Health, University of California, San Diego.

The Danish national medical register system represents an essentially complete aggregation of hospital discharge diagnoses for all persons living in Denmark since 1968. Through a central person register which links parents to children through a unique person identifier it is possible to reconstruct population scale genealogies. In this work, we have reconstructed the genealogies of 90,000 individuals genotyped as part of the iPSYCH case-cohort ascertained for the study of major psychiatric disorders. The genealogies of these 90,000 individuals include more than 1,500,000 individuals constituting more than 15,000,000 pairs of genetic relatives and span up to six generations. Integrating these data resources into a recently developed framework for efficient mixed model calculation, we estimate heritability of and genetic correlation among psychiatric and neurological disorders using one of the largest single cohorts. Further, we take advantage of the fact that our genealogies are seeded with genotyped subjects to compare the predictive performance of estimated genetic values calculated from the genealogies to those estimated via SNP-based polygenic risk scores.

**Paternal age, birth order, and early-onset in sporadic schizophrenia cases.** S. Wang<sup>1</sup>, P. Hsiao<sup>2</sup>, L. Yeh<sup>3</sup>, C. Liu<sup>4</sup>, C. Liu<sup>4</sup>, T. Hwang<sup>5</sup>, M. Hsieh<sup>6</sup>, Y. Chien<sup>6</sup>, Y. Lin<sup>6</sup>, S. Chandler<sup>6</sup>, S. Faraone<sup>6</sup>, S. Glatt<sup>6</sup>, M. Tsuang<sup>6</sup>, H. Hwu<sup>2,4,7</sup>, W. Chen<sup>2,7,8</sup>. 1) Department of Public Health and Department of Occupational Safety and Health, China Medical University, Taichung, Taiwan; 2) Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 3) Department of Healthcare Administration, College of Medical and Health Science, Asia University, Taichung, Taiwan; 4) Department of Psychiatry, College of Medicine and National Taiwan University Hospital, National Taiwan University, Taipei, Taiwan; 5) Center for Behavioral Genomics, Department of Psychiatry; & Institute for Genomic Medicine, University of California San Diego, La Jolla, California, USA; 6) Departments of Psychiatry and Behavioral Sciences and Neuroscience and Physiology, Medical Genetics Research Center, SUNY Upstate Medical University, Syracuse, New York, USA; 7) Institute of Brain and Mind Sciences, College of Medicine, National Taiwan University, Taipei, Taiwan; 8) Department of Public Health, College of Public Health, National Taiwan University, Taipei, Taiwan.

**Background:** Advanced paternal age has been associated with both increased risk of schizophrenia and earlier onset of schizophrenia. The leading hypothesis postulated to explain the paternal age effect is the increased *de novo* mutations with men's age. Among patients with schizophrenia, the birth order of the affected proband have been considered as a proxy for *de novo* mutations, and older paternal age is associated with higher proband's birth order. Nevertheless, it cannot be ruled out that such an association could be spurious because both paternal age and birth order are correlated with *de novo* mutations. In sporadic schizophrenia cases, a higher proband's birth order indicated a greater cumulated number of healthy senior siblings in the family, thus rendering a higher birth order proband a lower familial risk. Hence, we expected that the paternal age effect would be stronger in probands with higher birth order. This study aimed to examine whether the birth order would modify the effect of paternal age on early-onset of schizophrenia based on a large collection of schizophrenia patients. **Methods:** A total of 3093 schizophrenia patients from 3008 families were recruited from the Schizophrenia Trio Genomic Research in Taiwan (S-TOGET) project. Among the participants, 2923 without apparent family history upon brief clinical screening. Probands with a paternal age of <20 were excluded (n=14). We tested the association between paternal age and early-onset (<18) of schizophrenia in 2558 families with an affected offspring and multiple biological siblings (range 2-9). **Results:** Per 1-year increase in paternal age, there was an increased odds of being early-onset (OR=1.05, p=0.05 for third-born, and OR=1.11, p=0.01 for fourth- or later- born). However, there was no association of paternal age with early-onset in patients with lower birth order (OR=1.03, p=0.10 for first-born, and OR=1.02, p=0.29 for second-born). After adjusting for maternal age and sibship size, the interaction between birth order and paternal age reached a marginal statistical significance (p=0.07). **Conclusions:** The birth order of sporadic schizophrenia patients can modify the effect of paternal age on early-onset of schizophrenia. The paternal age effect is stronger in probands with a higher birth order, who may need more cumulative effect from *de novo* mutations from father to develop schizophrenia.

**3364T**

**Association of genetic profile for substance abuse potentials and urinary illicit drug detections.** T.J. Nappi, M. Nakano, J. Ying, C. Sailey. Molecular Testing Labs, 14401 SE 1st St. Vancouver, WA. 98684.

**Introduction:** The *ANKK1*, *COMT*, *DRD2*, and *OPRM1* genes have been studied due to their functions within the dopaminergic system. In fact, single nucleotide polymorphisms (SNPs) of *ANKK1* gene are associated with disruption of the homeostatic balance of dopamine reception. The *COMT* gene polymorphisms modulates dopamine metabolism. *DRD2* and *ANKK1* genes share a partial genomic region where a polymorphism Taq1A, also known as *ANKK1* variant rs1800497, is associated with substance abuse. Thus, the aims of this study was to evaluate the association of abusive compounds in urine and the patients' genetic profile. Additionally, a meta-analysis of addiction-risk associated genes and apparent substance abuse was introduced to provide evidence supporting the association. **Methods:** De-identified data from our database was prepared by performing a criteria-based query for all results with paired pharmacogenomics and toxicological testing. Genetic polymorphisms for *ANKK1* rs1800497, *COMT* rs34680, *DRD2* rs1799978/rs6277, and *OPRM1* rs1799971 were merged with paired testing for grouped narcotics and illicit stimulants: opioids/opiates, 6-acetylmorphine, amphetamines, and fentanyl. The meta-analysis was performed using the NCBI PubMed to aggregate meta-data associated with addiction-related SNPs. **Results:** Three hundred eighty-two individuals' toxicology and pharmacogenomics data were analyzed for gene variants and positivity rates of narcotics and illicit stimulants, however, genotype and allelic analysis for all addiction related genes did not reach statistical significance. The meta-analysis including this study and published 36 clinical studies exhibited the association between *ANKK1* variants and addiction was significant, yet the impact of the variant was small (odds ratio of 1.182,  $p < 0.001$ ). Although previous clinical studies were found to be the most impactful, this meta-analysis of this study found this variant's numerical with the averaged odds ratio of 1.182 ( $p < 0.001$ ). **Conclusion:** A clear association of addiction-related gene profiles and illicit drug use was not obtained in this study. The meta-analysis data remains to confirm the association of *ANKK1* as a genetic marker related to addiction. However, this association of *ANKK1* rs1800497 was not as strong as previously reported. Because polygenic interaction has been suspected for an increased susceptibility of drug addiction, further analysis of multiple gene variants paired with the illicit stimulants are needed.

**3365F**

**Integration of mQTL data and enhancer-promoter interactions with GWAS summary results identifies novel schizophrenia-associated genes.** C. Wu, W. Pan. Division of Biostatistics, University of Minnesota, Minneapolis, MN.

Although genome-wide association studies (GWAS) have identified thousands of variants associated with complex diseases, most identified variants are located outside gene coding regions and a biological interpretation of their function is largely unknown. By noting that enhancer-promoter interactions play important roles in regulating gene expression, a new gene-based method called E+G (Wu and Pan, Genetics, early online, 2018) has been proposed to both boost statistical power and offer biological insights by integrating enhancer-promoter interactions with GWAS association results. On the other hand, methylation quantitative trait loci (mQTLs) and expression quantitative trait loci (eQTLs) provide orthogonal ways of functionally annotating SNPs for complex traits and common diseases (Gamazon et al., Mol Psych 18, 340-346, 2013). Although some new gene-based methods, such as transcriptome-wide association study (TWAS) (Gamazon et al., Nat Genet 47, 1091-1098, 2015; Gusev et al., Nat Genet 48, 245-252, 2016), have been proposed to integrate eQTL data with GWAS results, the topic of integrating mQTL data with GWAS summary results remains largely untouched. Here, we propose integrating enhancer-promoter interactions and mQTL data with GWAS summary results to enhance mechanistic interpretability and boost statistical power. Through an application to two large-scale schizophrenia (SCZ) GWAS summary datasets, denoted SCZ1 and SCZ2, based on about 20,000 and 70,000 subjects respectively, we demonstrate that the proposed method could maintain correct Type 1 error rates and identify some novel SCZ-associated genes (containing no significant SNPs nearby). 80% of the significant genes identified by the smaller SCZ1 dataset were confirmed to be significant by the larger SCZ2 dataset, validating the high reproducibility of the proposed method. For the larger SCZ2 dataset with about 70,000 subjects, our proposed method identified 12 novel genes, such as *FAM177A1* and *CREB1*, which could not be uncovered by TWAS, E + G, and the standard gene-based method. We conclude that our proposed method is potentially useful, complementary to TWAS, E+G, and other existing standard methods.

**3366W**

**Examining X chromosome associations in sex-specific characteristics of bipolar disorder.** *W.A. Jones<sup>1</sup>, C.L. Colby<sup>1</sup>, S.L. McElroy<sup>2</sup>, M.A. Frye<sup>3</sup>, J.M. Biernacka<sup>1,3</sup>, S.J. Winham<sup>1</sup>.* 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Lindner Center of HOPE/University of Cincinnati, Cincinnati, OH; 3) Department of Psychiatry and Psychology, Mayo Clinic, Rochester, MN.

Bipolar disorder (BD) is a highly heritable genetic condition affecting 3% of males and females. However, important sex-differences exist in the characteristics of BD. For example, females with BD are at a greater risk of rapid cycling and cycle acceleration and more likely to engage in binge-eating behaviors. Conversely, males with BD more often have a comorbid substance use disorder. Despite the fact that there have been large-scale genome-wide association studies of BD, few studies have specifically explored the role of the X chromosome in BD or in its sex-related characteristics. This is in part due to the statistical challenge posed by X chromosome inactivation (XCI), an epigenetic process that silences one of the two copies of the X chromosome in females in order to have comparable gene expression to males; however, 10-15% of genes on the inactivated X chromosome are expressed (escape from XCI). In a sample of 957 patients from the Mayo Clinic Bipolar Disorder Biobank, we examined the association of over 14,000 X chromosome SNPs with sex-associated BD traits. These include bipolar illness characteristics such as presence of Type I vs. Type II disorder, rapid cycling, cycle acceleration, and increasing severity of mood episodes over time, and comorbidities such as substance use disorder, binge eating behavior, suicide attempts. For each SNP, we used a logistic regression model assuming additive genetic effects and adjusted for sex. We coded SNP effects in two ways: the Clayton approach that accounted for XCI, and the PLINK approach that assumes expression from both copies in females (escape from XCI). We then used a novel, combined statistical approach that takes into account prior knowledge about which regions of the inactivated X are silenced. No SNPs were significant after Bonferroni correction ( $p < 4 \times 10^{-6}$ ), but yielded top SNPs of biological interest. Top SNPs include rs1013536 with rapid cycling ( $p = 6.2 \times 10^{-4}$ ); this SNP lies in the WW3 gene, which encodes a protein involved in the WNT signaling pathway that is implicated in neurodevelopment and BD. Additionally, two intergenic SNPs (rs6522637 and rs6418114) may be associated with risk of substance use in BD ( $p < 5 \times 10^{-5}$ ), and are near PCDHX11, a protocadherin-encoding gene important in neural development. This work illustrates the use of our novel statistical approach to study X chromosome associations. Further work is needed to validate these findings in larger samples of BD patients.

**3367T**

**CNV association with neurodevelopmental phenotypes in a Finnish population cohort.** *E.C. Saarentaus<sup>1</sup>, M. Kurki<sup>1,2,3</sup>, L. Urpa<sup>1</sup>, A.S. Havulinna<sup>1,4</sup>, M. Perola<sup>4</sup>, V. Salomaa<sup>4</sup>, M. Peltonen<sup>4</sup>, O. Pietiläinen<sup>2,5</sup>, M. Daly<sup>1,2,3</sup>, A. Palotie<sup>1,2,3</sup>.* 1) Institute for Molecular Medicine Finland FIMM, Helsinki, Uusimaa, Finland; 2) Stanley Center for Psychiatric Research, The Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 3) Psychiatric and Neurodevelopmental Genetics Unit, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts, USA; 4) National Institute for Health and Welfare, Helsinki, Finland; 5) Department of Stem Cell and Regenerative Biology, Harvard University, Cambridge, USA.

Copy Number Variations (CNVs) are associated with syndromic and severe developmental disorders, such as intellectual disability, autism and schizophrenia. Commonly considered high-impact, CNVs are nevertheless observed in the general population. This presents a diagnostic challenge in evaluating their clinical impact. The size of a CNV is an important criterion in establishing the etiologic role of a variant. To investigate the effect of CNVs on general health, the risk for neurodevelopmental phenotypes, and socioeconomic and educational attainment in the Finnish population, we utilized longitudinal health record data together with genotype information from 22,996 individuals in the FINRISK population cohort. CNVs were identified from genotyped samples (Illumina HumanCoreExome DNA MicroArray) utilizing joint analysis with the PennCNV and iPsychCNV algorithms. In our preliminary analysis, carrying a large (>1Mb) deletion (124 cases, 0.54% of cohort) increased the risk for a neurodevelopmental or neuropsychiatric phenotype by up to half (16.1% vs 10.7%,  $p = 0.059$ ). Compared to non-carriers, the risk ratio for intellectual disability was 7.1 for deletions and 5.6 for duplications. Self-reported education was low for 46% of large deletions carriers, compared to 33% of non-carriers ( $p = 2.8 \times 10^{-3}$ ). Duplications (157 cases, 0.68% of cohort) were not associated with lower educational attainment (35% vs 33%;  $p = 0.55$ ). Large deletions were also associated with lower income (OR=1.6 [1.1–2.3],  $p = 0.017$ ). This effect was more marked for large deletions overlapping syndromic regions (OR=3.3 [1.1–11.1],  $p = 0.019$ ), ID associated genes (OR=10.9 [2.4–100.7],  $p = 1.6 \times 10^{-4}$ ), and genes with a high probability for loss-of-function intolerance (OR=1.9 [1.0–3.7],  $p = 0.038$ ). 81% of both large deletion and large duplications carriers had no neurodevelopmental diagnosis or prolonged use of antipsychotic medication. We observed no difference in self-reported general health between non-carriers and carriers of any of the CNV types. This highlights a low penetrance of even large non-syndromic CNVs. In conclusion, our results show that despite a significant disease-risk burden associated with megabase-sized copy number variants in the general population, the majority of carriers have no neurodevelopmental disorder. However, a significant burden remains for lower socioeconomic status and educational attainment.

## 3368F

**Excess of rare, inherited variation in children with developmental disorders.** K.E. Samocha<sup>1</sup>, T. Singh<sup>2</sup>, P. Danecek<sup>1</sup>, E.J. Gardner<sup>1</sup>, G. Gallone<sup>1</sup>, P.J. Short<sup>1</sup>, P. Constantinou<sup>1</sup>, H.V. Firth<sup>1,3</sup>, J.C. Barrett<sup>1</sup>, M.E. Hurles<sup>1</sup> on behalf of the Deciphering Developmental Disorders study. 1) Wellcome Sanger Institute, Hinxton, United Kingdom; 2) Broad Institute, Cambridge, USA; 3) East Anglian Medical Genetics Service, Cambridge University Hospitals NHS Foundation Trust, Cambridge Biomedical Campus, Cambridge, United Kingdom.

As part of the Deciphering Developmental Disorders (DDD) study, we collected exome sequences and detailed clinical phenotypes from ~13,500 children with undiagnosed developmental disorders as well as from their parents. We have identified a genetic diagnosis for ~35% of these children, with the vast majority of diagnoses being explained by a *de novo* variant. In order to understand the potential genetic contributions in the remaining cases, we sought to evaluate the burden of rare, inherited variation. We jointly called the exome data from DDD with ancestry-matched controls from the INTERVAL and UK10K cohorts (total n = 37,898). Across the ~10,000 parent-child trios in DDD, we found a significant burden of inherited protein-truncating variation compared to controls, which is concentrated in genes previously associated with developmental disorders ( $p < 10^{-6}$ ) and constrained genes (those intolerant of protein-truncating variation;  $p < 10^{-6}$ ). Children with parents that have similar clinical features have a disproportionately greater excess of inherited variation; conversely, children with a likely diagnostic *de novo* variant show no such burden in any gene set tested. We further investigated the distribution of rare, deleterious variants within each individual. There were significantly more case individuals than control individuals with two or more protein-truncating variants in constrained genes (chi-squared  $p < 10^{-6}$ ); however, we found no evidence of an increase in biparental inheritance. Additionally, we explored whether the genes that harboured a burden of inherited variation were the same as those with a significant excess of *de novo* variants. Finally, we stratified cases by their polygenic risk score for educational attainment to explore the interaction between common and rare inherited variation in developmental disorders. Overall, we have identified a significant excess of rare, inherited variants in children with developmental disorders, which points to complex, oligogenic patterns of inheritance.

## 3369W

**A multi-trait GWAS meta-analysis on refractive errors.** M.S. Tedja<sup>1</sup>, X. Han<sup>2</sup>, V.J.M. Verhoeven<sup>1</sup>, N. Eriksson<sup>3</sup>, N. Furlotte<sup>3</sup>, N. Amin<sup>1</sup>, C.M. Van Duijn<sup>1</sup>, S. MacGregor<sup>2</sup>, C.C.W. Klaver<sup>1,4</sup>, Consortium for Refractive Error and Myopia (CREAM). 1) Erasmus Medical Centre, Rotterdam, Zuid-Holland, Netherlands; 2) Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 3) 23andMe, Inc., Mountain View, CA, USA; 4) Radboud Universiteit Nijmegen, Nijmegen, Gelderland, Netherlands.

**Purpose:** Myopia is a complex genetic trait and its morbidity will become a public health issue in the near future. A recent large GWAS meta-analysis on refractive error (RE) of the CREAM and 23andMe (N=160,420) yielded 161 independent associated loci. These loci explain only 8% of the phenotypic variance. We now increased the sample size with the UK Biobank and performed a multi trait GWAS meta-analysis on Spherical Equivalent (SphE) and Age of Spectacle Wear (AFSW) in 526,984 participants. **Methods:** We first performed a multi trait analysis of GWAS (MTAG) on Spherical Equivalent (N<sub>UKBioBank</sub>=92,766, N<sub>CREAM</sub>=55,352) and Age of First Spectacle Wear (AFSW; N<sub>UKBioBank</sub>=350,305; N<sub>23andMe</sub>=104,293) to take into account the overlapping samples in the UK Biobank (N<sub>overlap</sub>=75,732). Subsequently, we selected index variants from the genome wide significant (GWS) genetic variants per trait using Plink --clump based on position (250 kb) and LD structure ( $r^2 < 0.1$ ). Finally, we performed gene-based tests using MAGMA and DEPICT gene set enrichment and tissue enrichment on both traits. **Results:** The GWAS meta-analysis of SphE and AFSW yielded 383 and 406 loci, respectively. Combined, thus considering the overlap in loci (>92%), we found 414 loci associated with RE. MAGMA revealed an additional 134 genes significantly associated with RE. Subsequently, the DEPICT gene set enrichment for SphE yielded 303 enriched gene sets and 385 for AFSW, of which 68% overlapped. A total of 409 unique gene sets were found replicating all previously found pathways, with "abnormal retina morphology" as most significant enriched gene set in both traits ( $P_{\text{SphE}} = 1.04 \text{ e-}11$ ;  $P_{\text{AFSW}} = 9.10 \text{ e-}13$ ). Finally, tissue enrichment analysis revealed "Retina Sense Organ" ( $P_{\text{SphE}} = 1.13 \text{ e-}7$ ;  $P_{\text{AFSW}} = 1.15 \text{ e-}8$ ; both  $\text{FDR} < 0.01$ ) as enriched tissue. **Conclusions:** This is the largest GWAS meta-analysis to date. It confirms previously proposed light dependent pathways and revealed new pathways for myopiagenesis. Future studies should focus on their functionality and impact on RE phenotypes.

**Evidence for rare variants linked to myopia in Amish families. J.E.**

Bailey-Wilson<sup>1</sup>, A.M. Musolf<sup>1</sup>, C.L. Simpson<sup>1,2</sup>, L. Portas<sup>3</sup>, F. Murgia<sup>3</sup>, Q. Li<sup>1</sup>, E. Ciner<sup>4</sup>, D. Stambolian<sup>5</sup>. 1) Computational and Statistical Genomics Branch, NIH/NHGRI, Baltimore, MD; 2) Dept of Genetics, Genomics and Informatics, University of Tennessee Health Science Center, Memphis, TN; 3) Institute of Population Genetics, CNR, Li Punti, Sassari, Italy; 4) Salus University, Elkins Park, PA; 5) Dept of Ophthalmology, University of Pennsylvania, Philadelphia, PA.

Myopia is a complex ocular disorder that affects about 25% of Americans. Because the Amish are a founder population with lower near work exposure than the general US population, families with multiple affected family members have a higher chance of containing highly penetrant variants of large effect. Here, we performed linkage of myopia with exome enriched array genotypes for 349 patients from 43 extended Amish families. Affection status was based on mean spherical equivalent in Diopters (D): affected ( $\leq -1$ D), unaffected ( $\geq 0$  D) or unknown ( $< 0$ D,  $> -1$  D). Two discrete types of two-point parametric linkage analysis were performed: variant-based and gene-based. Variant-based analysis tested for linkage between the phenotype and individual SNPs using TWOPOINTLODS while gene-based analysis tested for linkage between the phenotype and haplotypes of rare variants located within a particular gene (SEQLINKAGE and MERLIN). We assumed an autosomal dominant model with a disease allele frequency of 1% and a 90% penetrance for carriers and 10% phenocopy rate. Both the variant-based and gene-based tests identified chromosomal loci that were highly suggestive or significant. These locations varied across different families, which is not surprising for a complex trait like myopia. However, because each linkage was unique to a family and many of the linkages were present along long linked haplotypes (which would be expected in family data) it is likely that these linkage regions are carrying variants of high effect on disease risk. Our most interesting linked haplotypes were present at 1p36.22-32.2, 12q14.2-21.1, 3p14.1-q13.13, and 4p14-q12. The signal at 5p was the highest (LOD = 3.3) and was genome-wide significant (rare for a single family). Two regions have shown linkage in other studies: *MYP14* and *MYP3* at 1p36 and 12q21; thus our results serve to confirm these published linkages. All of the linked haplotypes contained rare variant(s) (minor allele frequency  $\leq 0.05$ ) that were part of the linkage. We have identified several linked regions to myopia in Amish extended families. Each family contained different linked regions and the high LOD scores within the different families suggest the possibility of highly penetrant, large risk effect genes. These regions contain good candidate genes, such as *GUCA1C* (3q13), which is known to be expressed in retinal photoreceptors. Targeted sequencing is planned on the linked haplotypes to elucidate the causal variant(s).

**Purpose.** To evaluate the relationship between genetic variants obtained and multiple glaucomatous visual field progression phenotypes. **Methods.** Whole Genome Sequence (WGS) data was collected at an average read depth of 30x using the Illumina X10 technology on 1,234 glaucoma patients. We focused our analyses on a subset of glaucoma patients who had longitudinal visual field (VF) test results available (1 – 19 years) allowing us to assess glaucoma VF loss. These individuals were analyzed in two separate ancestry groups, European (N = 600), and African Ancestry (N = 634). 6.2 Million SNPs were selected for analysis based on filters for minor allele frequency, Hardy-Weinberg equilibrium, and total genotype call rate across all loci interrogated. Two measures for global VF, and each of the six Garway-Heath VF (GHVF) were chosen as primary outcome metrics. Progression for individuals with at least three measures (N=476, N=264) were calculated from least squares regression for each of the fourteen VF metrics. We tested SNP associations against disease progression using regression analysis techniques. Results from each GWAS on global and GHVF phenotypes were combined within genes and genetic regions to create region based significance scores. **Results.** In the European ancestry population four genes previously connected with glaucoma onset were associated with glaucoma progression (TLR4 P=7.74E-07, CDKN2B-AS1 P=6.33E-06, ARHGEF12 P=8.78E-05, LMO7 P = 2.58E-05). In addition, a gene linked with a related eye disease but not linked to glaucoma was also strongly associated (CNTNAP2 P=3.85E-07). In the African ancestry population several onset genes were also associated with glaucoma progression (TMTC2 P=3.04E-08, TGFBR3 P=2.16E-06, CDKN2B-AS1 P=1.46E-05). CNTNAP2 (P=1.67E-06) was strongly associated with progression in the African population as well. **Conclusions.** Our data shows that known glaucoma onset genes that harbor variants are associated also linked with disease progression in addition to a wide variety of Glaucoma-related phenotypes. Two separate populations show strong signal for a novel progression candidate gene.

**Rare variants associated with age-related macular degeneration in the Amish.** A.R. Waksmunski<sup>1,2</sup>, J.N. Cooke Bailey<sup>3</sup>, R.P. Igo, Jr.<sup>3</sup>, Y.E. Song<sup>3</sup>, R. Laux<sup>3</sup>, D. Fuzzell<sup>3</sup>, S. Fuzzell<sup>3</sup>, L.D. Adams<sup>4</sup>, L. Caywood<sup>4</sup>, M. Prough<sup>4</sup>, W.K. Scott<sup>4</sup>, M.A. Pericak-Vance<sup>4</sup>, J.L. Haines<sup>1,2,3</sup>. 1) Department of Genetics and Genome Sciences, Case Western Reserve University, Cleveland, OH; 2) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH; 3) Department of Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 4) Hussman Institute for Human Genomics, University of Miami, Miami, FL.

Age-related macular degeneration (AMD) is a leading cause of blindness in the world. While 52 independent variants have recently been reported by the International Age-Related Macular Degeneration Genomics Consortium (IAMDGC) to be associated with AMD, about one-third of AMD heritability is still unexplained. To identify novel variants and loci for AMD, we analyzed Illumina HumanExome chip data from Amish populations in Ohio and Indiana. The Amish are members of an isolated, founder population that resulted from the settlement of a few hundred Swiss Anabaptists in North America nearly 300 years ago. Consequently, they may be enriched in genetic variation that is rare in the general Caucasian population and has been undetectable with traditional case-control genome-wide association studies. We obtained genotype data for 87 individuals with AMD, 79 individuals without AMD, and 15 related individuals with unknown AMD affection status. Of the 242,901 SNPs on the exome chip, 38,142 variants passed extensive quality control and were polymorphic in our 175 Amish samples. Using the Anabaptist Genealogy Database, we constructed a 2,118 person all-connecting path pedigree for these 175 Amish individuals that was used to calculate their expected kinship coefficients and elucidate family structure. We performed affecteds vs. unaffecteds association testing in our samples using the RObust Association-Detection Test for Related Individuals with Population Substructure (ROADTRIPS) software. We identified four variants associated with AMD at Bonferroni corrected significance ( $p < 1.30 \times 10^{-6}$ ). They included missense variants in a member of the lipocalin family involved in small molecule transport (*LCN9*,  $p = 9.54 \times 10^{-12}$ ), a regulator of a telomere elongation helicase (*RTEL1*,  $p = 1.99 \times 10^{-8}$ ), and a cell growth regulator (*CGRRF1*,  $p = 7.96 \times 10^{-7}$ ) as well as a synonymous variant in a gene that encodes a guanylate kinase-associated protein involved in protein-protein interactions at synapses and circadian entrainment (*DLGAP1*,  $p = 2.31 \times 10^{-7}$ ). These variants are low-frequency to rare (MAFs  $< 0.02$ ) in our Amish cohort as well as in the Genome Aggregation Database (gnomAD). They have not been previously associated with AMD and are not in linkage disequilibrium with any of the 52 AMD associated variants identified by the IAMDGC. The results obtained from these analyses nominate novel variants and loci for AMD in the Amish that warrant additional analyses to understand their roles in AMD etiology.

**Selecting causal risk factors from high-throughput experiments using multivariable Mendelian randomization.** S. Burgess<sup>1,2</sup>, V. Zuber<sup>1</sup>. 1) MRC Biostatistics Unit, University of Cambridge, Cambridge, United Kingdom; 2) Cardiovascular Epidemiology Unit, Department of Public Health and Primary Care, University of Cambridge, Cambridge, United Kingdom.

Modern high-throughput experiments provide a rich resource to investigate causal determinants of disease risk. Mendelian randomisation (MR) is the use of genetic variants as instrumental variables to infer the causal effect of a specific risk factor on an outcome. Multivariable MR is an extension of the standard MR framework to consider multiple potential risk factors in a single analysis model using genetic variants that are each associated with at least one of the risk factors, under the assumption that all causal pathways from the genetic variants to the outcome operate via the risk factors in the model. However, current implementations of multivariable MR use standard linear regression and hence perform badly with large numbers of risk factors. Here, we propose a novel approach to multivariable MR that performs risk factor selection to identify causal risk factors. Our approach uses Bayesian model averaging to quantify the evidence that a set of risk factors influences the outcome of interest. We show that our method is able to detect true causal risk factors reliably even when the candidate risk factors are highly correlated. This allows the identification of causal drivers of disease risk from high-throughput platforms that measure large numbers of related risk factors, such as *-omics* platforms or imaging data. We illustrate our approach by analysing publicly-available summarized data on metabolite measurements to find likely causal risk factors for age-related macular degeneration.

**Association of variants on the X chromosome with age-related macular degeneration.** M. Grunin, J.L. Haines, International Age-related Macular Degeneration Genomics Consortium. Case Western Reserve University, Cleveland, OH.

In genome wide association studies (GWAS), X chromosome variants have not been fully investigated. Sex-specific effects and X-specific quality control (QC) for GWAS are needed to examine these effects. Previous work identified 52 autosomal variants associated with AMD via the International Age-related Macular Degeneration Genomics Consortium (IAMDGC), but did not focus on X. Therefore, we aim to investigate variants in the X chromosome for association with AMD. We genotyped 29,269 European individuals (M/F:10,404/18,865; control/AMD:12,087/14,273) using the IAMDGC custom exome chip. X-specific QC was performed on both marker and individual level using XWAS 3.0 and Plink 1.9 before imputation with the Michigan Imputation Server using the Haplotype Reference Consortium r1.1 panel with X-specific imputation. Imputation generated a total of 1,221,623 variants for X alone. X-specific QC sensitive to gender was performed with XWAS, Plink, and R/Bioconductor post imputation for a final set of 597,585 variants. Age and informative PCs, along with subphenotypes, were used as covariates for logistic association analyses with Fishers correction. Gene and pathway analysis was performed with VEGAS, GSEASNP, DAVID, and mirPath. Via logistic association with sex correction, variants in or near the genes *SLITRK4*, *ARHGAP6*, *FGF13* and *DMD* were nominally associated with AMD ( $P < 1 \times 10^{-6}$ ; Fishers combined-corrected). Via association testing for the subphenotypes of choroidal neovascularization (CNV) and geographic atrophy (GA), variants in *DMD* were associated with GA patients ( $P < 1 \times 10^{-6}$ ; Fishers combined-corrected). Via gene based analysis with VEGAS, several genes were associated with AMD ( $P < 0.05$ , both truncated tail strength and truncated product P) including *SLITRK4* and *BHLHB9*. Pathway analysis using GSEASNP and DAVID showed genes associated with nervous system development (FDR-P:0.02), and blood coagulation (FDR-P:0.03). In addition, several variants in the region of a microRNA (miR) were associated with AMD ( $P < 0.05$ , truncated tail strength and truncated product P). Via DIANA mirPath analysis, downstream targets of these miRs show association with brain disorders and fatty acid elongation ( $P < 0.05$ ). Therefore, X chromosome variants may show an association with AMD pathogenesis, and these variants may be linked to novel pathways. Further analysis is needed to confirm these results and to understand their biological significance and relationship with development of AMD in worldwide populations.

Age-related macular degeneration (AMD), a leading cause of blindness, has a substantial and complex genetic burden. The Million Veteran Program (MVP) offers a unique opportunity to identify new genetic determinants of AMD. MVP has genomic data on a custom Affymetrix Biobank chip available for > 460,000 Veterans of diverse ethnic backgrounds. We used Veterans Administration (VA) electronic health records within the MVP database to identify AMD patients; (ICD9/ICD10 codes for AMD from at least two eye clinic visits within the VA system and age > 50 years) and controls (either no ICD codes for AMD or no eye clinic visits, age > 65 years). Our genomewide association study (GWAS) on 312,204 common genetic variants (minor allele frequency > 0.5%) included 17,818 AMD cases and 142,522 controls of European descent, adjusting for sex and 10 principal components. We identified 12 genomewide significant (GWS) loci reported previously (Fritsche et al. 2016, *Nat Genet* 48, 134), and loci at *OCA2/HERC2*, *CLUL1* and *COL10A1*. The index SNP rs12913832 (dominant OR = 0.850 in "brown-eye" A allele,  $p = 3.2 \times 10^{-22}$ ), in intron 86 of *HERC2*, is in an enhancer controlling *OCA2* expression, a major determinant of eye color. *OCA2* controls melanosome maturation. In the retinal pigment epithelium (RPE), eumelanin focuses light and detoxifies free radicals. Association at rs12913832 was abolished when self-reported eye color (blue vs. light/dark brown) was included as a covariate, but was nominally significant (OR = 0.749,  $p = 0.015$ ) within the subset of brown-eyed Veterans. We examined 26 previously reported GWS variants in 12 candidate loci for iris color available in the Affymetrix Biobank panel, or a close surrogate ( $r^2 > 0.5$ ). Markers in four loci—*HERC2*, *OCA2*, *TYR* and *NPLOC4/HGS*—were significantly associated with AMD after correction for multiple testing (nominal  $p < 0.002$ ). The association at *NPLOC4/HGS*, and at one rare variant in *OCA2* (rs1800414), remained significant when either rs12913832 genotype (dominant in A) or self-reported eye color (blue vs. light/dark brown) was included in the model as a covariate. These results establish a link between blue eye color and increased AMD risk in U.S. Veterans of European descent, and also suggest roles for genes controlling pigmentation in AMD independent of iris color. For example, lighter-eyed individuals produce less eumelanin in the RPE and choroid, and focal hyperpigmentation of the RPE is associated with choroidal neovascularization.

**Disorders of sexual differentiation, the implications of life at early diagnosis: Clinical case presentation of true hermaphroditism in a male XY.** F. Cuellar Lopez<sup>1</sup>, J.M. Aparicio Rodriguez<sup>2</sup>, H. Tovar Gonzalez<sup>3</sup>. 1) Pediatric Urology; 2) Genetics; 3) Psychology Hospital Para El Niño Poblano, San Andrés Cholula Puebla, MexicoO.

Children have right to benefit from the decisions taken at the appropriate time. The medical team recommend, but parents eventually or patients decide. Complete and adequate physical examination of the patient is fundamental at birth by a health care professional to carry out the diagnosis and treatment by a multidisciplinary medical team and thus offer a better quality of life, physical, social and mental to the affected patients. In this study a case of a patient with disorder of sexual differentiation of the type 46, XY true Hermaphroditism with early detection is observed, however the patient management was late as a result of bad decisions by parents and counselors. However the treatment approach was successful although it was delayed. Disorders of sexual differentiation "the sex of a person must be specified not only to the basis of a single criterion, but multiple criteria".

Leslie<sup>12</sup>. 1) University of Pittsburgh, Pittsburgh, PA; 2) Boston University; 3) University of Puerto Rico; 4) University of Southern Denmark; 5) University of Colorado; 6) University of British Columbia; 7) McGovern Medical School and School of Dentistry UT Health at Houston; 8) University of Iowa; 9) Federal University of Rio de Janeiro; 10) INAGEMP (National Institute of Population Medical Genetics) Brazil; 11) University of the Philippines Manila; 12) Emory University.

**Background:** Genome-wide scans have been successful in identifying genetic variants associated with risk of non-syndromic orofacial clefts (OFCs), notably common variants (i.e., occurring at frequencies of 1% or higher). These studies have shown that functional OFC risk alleles tend to be located in non-coding, regulatory elements and cumulatively explain only part of the heritability of OFCs. Complementary approaches are needed to discover low-frequency variants, which may account for some of the "missing" heritability. Here we report a scan of low-frequency variants located within putative craniofacial enhancers with the goal of identifying novel sets of OFC risk variants and implicating new regulatory elements in OFC pathogenesis. **Methods:** A multi-ethnic sample including 1995 cases of cleft lip with or without cleft palate (CL/P), 221 cases with cleft palate (CP) only, and 1626 unaffected controls was used in this analysis. Putative craniofacial enhancers were identified from a literature search of ChIP-Seq studies in craniofacial tissues or cell lines. Of these, 119 putative enhancer regions had multiple low-frequency (0.01% to 1%) variants that we genotyped in participants using a custom Illumina panel. Two complementary statistical approaches, SKAT and CMC, were used to test association of the aggregated low-frequency variants across each enhancer region with CL/P and CP. **Results:** We discovered a significant association (SKAT p-value =  $4.95 \times 10^{-6}$ ) between CP and a branchial arch enhancer, mm60, located on chromosome 3p13, near *FOXP1*. Additionally, we observed a suggestive association (CMC p-value = 0.001) between CL/P and a forebrain enhancer, hs1717, located on chromosome 9q22.33, which is near *FOXE1*. **Conclusions:** These findings demonstrate that low-frequency variants in craniofacial enhancer regions contribute to the complex etiology of non-syndromic OFCs. **Funding:** USA NIH grants R00-DE025060, X01-HG007485, R01-DE016148, U01-DE024425, R37-DE008559, R01-DE009886, R21-DE016930, R01-DE014667, R01-DE012472, R01-DE011931, R01-DE011948, U01-DD000295, R25-MD007607, K99-DE024571, S21-MD001830, U54-MD007587 and NSF grant DBI-1263020; Robert Wood Johnson Foundation AMFDP Grant 72429; Research Institute of the Children's Hospital of Colorado; Philippines Institute of Human Genetics, National Institutes of Health, University of the Philippines; Brazil FAPERJ grant E-26/20300/2017; Brazil CNPq grants 310772/2017-6, 400427/2013-3.

**An evaluation of mating asymmetry estimation.** *J. Hudson<sup>1</sup>, M. Tsa<sup>2,3</sup>, M.H. Roy-Gagnon<sup>3</sup>, K.M. Burkett<sup>1</sup>.* 1) Department of Mathematics and Statistics, University of Ottawa, Ottawa, Ontario, Canada; 2) Department of Pediatrics, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan; 3) School of Epidemiology, Public Health and Preventive Medicine, University of Ottawa, Ottawa, Canada.

Population forces such as assortative mating or sex specific migration can cause mating asymmetry (MA) in human populations. If present, MA would result in differential mating type frequencies in case-parent trios, where the frequencies of the mother-father mating types differ from those of the reverse father-mother mating types. MA would thus confound tests of maternal genetic effects or imprinting effects. Therefore, a reliable estimator of MA levels is important for assessing how different levels of MA affect maternal genetics effect and imprinting tests. A mating asymmetry statistic named MaS was proposed by Bourgey et al. 2011 to estimate MA levels assuming Hardy Weinberg genotype proportions (HWP). However, MaS was shown to overestimate MA levels in small samples. We propose an alternate mating asymmetry statistic that does not assume HWP and a related likelihood ratio test (LRT) that measures deviations from expected symmetry in mate-pair frequency among the six informative mating types through the estimation of three asymmetry parameters. We use this statistic to estimate differential mating type frequencies from genome-wide single nucleotide polymorphism (SNP) in orofacial cleft case-parent trios from an international consortium (Beaty et al. 2010). We examine the effect of sample size on the statistic by using sub-samples of the data and simulated data. Upon repeated sampling of small sample sizes we note that there is little consensus between MaS values across sub-samples when the sample consists of fewer than 300 mate-pairs. The problem is also seen to a lesser extent with the LRT; it is less susceptible to bias with small sample size than the MaS. We also investigate alternate statistics that take into account sample size. Removing the HWP restrictions leads to different MaS values; however the differences do not change any conclusion of a moderate-to-high MA SNP. The LRT has no assumption of HWE and so it correlates better with the new statistic. We observed high values of the mating asymmetry statistic with non-significant likelihood ratio tests, indicating an overestimation of MA levels by the statistic in smaller samples or when allele frequencies are small. We also found that results from a maternal genetic effect test were positively correlated with the LRT. Our results highlight the importance of reliable estimation and testing of MA to understand its impact on maternal genetic effect testing.

**Maternal and child folate pathway gene-environmental interaction effects on orofacial clefts.** *M.C. Tsa<sup>1,2</sup>, J. Hudson<sup>3</sup>, J. Little<sup>1</sup>, K.M. Burkett<sup>2</sup>, M.H. Roy-Gagnon<sup>1</sup>.* 1) School of Epidemiology and Public Health, University of Ottawa, Ottawa, Ontario, Canada; 2) Department of Pediatrics, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan; 3) Department of Mathematics and Statistics, University of Ottawa, Ottawa, Canada.

Orofacial clefts (OFC) are among the most common congenital malformations with multiple factors contributing to their occurrence. Several genes in the folate metabolic pathway have been found to be associated with the occurrence of OFC. However, reported effects of folate supplementation during pregnancy on OFC risk are inconsistent. This study aimed to jointly investigate the effects of child and maternal gene-environmental interaction on OFCs. We accessed data from an international consortium (Beaty et al. 2010) through dbGAP. For this analysis we included 730 European and 762 Asian case-parent trios with cleft lip with or without palate and non-missing information on maternal vitamin supplements. We selected 624 SNPs within 29 genes involved in the folate metabolism pathway, including components of cross-membrane transport, cytosolic and mitochondrial metabolism. Using log-linear models implemented in Haplin, we tested child and maternal genetic effects and their interaction with reported maternal vitamin supplement use. We used the minimum p values across the SNPs to evaluate the effects of the overall folate pathway and its subdividing components. We found significant effects of folate metabolic pathway components on OFCs (minimum p-values < 0.01). Across the two ethnicities, the cytosolic metabolism MTRR gene showed significant main genetic and gene-environmental interaction effects in both maternal and child genotypes (minimum p-values < 0.006). We also found an association with SNP rs514933, located in the folate cross-membrane transport gene FOLR2, in the Asian cohort with maternal multivitamin supplements, with relative risk estimate (95% confidence interval) of 0.55 (0.35-0.87) and 0.61 (0.61-0.96) for the child and mother genotypes, respectively. This association was not observed in those without maternal vitamin supplements (maternal and child gene-environmental interaction p values < 0.01). Our findings indicate that maternal folate supplement use interacts with the genotype of the mother and the genotype of the child in affecting risk for OFC. Using pathway-level gene-environment analysis helps consolidate the role of folate metabolism genes. .

**Association between distance from hospital birth and patient's home with morbimortality outcomes in Bogotá and Cali in years 2015 - 2016.** C. Tovar-Sánchez<sup>1</sup>, G. Botta-Méndez<sup>1</sup>, C. López-Burbano<sup>2</sup>, S. Puentes-Mahecha<sup>3</sup>, J. Holguín<sup>4</sup>, P. Hurtado-Villa<sup>2</sup>, I. Zarante<sup>1</sup>. 1) Institute of Human Genetics, Pontificia Universidad Javeriana, Bogotá; 2) Faculty of Health Sciences, Pontificia Universidad Javeriana, Cali; 3) Secretaria de Salud de Bogotá, Congenital Malformations Surveillance Programme of Bogotá; 4) Secretaria de Salud Pública Municipal de Cali, Congenital Birth Defects Surveillance Programme of Cali.

CMSP: Congenital Malformations Surveillance Programme, CBDSP: Congenital Birth Defects Surveillance Programme, AGA: Appropriate for gestational age, SGA: Small for gestational age, WGA: weight for gestational age **Objective:** Determine the distances from the residency to the birth hospital in patients with congenital defects and their association with WGA and mortality in the cities of Bogotá and Cali in the years 2015-2016. **Methods:** The SIVIGILA database of congenital defects was extracted for the cities of Bogotá and Cali in years 2015 - 2016. All the residence addresses of the patients were searched and confirmed using the Google Maps Software, subsequently the distance in km between the place of residence and the hospital of birth was established, the longest distance and the shortest distance in vehicle were calculated and an average of both was performed. The average distances for each city was calculated with them standard deviation, the Odds ratio was calculated for mortality and WGA according the distance. **Results:** In Bogotá from a total of 1.503 addresses, 961 were located and calculated the distance. In Cali from a total of 644 addresses, 282 were located and calculated the distance. The mean distance from the residency to the hospital in Bogotá was 12.85 ± 6.4 km, and in Cali the mean distance was 8.15 ± 3.5 km. In Bogotá 89% and in Cali 79% lived farther than 5 km from the hospital. In Bogotá was found an OR of 0.96 (CI [0,55; 1,65]) for early mortality and OR of 1.03 (CI [0,77; 1,39]) for WGA. In Cali was found an OR of 0.81 (CI [0,40; 1,62]) for early mortality and OR of 1.12 (CI [0,54; 2,30]) for WGA. **Discussion:** The average distance between the residencies to birth hospital is very high compared to the literature, where approximately 70% of the patients lived less than 5 km from the hospital. There is no association between the distance from the birth hospital to the residency and the early mortality or WGA in patients with congenital malformations in the cities of Bogotá and Cali in the years 2015-2016, however it will be interesting to determine the relationship of the distance with chronic outcomes as secondary complications. **Conclusions:** The far distances found in this study, are due to our model of patients health system assurance, among other possible explanations. Although we did not found association between distances to the hospital with mortality, it's necessary to study other outcomes, counting that our cities have heavy traffic.

**3381W**

**Association between prevalence of Down syndrome and maternal ages in the cities of Bogotá and Cali, Colombia in the years 2001-2018.** C.M. López-Burbano<sup>1</sup>, C. Tovar-Sánchez<sup>2</sup>, J. Holguín<sup>3</sup>, S. Puentes-Mahecha<sup>4</sup>, I. Zarante<sup>2</sup>, P. Hurtado-Villa<sup>1</sup>. 1) Faculty of Health Sciences, Pontificia Universidad Javeriana, Cali; 2) Institute of Human Genetics, Pontificia Universidad Javeriana, Bogotá; 3) Secretaria de Salud Pública Municipal de Cali, Congenital Birth Defects Surveillance Programme of Cali; 4) Secretaria de Salud de Bogotá, Congenital Malformations Surveillance Programme of Bogotá.

**Objective:** Determine the association between maternal age and the prevalence of Down syndrome (DS) in the cities of Bogotá and Cali between the years 2001 to 2018. Determine the temporal prevalence of DS in mothers older than 35y. **Methods:** The database of the Birth Defects Surveillance Programme of Bogotá and Cali, was used in the years 2001-2018 to determine the association of maternal ages and prevalence of DS. The patients were grouped by five-year periods and the prevalences of each group were calculated. ORs were calculated for mothers over 35 years of age. Additionally, temporary prevalence were calculated in patients over 35 years of age. All the prevalence rates \*10.000 were calculated with their respective limits by Poisson Method and ORs with their CI. **Results:** 534.843 births were evaluated, 472.645 in the city of Bogotá and 62.198 in Cali in the years 2001-2018. 691 cases of DS were found, 607 in Bogotá and 84 in Cali. Was calculated a prevalence rate of DS in patients < 30 years of 6,75, in 30 - 34 years 10,90, in 35 - 39 years 35,53 and in > 40 years 122,39, with a global prevalence of 12,9\*10.000 newborns. It was found for ≥ 35y an OR of 7,18 (CI [6,16-8,38]). Additionally was calculated the temporal prevalences of DS in ≥ 35y in years 2006-2018, finding no temporal variation with an average of 51.9\*10.000 newborns. **Discussion:** The age of the mother is the main factor that has been shown to increase the risk of having a baby with DS. This risk increases every year, especially after the mother is 35 years. Younger women are more likely to have babies so the majority of total number of babies with DS is in women under 35 years. However, more women are waiting to have a child and births in mothers older than 35 years has tripled. The prevalence of DS in > 40 years is 19 times the prevalence of < 30 years. **Conclusions:** The global prevalence of DS found in this cohort is similar at the prevalence reported at the literature. In those studies they argued that its results are due to terminations of pregnancies and increasing prenatal diagnosis. In our country, we must focus on the search of the causes of influencing this prevalence in order to contribute with accurately information for health system planning.

**3382T**

**Perinatal mortality associated with congenital anomalies of the central nervous system in Colombia from 2005 to 2014.** *M. Sierra<sup>1</sup>, J. Rumbo<sup>1</sup>, A. Salazar<sup>1</sup>, K. Sarmiento<sup>2</sup>, F. Suarez<sup>3</sup>, I. Zarante<sup>2,3</sup>.* 1) Facultad de Medicina. Pontificia Universidad Javeriana. Bogotá D.C., Colombia; 2) Departamento de Ciencias Fisiológicas. Pontificia Universidad Javeriana. Bogotá D.C., Colombia; 3) Instituto de Genética Humana. Pontificia Universidad Javeriana. Bogotá D.C., Colombia.

**Introduction:** Currently in Colombia, congenital anomalies are the second cause of death in children under one year of age. Among these, heart birth defects and Central Nervous System (CNS) anomalies are attributed with the higher mortality. **Objective:** To describe the frequency of mortality during the first year of life attributed to CNS anomalies in the Colombian territory during the period 2,005-2,014. **Methodology:** The Integral System of Social Protection (SISPRO) a national database that provides specific information related to mortality, was used for establishing children rates of death associated with anomalies of the CNS. The ICD10 nomenclature was used to group the CNS pathologies. Six age-related mortality groups were generated: mortality from neonate to 7 days of life, from 7 to 28 days, 28 days to 3 months, 3 months to 6 months and mortality after 6 months. The frequency of mortality was established for each group of age, type of anomaly, year of presentation and country geographical distribution. **Results:** 4,706 infant deaths were reported in the first year of life attributable to CNS anomalies, anencephaly was found as the leading cause of death in fetal age (51.8%) and in children under 7 days (33%). Hydrocephalus was the leading cause after 7 days of age (32.9%). Regarding georeferencing, the highest number of anomalies were registered in the capital city Bogotá (15.6%), followed by the department of Antioquia (13.6%) and Department Valle del Cauca (9.2%). **Conclusion:** neural tube defects like anencephaly are leading cause of fetal and neonatal death in Colombia, the distribution of cases affects principal cities in the country. Implications for public health, folic acid fortification, and prevention of CNS birth defects are discussed.

**Changing frequencies of the main autosomal trisomies in the NIPT era: Population-based data from the Czech Republic.** *A. Sipek Sr<sup>1,2,3</sup>, V. Gregor<sup>1,2</sup>, A. Sipek Jr<sup>4</sup>, J. Jirova<sup>5</sup>, J. Klaschka<sup>6,7</sup>, M. Maly<sup>6,8</sup>.* 1) Department of Medical Genetics, Thomayer Hospital, Prague, Czech Republic; 2) Department of Medical Genetics, Prenatal Sanatorium, Prague, Czech Republic; 3) Institute of Biology and Medical Genetics, 3rd Faculty of Medicine, Charles University, Prague, Czech Republic; 4) Institute of Medical Biology and Genetics, 1st Faculty of Medicine, Charles University, Prague, Czech Republic; 5) Institute for Health Information and Statistics, Prague, Czech Republic; 6) Institute of Computer Science of the Czech Academy of Sciences, Prague, Czech Republic; 7) Institute of Biophysics and Informatics, 1st Faculty of Medicine, Charles University, Prague, Czech Republic; 8) National Institute of Public Health, Prague, Czech Republic.

**Introduction:** Down, Edwards and Patau syndrome are the most common chromosomal anomalies diagnosed during the prenatal diagnostics. The major goal of this population-wide study was to identify any possible trends that can be associated with the gradual implementation of non-invasive prenatal genetic testing in the Czech Republic. **Methods:** The population-based data on prenatally diagnosed cases were obtained from the National Registry of Congenital Anomalies of the Czech Republic (2012-2016 time period). This registry is run by the Institute of Health Information and Statistics of the Czech Republic, the reporting is compulsory by the law and the registry has population-wide coverage. The proportion of the number of the three major autosomal trisomies was compared to the proportion of all other chromosomal aberrations that were identified during prenatal diagnostics. The annual number of live births in the Czech Republic was used as a denominator. The ratios were subjected to the logistic regression. Statistical evaluation was carried out by the statistical software R. **Results:** Down, Edwards and Patau syndromes together presented 62.6% of all prenatally diagnosed chromosomal aberrations. The overall frequency (per 10 000 live births) of major autosomal trisomies have increased from 30.86 in 2012 to 37.41 in 2016 (Poisson regression:  $p = 0.014$ ). Also the proportion of major autosomal trisomies increased from 57.22 % (of all prenatally diagnosed aberrations) in 2012 to 66.09 % in 2016 (logistic regression:  $p < 0.001$ ). **Discussion:** We confirmed that the overall frequency of major autosomal trisomies (and their proportion) is increasing. The possible explanations are the improving methods of prenatal diagnostics and also the increasing average maternal age in the Czech Republic. **Acknowledgements:** Supported by Ministry of Health of the Czech Republic, grant nr. AZV 17-29622A and RVO project: "Thomayerova nemocnice – TN, 00064190".

**Associated anomalies in cases with anorectal anomalies.** C. Stoll, Y. Alembik, B. Dott, M.P. Roth. Genetics, Faculté de Médecine, Strasbourg, France.

Anorectal anomalies (ARA) are a common type of congenital anomaly. The etiology of ARA is unclear and its pathogenesis is controversial. Cases with ARA often have other non-ARA associated congenital anomalies. The purpose of this study was to assess the prevalence and the types of these associated anomalies in a defined population. The associated anomalies in cases with ARA were collected in all livebirths, stillbirths and terminations of pregnancy during 29 years in 387,067 consecutive births in the area covered by our population-based registry of congenital malformations. Of the 202 cases with ARA, representing a prevalence of 5.21 per 10,000, 100 (49.5%) had associated anomalies. Cases with associated anomalies were further classified into groups with chromosomal abnormalities, non chromosomal recognized conditions, and non syndromic multiple congenital anomalies (MCA). There were 7 (3.3%) cases with chromosomal abnormalities including 2 trisomies 18, and 31 (15.3%) nonchromosomal recognized dysmorphic conditions including 17 cases with VACTERL association and 2 cases with OEIS sequence (Omphalocele, Exstrophy of bladder, Imperforate anus, Spinal defect). Sixty two (30.7%) of the cases had MCA. Anomalies in the urogenital, the musculoskeletal, the cardiovascular, the digestive, and the central nervous systems were the most common other anomalies. The anomalies associated with ARA could be classified into a recognizable malformation syndrome or pattern in 38 out of 100 cases (38 %). This study included special strengths: each affected child was examined by a geneticist, all elective terminations were ascertained, and the surveillance for anomalies was continued until 2 years of age. In conclusion the overall prevalence of associated anomalies, which was close to one in two cases, emphasizes the need for a thorough investigation of cases with ARA. A routine screening for other anomalies may be considered in infants and in fetuses with ARA.

**Polygenic risk score predicts mild cognitive impairment and Alzheimer's disease significantly better than APOE in ADNI dataset.** G. Leonenko<sup>1</sup>, M. Shoaib<sup>2</sup>, R. Pither<sup>3</sup>, R. Sims<sup>4</sup>, S.M. Laws<sup>5</sup>, O. Oshota<sup>3</sup>, P. Daunt<sup>3</sup>, A. Gibson<sup>2</sup>, K. Banks<sup>3</sup>, G. Davidson<sup>3</sup>, J. Hardy<sup>2</sup>, J. Williams<sup>1,5</sup>, V. Escott-Price<sup>1,5</sup>. 1) Cardiff University, Cardiff, United Kingdom; 2) UCL Institute of Neurology, London, United Kingdom; 3) Cytox Ltd, UK, Oxford, United Kingdom; 4) Edith Cowan University, and Cooperative Research Centre (CRC) for Mental Health, Perth, Australia; 5) Dementia Research Institute, Cardiff, United Kingdom.

Alzheimer's disease (AD) is the most common neurodegenerative disorder, affecting millions of people worldwide. The pathological process begins decades before the AD onset and so early identification of adults at elevated risk for AD is crucial. Mild cognitive impairment (MCI) is an intermediate phenotype that in some individuals progresses to AD, and may indicate the first manifestation of AD. Based on genome-wide association powerful data, polygenic risk score (PRS) analysis has been successfully applied to AD. The aim of this study is to examine whether PRS based upon AD genomic data can predict the MCI and AD in the Alzheimer's Disease Neuroimaging Initiative (ADNI) dataset. ADNI is a longitudinal study that assesses clinical, imaging and genetic data during aging in MCI, AD and control samples. 724 individuals with available genotypic information were analysed (MCI- 424, AD- 50 and 250-cognitively normal individuals), respectively. Whole-genome sequencing data were used which was preliminary filtered according to standard quality control methods. The International Genomics of Alzheimer's Project (IGAP) consortium summary statistics were used as an independent discovery dataset for the construction of PRS in the ADNI data. Prediction modelling in MCI/controls and AD/controls samples was performed taking age, sex, *APOE* *e2* and *e4* risk alleles, and PRS as predictors. The highest prediction accuracy was achieved using full model, for both AD and MCI status in the ADNI data, the area under the curve AUC=81% for AD and AUC=75% for MCI. In addition, the prediction accuracy was considerably higher when compared to the model based upon *APOE* risk alleles only for both MCI and AD (increase in AUC 15%,  $p < 2 \times 10^{-16}$  and 10%,  $p = 1.6 \times 10^{-5}$ , respectively). The results show that PRS improves the prediction accuracy over and above *APOE*. Furthermore, the results demonstrate the ability of the AD PRS to differentiate individuals with MCI from those who are cognitively normal. As expected, however, the prediction accuracy for identifying individuals with MCI is slightly lower than for AD cases. These findings could potentially facilitate AD clinical trials.

**Genome-wide causal studies on Alzheimer's disease.** *H. Qin<sup>1</sup>, R. Jiao<sup>2</sup>, M. Xiong<sup>2</sup>.* 1) Tulane University, School of Public Health and Tropical Medicine, New Orleans, LA; 2) University of Texas, Health Science Center, Houston, TX.

Despite significant progress in dissecting the genetic architecture of complex diseases by association analysis, understanding the etiology and mechanism of complex diseases remains elusive. Using association analysis as a major analytic platform for genetic studies of complex diseases is a key issue that hampers the theoretic development of genomic science and its applications in practice. Causal inference represents a promising avenue for dissecting mechanisms of complex diseases. Most genomic, epigenomic and image data are observational data. Many confounding variables are not or cannot be measured since performing experiments is unethical or infeasible in many cases. The unmeasured confounding variables would invalidate the most traditional causal inference analysis. As such, most genetic studies inferring causal relations must be based on observational data. Despite its fundamental role in science, engineering and biomedicine, the traditional causal inference from observational data alone is unable to identify unique causal-effect relations among variables. These "ununique" causal solutions seriously limit their translational application. In the past decade, causal inference theory is undergoing exciting and profound changes from discovering only up to Markov equivalent class to identifying unique causal structure. The newly developed causal inference principles with unique causal solutions would open up a new era of "causal revolution" and provide powerful tools for changing the paradigm of genetic and epigenetic studies from association analysis to causal inference. In this report, we will present nonlinear additive noise models (ANMs) for genome-wide causal studies (GWCS) of a qualitative trait which can uniquely discover the causal relationships. To examine the feasibility and utility of GWCS, we applied the ANM to Alzheimer's Disease (AD) dataset with 1,904 individuals and 3,482,609 common SNPs in 51,034 genes. A total of 107 causing common SNPs in 36 genes were identified, 17 of them including CLE-C16A, PCDH15, RARS, PCDHGA, GUCY1B3, and CLSTN2 were reported to be involved in AD disease in the literature. .

**3387W**

**Change the paradigm of genetic studies of multiple traits from association analysis to causation analysis.** *T. Xu, M. Xiong.* School of Public Health, University of Texas Health Science Center at Houston.

The widely used methods for dissecting genetic structures of multiple traits are multivariate association analysis. Despite significant progress in dissecting the genetic architecture of complex diseases by association analysis, the overall contribution of the new identified genetic variants is very small and a large fraction of genetic variants is still hidden. It is well known that a large proportion of association loci do not provide disease causing signals. There is also increasing evidence that a large proportion of causal loci cannot be derived from a set of association loci. There are urgent need to develop statistical methods for identifying causal loci. The purpose of this abstract is to summarize our works on developing methods for discovery of variables that cause variation of multiple phenotypes. Specifically, we utilize a causal discovery trace method to test causality between two sets of continuous variables. Trace method can be used to identify the direction of causation, if exists, of two linearly dependent multivariate variables. We propose permutation test as a possible approach to calculating P-values for testing causality between two sets of continuous variables. The developed trace method for causal analysis was applied to test causality between gene expression pathways and cognitive assessments. Data were downloaded from Alzheimer's Disease Neuroimaging Initiative (ADNI). Both simulation and application on ADNI data is provided. We also apply Hotelling's test to compare results among causation and association studies. Results were very encouraging. A total of 8 pathways were identified to cause the development of Alzheimer's disease.

**Martingale residuals of Cox model reveal genomic associations with lifespan.** P.K. Joshi<sup>1</sup>, P.R.H.J. Timmers<sup>1</sup>, D.W. Clark<sup>1</sup>, T. Esko<sup>2</sup>, Z. Kutalik<sup>3</sup>, K. Fischer<sup>2</sup>, J.F. Wilson<sup>1</sup>. 1) University of Edinburgh, Edinburgh, Scotland, United Kingdom; 2) Institute of Social and Preventive Medicine, University Hospital of Lausanne, Lausanne, Switzerland; 3) Estonian Genome Center, University of Tartu, Tartu, Estonia.

Introduction: Cox models<sup>1</sup> are the natural framework for measuring the effects of genetic variants on survival, but also provide a potential to improve disease onset modelling over logistic case-control methods. However, genomic data requires a very large number of models to be fit, causing run time issues, and specialist genomic software such as Bgenie<sup>2</sup>, and BOLTLMM<sup>3</sup> have not implemented Cox modelling. We have recently used martingale residuals of the cox model<sup>4</sup> to convert survivorship into a quantitative trait, amenable to conventional genomic analysis and found 4 genome-wide significant associations<sup>5</sup>. Aim: to demonstrate the properties of the Martingale residuals, in the estimation of hazard ratios, in particular, their mean and variance, the consequent power and to demonstrate their application in real data. Method: properties such as unbiasedness of the hazard estimate, its standard error, and consequent power relative to full model fit were established by review of established literature, direct proof, and simulation of lifespan with survivorship following the Gompertz-Makeham law and proportionate hazards. Results: Martingale residuals must be adjusted inversely proportional to the proportion dead, and then give unbiased estimates of the hazard ratio. The variance of the residuals also depends on the proportion dead. Nonetheless, power is close to that of using full model fit. Thirty-five genome-wide significant hits for survival are obtained using this method from meta-analysis of UK Biobank and previous published data. Conclusion: Martingale residuals of the cox model are the natural framework for modelling disease onset and survival in large scale genomic data. 1 Cox, D. R. Regression Models and LifeTables. J. R. **Gene methylation co-regulation network analysis of mortality in the elderly.** J.B. Lund<sup>1</sup>, J. Baumbach<sup>2</sup>, K. Christensen<sup>1</sup>, Q. Tan<sup>1,3</sup>. 1) Department of Public Health, Unit of Epidemiology and Biostatistics, Odense, Denmark, Denmark; 2) Wissenschaftszentrum Weihenstephan, Technical University of Munich, Freising-Weihenstephan, Germany; 3) Unit of Human Genetics, Department of Clinical Research, University of Southern Denmark, Odense, Denmark.

Mortality is a hot topic within genetics and epidemiology and is especially a focus in older population studies. While remaining blurry, today's technologies enable us to explore much of these uncharted lands of mortality in greater detail and find causes of mortality through means of epigenetics e.g. histone modifications or methylation-based data. In this study, we explore methylation data and aims to find mortality associated gene-clusters to help shed light on mortality in the older populations. Based on large-scale mortality data on the Lothian birth cohorts of older people (LBC1921, LBC1936, N=1,425), we summarized DNA methylation levels at the promoter regions (TSS200, 1stExon, TSS1500) collected using Illumina 450K bead chip arrays. We then perform weighted-gene methylation correlation network analysis, in order to elucidate gene-clusters with significant mortality association, utilizing Cox proportional hazards models and the clusterProfiler R-package. By analysis of gene promoter methylation levels, 27 gene-modules were discovered whereof 19 significant gene-modules ( $p < 0.05$ ,  $p = 0.00014$  to  $0.044$ ) were identified through means of their eigengene (first principal component) with respect to mortality. The overall module significance found using Kruskal Wallis Test reported a P-value of  $3.5E-282$ . Using the top genes ranked by Cox models, with criterion  $p < 0.05$  ( $N=3,535$ ), we filtered modules based on intramodular connectivity correlated with module membership ( $p < 0.05$ ) and minimum size of 20 genes, yielding a total of 12 gene clusters. Processing each gene cluster by dividing the cluster into sets of positive and negative associated genes based on hazard ratio with respect to mortality, based on previously mentioned Cox models. We applied each set to clusterProfiler for the discovery of KEGG pathways, Gene Ontology (GO) terms and Gene Set Enrichment Analysis (GSEA). Among the significantly ( $FDR < 0.05$ ) revealed items are several pathways related to gene ontologies, extracellular matrix, and intra/extracellular cell parts; And gene sets involved in diabetes among other things. Examining gene promotor methylation enables the possibility of gene co-regulation analysis and its associated functions. We detected a rich flora of highly significant gene functions and pathways in older people with high correlation between gene items and mortality.

**Association of APOE haplotype with cognitive function in a healthy elderly cohort.** M. Riaz<sup>1</sup>, R. Sebra<sup>2</sup>, J. Ryan<sup>1</sup>, A. Huq<sup>1,3</sup>, R. Wolfe<sup>1</sup>, R. Woods<sup>1</sup>, E. Storey<sup>1</sup>, RajC. Shah<sup>4</sup>, A. Murray<sup>5</sup>, E. Schadt<sup>5</sup>, J. McNeil<sup>1</sup>, P. Lacaze<sup>1</sup>, ASPREE Investigator Group, ASPREE Healthy Ageing Biobank. 1) Department of Epidemiology and Preventive Medicine, School of Public Health and Preventive Medicine, Monash University, Melbourne, Australia; 2) Icahn Institute and Dept. of Genetics & Genomic Sciences at Mount Sinai School of Medicine, New York, NY, United States; 3) Department of Genetic Medicine, Royal Melbourne Hospital, Melbourne, Australia; 4) Department of Family Medicine and Rush Alzheimer's Disease Center, 2468Rush University Medical Center, Chicago, IL, USA; 5) Berman Center for Outcomes and Clinical Research, Minneapolis Medical Research Foundation, Minneapolis, MN, USA.

ASPirin in Reducing Events in the Elderly (ASPREE) was a randomized clinical trial of daily low-dose aspirin for primary prevention in 16,703 Australians aged over 70 years and 2,411 Americans aged over 65 years. ASPREE examined the impact of aspirin on a range of clinical outcomes over a five-year period and is now entering a new phase as a longitudinal observational study of healthy ageing, with follow up continuing for a planned further 6.5 years. At baseline, median age of ASPREE participants was 74 years with all confirmed to have no serious CVD history, no prior diagnosis of Alzheimer's disease (AD) and Modified Mini-State Examination (3MS) score  $\geq 78$ . Approximately 15,000 ASPREE participants provided consent and biospecimens for genetic analysis through ASPREE Healthy Ageing Biobank. To date, we have performed DNA sequencing on 11,541 samples using a targeted 'super panel' covering > 750 genes used in clinical testing including pan-cancer, cardiovascular and neurological gene coverage. Here we present genotyping results for *Apolipoprotein E (APOE)* gene, a major cholesterol carrier in the brain and strong genetic risk factor for AD. We stratified on *APOE* genotype;  $\epsilon 3/\epsilon 3 = 7127$  (61.7%),  $\epsilon 3/\epsilon 4 = 2448$  (21.2%),  $\epsilon 2/\epsilon 3 = 1479$  (12.8%),  $\epsilon 2/\epsilon 2 = 64$  (0.6%),  $\epsilon 1/\epsilon 3:\epsilon 2/\epsilon 4 = 254$  (2.2%) and  $\epsilon 4/\epsilon 4 = 169$  (1.5%). We identified 64  $\epsilon 2$  homozygotes and 169  $\epsilon 4$  homozygotes, both rare in the population. We observed slightly higher learning and memory measures (HVLT-R) in  $\epsilon 2/\epsilon 2$  and  $\epsilon 2/\epsilon 3$  (HVLT-R mean = 8.0, SD = 2.8) compared to  $\epsilon 3/\epsilon 3$  (HVLT-R mean 7.0, SD = 2.8) which remained after controlling for smoking, gender, age, body mass index, years of education, LDL and alcohol use ( $P = 0.02$ , adjusted difference in means = 0.17, 95% confidence interval (CI) = 0.02 to 0.32). We investigated 46 *APOE*  $\epsilon 4/\epsilon 4$  individuals aged > 75 years and observed a similar difference in episodic memory (HVLT-R mean = 6.0, SD = 3.0) compared to 2871  $\epsilon 3/\epsilon 3$  at age > 75 years (HVLT-R mean = 7.0, SD = 2.9) which was explained by controlling for all above mentioned covariates ( $P = 0.11$ , adjusted difference in means = -0.67, 95% CI = -1.50 to +0.15). Whole genome sequencing (WGS) of *APOE*  $\epsilon 4/\epsilon 4$  and  $\epsilon 2/\epsilon 2$  is underway to accompany the extensive longitudinal clinical and phenotypic data already available and that will be further extended in future. This uniquely ascertained and well-phenotype elderly population provides a significant opportunity to further examine the role of *APOE* in ageing and health.

**Integrative network analysis identifies relationships between metabolomics, genomics, and risk factors for Alzheimer's disease.** B.F. Darst<sup>1</sup>, Q. Lu<sup>2</sup>, S.C. Johnson<sup>3,4,5</sup>, C.D. Engelman<sup>1,3,5</sup>. 1) Department of Population Health Sciences, University of Wisconsin School of Medicine and Public Health, Madison, WI; 2) Department of Biostatistics & Medical Informatics, University of Wisconsin, Madison, Madison, WI; 3) Wisconsin Alzheimer's Institute, University of Wisconsin School of Medicine and Public Health, Madison, WI; 4) Geriatric Research Education and Clinical Center, Madison, WI; 5) Alzheimer's Disease Research Center, University of Wisconsin School of Medicine and Public Health, Madison, WI.

Integrative multi-omics approaches could be useful for the identification of underlying mechanisms that contribute to complex diseases, such as Alzheimer's disease (AD). We performed an integrated network analysis to investigate relationships between genomics, metabolomics, and AD risk factors using the Wisconsin Registry for Alzheimer's Prevention (WRAP). Analyses included 1,111 Caucasian participants with whole blood expression for 11,376 genes (imputed from genome-wide genotyping using PrediXcan), 1,097 fasting plasma metabolites, 364 fasting cerebral spinal fluid metabolites, and 19 AD risk factors. After adjusting each of the 12,856 variables for potential confounders, residuals were used to test all 82,631,940 possible pairwise Spearman correlations. Inter-omic correlations meeting a Bonferroni-adjusted  $P < 6.1 \times 10^{-10}$  were used to develop an undirected graphical network, which included 908 edges (correlations) and 532 nodes (variables). Although no genes were directly correlated with AD risk factors, many genes were indirectly linked to AD risk factors through plasma metabolites. One correlation between *CPS1* and glycine has been reported in numerous previous investigations, as have correlations between glycine, body mass index (BMI), waist-hip ratio (WHR), and homeostatic model assessment for insulin resistance (HOMA-IR), which were also identified in our network. Mediation analyses revealed that although direct associations between *CPS1* and these three risk factors could not be detected, there were strong mediation effects such that lower *CPS1* expression led to higher plasma glycine levels, which led to lower BMI, WHR, and HOMA-IR (unadjusted  $P < 2.0 \times 10^{-16}$  for each of the three outcomes). Thus, *CPS1* may have protective effects for certain AD risk factors. These results demonstrate the feasibility of performing integrative omics analyses and the potential utility of other hypotheses generated by this network.

**Inferring the rate of aging from quantitative traits using machine learning methods.** J. Ding<sup>1</sup>, E.D. Sun<sup>1</sup>, T.J. Butler<sup>1</sup>, G.R. Abecasis<sup>2</sup>, F. Cucca<sup>3</sup>, I.G. Goldberg<sup>1</sup>, L. Ferrucci<sup>1</sup>, D. Schlessinger. 1) National Institute on Aging, 251 Bayview Boulevard, Suite 100, Baltimore, MD; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan Ann Arbor, MI; 3) Institute of Genetic and Biomedical Research, National Research Council, Monserrato, Cagliari, Italy.

It is widely thought that individuals age at different rates. A method that measures physiological age independently of chronological age could therefore be a first step to understand relevant mechanisms; but searches for individual biochemical markers of physiological age have had limited success. In this study, we assessed the extent to which an individual's physiological age could be determined as a composite score inferred from a broad range of biochemical and physiological data. Data were collected in population studies in Sardinia ("SardiNIA") and Tuscany ("InCHIANTI"). We used machine learning strategies on data for ~6,000 Sardinian participants, who ranged in age from 12 to 81. The best predictive models were determined from multiple combinations of dimensionality reduction, classification, and regression algorithms. They reached very strong correlations ( $R > 0.9$ ) between predicted and actual ages, and showed relative stability in successive visits of the same individuals ( $R > 0.5$ ). Similar results were also seen for participants in the InCHIANTI study. We then defined an Effective Rate of Aging (ERA) for each participant, a continuous trait measured as the ratio of an individual's predicted age to his/her chronological age. The inference that individuals have a characteristic rate of aging is supported by findings that in the SardiNIA cohort, the inferred values of ERA showed genetic heritability of 40%. This has been sufficient to initiate genome-wide association studies that identify genetic variants influencing the rate of aging in genes that affect telomere length and metabolic activity.

**Testing for pleiotropy using functional linear regression: An application with neurodegeneration endophenotypes.** A.J. Dugan, D.W. Fardo, O.A. Vsevolozhskaya. Department of Biostatistics, University of Kentucky, Lexington, KY.

Because the brain directly affects cerebrospinal fluid (CSF), CSF measures are promising biomarker endophenotypes for neurological diseases such as Alzheimer's disease (AD) (Kauwe et al., 2014). Several CSF analytes associated with AD neuropathology also have genetic associations and are known to be highly correlated (Kim et al., 2011). This apparent pleiotropy is of interest. Existing methods for the joint testing of multiple related phenotypes only allow for the testing of single variants. We propose using penalized splines to fit a smooth function,  $G(t)$  (where  $t$  indexes a genetic variant's position over a genetic region), to the SNP-level allele counts over genetic regions. When this smoothed function,  $G(t)$ , is treated as the outcome in a reverse-regression model, pleiotropy may be tested by including multiple phenotypes in the model as predictors. We propose the use of simultaneous confidence bands to allow for the testing of associations at both the genetic-region and SNP levels without the need to correct for multiple testing. We will apply this approach to data from the Alzheimer's Disease Neuroimaging Initiative (ADNI) to test for pleiotropy with CSF analytes over genetic regions known to be associated with AD.

**A fast family-based quantitative trait association test for nuclear and extended pedigrees for the analysis of whole genome sequence data.** Z. Zhang, S. Leal. Baylor College of Medicine, Houston, TX.

Whole genome sequence data is being used to elucidate the genetic etiology of complex traits. One strategy is to perform association study using families, because pathogenic variants within families are likely to have larger effect sizes than those for sporadic cases. Although there are several family-based association methods for binary traits, there are only a couple for analyzing quantitative traits, e.g. famSKAT and FFBSKAT. We recently extended the Rare variant (RV)-generalized disequilibrium test (GDT) to analyze quantitative traits RV-QGDT. This method analyzes rare variants in aggregate and can be used for any pedigree type including with missing data. We evaluated speed, type I error and power for nuclear and extended pedigrees (10 members). We found that RV-QDGT is five times faster than famSKAT and comparable to FFBSKAT. FFBSKAT and famSKAT give almost identical results, because they implement the same algorithm. We evaluated power for  $\alpha=2.5 \times 10^{-6}$  for a variety of pedigree types. For 1000 sib-pairs power was 52.5% (FFBSKAT) and 69.2% (RV-QGDT) for no missing data and when 50% of the founders are missing sequence data power is >15% higher for RV-QGDT than FFBSKAT. For 1000 multiplex families, the power gain is 6% for RV-QGDT compared to FFBSKAT when none of the family members are missing data and increases to 12.5% when 50% of the parents or grand-parents are missing their sequence data. We will further demonstrate the power and utility of RV-QGDT method using simulated and late-onset Alzheimer's disease families, to elucidate genetic factors underlying complex disease etiology. .

**Fine-mapping and colocalization at the *IL1RL1* locus to identify asthma susceptibility effector genes.** S. Ghosh<sup>1</sup>, D.N. Mayhew<sup>2</sup>, Q. Lu<sup>3</sup>, J.D. Hoffman<sup>1</sup>. 1) Department of Genetics, GlaxoSmithKline, Collegeville, PA; 2) Department of Computational Biology, GlaxoSmithKline, Collegeville, PA; 3) Target and Pathway Validation, GlaxoSmithKline, Collegeville, PA.

Many genes are associated with asthma susceptibility. Of importance are the dual, strong associations in both *IL33* ligand (chr 9p24.1) and its receptor subunit (*IL1RL1*) regions (2q12.1). We performed extensive genetic fine mapping around the *IL1RL1* locus using UK Biobank phenotype and genotype data to identify asthma susceptibility effector genes as well as relationships to other markers of asthma susceptibility, peripheral eosinophil and neutrophil counts at this locus. Asthma cases and controls were defined using the nurses-interview questionnaire (Field 20002) and HES ICD10 codes falling under the J45 tree. Neutrophil and eosinophil counts on all UK Biobank samples underwent a residual rank-normalization process for downstream analyses. Asthma, eosinophil, and neutrophil genome-wide association studies were carried out using BOLT-LMM. Post GWAS, we carried out approximate conditional analysis using GCTA for each phenotype. Colocalization was then performed for each asthma signal with GTEx version 7 lung eQTL data. Colocalization was additionally completed across asthma, eosinophil and neutrophil count signals. We identified 64k asthma cases and 424k controls and 436,579 subjects with both neutrophil and eosinophil counts for analysis. Approximate conditional analysis identified two conditionally distinct independent associations with asthma led by index variants rs10197862 (1.1e-73) and rs10179654 (1.31e-15). For eosinophil counts, we observed 5 conditionally distinct GWAS significant associations with index variants rs9807989, rs11676124, rs1041973, rs1921622, rs6543122. In the neutrophil GWAS we observed one signal with index variant rs13019066. We observed strong colocalization of GTEx lung tissue eQTLs for *IL1RL1* and *IL18R1* with the rs10179654 conditional association in asthma ( $H_4 > 0.90$ ). We also observed colocalization of one of the eosinophil count signals lead by rs1041973 with the rs10179654 lead asthma variant. We do not observe colocalization of neutrophils with either asthma association. Our results highlight 2 independent genetic associations for asthma and colocalization of one of the associations with both *IL1RL1* and *IL18R1* expression as well as eosinophil counts. However, our findings suggest that the asthma signals are independent of the neutrophil associations at the locus and only partially overlapping with the eosinophil signals. Further dissection of the secondary asthma signal in asthma susceptibility is ongoing.

**Constructing homogeneous subgroups for phenome-wide association studies via the K-means algorithm.** A.R. Hsieh<sup>1</sup>, C.J. Lee<sup>2</sup>, C.S.J Fann<sup>2</sup>. 1) Graduate Institute of Biostatistics, China Medical University, Taichung, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

The accelerated growth of genomic and phenotypic data has provided an unprecedented opportunity for studying complex trait genetics. Phenome-wide association study (PheWAS) is a genotype-to-phenotype approach to investigate the association between a genetic variant and a wide spectrum of phenotypes, i.e. phenome. A major challenge of PheWAS is the endogenous heterogeneity of controls due to shared biological processes underlying phenotypes and high dimensionality of datasets consisting of genotypic data and a plethora of biological measurements. One widely used dimension reduction approach is defining case/control status by grouping and counting ICD-9 codes. However, co-morbid diseases can share similar defective biological processes and thus a similar genetic background. These confounding factors are poorly accounted for when using ICD-9 criteria in choosing cases and controls. Thus heterogeneity in control groups is highly likely to dilute statistical power when performing PheWAS. Here we propose a strategy based on machine learning method to reduce the heterogeneity problem by considering both disease status and other clinical manifestations. Our proposed strategy combines a synthetic oversampling technique with K-means clustering to divide samples into subgroups. For controls, we classify these individuals by the similarity in their phenome via a K-means clustering algorithm. The cases are synthetically oversampled to produce a balanced dataset i.e. equal numbers of cases and controls. When performing PheWAS, controls are selected only if they are not in the subgroup where the phenotype of interest is included, i.e. case-control PheWAS comparisons will be carried out within each given phenotype class. An automation procedure is created from clustering steps to oversampling when different phenotypes are analyzed in PheWAS. As a proof of concept, we tested our PheWAS approach on 7427 individuals from the Taiwan Biobank dataset. By using hypertension as the phenotype, we validated three out of 5 published hypertension-associated SNPs ( $p < 0.05$ ). In comparison, none of these SNPs were found by using original data. The results show that our proposed strategy can improve the performance of PheWAS. Our findings highlight a new way to mine BIG DATA that can help to uncover pleiotropic genetic effects in gene mapping studies.

**Replication of prior GWAS catalog variants within the eMERGE Network PGRNseq Cohort.** I.B. Stanaway<sup>1</sup>, J.E. Jackson<sup>2</sup>, A.S Gordon<sup>1</sup>, L.J. Rasmussen-Torvik<sup>3</sup>, D. Carrell<sup>4</sup>, J.M. Erwin<sup>1</sup>, T.O. Hall<sup>1</sup>, M.R. Palmer<sup>1</sup>, E.A. Rosenthal<sup>1</sup>, S.V. Driest<sup>5</sup>, C. Prows<sup>6</sup>, M.S. Williams<sup>6</sup>, S. Pendergrass<sup>7</sup>, E. Leary<sup>8</sup>, G. Hripcsak<sup>9</sup>, F. Mentch<sup>9</sup>, J. Denny<sup>9</sup>, H. Hakonarson<sup>9</sup>, G.P. Jarvik<sup>1</sup>, D.R. Crosslin<sup>1</sup>, eMERGE Network. 1) University of Washington, Seattle, WA; 2) Vanderbilt University, Nashville, TN; 3) Northwestern University, Chicago, IL; 4) Kaiser Permanente, Seattle, WA; 5) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 6) Geisinger Research, Rockville, MD; 7) Marshfield Clinic, Marshfield, WI; 8) Columbia University, New York, NY; 9) Children's Hospital of Philadelphia, Philadelphia, PA.

Electronic medical records (EMR) provide a mechanism to systematically evaluate GWAS significant phenotype-SNP pairs for replication. We used the PGRNseq panel of ~82 genes in 9007 participants from the Electronic Medical Record and Genomics (eMERGE)-PGx project to examine associations of 66 SNPs (MAF>0.01) with phenotypes similar to those in the NHGRI GWAS Catalog. We created a list of matched phenotypes between the GWAS catalog and eMERGE EMR for SNPs where the GWAS entry matched one or more EMR codes. For example, uric acid level is a risk factor for gout. The GWAS entries for rs2231142 and "Uric Acid" levels were matched with three EMR code descriptions containing "Gout". We considered 1021 tests with matched EMR defined case-control phenotypes for associations using logistic regression while controlling for the first two principal components of ancestry, sex, and eMERGE site. We report 5 SNPs with associations ( $p < 0.05/66$  SNPs; see Table) considering the traits for each SNP are correlated, and 5 significant SNP-trait pairs, when adjusting for multiple contrasts stringently for all tests considered ( $p < 0.05/1021$ ; **bolded**). We conclude that in this moderate sample size, related phenotypes from the EMR are associated with variants previously identified by GWAS.

**Gene-based kernel machine test for longitudinally measured binary phenotype.** *W. Wu, Z. Wang.* Department of Biostatistics, Yale School of Public Health, New Haven, CT.

Gene-based tests have become popular for the identification of rare variants that are associated with disease traits. Longitudinal repeated measures have been increasingly used in Genome-wide association studies for they not only provide the temporal development of traits of interest but also increase statistical power. However, most of the gene-based tests for longitudinal phenotypes exist so far are only for continuous outcomes, and thus are not suitable for discrete outcomes which are frequently used in the study of recurrent diseases and substance abuse. In this paper, we propose a group of region-based tests that is capable for performing tests for binary longitudinal phenotypes. The tests extends the longitudinal kernel machine test (LSKAT) under the generalized linear mixed effect model framework which incorporates several random effects to take into account the within-subject correlation and temporal fixed effects to describe temporal development of traits. In the simulation studies, by comparing this test with several other existing tests, we demonstrated that this test achieves consistently high power under different settings and remain robust when the covariance structure is miss-specified. We illustrate our method using data from the Framingham Heart Study to explore the association of repeated measures of BMI/obesity with rare and common variants.

**Application of ComPaSS-GWAS to genome-wide association analysis of methylmalonic acid concentration, serum vitamin B12 concentration and holo-transcobalamin in the Trinity Student Study population.** *C.M. Justice<sup>1</sup>, J.A. Sabourin<sup>1</sup>, A.J.M. Sorant<sup>1</sup>, L.C. Brody<sup>2</sup>, J.E. Bailey-Wilson<sup>1</sup>, A.F. Wilson<sup>1</sup>.* 1) Computational and Statistical Genomics Branch, National Human Genome Research Institute, NIH, Baltimore, MD; 2) Gene and Environment Interaction Section, National Human Genome Research Institute, NIH, Bethesda, MD.

ComPaSS-GWAS is a method based on Complementary Pairs Stability Selection that uses a regression based genome-wide association study (GWAS) on each half of a randomly split sample to identify corroboration between these two independent halves and then aggregates the results over many random sample splits. This corroboration aspect of ComPaSS-GWAS can be taken to be an alternative to an independent replication study, when no replication population is available. Furthermore, aggregating over many random splits prevents the loss of power that occurs when a sample is split only once in order to create a discovery and replication sample. A marker is considered as significantly associated if it is corroborated in GWAS at a critical value of  $1 \times 10^{-3}$  in both halves of the split and corroborated across both halves in at least 60 percent of the splits. ComPaSS-GWAS was applied to the Trinity Student Study (TSS) to validate the method. The TSS is composed of 2,232 healthy young Irish adults genotyped for 757,533 SNPs and phenotyped for over 30 quantitative traits [Molloy et al., 2016]. Associations between several genetic loci and methylmalonic acid concentration (MMA), serum vitamin B12 concentration (SB12) and transcobalamin bound vitamin B12 (HoloTC) have been previously published, for which the replication cohort consisted of 5,186 subjects aged > 60 years participating in the Trinity, Ulster, Department of Agriculture (TUDA) Study [Molloy et al., 2016; Velkova et al., 2017]. ComPaSS-GWAS identified all the regions (or genes) that have been previously reported. For MMA, sixty-six SNPs had a ComPaSS-GWAS score greater or equal to 0.6, while twenty-nine SNPs and twenty-six SNPs reached this threshold for HoloTC and SB12, respectively. All of these SNPs also obtained a GWAS  $p$ -value <  $5 \times 10^{-8}$  for the analysis of the TSS discovery cohort as a whole. There were four additional SNPs that had a GWAS  $p$ -value <  $5 \times 10^{-8}$ , but these did not achieve a ComPaSS-GWAS score  $\geq 0.6$ . However, all four of these SNPs were located in genetic regions for which other SNPs in close proximity did meet the  $\geq 0.6$  threshold.

Glycosylation, attachment of complex carbohydrates to surface of molecules, is a very common post-translational modification of proteins and can have a major impact on their function. Glycosylation of Immunoglobulin G (IgG) influences its interaction with effector cells of the immune system and was associated with many physiological states. Even though the main enzymes of glycosylation are well established, little is known about their genetic regulation or role in diseases. To address these questions, we performed genome-wide association analyses (GWAS) of 77 IgG N-glycosylation traits in eight European populations (discovery N=8090, replication N=2388) using HapMap2 imputed genotypes and assessed pleiotropy with complex traits and diseases using summary-level Mendelian randomisation analysis. We discovered twenty-seven significantly associated loci ( $\lambda$ ), 12 of which replicate previous findings, including 4 glycosylation enzymes *MGAT3*, *FUT8*, *ST6GAL1*, *B4GALT1*, while 15 are novel. We prioritised genes in associated loci based on pleiotropy with gene expression, coding region variants and enrichment in relevant gene-sets. For 9 genes we found evidence of a non-synonymous amino acid change, 4 were pleiotropic with expression in B-cells and 11 with expression in peripheral blood, while the remaining genes were selected based on the enrichment in antibody synthesis related pathways and cells. Capitalising on the omics nature of our data, we estimated the similarity of glycome-wide association estimates and proposed how associated genes connect in a functional network that regulates main glycosylation enzymes. Using summary level Mendelian Randomisation analyses we found evidence of pleiotropy with autoimmune and inflammatory diseases in six IgG N-glycosylation loci. In one locus we also showed that IgG N-glycosylation is pleiotropic with both expression of *ORMDL3*, *GSDMB* and *IKZF3* genes in B-cells and peripheral blood and risk for inflammatory bowel disease, rheumatoid arthritis, cirrhosis, asthma and allergy. With this study we expanded the network of genes involved in glycosylation of immunoglobulin G providing us with further insights how these molecules could be involved in complex human diseases.

**Leveraging functional enrichment improves polygenic prediction accuracy.** C. Marquez Luna<sup>1</sup>, S. Gazal<sup>2,3</sup>, P. Loh<sup>3,4</sup>, N. Furlotte<sup>5</sup>, A. Auton<sup>5</sup>, A. Price<sup>1,2,3</sup>, 23andMe Research Team. 1) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; 2) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 4) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts, USA; 5) 23andMe Inc., Mountain View, CA, USA.

Genetic variants in functional regions of the genome (e.g. coding, conserved, regulatory) are enriched for complex trait heritability. We developed a new method for polygenic prediction, LDpred-funct, that leverages trait-specific enrichments inferred by stratified LD score regression under the baseline-LD model (Gazal et al. 2017 Nat Genet), which includes binary functional annotations as well as continuous-valued annotations modeling LD-dependent causal architectures. LDpred-funct first analytically estimates posterior mean causal effect sizes, accounting for LD between variants and statistical noise and using per-SNP heritability inferred under the baseline-LD model as a Gaussian prior (to avoid overfitting, the baseline-LD model is fit using training data only). LDpred-funct then uses cross-validation within validation samples to regularize causal effect size estimates in bins of different magnitude, improving prediction accuracy for sparse architectures. We applied LDpred-funct to 16 highly heritable traits in the UK Biobank. We used association statistics from British-ancestry samples as training data (avg N=365K) and samples of other European ancestries as validation data (avg N=22K), to minimize potential confounding due to shared population stratification or cryptic relatedness between samples. We analyzed 6 million genotyped and imputed SNPs with minor allele frequency greater than 1% that passed quality control filters. LDpred-funct attained a +27% relative improvement in prediction accuracy across the 16 traits compared to the best method that does not use functional data (avg LDpred-funct prediction  $R^2=0.173$ ; highest  $R^2=0.417$  for height), consistent with large improvements in simulations with real genotypes and phenotypes generated under the baseline-LD model. Omitting the regularization step reduced the relative improvement to +18% across the 16 traits, which is entirely attributable to leveraging functional enrichment and LD-dependent architectures using the baseline-LD model. For height, meta-analyzing training data from UK Biobank and 23andMe cohorts (total N=1107K) increased the prediction  $R^2$  to 0.430; the moderate improvement despite the much larger sample size is consistent with the 30% higher heritability in UK Biobank. Our results show that leveraging functional enrichment substantially improves polygenic prediction accuracy, bringing polygenic prediction of complex traits closer to clinical utility.

**Identity-by-descent mapping in a large electronic health record-linked DNA biobank.** *L.E. Petty, H. Chen, J.E. Below.* Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville, TN.

Since the early GWAS era, there has been considerable attention given to the significant remaining disparity between the estimated heritability of many complex traits and the variance explained by known loci for these traits, or so-called "missing heritability". Large-scale DNA biobanks present a unique opportunity to bridge the gap between family- and population-based methods for gene discovery by leveraging patterns of genomic sharing due to distant relatedness. To identify the effects of genomic segments shared due to relatedness on the human phenome, we applied identity-by-descent (IBD) mapping in BioVU, Vanderbilt University Medical Center's large ( $n > 280k$ ) DNA biobank linked to extensive electronic health records. We identified identity-by-descent shared segments using GERMLINE and created clusters of three or more individuals with a shared haplotype using DASH. We then performed association testing of these clusters with phenotype. Preliminary analysis of body mass index for a subset of 6,120 individuals genotyped on the Illumina Multi-Ethnic Global Array, including 815,371 variants after QC, identified several significantly associated clusters with shared haplotypes spanning regions of the genome harboring genes known to impact body mass index (*CADM2*, *CDC20/PTPRF*, *ANGPTL4*), as well as several genome-wide significant regions that are potentially novel. These preliminary findings demonstrate the utility of this approach in a regionally ascertained DNA biobank, a population likely to be enriched for distant relatedness, both as a method for validating known gene-trait associations identified through GWAS and for discovery of novel regions that may bear less common variants that GWAS is not powered to detect. This motivates application of identity-by-descent mapping to all BioVU samples and to the other phenotypes ascertained through electronic health records. Results will be presented for the full available BioVU sample, phenome-wide.

**ComPaSS-GWAS reduces the type I error rate of a quantitative trait GWAS when the normality assumption of regression residuals is violated.** *J.A. Sabourin, A.F. Wilson.* Genometrics Section, CSGB, NHGRI, NIH, Baltimore, MD.

When a quantitative phenotype is not adequately transformed in a regression based GWAS, the residuals of the fitted model may violate the normality assumption of the residuals and result in an inflation of the type I error rate. Previous work has shown that the amount of inflation when the normality assumption is violated is affected by at least two factors. The first is the degree of non-normality of the residuals, where more non-normality results in more inflation; the second is the minor allele frequency (MAF) of the SNP being tested, where the lower the MAF, the higher the inflation. ComPaSS-GWAS is a new method based on Complementary Pairs Stability Selection that uses a regression based GWAS aggregated over many random sample splits for internal corroboration. This approach has been shown to ameliorate the loss of power seen in a traditional two-stage GWAS approach with a single split, and have similar power to a traditional GWAS on the full sample. In this study, the type I error rate for ComPaSS-GWAS is investigated for different degrees of non-normality of the residuals for SNPs in different MAF ranges to evaluate the amount of inflation relative to a traditional GWAS. Simulations were performed based on the GAW19 data (1764 unrelated individuals, 73,488 SNPs). One thousand replicates of non-genetic traits following a standard normal distribution were simulated to identify parameters for the traditional GWAS and ComPaSS-GWAS that achieved equivalent type I error rates on common variants. One thousand replicates of non-genetic traits following a gamma distribution with shape and scale parameters of 3 and 20 respectively (moderate non-normality) and a gamma distribution with shape and scale parameters of 1.2 and 2 respectively (substantial non-normality) were simulated and used to evaluate the inflation of type I error rates for different ranges of MAF. For the gamma traits with a moderate degree of non-normality, the traditional GWAS had minor inflation in SNPs with MAF between 1% and 5% and substantial inflation for SNPs with MAF  $< 1\%$  (consistent with previous findings). Results for the gamma distribution with substantial degree of non-normality were similar, but with a larger amount of inflation. ComPaSS-GWAS had only minor inflation for SNPs with MAF  $< 1\%$ . These results suggest that ComPaSS-GWAS is more robust to the violation of normality than the traditional GWAS.

**Estimating the autocorrelation of causal SNP effect size magnitudes as a function of genomic distance.** A.P. Schoech<sup>1,2</sup>, L. O'Connor<sup>1,2</sup>, O. Weissbrod<sup>1,2</sup>, N. Patterson<sup>2</sup>, Y. Reshef<sup>1,2</sup>, A.L. Price<sup>1,2</sup>. 1) Harvard T.H. Chan School of Public Health, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA.

Common diseases and complex traits are highly polygenic, but the location of most causal genetic variants remain unknown. It is possible that these causal variants systematically cluster together, i.e. that causal variants tend to be located close to other causal variants. Allelic heterogeneity, i.e. multiple causal variants at a locus, as well as functional regions that are enriched for causal variants, strongly suggest that this is the case. However, it is currently unknown to what extent and on which length scale along the genome causal effect size magnitudes are correlated. We introduce a method that estimates the correlation between the squared causal effect sizes of nearby SNPs, as a function of their genomic distance. Our method is not confounded by linkage disequilibrium (LD), which causes nearby SNPs to have correlated squared marginal effect sizes due to tagging. The main idea behind the method is that the product of squared association statistics of two neighboring SNPs increases on average if the causal SNPs that they tag have correlated absolute effects. We regress the product of the squared association statistics on the sum of fourth moment LD values of the regression SNPs to other linked SNP pairs that are a specified distance apart. We show that the resulting regression coefficients can be used to infer the correlation of squared causal SNP effect sizes. We evaluated our method using LD patterns in UK Biobank and simulated traits, obtaining unbiased estimates under a range of genetic architectures. The method is computationally scalable to biobank sized data sets (hundreds of thousands of individuals and millions of SNPs) and only requires LD data and association summary statistics. We also developed a related method that obtains unbiased estimates of the correlation of *signed* SNP effects as a functions of the genomic distance between the SNPs, which occurs when one type of alleles, e.g. derived alleles, locally have systematically positive or negative effects on the trait due to natural selection. Estimating the strength and length scale of SNP effect autocorrelation along the genome can shed light on important questions about complex trait architecture and fine mapping, but the method also allows for using different distance measures than genomic distance, e.g. being located in the same topologically associated domains (TADs) or in genes that are connected in a gene network.

**Using identity by descent to improve genotype imputation.** M. Abney, A. El Sherbiny. Human Genetics, University of Chicago, Chicago, IL.

Genotype imputation often results in many genotypes being poorly imputed, particularly in studies where the individuals are not well represented in standard reference panels. Here, we introduce Kinpute, a novel method and software package that can dramatically improve the quality of imputed genotypes. Kinpute uses identity by descent (IBD) information---due to either recent, familial relatedness or distant, unknown ancestors---to extract additional information from the reference panel that can be used to infer genotypes in the study sample. Kinpute is designed to use a within-study reference panel and works in conjunction with other genotype imputation software to improve the quality of the imputed genotypes. In addition, Kinpute can select an optimal set of study individuals to sequence as the within-study reference panel. We ran Kinpute on a data set with many related individuals following imputation with Impute2. Across essentially all genotype classes, Kinpute raised the  $R^2$  of the imputed dosage with the true genotype compared to Impute2. For instance, for common SNPs with high INFO score ( $> 0.4$ ), for those genotypes that had low imputation certainty (maximum genotype probability of 0.9), Kinpute improved the  $R^2$  of 0.32 from Impute2 to 0.68. This class of genotypes represented approximately 10% of all genotypes. Even for common SNPs with high INFO and high genotype certainty, Kinpute improved the 0.90  $R^2$  from Impute2 to 0.93 (60% of all genotypes). When IBD is present in the sample, a method such as Kinpute can substantially improve the genotype imputation of sequence data in a population that is not well represented in standard reference panels.

**Estimating and accounting for unobserved covariates in high dimensional correlated data.** *C.G. McKennan, D. Nicolae.* Department of Statistics, University of Chicago, Chicago, IL.

An important phenomenon in high dimensional biological data is the presence of unobserved covariates that can have a significant impact on the measured response. When these factors are also correlated with the covariate(s) of interest (i.e. disease status), ignoring them can lead to increased type I error and spurious false discovery rate estimates. There have been a number of methods developed by the statistics and genetics community to estimate and account for these latent factors in downstream analyses when samples are assumed independent, including Surrogate Variable Analysis (SVA), Removing Unwanted Variation (RUV) and Confounder Adjusted Multiple Testing (CATE). However, many datasets have complex sample correlation structure, which includes data with multiple samples from the same individual under different treatment conditions or from different tissues, as well as data from related individuals (e.g. twin studies). Unsurprisingly, standard latent factor adjustment methods tend to produce spurious and inaccurate estimates for data with non-trivial sample correlation structure. For example, methods to estimate the number of latent factors,  $K$ , like parallel analysis used in SVA and bi-cross validation used in CATE tend to estimate  $K$  to be on the order of the sample size, which drastically reduces the number of degrees of freedom and power in downstream analyses. This motivated us to develop CorrConf, a provably accurate and computationally efficient method to estimate the number and column space of unobserved covariates in data with correlated observations. Our method (to the best of our knowledge) is the first subspace estimation procedure designed specifically for data with complex correlation structure, and we prove that our estimates for the effects of interest are asymptotically equivalent to the generalized least squares estimator when the latent factors are observed. We apply our method to both longitudinal DNA methylation data to identify ancestry specific methylation patterns that are conserved from birth to early childhood, as well as gene expression data to identify anthracycline response eQTLs in cardiomyocytes.

**On performing gene expression imputation and gene-level association analysis in multiethnic or admixed populations.** *A.I. Konkashbaev<sup>1</sup>, E.R. Gamazon<sup>1,2</sup>.* 1) Vanderbilt University Medical Center, Nashville, TN; 2) Clare Hall, University of Cambridge, Cambridge, United Kingdom.

Transcriptome-wide association analysis, such as implemented in PrediXcan and FUSION, has been utilized to identify numerous disease-associated genes. The approach estimates the genetically determined component of gene expression using GWAS data and a transcriptome panel measured only in a reference dataset. Imputation models are generated using local genetic variation to predict the molecular traits; the genetically determined phenotype is then used to map trait-associated genes. However, the impact of ancestry on this high-dimensional analysis remains to be clarified. Here we present an approach to building imputation models in a multiethnic or admixed population. Using GTEx skeletal muscle ( $n=60$ ) and NIGMS Human Variation Panel ( $n=81$ ) African American data, as reference transcriptome panels, we compare several approaches – penalized regression, random forest, polygenic score – for control of type I error rate and statistical power in a heterogeneous population. We then define a statistic, analogous to the traditional fixation index  $F_{st}$ , for genetic variants, that measures population differentiation at the gene-level. We provide application of our ancestry-aware models to publicly available GWAS datasets. Our study has important methodological implications for the application of transcriptome-wide association analysis to current GWAS data.

**3408W**

**The susceptibility of genome-wide association studies to recent fine-scale population structure.** *K.A. Rand<sup>1</sup>, J.M. Granka<sup>1</sup>, E.P. Sorokin<sup>1</sup>, M. Zhang<sup>1</sup>, J. Byrnes<sup>1</sup>, E.L. Hong<sup>1</sup>, K.G. Chahine<sup>2</sup>, C.A. Ball<sup>1</sup>.* 1) AncestryDNA, San Francisco, CA; 2) AncestryDNA, Lehi, UT.

Large, heterogeneous genetic datasets have identified associations of thousands of single nucleotide polymorphisms (SNPs), sometimes subtly, with hundreds of human diseases and traits. Numerous methods have been developed to account for confounding effects of population structure unavoidable in such datasets; these include linear mixed models (LMMs) and the inclusion of population-level principal components (PCs) in fixed models. However, the susceptibility of GWAS to subtle, fine-scale population structure unidentifiable from PCs or  $F_{ST}$  has not been fully studied. Here, we address whether ultra-fine scale population structure, such as from post-colonial U.S. history or recent British history (Leslie Nature 2015), could produce an inflation of false positive GWAS associations, even for common variants. To do so, we use simulated phenotype data and genome-wide SNP data from over 1 million AncestryDNA customers who have consented to research. Among these individuals, we identify recent fine-scale population structure using community detection algorithms across a network of identity-by-descent (Han Nature Communications 2017) that corresponds to history within the last several hundred years and are driven by both spatial and cultural factors such as religion. We simulate phenotypes under various null and alternative models, as well as under models where latent environmental variables associated with sub-populations affect the phenotype to varying degrees. Under both balanced and imbalanced sampling across fine-scale populations, we examine results of GWAS obtained from various methods. The susceptibility of current GWAS approaches to fine-scale structure is dependent upon the degree of genetic differentiation among identified sub-populations, as well as the degree of sampling bias. In cases where latent environmental variables affecting the phenotype are related to fine-scale population structure, accounting for such structure using LMMs markedly improves GWAS accuracy. This highlights that even when underlying confounders are unknown, accounting for fine-scale structure can lessen effects of hidden environmental covariates without compromising power. Furthermore, our results suggest that accounting for fine-scale structure is even more critical when studying rare variant associations.

**Selection and cis-epistasis in human transcriptome biology.** *A.B. Faucon, P.D. Evans, E.R. Gamazon, X. Zhong, L.K. Davis, N.J. Cox.* Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN.

A recent BioRxiv paper [1] described the observation that — for a subset of genes — the most deleterious alleles are disproportionately observed to show reduced expression. One hypothesis for such an observation is that for these genes, there are fitness consequences to the deleterious variants in heterozygotes, and consequently, deleterious alleles found on haplotypes with lower than average expression may be more likely to survive and be characterized in transcriptome studies. Deleterious alleles found on haplotypes with lower expression may be more likely to be characterized in population-based transcriptome studies (GTEx) and provide a lens through which to study epistatic selection between coding and regulatory variation in human evolution. There are a variety of corollaries to this hypothesis that might be considered as well, including some related to the expectation that deleterious alleles on highly expressed haplotypes may yield more penetrant phenotypes. Therefore, we hypothesize that deleterious alleles on highly expressed haplotypes, through increased penetrance, may provide an analytic tool through which to understand disease associations in large-scale EHR / biobanks. Conceptually, this can be understood with a simple framework of a plot with deleteriousness on the x-axis and genetically determined expression on the y-axis. The region with high deleteriousness and low expression (or low deleteriousness and high expression) is reflective of epistatic selection and can be studied in transcriptome studies. On the other hand, we can do a PheWAS of the region with high deleteriousness and high genetically determined expression to investigate disease mechanisms that may arise from "disrupting" what is "expected" in reference transcriptome panels. We used phased data from GTEx to determine coding variants on haplotypes with differential expression but focused on genetically predicted expression of the haplotypes, rather than a single eQTL. Next, for those high CADD variants with which we see the most significant enrichment/depletion, we utilize PrediXcan applied to a large-scale electronic health records tied to a biobank (BioVU) to determine associated phenotypes. We hypothesize that for genes with differential expression in tissues, we will be more likely to see more deleterious variants on low expressing haplotypes, but deleterious variants on high expressing haplotypes will be associated with more phenome. 1. Castel et al. *BioRxiv* (2018): 190397.

**Mixed-linear model adjustment recalibrated with LD structure improves statistical power for the detection of significant ieQTLs.** *N. Patel<sup>1</sup>, W.S Bush<sup>1</sup>, A.E Fish<sup>2</sup>, J.A Capra<sup>2</sup>.* 1) Institute for Computational Biology, Department of Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 2) Vanderbilt Genomics Institute, Department of Biological Sciences, Vanderbilt University, Nashville, TN.

With the availability of the large-scale reference datasets containing genotype and gene expression data of hundreds of individuals, it is now possible to quantify the influence of various genetic components on gene expression. While the bulk of genetic variation in gene expression appears to be additive, several studies have investigated dominant and interaction effects. Our prior work suggests the approaches used to detect interaction eQTLs (ieQTLs) are susceptible to various statistical, biological and technical limitations, which likely limited their power and clouded their biological interpretation. We have previously described a novel approach for ieQTL analysis based on mixed linear model regression within the cis-regulatory region. When we applied this approach to the 1119 false positive interactions identified in a discovery set of 210 individuals genotyped as part of the HapMap Phase II, we were able to eliminate all but six of them. However, from simulation studies, we estimated the statistical power for this approach to be too low for interactions with medium and large effect sizes. Here, we present a modified method that accounts for the LD structure of the cis-regulatory region to remove variants near the ieQTLs that are in strong LD ( $r^2 > 0.4$ ) when building the Genetic Relationship Matrices. This approach provides similar ability to eliminate confounded models/interactions compared to the ones obtained from a simple mixed linear model analysis for the false positives in the HapMap dataset, with a significantly improved statistical power. We also apply this method to the 3319 random interactions near 10 genes derived from the Genotype-Tissue Expression (GTEx) whole blood data set and find 18 ieQTLs to be significantly associated with the expression.

**Genetic regulation of transcriptional response in African American hepatocytes upon multiple drug treatments.** *M. Perera<sup>1</sup>, Y. Zhong<sup>1</sup>, T. De<sup>1</sup>, Y. Xu<sup>2</sup>, C. Alarcon<sup>1</sup>.* 1) Northwestern University, Chicago, IL; 2) University of Chicago, Chicago, IL.

Drug-Drug interaction and inter-individual differences in drug response are long-standing issues in medicine and are key goals for precision medicine. However, drug perturbation experiments have been limited to immortal cell lines which do not reflect the true physiology and gene expression of the liver, a key organ for drug metabolism. Here, we genotyped 60 primary human hepatocytes derived from donors of African American (AA) ancestry and treated them with 6 known inducers of drug metabolism (Omeprazole, Phenobarbital, Dexamethasone, Carbamazepine, Phenytoin and Rifampicin). We measured the transcriptome before and after treatment. We performed pair-wise differentially expressed (DE) gene analysis and demonstrated that Phenobarbital and Omeprazole have the strongest response and Carbamazepine has the lowest response in terms of the number of DE genes. Commonly overexpressed DE genes are enriched for targets of a transcriptional factor, *TCF11*, which suggests its role as a general factor in modulating drug metabolism. DE gene analysis revealed the similarity between Phenytoin and Carbamazepine, which may result from their common therapeutic application on epilepsy. We identified genetic associations with drug-induced gene expression (di-eQTLs) and found a bimodal sharing pattern of di-eQTLs across drug treatments, with the majority of di-eQTLs found uniquely in one condition ( $n = 11,809$ ) or common to all 7 conditions ( $n = 11,601$ ). Genes of unique di-eQTLs to drug induction are enriched for cytochrome P450 family, suggesting differential transcriptional regulation of drug metabolism. Interestingly, *LRP12* which mediates the metabolism of lipophilic molecules is under genetic regulation only with drug treatments (not found in the untreated condition). With Meta-Tissue, we mapped eQTLs across all conditions in meta-analysis approach and identified eQTLs (e.g. rs368942766 with *DYNLRB2*) with large effect size heterogeneity ( $I_2 > 15$ ). We finally evaluated condition-specific eQTLs with respect to their functional characteristics, genomic context, and relationship to disease-associated variants. In conclusion, this is the first study that characterizes signatures of regulatory changes that affect drug metabolism specifically in a minority population. These results demonstrate that both drug-specific and cross-drug mechanisms underlie drug metabolism induction, an important interaction pathway in pharmacology.

**The impact of smoking on BMI depends on your genome.** *C. Amador<sup>1</sup>, P.K. Joshi<sup>2</sup>, J.F. Wilson<sup>2</sup>, P. Navarro<sup>1</sup>, C.S. Haley<sup>1,3</sup>.* 1) MRC Human Genetics Unit, University of Edinburgh, Edinburgh, EH4 2XU, United Kingdom; 2) Centre for Global Health Research, Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh EH8 9AG, United Kingdom; 3) Roslin Institute and Royal (Dick) School of Veterinary Studies, University of Edinburgh, Edinburgh, EH25 9RG, United Kingdom.

Obesity has increased in the past decades and continues to increase almost universally. It is linked to health conditions such as type II diabetes, coronary heart disease and cancer, hence, pressure has increased to tackle a problem that has a large impact on healthcare systems. To tackle obesity efficiently, we require better understanding of its causes of variation in the population. Although obesity related traits are highly heritable (twin studies show a heritability for BMI of up to 60%) known causal variants have very small effects and account for a small proportion of the heritability. Obesogenic environments have been identified (e.g. lifestyle choices, caloric diets, physical inactivity) but their specific impact and potential interaction with genetic variation have not been properly quantified. We take a new approach and study the impact on BMI of genetic variation, jointly with two specific environmental variables (smoking and alcohol intake), and the interactions between the genome and these environments. To do this we estimate the total variance that genome-by-environment interactions (GxE) explain in a variance component analysis using similarity matrices for individuals based on their genomes and their environment (smoking and alcohol intake) and a genome-by-environment interaction similarity matrix. This method allows estimation of the effect of sharing both genes and lifestyles in addition to their independent effects. Using data from UK Biobank we estimated the heritability of BMI to be 50% and an effect of smoking on BMI of 1% of the variance. However, when including an interaction term, it explained an extra 2.5%, suggesting that smoking has a larger impact on BMI depending on the genetic variants carried. This value was larger when modelling females and males separately, with up to a 5% of the variance explained by genome-by-smoking interactions in males and 3% in females. Similar results were also observed for alcohol intake. GxE is a potential source of missing heritability and these results suggest the effect can be substantial with genome-by-environment effects explaining more variation than the corresponding environmental effects. A detailed description of these interactions can improve our understanding of trait architecture and prediction and potentially improve treatment and interventions to tackle obesity.

**Phenome-wide analyses of pharmacomimetic variants in their genomic context: New opportunities for genetic validation of therapeutic targets in UK Biobank.** *J.D. Hoffman<sup>1</sup>, K.J. Song<sup>1</sup>, I. Tachmazidou<sup>1</sup>, A. Pandey<sup>1</sup>, M.G. Ehm<sup>1</sup>, J.C. Whittaker<sup>2</sup>, M.R. Nelson<sup>1</sup>, T. Johnson<sup>1</sup>, L.M. Yerges-Armstrong<sup>1</sup>, R.A. Scott<sup>1</sup>.* 1) Department of Genetics, GlaxoSmithKline, Collegeville, PA; 2) Department of Computational Biology, GlaxoSmithKline, Collegeville, PA; 3) Statistical Platforms and Technologies, GlaxoSmithKline, Collegeville, PA.

The majority of drugs in clinical development fail to reach approval, with late stage failures mainly due to lack of efficacy or unforeseen adverse events. Genetic support for a target increases the likelihood of it being safe and efficacious and, as such, it is of interest to robustly evaluate genetic support for potential therapeutic targets by phenome-wide association testing of variants predicted to mimic pharmacologic target perturbation of a given target: "pharmacomimetic" (PM) variants. Such approaches enable evaluation of the primary indication hypothesis as well as possible alternative indications and adverse effects, but several downstream analyses are required to allow robust inference. Here, we evaluate the association of common and rare published PM variants for 29 targets approved or in clinical development, with up to 2413 phenotypes in 379,337 unrelated participants from UK Biobank. Where we identified associations reaching statistical significance ( $p < 2.07 \times 10^{-5}$ ), we performed approximate conditional analyses and fine-mapping to evaluate the evidence for the index variant as credibly causal in its genomic context. Across the variants, we identified over 400 statistically significant associations with 157 phenotypes. In addition to replicating associations related to the primary indication, we identified associations with previously unreported traits representing potential repositioning opportunities or safety flags. For example, rs1837253 at *TSLP* associated with the primary indication of asthma, and also had a colocalized (Posterior-probability (PP)=0.99) association with COPD ( $p = 6.5 \times 10^{-8}$ ) in the same direction. Among several such examples, we found multiple associations with rs12916 (an eQTL at *HMGCR*, encoding the target of statins), apparently supporting the lipid-lowering and weight-increasing effects of statins. However, the cholesterol association ( $p = 3.0 \times 10^{-45}$ ) led by rs12916 did not colocalize with the BMI association ( $p = 7.25 \times 10^{-17}$ ; PP=0), which was led by a missense variant at the nearby *POC5* (rs2307111;  $p = 7.3 \times 10^{-35}$ ). Furthermore, rs12916 was not in the 95% credible set for the BMI association. We demonstrate the value of large-scale studies with access to complete genome-wide data to evaluate genetic evidence to support therapeutic target validation. In particular, we highlight the potential for incorrect inference without thorough evaluation of genomic context and the importance of such evaluations in future PheWAS analyses.

**HLA association in Chronic Fatigue Syndrome/Myalgic Encephalopathy (CFS/ME) implicating the involvement of the immune system.** A. Lande<sup>1,2</sup>, O. Fluge<sup>3</sup>, S.T. Flåm<sup>1</sup>, O. Mella<sup>3</sup>, O.D. Saugstad<sup>4</sup>, T. Egeland<sup>2,5</sup>, M.K. Viken<sup>5</sup>, B.A. Lie<sup>1,2,5</sup>. 1) Oslo University Hospital, Oslo, Norway; 2) Institute of Clinical Medicine, University of Oslo; 3) Department of Oncology and Medical physics, Haukeland University Hospital, Bergen, Norway; 4) Department of Pediatric Research, Oslo University Hospital; 5) Department of Immunology, Oslo University Hospital.

**Introduction** Etiology and pathophysiology in Chronic fatigue syndrome/Myalgic encephalopathy (CFS/ME) are largely unknown and highly controversial. Immune dysregulations have been reported among patients, and autoimmune mechanisms have been hypothesized as being part of the etiology. We want to contribute to the evaluation of this hypothesis, by investigating Human leukocyte antigen (HLA) associations in CFS/ME. **Materials and methods** We performed high resolution HLA genotyping of classical HLA class I and II genes by next generation sequencing 309 adult, Norwegian CFS/ME patients, all diagnosed according to the 2003 Canadian criteria. 140 of the patients had severe or very severe disease. Allele frequencies for the loci *HLA-A*, *-B*, *-C*, *-DRB1*, *-DQB1* and *-DPB1* were compared to a Norwegian HLA reference panel of 4514 healthy individuals. **Results** In this material, we identified a positive association between CFS/ME and the allele HLA-DQB1\*03 (Allele frequency<sub>CFS/ME</sub> = 0.36, Allele frequency<sub>Controls</sub> = 0.32, OR = 1.20,  $p_{adj}$  = 0.032). **Discussion** Our result is in accordance with a previous study of 110 patients with Chronic fatigue immune dysfunction syndrome, where they also reported an association with DQB1\*03 (OR = 1.83). We are currently following up our analysis with higher resolution HLA genotypes and analyses of HLA haplotypes in a cohort comprising altogether 425 Norwegian CFS/ME patients, as well as stratifying the results for clinical parameters. Since HLA associations are well documented in most autoimmune diseases, a confirmed HLA-DQB1 association points towards an involvement of the immune system in CFS/ME.

Lung function is an important measure of health and a predictor of morbidity and mortality in the general population. Genome-wide association studies (GWAS) have identified over 100 loci for lung function traits, opening the opportunity using summary-based integrative approaches to combine with publicly available eQTL data. One method is the S-PrediXcan approach. In applying such approaches, it is unclear whether to perform tissue-specific analyses using disease relevant tissues only, or if it can be beneficial to leverage eQTL resources from other tissues. We applied gene-based S-PrediXcan to integrate GWAS results for spirometric pulmonary function (FEV1, FVC, and FEV1/FVC ratio) results from the CHARGE consortium (n>90,000) and UK BiLEVE (n>48,000) with genetically-regulated gene expression (GRex) inferred using cis-eQTL SNP data from lung (n=333) and whole blood (n=315) in the Genotype-Tissue Expression (GTEx) project v7p. After combining S-PrediXcan (using a false discovery rate [FDR] <0.05) with a Bayesian colocalization analysis for GWAS of pulmonary function traits in CHARGE, followed by replication in UK BiLEVE (Bonferroni p-value<0.05), 74 GRex were identified that were associated with at least one lung function trait. Of the identified genes, 10 were identified through integration using both the GTEx lung and whole blood models, 29 were identified exclusively for lung tissue, and 35 were identified exclusively for whole blood. In follow-up analysis using RNA-seq on bronchial epithelial brushings from 129 participants in the Subpopulations and Intermediate Outcome Measures in COPD Study (SPIROMICS), we observed statistically significant associations of lung function with gene expression levels for 8 of the 74 genes based on a FDR qvalue<0.1, of which 4 were identified from our integrative analyses with lung tissue (*PYGB*, *MMP15*, *DNAH5*, *TYRO3*) and 4 from whole blood (*PABC4*, *STMN3*, *ZNF668*, *HM13*). *ZNF668*, *DNAH5*, *TYRO3*, *HM13* represent new loci, while *PYGB*, *PABPC4*, *MMP15*, and *STMN3* lie in regions previously identified by GWAS. While we identified distinct sets of genes through integration with lung vs. whole blood eQTL, equal numbers were validated through gene expression on bronchial brushings, suggesting further gains may be achieved by combining eQTL evidence across tissues.

**3416F****Gene-based rare variant association tests for ancestry-matched**

**case-control data.** C. Wang<sup>1,2</sup>, B. Sun<sup>2</sup>, Z. Wang<sup>3</sup>, M. Deng<sup>3,4,5</sup>, H. Chen<sup>6,7</sup>. 1) Department of Epidemiology and Biostatistics, School of Public Health, Tongji Medical School, Huazhong University of Science and Technology, Wuhan, Hubei, China; 2) Computational and Systems Biology, Genome Institute of Singapore, Singapore; 3) Center for Quantitative Biology, Peking University, Beijing, China; 4) LMAM, School of Mathematical Sciences, Peking University, Beijing, China; 5) Center for Statistical Sciences, Peking University, Beijing, China; 6) Human Genetics Center, Department of Epidemiology, Human Genetics and Environmental Sciences, School of Public Health, The University of Texas Health Science Center at Houston, Houston, Texas, U.S.A; 7) Center for Precision Health, School of Public Health & School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, Texas, U.S.A.

With an increasingly large amount of human sequencing data available, analysis incorporating external controls becomes a popular and cost-effective approach to boost statistical power in disease association studies. To prevent spurious association due to population stratification, it is important to carefully match the ancestry backgrounds of cases and external controls. However, popular rare variant association tests based on logistic regression models, including the burden test, sequence kernel association test (SKAT) and the mixed effects score test (MiST), which is a hybrid version of burden and SKAT, are conservative for matched case-control samples when all matched strata have the same case-control ratio and might become anti-conservative when case-control ratio varies across strata. To account for the matching structure, we propose gene-based tests based on a conditional logistic regression (CLR) model, namely CLR-burden, CLR-SKAT, and CLR-MiST. We show that the CLR model coupled with ancestry matching is a general approach to control for population stratification. Through extensive simulations of population stratification and matching schemes, we demonstrate that both CLR-burden and CLR-SKAT are more powerful than standard burden test and SKAT respectively in ancestry-matched data while robustly controlling the type 1 error, and CLR-MiST is most powerful under a wide range of scenarios. Furthermore, because CLR-based tests allow for different case-control ratios across strata, a full-matching scheme can be employed to fully utilize available cases and controls to accelerate the discovery of disease genes.

**3417W**

**Using maximal segmental score to estimate region-specific p-values in sequencing data for recessive diseases.** C.C. Chang<sup>1</sup>, I-B. Lian<sup>2</sup>, J. Ott<sup>3</sup>, C.S.J. Fann<sup>1</sup>. 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Graduate Institute of Statistics and Information Science, National Changhua University of Education, Taiwan; 3) Rockefeller University, New York, NY, USA.

Advances in high-throughput DNA sequencing technology have generated a great momentum for genomic data. For rare variant association test, the power for detecting low frequency or by traditional association methods is lower. Previously, we proposed Maximum Segmental Score method (MSS) that is capable of scanning genetic variants to identify regions most likely harboring disease gene with rare and/or common causal variants. The method uses aggregate scores to identify the region with possible disease association<sup>1</sup>. If the disease-causing variant occurs with high frequency in the affected families, family studies may provide a significant boost in statistical power. One of the advantages of using samples from families of the same ethnical group is to reduce bias arisen from population stratification which can lead to false-positive results. Instead of the usual ways to do case-control studies, we compared a given case (or a few cases) with all controls and carried out such a comparison for each variant. In our method, there were many more controls than cases, therefore, permutation tests were carried out to obtain empirical p-values. We considered a sequence of p-values obtained by marker-wise tests. Euclidean distance was used to measure the difference between cases and controls and the mean values were compared between the two groups by a t statistic. Firstly, the p-values were transformed into a sequence of scores according to a specific scoring system. Secondly, MSS was applied to scan the sequence of scores to identify the region with the highest cumulative score. Finally, the tail probability was calculated. The segment with the highest score would suggest the likelihood of putative disease genes within the region. We applied our approach on two autosomal recessive diseases. Three multiple intestinal atresia cases were chosen from three families respectively and 30 controls drawn from UK10K data. The result found the TTC7A gene as being most significant. One osteogenesis imperfecta case was used along with 32 controls from UK10K data, the result showed that the BMP6 gene was most significant. Both genes had been published previously by method based on Hamming Distance Ratio (HDR)<sup>2</sup>. These results demonstrate that our extended method of MSS is able to identify putative disease genes with very small numbers of cases using sequencing data for recessive diseases. 1. **Medium-coverage DNA sequencing in the design of the genetic association study.** C. Xu, R. Zhang, H. Shen, H.W. Deng. Center of Genomics and Bioinformatics, Department of Global Biostatistics and Data Science, Tulane University, New Orleans, LA, 70112, USA.

DNA sequencing is a widely used tool in genetic association study. Sequencing cost remains a major concern in sequencing-based study, although the application of next generation sequencing has dramatically decreased the sequencing cost and increased the efficiency. The choice of sequencing depth and the number of samples will largely determine the final study investment and performance. Many studies have been conducted to find a cost-effective design of sequencing depth that can achieve certain sequencing accuracy using minimal sequencing cost. The strategies previously studied can be classified into two groups: 1) single-stage to sequence all the samples using either high (>~30x) or low (<~10x) sequencing depth; and 2) two-stage to sequence an affordable number of individuals at a high-coverage followed by a large sample of low-coverage sequencing. However, limited studies examined the performance of the medium-coverage (10x-30x) sequencing depth for a genetic association study, where the optimum sequencing depth may exist. In this study, using a published simulation framework, we comprehensively compare the medium-coverage (MC) sequencing to the single- and two-stage high/low-depth sequencing in terms of the power and type I error of the variant discovery and association testing. We find, given certain sequencing effort, MC yields a close discovery power and better type I error control compared with the best scenarios using other design. However, MC is not as competent as other sequencing coverages with respect to the association power, especially for the rare variants and when the sequencing investment is limited.

**Genetics and nicotine dependence: Heaviness of smoking index in European individuals.** C. Batini, N. Shrine, Q. Wang, M.D. Tobin. Department of Health Sciences, University of Leicester, Leicester, UK.

Smoking is one of the leading risk factors of the top five causes of death worldwide, including heart and respiratory diseases, killing around 6 million people a year. Smoking behaviour is a very complex trait but, based on twin studies, it has been shown to have genetic heritability ranging between 35% and 75% depending on the specific phenotype considered, with nicotine dependence being the highest. Here we use the categorical Heaviness of Smoking Index (HSI) to quantify nicotine dependence in all UK Biobank (UKB) ever smokers for which data on both cigarettes per day and time to the first cigarette of the day were available, for a total of 34,752 UKB participants. Of these, 54% show low nicotine addiction, while high addiction was observed only in a minor group, and more frequently in men (9%) than women (4%). We present here a preliminary genome-wide association study of categorical HSI using a linear mixed model to test associations in 32,212 UKB individuals of European origin. Genome-wide significant associations ( $p < 5 \times 10^{-8}$ ) highlight signals previously reported for other smoking behaviour traits: *DBH* for smoking cessation, *CHRNA3* for cigarettes per day and *CHRNA4* for nicotine dependence measured by the Fagerström Test. Associations passing a suggestive significance threshold ( $p < 10^{-5}$ ) indicate novel loci on chromosomes 3, 11 and 22. Replication analyses, association testing in non-European ancestries in UKB and functional *in silico* follow-up will be carried out to help understanding the biological background of nicotine addiction and informing the identification of future drug targets for smoking cessation.

**Universal Control Repository: A practical framework for aggregating control genotype data.** D. Chen<sup>1,4</sup>, K. Tashman<sup>1,4</sup>, D. Palmer<sup>1,4</sup>, K. Panayidou<sup>2,5</sup>, T. Zheng<sup>3</sup>, C. Churchhouse<sup>1,4</sup>, K. Roeder<sup>2,5</sup>, A. Bloemendal<sup>1,4</sup>, B. Neale<sup>1,4</sup>. 1) Stanley Center, Broad Institute, Cambridge, MA; 2) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA; 3) Department of Statistics, Harvard University, Cambridge, MA; 4) Analytical and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 5) Computational Biology Department, Carnegie Mellon University, Pittsburgh, PA.

A major obstacle to the successful identification of genetic risk factors is the availability of large control samples for association studies. Genotyping is often restricted to cases to reduce costs, making analysis impossible without incorporating external controls. While many control resources are available through repositories such as dbGap, administrative and computational barriers to entry are substantial. Further, confounding due to both population stratification and technical biases across genotyping technologies require computational and statistical expertise. We build on the work of Bodea et al. AJHG (2016) to develop the UNiversal COntrol Repository Network (UNICORN) as a scalable framework for aggregating control samples while allowing users to perform ancestry-controlled GWAS without the exchange of individual-level genotype data. To this end, we have aggregated 600,000 control samples comprising 110,000 samples obtained from 23 collections within dbGaP, with a further 30,000 and 488,000 incoming from the PGC consortium and UK Biobank respectively. These were genotyped on a plethora of technologies including Illumina and Affymetrix arrays. At present the majority of controls are of European ancestry, but we have increasing numbers from other major ancestries, including around 40,000 African samples, 20,000 East Asian samples and 5,500 Latino samples. Merging data from multiple genotyping array platforms creates various challenges, which we address with a multi-stage pipeline. We first performed pre-imputation quality control at the cohort and platform levels. We then imputed the platform-level data using the Michigan Imputation Server, merged the results and performed further post-imputation QC. Finally, we used this merged data to identify, remove and re-impute additional poorly performing SNPs on a per-platform basis. The pipeline was implemented in Hail<sup>1</sup>, scalable open source genetics software. This reproducible framework allows additional controls to be incorporated easily, and enables users to run the pipeline on case sets. UNICORN provides an aggregated and imputed global control resource, in which batch effects have been controlled and ancestry has been modeled. Our unified QC pipeline ensures reproducibility, extensibility and usability. We envision future routine use of this resource to boost power in case-control GWAS and to enable studies in situations where controls are lacking.

**Correcting index event bias in genome-wide association studies of prognosis or survival.** F. Dudbridge<sup>1</sup>, R.J. Allen<sup>1</sup>, A.F. Schmidt<sup>2,3,4</sup>, L.V. Wain<sup>1</sup>, R.G. Jenkins<sup>5</sup>, A.D. Hingorani<sup>3</sup>, R.S. Pate<sup>3</sup>. 1) Department of Health Sciences, University of Leicester, Leicester, UK; 2) Groningen Research Institute of Pharmacy, University of Groningen, Groningen, The Netherlands; 3) Institute of Cardiovascular Science, Faculty of Population Health Sciences, University College London, London, UK; 4) Department of Cardiology, University Medical Centre Utrecht, Utrecht, The Netherlands; 5) Division of Respiratory Medicine, University of Nottingham, Nottingham, UK.

Following the completion of numerous genome-wide association studies of disease susceptibility, there is increasing interest in identifying genetic associations with disease prognosis, survival or other subsequent events. However, such studies are vulnerable to index event bias, by which selection of subjects according to their disease status creates biased associations if common causes of susceptibility and prognosis are not accounted for. This is a particular problem for polygenic traits and is also a potentially serious bias in Mendelian randomization studies. We propose a novel correction for index event bias using the residuals from the regression of genetic effects on prognosis on the corresponding effects on susceptibility. Assuming that direct effects on prognosis are independent of those on susceptibility, our approach yields correct type-1 error rates and unbiased estimates of prognosis effects. Under genetic correlation between susceptibility and prognosis, our approach has reduced type-1 error and bias compared to the standard unadjusted analysis. Our approach can have greatly increased power for SNPs with concordant direction of effects between susceptibility and prognosis. In a study of idiopathic pulmonary fibrosis, we resolved a paradoxical association with increased survival of the strong susceptibility gene *MUC5B*; under our adjusted analysis the risk allele had a highly significant association with decreased survival. In re-analysis of a study of Crohn's disease prognosis, our approach attenuated four genome-wide significant associations to a suggestive level. We recommend our approach as a standard analysis for genome-wide association studies of events subsequent to disease onset.

**Genetic associations with sleep apnea in a European population.** Y. Huang, R. Gentleman, 23andMe Research Team. Research, 23andMe, Inc, Mountain View, CA.

**Background:** Sleep apnea is characterized by uncontrollable pauses or repetitive periods of shallow breathing. It affects approximately 3% to 7% of adults and is associated with increased risk for diabetes, cardiovascular conditions as well as premature mortality. While obesity has been considered to be one major risk factor in the development and progression of sleep apnea, previous studies have also suggested inheritance and familial factors in both sleep apnea and obesity. The genetic basis of sleep apnea is still not yet well understood. **Objective:** To investigate associations between genetic risk loci, body mass index (BMI), and risk of sleep apnea in European population using the 23andMe database. **Methods:** We conducted a genome-wide association study using logistic regression with self-reported sleep apnea as the dependent variable. Covariates included age, sex, BMI, and ancestry-informative principal components (PC) 0-4. Multivariable logistic regression models adjusting for potential confounders, including diabetes and high blood pressure, were further used to determine the relationship between BMI and sleep apnea. **Results:** A total of 1,925,006 (case: 184,110, control: 1,740,896) Europeans who had consented to participate in research were included. Fifteen loci or genes have surpassed the genome-wide significance threshold ( $P = 5 \times 10^{-8}$ ). rs2336715 (MSRB3,  $P = 1.5 \times 10^{-12}$ ) and rs592333 (DLEU1-DLEU7,  $P = 2.8 \times 10^{-12}$ ), associated with snoring in previous research, were indicated to be significantly related to sleep apnea. Although strongly associated with BMI or type II diabetes, rs531385 (SEC16B,  $P = 2.9 \times 10^{-10}$ ) and rs17715065 (EBF1,  $P = 1.2 \times 10^{-11}$ ) still remained at genome-level significance after adjusting for the BMI. Moreover, in the secondary analysis, people who reported being overweight (odds ratio (OR): 2.08, 95% confidence interval (CI): 2.05 - 2.12) or obese (OR: 6.00, 95% CI: 5.91 - 6.10) were more likely to have sleep apnea compared to those who were normal or underweighted after adjusting for confounders. **Conclusions:** Our findings highlighted sleep apnea susceptibility genes in the European population, especially those with higher BMI. Further research in various ancestry groups is needed to evaluate these potential relationships in more detail. .

**Genetic associations to gut microbiome variation in the Flemish Gut Flora Project.** D.A. Hughes<sup>1</sup>, J. Wang<sup>2</sup>, R. Bacigalupe<sup>3</sup>, K. Wade<sup>1</sup>, L. Corbin<sup>1</sup>, N. Timpson<sup>1</sup>, J. Raes<sup>3</sup>. 1) MRC Integrative Epidemiology Unit, Bristol Medical School, University of Bristol, Bristol, UK; 2) Institute of Microbiology, Chinese Academy of Science, Beijing, China; 3) VIB-KU Leuven Center for Microbiology, Rega Instituut, Leuven, Belgium.

The Flemish Gut Flora Project (FGFP) is a large, population-level, cross-sectional, microbiome collection derived from individuals living in Flanders, Belgium. Previous work from this sample has highlighted many associations between microbiota diversity and abundance to health, dietary and lifestyle choices, and stochastic biological outcomes like stool consistency. Here we expand on these observational results by testing for associations between genotype and microbiota phenotypes, including alpha and beta diversity, enterotype, as well as abundance estimates for some 88 common, taxonomic units. Given the variety and uncertainty in the field as how to best handle this zero-inflated ecological data, we explicitly evaluate a variety of normalization procedures, as well as test zero-inflated taxa in data in binary, presence absence generalized linear models. These data will be vital in (a) understanding how to best handle such complex data, (b) identifying loci that contribute to the heritability of gut microbiota flora diversity, (c) and in identifying markers that can be used in mendelian randomization analysis to infer causal relationships between microbiome diversity and other phenotypes of interest.

**Genome-wide association study of longitudinal change in quantitative emphysema.** *W. Kim<sup>1</sup>, M. Parker<sup>2</sup>, M.H. Cho<sup>2,3</sup>, E. Silverman<sup>2,3</sup>, T.H. Beaty<sup>1</sup>, COPDGene Investigators.* 1) Department of Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 2) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 3) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, MA.

**Introduction:** Genome-wide association studies (GWAS) have identified genetic factors associated with cross-sectional measures of quantitative emphysema, but the genetic determinants of longitudinal change in quantitative emphysema remain largely unknown. Our study aims to identify the genetic influences of emphysema progression measured by computed tomography (CT) imaging in current and ex-smokers from the COPDGene study, a longitudinal cohort enrolling Non-Hispanic White (NHW) and African American (AA) subjects between the ages of 45 and 80 years at baseline with a minimum 10 pack-year smoking history. **Methods:** Among subjects who completed baseline and 5-year follow-up visits, genetic and longitudinal CT data were available on 4,238 subjects (3,078 NHWs and 1,160 AAs). Two quantitative emphysema measures from CT imaging, percent emphysema and adjusted lung density, were considered for GWAS. Longitudinal change in quantitative emphysema was defined as the difference in emphysema measures between phase 1 and 2. Multiple linear regression was performed under an additive genetic model, stratified by race, using genome-wide markers imputed to the Haplotype Reference Consortium panel. Baseline measures of age, pack-years of smoking, smoking status and emphysema (percent emphysema and adjusted lung density, accordingly), sex and principal components of genetic ancestry were included as covariates. We also performed GWAS of baseline measure of quantitative emphysema to determine whether genetic determinants of change in emphysema are also associated with baseline emphysema severity. **Results:** We identified five genetic loci associated with change in percent emphysema at traditional genome-wide significance ( $P < 5 \times 10^{-8}$ ), markers in or near *LOC100133091*, *ST6GALNAC3*, *TPK1*, and *SLC26A4* among AAs and *MAT2B* among NHWs. All associations had low minor allele frequency < 5%, and only the *MAT2B* locus passed a revised threshold for densely imputed data ( $P = 5 \times 10^{-9}$ ). Notably, these genetic loci were not reported from previous GWAS of cross-sectional quantitative emphysema and were not significantly associated with baseline measure of quantitative emphysema. **Conclusions:** Our study identified one genetic locus significantly associated with longitudinal change in percent emphysema among NHW heavy smokers. Confirmation of our finding may help identify genes influencing progression of emphysema as distinct from genes influencing development of emphysema.

**Three novel loci were identified for plasma acylcarnitine levels and their ratios in genome-wide association study.** *H. Li, S. Huo, X. Lin.* Shanghai Institute For Biological Sciences, Cas, Shanghai, China.

Plasma acylcarnitine levels have been reported to be associated with metabolic disorders such as obesity and diabetes. However, the understanding of human genetic variation affecting plasma acylcarnitine levels remains limited. We performed a genome-wide association study of acylcarnitine levels and their ratios in 2865 unrelated Chinese Hans from the Study on Nutrition and Health of Aging Population in China, a population-based a cohort study. We identified three genome-wide significant novel loci at *FADS1* ( $\beta$ : 0.252-0.481,  $P \leq 6.16 \times 10^{-17}$ , for associations with plasma levels of C20:4n-6, and acylcarnitine ratios including C14OH/C20:4n-6, C14:1OH/C20:4n-6, C16:1/C20:4n-6, C16:2/C20:4n-6, C18/C20:4n-6, C18:2/C20:4n-6, and C20/C20:4n-6, respectively), *ACADVL* ( $\beta$ : -0.272 - 0.356,  $P \leq 9.32 \times 10^{-11}$ , for association with acylcarnitine ratios including C3DC/C12, C6/C12, C6/C14, C6OH/C12, C6OH/C14, C8/C12, C8/C14, C10/C12, C12/C12OH, C12OH/C14, C14OH/C16:2, and C14:1OH/C16:2, respectively) and *ACSM5* ( $\beta$ : -0.263-0.257,  $P \leq 9.95 \times 10^{-10}$  for associating with C2/C7DC and C7DC/C12OH ratio, respectively). We also confirmed six loci ( $P \leq 9.89 \times 10^{-10}$ ) (*CPT2*, *ACADM*, *CPS1*, *MCCC1*, *ETFDH*, and *ACADS*) previously reported for associations with plasma levels of various components of acylcarnitines and their ratios in European populations. Notably, two novel independent association signals were observed at loci *CPS1* (rs715) and *CPT2* (rs12082305) for associations with plasma C6DC(rs715) and C16(rs12082305) levels ( $P \leq 9.89 \times 10^{-10}$ ) and acylcarnitine ratios including C6/C16, C6OH/C16, C6DC/C7DC, C6DC/C16, C6DC/C10DC, C14OH/C18 and C14OH/C20 ( $P \leq 7.99 \times 10^{-10}$ ). Our findings provide new insights into the genetic basis underlying carnitine metabolism.

**Genome-wide association study in 400k individuals identifies 139 novel signals of association with lung function highlighting pathways and pleiotropy.** N. Shrine<sup>1</sup>, A.L. Guyatt<sup>1</sup>, V. Jackson<sup>1</sup>, A.M. Erzurumluoglu<sup>1</sup>, C. Batini<sup>1</sup>, N. Reeve<sup>1</sup>, K. Song<sup>2</sup>, P. Sakornsakolpat<sup>3,4</sup>, B.D. Hobbs<sup>3,5</sup>, M.H. Cho<sup>3,5</sup>, D.P. Strachan<sup>6</sup>, A.P. Morris<sup>7</sup>, I.P. Hall<sup>8</sup>, M.D. Tobin<sup>1,9</sup>, L.V. Wain<sup>1,9</sup>, SpiroMeta consortium, Lung eQTL study. 1) Department of Health Sciences, University of Leicester, Leicester, UK; 2) Target Sciences - R&D, GSK Medicines Research Centre, Gunnels Wood Road, Stevenage, Hertfordshire, SG1 2NY, UK; 3) Chan-ning Division of Network Medicine, Brigham and Women's Hospital, Boston, Massachusetts, USA; 4) Department of Medicine, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand; 5) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, Massachusetts, USA; 6) Population Health Research Institute, St George's, University of London, London, UK; 7) Department of Biostatistics, University of Liverpool, Liverpool, UK; 8) Division of Respiratory Medicine, University of Nottingham, Nottingham, UK; 9) National Institute for Health Research Biomedical Research Centre – Respiratory theme, Glenfield Hospital, Leicester, UK.

Chronic obstructive pulmonary disease (COPD) accounted for 2.9 million deaths globally in 2016. Spirometrically-determined lung function is used in the diagnosis and grading of COPD. Genome-wide association studies (GWAS) of lung function quantitative traits are a more powerful alternative to COPD case-control studies for increasing the yield of associated genetic variants. The variants thus identified highlight the genes and pathways underpinning lung function and development of COPD potentially leading to novel preventive and therapeutic strategies for COPD. Through enhanced quality control and characterisation of spirometric measures of lung function in UK Biobank, completion of UK Biobank genotyping and expansion of the SpiroMeta Consortium, we undertook the largest genome-wide association study of quantitative lung function traits performed to date, comprising 400k individuals of European ancestry. We report 139 new independent signals of association with forced expiratory volume in 1s (FEV<sub>1</sub>), forced vital capacity (FVC), FEV<sub>1</sub>/FVC and peak expiratory flow (PEF), bringing the number of new and previously reported signals of association with lung function to 279. Fine-mapping of signals, together with gene and protein expression analyses with improved tissue specificity and stringency, has implicated new genes and pathways highlighting the importance of cilia development, TGFB-signalling, and elastic fibres in the aetiology of airflow obstruction. Many of the genes and pathways contain drug targets including those in development for indications other than COPD. Phenome-wide association testing of 279 lung function signals with 2,411 phenotypes in UK Biobank revealed genetic variants with apparent specificity of lung function effects and others with pleiotropic effects that might indicate shared biological pathways between different diseases. Investigating the nature of the pleiotropic effects of some of these variants associated with multiple traits may indicate the relevance of drug repurposing.

## 3427T

**Impact of ancestral variation in the levels and genetics of n-3 and n-6 long chain polyunsaturated fatty acids in distinct Hispanic subgroups.** C. Yang<sup>1</sup>, L.M. Reynolds<sup>2</sup>, T.D. O'Connor<sup>3</sup>, A.C. Wood<sup>4</sup>, R. Dutta<sup>5</sup>, M.C. Seeds<sup>6</sup>, I. Ruczinski<sup>7</sup>, R.A. Mathias<sup>8</sup>, R.N. Lemaitre<sup>9</sup>, S.S. Rich<sup>1</sup>, F.H. Chilton<sup>10</sup>, A. Manichai-kul<sup>1</sup>. 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 3) Institute for Genome Sciences, University of Maryland School of Medicine, Baltimore, MD; 4) ARS/USDA Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, Houston, TX; 5) Department of Urology, Wake Forest School of Medicine, Winston-Salem, NC; 6) Department of Internal Medicine/Section on Molecular Medicine, Wake Forest School of Medicine, Winston-Salem, NC; 7) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 8) Department of Medicine, Johns Hopkins University, Baltimore, MD; 9) Cardiovascular Health Research Unit, Department of Medicine, University of Washington, Seattle, Washington; 10) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC.

**Background.** Genetic variants in the fatty acid desaturase (FADS) cluster are associated with LC-PUFAs levels and numerous molecular and clinical phenotypes. PUFA metabolism has had limited attention in non-Caucasian populations. In this study we examined the hypotheses that (a) Hispanic American ancestry is predictive of LC-PUFA levels, and (b) distinct patterns of genetic association are observed in different Hispanic subgroups. **Methods.** 1,225 Hispanic American participants from the Multi-Ethnic Study of Atherosclerosis (MESA) were assayed by gas chromatography for plasma phospholipid n-3 eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA), docosahexaenoic acid (DHA) and n-6 (arachidonic acid, AA) PUFAs. Hispanic country of origin was inferred using participant-reported birthplaces for their parents and grandparents. Regression analysis was used to assess associations of LC-PUFA levels with percent Native American ancestry, computed using ADMIXTURE, and FADS cluster SNPs, available via genome-wide genotyping with imputation to the 1000 Genomes Phase 3. Regression models included covariate adjustment for age, sex, study site, four PCs of ancestry and batch. **Results.** The MESA Hispanic cohort represented the following subgroups: Central America (n=86), Cuba (n=47), Dominican (n=152), Mexico (n=644), Puerto Rico (n=169) and South America (n=100). Higher proportions of Native American ancestry associated with lower levels of all LC-PUFAs in participants of Central American, South American or Mexican origin compared to those of Dominican, Cuban or Puerto Rican origin. For example, each 10% increase in Native American ancestry associated with decreases of 0.40 and 0.14 percent of total fatty acids for AA ( $p=2.0 \times 10^{-16}$ ) and DHA ( $p=2.0 \times 10^{-16}$ ), respectively. In genetic analysis, there was a strong association between AA and rs97384 (FADS2, intronic,  $p=1.2 \times 10^{-10}$ ) in the Central America subgroup, and between AA and rs174533 (MYRF, intronic,  $p=1.5 \times 10^{-12}$ ) in the South America subgroup, with 78kb separating the two SNPs (R-squared=0.40 for these two SNPs in 1000G AMR). EPA was associated with rs174536 (MYRF, intronic,  $p=3.09 \times 10^{-24}$ ) in the Mexico subgroup, but did not demonstrate statistically significant associations in other subgroups. **Summary.** Statistically significant differences in LC-PUFA levels and genetic associations were observed across subgroups in the MESA Hispanic cohort, suggesting that certain Hispanic subgroups may have deficiencies in LC-PUFAs.

**3428F**

**Genetic correlation between polypoidal choroidal vasculopathy and age-related macular degeneration.** Q. Fan<sup>1</sup>, C.Y. Cheng<sup>2</sup>, C.P. Pang<sup>3</sup>, K.H. Park<sup>4</sup>, N. Yoshimura<sup>4</sup>. 1) CQM Duke-NUS University, Singapore, Singapore; 2) Singapore Eye Research Institute, Singapore Singapore; 3) Department of Ophthalmology and Visual Sciences, the Chinese University of Hong Kong, Hong Kong, China; 4) Department of Ophthalmology and Visual Sciences, Kyoto University Graduate School of Medicine, Kyoto, Japan; 5) Department of Ophthalmology, Seoul National University Bundang Hospital, Gyeonggi, Korea.

Polypoidal choroidal vasculopathy (PCV) is a subtype of age-related macular degeneration (AMD) and more frequently seen in East Asians. PCV has both common and distinct clinical manifestations with typical neovascular AMD (tAMD). We aim to examine the extent to the shared genetic variants between these two subtypes. We performed the meta-analysis of association in a total of 2,219 PCV and AMD patients and 5,275 controls of East Asian descent from the Genetics of AMD in Asians (GAMA) Consortium. PCV and tAMD are genetically highly correlated ( $r_s = 0.69$ ). A total of eight known loci were significantly associated with PCV, from the SNP-based test and the gene-based tests. Weaker association for PCV was observed at *ARMS2-HTRA1*, compared with tAMD. Variants at *CFH*, *CETP*, and *VEGFA* exhibited different association signals in East Asians, in contrast to those in Europeans. Our data suggest a substantially shared genetic susceptibility for PCV and tAMD.

**3429W**

**Genome-wide haplotype association studies: Comparison of novel methods.** B. Laabs, I.R. König. Institut für Medizinische Biometrie und Statistik, Universität zu Lübeck, Universitätsklinikum Schleswig-Holstein, Campus Lübeck, Lübeck, Germany.

Standard genome-wide association studies (GWAS) based on single SNPs are known not to exploit the entire genetic information, thus possibly missing relevant genetic associations. Important gaps might be filled analyzing multiple SNPs simultaneously by the analysis of genetic interactions or haplotypes. The latter are particularly promising in that a haplotype not only contains the information of the SNPs themselves, but also of their interactions and unmeasured loci between them. One of the disadvantages of haplotype-based GWAS over SNP-based GWAS is that they need preprocessing to be applicable. For example, it is necessary for the most haplotype-based approaches to determine haploblocks which build different haplotypes. Another challenge for haplotype-based GWAS in the past was the handling of rare haplotypes. Most of the older methods avoided the resulting statistical problems by summing up all rare haplotypes in one category. However, especially these rare haplotypes could carry information of rare functional variants. In the last few years a number of new methods for haplotype-based GWAS have been proposed which are able to estimate the association with rare haplotypes. In this contribution, we compare some of the methods which are able to deal with rare haplotypes with regard to the power to detect functional haplotypes. Additionally we use one of the standard approaches (haplo.glm) that pools rare haplotypes using a fixed threshold as reference. We apply these methods to a GWAS data set with given pre-specified haploblocks and compare the findings with the results of earlier studies using haplotype-based GWAS.

**Leveraging biological pathways and gene networks to understand the genetic architecture of diseases and complex traits.** S.S. Kim<sup>1,2</sup>, C. Dai<sup>1</sup>, F. Hormozdiazari<sup>2</sup>, B. Geijn<sup>2</sup>, S. Gazal<sup>2</sup>, Y. Park<sup>1</sup>, L. O'Connor<sup>2</sup>, P. Loh<sup>4</sup>, H. Finucane<sup>2</sup>, A.L. Price<sup>2,3,5</sup>. 1) Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, MA; 2) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 4) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 5) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA.

Recent studies have implicated many biological pathways that are enriched for disease loci and heritability, and have suggested that gene networks can help refine these signals. Here, we constructed a broad set of pathway, network, and pathway+network annotations and applied stratified LD score regression to 42 independent diseases and complex traits (average N=323K) to identify enriched annotations conditioned on all genes and on the baseline-LD model (Gazal et al. 2017 Nat Genet). We constructed annotations from 18,119 known biological pathways, including 100kb windows around each gene. We identified 156 pathway-trait pairs whose enrichment was statistically significant (FDR<5%) after conditioning on all other annotations, a stringent step that greatly reduced the number of pathways detected. These annotations had an average enrichment of 4.13 (s.e. 0.12). Most pathway-trait pairs were previously unreported, such as GABA-A receptor activity for autism, which is consistent with known downregulation of GABA receptors in autism cases. For each of 4 published gene networks, we constructed probabilistic annotations based on closeness centrality, a gene-specific measure of how close a gene is to other genes in the network. Each network annotation was significantly enriched: up to 1.37x (s.e. 0.05), meta-analyzed across traits. The enrichments were fully explained by correlations between network annotations and regulatory annotations from the baseline-LD model, validating the baseline-LD model and demonstrating the importance of accounting for regulatory annotations in gene network analyses. For each of the 156 enriched pathway-trait pairs, we constructed pathway+network annotations reflecting all-new sets of candidate genes linked to the input pathway via the input gene network, by applying a machine learning method that leverages topological patterns and network centrality metrics (Li et al. 2018 Nat Methods). For each of 4 gene networks, these pathway+network annotations were significantly enriched for the corresponding traits: up to 1.36 (s.e. 0.02), averaged across 156 pathway-trait pairs. The pathway+network enrichments were significant conditional on network annotations, but were largely explained by regulatory annotations from the baseline-LD model. In conclusion, both biological pathways and gene networks can be highly informative for disease and trait architectures, but the information in gene networks may be subsumed by regulatory annotations.

**Previously ignored high-frequency common variants greatly contribute to heritability of a common disease.** Y. Nagao<sup>1,2</sup>. 1) Department of Clinical Genetics, Tokai University, Isehara, Kanagawa, Japan; 2) Department of Pediatrics, Takashimadaira Chuo General Hospital, Itabashi, Tokyo, Japan.

Genome-wide association studies are also called common variant association studies because almost all the identified single nucleotide polymorphisms belong to common variants. In the conventional studies the estimation of heritability for a disease was performed for the sets of variants with an assumption that each allele of a variant shows a co-dominant effect, and variants had been classified by minor allele frequency (MAF). In the published report I showed a method to calculate heritability of an individual polymorphism ( $h_p^2$ ). Here I estimate  $h_p^2$  of a variant that acts in three different manners; a co-dominant, a dominant and a recessive manner, utilizing the method. The results suggest that  $h_p^2$  of a high-frequency common variant ( $p > 0.5$ ) is too high to be ignored. Especially high-frequency variants which act in a recessive manner have the highest  $h_p^2$  among all the variants with same odds ratio (OR). In the conventional studies a high-frequency variant had been treated as a variant that has a MAF of another allele and a reciprocal of OR, and it is thought that such variants account for about half of the total. However, contribution of variants to heritability had been evaluated only for those with OR larger than 1.0. A trial calculation of heritability for schizophrenia when considering high-frequency common variants suggest that it is estimated 1.7 times the conventional heritability explained by common variants. Missing heritability might be solved by re-examining previously ignored variants, i.e., those with OR less than 1.0 when classified by MAF. .

## 3432W

**Reconciling S-LDSC and LDAK models and functional enrichment estimates.** *A.L. Price<sup>1,2,3</sup>, S. Gazal<sup>1,2</sup>, H.K. Finucane<sup>2</sup>*. 1) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 3) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA.

Recent work has highlighted the importance of accounting for LD-dependent genetic architectures in analyses of functional components of heritability, motivating the development of the LDAK model and the baseline-LD model used by S-LDSC. Although both models include LD-dependent effects, they produce different estimates of functional enrichment, e.g. 9.35x ( $\pm 0.80$ ) enrichment for conserved regions using baseline-LD (Gazal et al. 2017 Nat Genet; average  $N=96K$ ) vs. 1.34x ( $\pm 0.26$ ) using LDAK (Speed et al. 2017 Nat Genet; average  $N=7K$ ). Here, we perform formal model comparisons and empirical analyses using a combined model to reconcile these findings. We performed model comparisons using a likelihood approach. We compared an infinitesimal model with no LD-dependent effects ("GCTA model"), the LDAK model, and the baseline-LD model. For 16 highly heritable UK Biobank traits, we computed likelihoods using  $N=20K$  samples and either  $M=2.8M$  imputed 1000G SNPs or  $M=4.7M$  imputed HRC SNPs, using enrichment parameters that we fitted (where applicable) using a disjoint set of samples. In the  $M=2.8M$  analysis, LDAK outperformed GCTA (change in log likelihood ( $\Delta LL$ )=334), consistent with Speed et al. 2017; however, in the  $M=4.7M$  analysis, GCTA slightly outperformed LDAK ( $\Delta LL=15$ ). Baseline-LD outperformed LDAK in both analyses ( $\Delta LL \geq 644$ ), with  $\Delta LL > 0$  for at least 15/16 traits. We obtained similar results for a model including only the LD and MAF annotations from baseline-LD ( $\Delta LL \geq 439$  vs. LDAK) and for a model combining baseline-LD annotations with annotations constructed using LDAK weights (baseline-LD+LDAK;  $\Delta LL \geq 761$ ). Model comparisons based on accuracy of out-of-sample polygenic predictions computed using each model as a prior (Marquez-Luna et al. ASHG abstract) produced similar findings. We determined that S-LDSC with the baseline-LD+LDAK model (unlike baseline-LD or LDAK) produces unbiased estimates in simulations both under the LDAK model and under the baseline-LD model. In analyses of 16 UK Biobank traits and 28 main functional annotations, functional enrichment estimates obtained using baseline-LD+LDAK (e.g. 7.51x ( $\pm 0.49$ ) for conserved regions) were not significantly different from those obtained using baseline-LD (e.g. 8.11x ( $\pm 0.54$ )), but were significantly larger than those obtained using LDAK (e.g. 2.62x ( $\pm 0.17$ )). Our results support the use of the baseline-LD model and confirm the existence of functional annotations that are highly enriched for complex trait heritability.

## 3433T

**Distinguishing maternal and fetal contribution to the heritability – a novel approach for complex pregnancy and early fetal phenotypes.** *A.K. Srivastava<sup>1,2</sup>, J. Juodakis<sup>3</sup>, J. Bacelis<sup>4</sup>, J. Chen<sup>5</sup>, K. Teramo<sup>6</sup>, M. Hallman<sup>7</sup>, B. Jacobsson<sup>8,9</sup>, L.J. Muglia<sup>1,2</sup>, G. Zhang<sup>1,2</sup>*. 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 2) Center for Prevention of Preterm Birth, Perinatal Institute, Cincinnati Children's Hospital Medical Center and March of Dimes Prematurity Research Center Ohio Collaborative, Cincinnati, OH, USA; 3) Department of Obstetrics and Gynecology, Institute of Clinical Sciences, Gothenburg, Sweden; 4) Department of Obstetrics and Gynecology, Sahlgrenska University Hospital Östra, Gothenburg, Sweden; 5) Division of Bioinformatics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 6) Obstetrics and Gynecology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; 7) PEDEGO Research Unit and Medical Research Center Oulu, University of Oulu and Department of Children and Adolescents, Oulu University Hospital, Oulu, Finland; 8) Department of Obstetrics and Gynecology, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden; 9) Department of Genetics and Bioinformatics, Area of Health Data and Digitalization, Norwegian Institute of Public Health, Oslo, Norway.

The last decade has witnessed several technical and theoretical advances towards solving the mystery of missing heritability for various complex traits/diseases. However, pregnancy outcomes such as gestational age and fetal growth measures at birth, conjointly defined by maternal and fetal genomes attained restricted expedition – possibly due to lack of appropriate approaches to avoid confounding by shared alleles between mother and fetus. Here, we propose a novel approach of treating mother-fetus pairs as a single analytical unit composed of three alleles - maternal transmitted, maternal non-transmitted and paternal transmitted. We generate three separate relatedness matrices using only maternal transmitted alleles, only maternal non-transmitted alleles and only paternal transmitted alleles. We fit the relatedness matrices concurrently in linear mixed model to identify the additive genetic variance attributed to each of three components. We test the validity and robustness of the approach using simulated genotype and phenotype data. Further, we apply the approach on empirical dataset (~6000 mother-fetus pairs) to estimate the heritability of gestational age and fetal anthropometric traits at birth. The study suggests that narrow-sense heritability of gestational age is mainly attributed to maternal transmitted (12.9%) and non-transmitted (10%) alleles whereas paternal transmitted alleles have negligible contribution to its heritability. On the contrary, narrow-sense heritability of fetal birth weight and birth length are mainly owed to maternal transmitted alleles (10-15%) whereas maternal non-transmitted and paternal transmitted alleles have negligible contribution. Further, this method can be extended to trios by fitting an additional relatedness matrix into the model, generated from paternal non-transmitted alleles. Our method provides an advancement to existing methods for the heritability estimation and detect explicit contributions of maternal and fetal alleles for duos and also, paternal alleles for trios.

**Assessment of genome-wide significance of conditionally independent signals.** S. Ghasemi<sup>1,2</sup>, A. Teumer<sup>1,2</sup>, T. Becker<sup>1</sup>. 1) Institute for Community Medicine, University Medicine Greifswald, Greifswald, Germany; 2) DZHK (German Center for Cardiovascular Research), partner site Greifswald, Greifswald, Germany.

The presence of multiple independently associated SNPs within the same linkage disequilibrium (LD) region is a common phenomenon. In contrast to tests for primary association, conditional tests should not be applied on a genome-wide scale but are limited to the genomic regions surrounding primary GWAS index signals. Therefore, the established genome-wide significance level  $\alpha = 5 \times 10^{-8}$  in conditional analyses is too strict and implies an unnecessary loss of power to detect secondary signals. We developed a "quasi-adaptive" method not only to take into account the reduced number of tests but to use  $R^2$  and physical distance LD ( $R^2$ , D) to the index SNP to prioritize surrounding SNPs for analysis. In this regard first, we identify surrounding LD region for each index SNP, then compute  $R^2$  and physical distance D with the index SNP for each SNP, and construct a general priority function  $f = f(R^2, D)$ . Next, for each candidate SNP, we compute conditional p-values with GCTA. Our conditional analysis controls family-wise error rate at  $\alpha = 0.05$ . We spend this amount of  $\alpha$  level over the candidate SNPs from the LD regions. The distribution, however, is not even. Instead, SNPs with higher priority will get a higher  $\alpha$  value. To this purpose, we use a distribution function  $G = G(\alpha, f)$  which assigns to each SNP its SNP-specific  $\alpha$ -threshold. Finally, for each SNP, the GCTA p-values are compared to the SNP-specific  $\alpha$ -threshold, in order to assess significance. In essence, SNPs with higher priority have to meet less stringent alpha-levels, or, in other words, more alpha is spent on SNPs with higher priority. As a proof-of-concept, we applied our method on a GWAS on thyroid-stimulating hormone (TSH) using the SHIP cohort ( $n = 3603$ ) focusing on four published associations (Rawal *et al.* 2012): (PDE8B, CAPZB, NR3C2, LOC440389). We could find the signal rs16956373 genome-wide conditionally independent significant for the index SNP rs3813582 (LOC440389) that would not have been found with the standard approach (i.e. requiring  $\alpha = 5 \times 10^{-8}$ ). We developed an algorithm with increased power for detecting secondary SNP signals and applied it successfully to a GWAS. Ongoing steps include replication of the findings in a larger GWAS and a simulation study to assess the overall experiment-wise type I error of our method.

**A GWAS and candidate gene study for maternal nondisjunction of chromosome 21.** J.M. Chernus<sup>1</sup>, E.G. Allen<sup>2</sup>, Z. Zeng<sup>3</sup>, E.R. Hoffmann<sup>4</sup>, T.J. Hassold<sup>5</sup>, E. Feingold<sup>1,3</sup>, S.L. Sherman<sup>2</sup>. 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA, USA; 3) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 4) Center for Chromosome Stability, University of Copenhagen, Copenhagen, Denmark; 5) School of Molecular Biosciences and Center for Reproductive Biology, Washington State University, Pullman, WA, USA.

Maternal meiotic nondisjunction is the leading cause of human pregnancy loss, birth defects, and intellectual disabilities. Known risk factors include increasing maternal age and altered patterns of meiotic recombination. To better understand the genetic components of risk and the processes underlying errors in meiosis, we conducted the first genome-wide association study of maternal nondisjunction of chromosome 21. Our study group consisted of 2,186 participants genotyped on an Illumina SNP array, comprising 749 live-born children with standard, maternally-derived trisomy 21 and 1,437 of their parents. First, within each family, genotypes of the parents and child were used to determine the maternal origin of the trisomy and the stage of meiosis in which nondisjunction occurred (meiosis I (MI) or meiosis II (MII)). As our previous work has suggested that MI and MII nondisjunction may differ in etiology, we performed a novel set of four genome-wide scans designed both to identify variants associated with nondisjunction in either stage of meiosis and to distinguish variants with an effect specific to just one stage. In addition to annotating GWAS signals, we also investigated candidate genes and loci linked to chromosome dynamics during meiosis and loci associated with genome-wide recombination counts in humans. The candidate gene study showed statistically significant associations, including *RAD21L1*, *SMEK1*, *SYCP1*, *SYCP2*, *SYCE2*, and *MND1*. In the genome-wide studies, several suggestive ( $p < 10^{-5}$ ), but not genome-wide significant, associations were observed in or near genes with plausible roles in relevant meiotic processes, such as *SLC39A10* (involved in zinc homeostasis, crucial to mouse oocyte maturation) and *MYO10* (thought to be required for meiotic cytokinesis). These results suggest for the first time that common variation in genes responsible for normal meiotic processes confers risk for nondisjunction.

**3436T****Dissecting the causal relationship between maternal phenotypes and birth outcomes: A genetic score analysis in mother/infant pairs.** J. Chen<sup>1</sup>, A. Srivastava<sup>2,3</sup>, J. Bacelis<sup>4</sup>, J. Juodakis<sup>5</sup>, K. Teramo<sup>6</sup>, M. Hallman<sup>7</sup>, B. Jacobsson<sup>8,9</sup>, L. Muglia<sup>2,3</sup>, G. Zhang<sup>2,3</sup>.

**Background:** This study aimed to investigate the causal mechanisms underlying the observed associations between maternal phenotypes and birth outcomes using a parental-specific genetic score approach. **Methods and Findings:** We conducted a genetic score analysis using phenotype and genome-wide single nucleotide polymorphism (SNP) data of 8,067 mother/infant pairs from multiple birth cohorts collected from European countries and the United States. We built genetic scores using SNPs known to be associated with adult height, BMI, blood pressure and blood glucose level to index these maternal phenotypes respectively. To avoid the interference in causal inference due to the transmission of maternal alleles, we inferred parental transmission of the SNPs and constructed parental-specific haplotype genetic scores. Our haplotype-based genetic score association analysis showed that maternal non-transmitted haplotype score of height was significantly associated with longer gestational duration ( $P=9.5E-5$ ), larger birth weight ( $P=1.3E-6$ ) and birth length ( $P=7.4E-3$ ); but the latter two birth size measures were more significantly associated with maternal and paternal transmitted height scores (all  $P<1E-12$ ). Our results also showed that maternal transmitted BMI score was associated with birth weight ( $P=6.4E-4$ ). In addition, both the maternal transmitted and the paternal transmitted haplotype scores of blood pressure were significantly associated with reduced birth weight ( $P = 2.3E-3$  and  $1.4E-3$ , respectively), suggesting genetic variants associated with blood pressure have direct genetic effects in the fetuses. In contrast, the maternal non-transmitted haplotype score of blood glucose was significantly associated with increased birth weight ( $P = 3.2E-5$ ) while the paternal transmitted haplotype score of blood glucose was significantly associated with decreased birth weight ( $P = 2.5E-2$ ) indicating that the birth weight is positively causal influenced by the maternal blood glucose level but negatively influenced by blood glucose increasing alleles carried by the fetuses. **Conclusions:** Our results confirmed the causal impact of maternal height on gestational duration and also demonstrated the strong causal effect of maternal blood glucose level on fetal growth. In addition, our results also showed that genetic variants associated with adult height, BMI, glucose, and blood pressure have various direct genetic effects on fetal growth.

**3437F****Exploring the effect of parental height on a newborn's birth weight.** Y. Lee<sup>1</sup>, H. Gjessing<sup>1,2</sup>, A. Jugessur<sup>1,2</sup>, P. Magnus<sup>1</sup>. 1) Norwegian Institute of Public Health, Oslo, Norway; 2) University of Bergen, Bergen, Norway.

Parental height and newborn's birth weight are associated. To understand the underlying etiology, we used parental polygenic risk scores for height as instrumental variables. Genotype data from 10,496 complete newborn parent trios were available from the 'HARVEST' study, which is part of the Norwegian Mother and Child Cohort Study. We identified 697 SNPs in HARVEST that were genome wide significant ( $p<5\times 10^{-8}$ ) for height, and these were used to generate a polygenic risk score (PRS). The birth weight (gram) of newborns was extracted from the Medical Birth Registry of Norway. Two stage least square regression was used, with and without adjusting for the newborn's own PRS. The effect of mother's height (cm) on newborn's birth weight (gram) with and without adjustment for the newborn's own PRS for height were 12.1 (95% CI: 7.7, 16.5) and 20.5 (95% CI: 16.9, 24.1) respectively. The father's height also increased the newborn's birth weight (12.8; 95% CI: 9.3, 16.2), but this effect substantially decreased after adjusting for newborn's PRS (3.3; 95% CI: -0.8, 7.3). Maternal height increases newborn's birth weight independently of the newborn child's PRS. By contrast, the effect of paternal height was attenuated after adjusting for the newborn child's PRS. These results, with some assumptions, suggest that maternal height is causally related to fetal growth.

**Examining the role of reverse causality in Mendelian randomization.** *S.M. Lutz<sup>1</sup>, J.E. Hokanson<sup>1</sup>, C. Lange<sup>2</sup>*. 1) University of Colorado, Anschutz, Aurora, CO; 2) Harvard T.H. Chan School of Public Health, Boston, MA.

In the past few years, Mendelian Randomization (MR) has gained in popularity as a tool to examine if a phenotype of interest causes the outcome by using Single Nucleotide Polymorphisms (SNPs) as instrument variables for the phenotype of interest. MR assumes that the only path from the SNPs to the outcome is through the phenotype of interest (i.e. no pleiotropic relationships exist). Although, it is not always known which variable is the phenotype of interest and which variable is the outcome. For instance, if an investigator wants to use MR to examine the role of depression on BMI, it is not clear if BMI causes depression or if depression causes a change in BMI. In a scenario like this, investigators have run the MR analysis twice: 1) with BMI as the phenotype of interest and depression as the outcome and 2) with depression as the phenotype of interest and BMI as the outcome. It is not clear how reverse causality influences the type 1 error rate for MR, especially in the presence of pleiotropy. Through simulation studies, we examined the type 1 error rate for 4 popular MR methods when the role of the intermediate phenotype and outcome were reversed (i.e. reverse causality) with and without a pleiotropic relationship of at least one SNP on the outcome. When there is a pleiotropic relationship with at least one SNP and the outcome, the type 1 error rate is inflated for all MR approaches in the scenario of reverse causation. We apply this approach to the COPDGene study, a case-control study of Chronic Obstructive Pulmonary Disease (COPD) in current and former smokers to examine the role of methylation and cigarette smoking.

**3439T**

**A Mendelian randomization study detects the distortive effects of health-related traits on food frequency questionnaire responses.** *C. McDonnell<sup>1</sup>, E.J. Grzeszkowiak<sup>1</sup>, J.F. Wilson<sup>1,2</sup>, N. Pirastu<sup>1</sup>*. 1) Centre for Global Health Research, Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Teviot Place, Edinburgh, Scotland, EH8 9AG; 2) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, Scotland, EH4 2XU.

**Background** Nutrition is an important contributor to the development of obesity and chronic disease. Carrying out nutritional research is, however, difficult due to known bias in dietary questionnaires caused by misreporting of food intake by people with particular health conditions. Measuring this bias is challenging because it requires knowledge of true food consumption that is difficult to obtain in a large study. Our aim was to verify if measuring this bias is possible using Mendelian randomization to test the effect of BMI on reported food consumption. **Methods** We created genetic instruments for several exposures for which dietary advice is usually given (body mass index, LDL, HDL, & total cholesterol, diastolic and systolic blood pressure and triglycerides), by LD pruning of publicly available summary statistics. We ran association analysis of the selected traits on the FFQ traits available in UK Biobank ( $n \sim 500,000$ ) to use as outcomes. After removing SNPs with heterogeneous effects, MR was conducted with an inverse variance-weighted method or with MR Egger regression if the intercept of the regression was significantly different from zero. **Results** We identified significant results suggesting a causal effect of all health-related trait exposures on food intake. We report Benjamini & Hochberg-corrected p-values. Individuals genetically predisposed to a higher BMI reported lower: beef intake ( $p=1.4 \times 10^{-3}$ ), fat content of milk ( $p=1.2 \times 10^{-36}$ ) and addition of spread to bread ( $p=8.4 \times 10^{-16}$ ), whilst reported increased intake of fresh fruit ( $p=8.5 \times 10^{-4}$ ) and salad ( $p=5.3 \times 10^{-4}$ ). We detected a similar pattern for total and LDL cholesterol, with individuals with genetically raised lipids reporting lower beef ( $p=5.0 \times 10^{-2}$ ,  $p=5.7 \times 10^{-3}$ ), fat content of milk ( $p=5.7 \times 10^{-28}$ ,  $p=5.7 \times 10^{-28}$ ), addition of spread to bread ( $p=7.9 \times 10^{-4}$ ,  $p=1.9 \times 10^{-3}$ ), along with cheese ( $p=3.8 \times 10^{-10}$ ,  $p=2.4 \times 10^{-9}$ ) and salt intake ( $p=7.3 \times 10^{-6}$ ,  $p=6.2 \times 10^{-6}$ ). There was an increased reporting of fresh fruit ( $p=6.9 \times 10^{-4}$ ,  $p=7.6 \times 10^{-5}$ ) and salad ( $p=9.1 \times 10^{-3}$ ,  $p=4.8 \times 10^{-2}$ ). Additionally, those with higher diastolic blood pressure reported a lower salt intake ( $p=3.0 \times 10^{-2}$ ). **Conclusion** Our results suggest that the studied exposures are indeed influencing the reported food consumption. This corresponds with previous epidemiological studies on FFQ reporting but for the first time, we can give an estimate of this bias using a large sample size. This will be important for correctly estimating food-health relationships.

**Phenome-wide Mendelian randomization study mapping the influence of the plasma proteome on complex diseases.** J. Zheng<sup>1</sup>, V. Haberland<sup>1</sup>, D. Baird<sup>1</sup>, A. Gutteridge<sup>2</sup>, J. Dopierala<sup>2</sup>, J. Staley<sup>1</sup>, B. Sun<sup>4</sup>, J. Danesh<sup>4</sup>, H. Runz<sup>3</sup>, J. Maranville<sup>3</sup>, A. Butterworth<sup>3</sup>, J. Yarmolinsky<sup>3</sup>, B. Elsworth<sup>1</sup>, C. Laurin<sup>1</sup>, V. Walker<sup>1</sup>, J. Liu<sup>3</sup>, K. Estrada<sup>3</sup>, M. Nelson<sup>3</sup>, P. Haycock<sup>1</sup>, G. Davey Smith<sup>1</sup>, G. Hemani<sup>1</sup>, R. Scott<sup>2</sup>, T. Gaunt<sup>2</sup>. 1) MRC Integrative Epidemiology Unit, Bristol Medical School, University of Bristol; 2) Glaxosmithkline, Gunnels Wood Road, Stevenage, Hertfordshire, SG1 2NY, UK; 3) Biogen, 225 Binney Street, Cambridge, MA 02142; 4) MRC/BHF Cardiovascular Epidemiology Unit, Department of Public Health and Primary Care, University of Cambridge, Cambridge CB1 8RN, UK; 5) Celgene, 1 Longwalk Rd, Hayes, Uxbridge UB11 1DB.

Drug development is a lengthy, expensive process beset by high failure rates due to lack of efficacy or adverse safety signals. As such, approaches to predict safe and effective targets as early as possible in the drug development process are much needed. Genetic analysis of the plasma proteome provides a promising opportunity to validate novel or existing targets through prediction of efficacy or potential adverse effects and by guiding target-indication pairing. Here, we performed two sample Mendelian randomization (2SMR) to map the putative causal effects of thousands of plasma proteins against hundreds of human diseases. Combining GWAS summary data from four protein quantitative trait locus (pQTL) studies, we identified 1,449 plasma proteins with genetic instruments. To increase reliability of the instruments, we focused on those with no strong evidence of heterogeneity across studies and performed 2SMR of each protein on 130 diseases in MR-Base (163,604 tests, Bonferroni-corrected P threshold of  $3.05 \times 10^{-7}$ ). For MR results that reached statistical significance, we further evaluated the findings by performing colocalization analysis to investigate whether the pQTL was also likely to be driving or in linkage disequilibrium with a distinct disease association. All analyses were performed in the TwoSampleMR and coloc R packages. Using 2SMR, we observed 866 associations across 105 diseases, 395 of which remained promising after heterogeneity test of instruments across pQTL studies and colocalization analysis. For example, MR using two independent cis-acting SNPs (rs11581607 and rs3762318) showed that reduced *interleukin 23 receptor* (IL23R) level was associated with decreased risk of inflammatory bowel disease (IBD) (OR=0.37, 95%CI=0.34 to 0.40,  $P=1.92 \times 10^{-143}$ ). Colocalization analysis suggested both traits shared the same causal variants. An existing IL23R antagonist, Ustekinumab, demonstrated efficacy in reducing Crohn's disease activity index in a phase 2 trial, and is currently in phase 3 trials for IBD ([www.clinicaltrials.gov](http://www.clinicaltrials.gov)). Our study identified thousands of putatively causal associations between the plasma proteome and the human phenome. These associations are necessary but not sufficient to prove causality, as potential horizontal pleiotropy remains an alternative explanation. We will release the MR and colocalization analysis results to the public. We are further exploring the translational value of our findings for drug discovery and development.

Despite the call for X-inclusive whole-genome association scans in 2013 (Wise et al.), to date it is yet to be a common practice presumably due to the additional analytic complexities. Several statistical methods have been developed, each of which only partially address the X-chromosome considerations. For example, some allow for sex-specific allele frequencies, while others are designed to handle the possibility of random, skewed or no X-inactivation. Assumption of additivity, choice of reference allele and sex-by-SNP interaction analysis have received little attention to date. Through theoretical justifications, simulation and application results, we provide a unified regression-based framework that simultaneously resolves these X-chromosome issues. Unlike the autosomes, we show that the choice of reference allele can impact X-chromosome inference if sex-specific effects are not accounted for in an analysis. Further, the current standard practice that models the main effect of a SNP assuming additivity can be called into question. Adding a dominant term (equivalent to using the genotypic model) increases the degrees of freedom (d.f.), and is in general avoided due to expected power loss if the additivity assumption is true or approximately so. Yet, if the absolute power loss is low in comparison to the potential power gain in the presence of non-additivity, genotypic models should be revisited. Likewise, modeling SNP-sex interaction comes at the cost of increased d.f., but may be crucial for X-chromosome analysis. For autosomes, we show analytically that under an additive model, compared with the classical 1 d.f. additive test, the maximum power loss of the 2 d.f. test is capped at 11.4%, regardless of the sample size, genetic effect size and the significance alpha level. With departure from additivity, the power gain can be more than 40%. Similarly, for analysis of the X-chromosome, with a 3 d.f. test that includes a sex-by-SNP interaction term, power loss is capped at 18.8% while the gain can be as high as 60%. Theoretical insights demonstrate why the proposed 3 d.f. regression-based test addresses all the aforementioned X-chromosome analytic complexities. In a sample of over 7,000 individuals with cystic fibrosis from the International CF gene modifier consortium, application of this approach to a new X-inclusive whole-genome scan of meconium ileus provides compelling empirical corroboration.

**A genome wide association study on next-generation sequencing profiled plasma miRNA levels.** M. Roux<sup>1,2</sup>, F. Thibord<sup>1,2</sup>, C. Perret<sup>1,2</sup>, M. Ibrahim<sup>3,4</sup>, L. Goumidi<sup>4</sup>, P. Suchon<sup>3,4</sup>, M. Germain<sup>3,4</sup>, J-F. Deleuze<sup>5</sup>, P-E. Morange<sup>3,4</sup>, D-A. Trégouët<sup>1,2</sup>, GENMED consortium. 1) Sorbonne Universités, Université Pierre et Marie Curie (UPMC Univ Paris 06), Institut National pour la Santé et la Recherche Médicale (INSERM), Unité Mixte de Recherche en Santé (UMR\_S) 1166, Team Genomics & Pathophysiology of Cardiovascular Diseases, 75013 Paris, France, 75013 Paris, France; 2) Institute for Cardiometabolism and Nutrition (ICAN), 75013 Paris, France; 3) Laboratory of Haematology, La Timone Hospital, Marseille, France; 4) Institut National pour la Santé et la Recherche Médicale (INSERM), Unité Mixte de Recherche en Santé(UMR\_S) 1062, Nutrition Obesity and Risk of Thrombosis, Center for CardioVascular and Nutrition research (C2VN), Aix-Marseille University, Marseille, France; 5) Centre National de Recherche en Génomique Humaine (CNRGH), Direction de la Recherche Fondamentale, CEA, Institut de Biologie François Jacob, Evry, France.

There is now established evidence that circulating miRNAs can be used as reliable biomarkers for human diseases. The identification of genetic variants that influence levels of circulating miRNAs in the context of miRNA Quantitative Trait Loci (miQTL) can help to better decipher the miRNAs dependent pathophysiological mechanisms. As part of the MARTHA study, we profiled 334 samples for plasma miRNA levels using a next generation sequencing technology and sought for single nucleotide polymorphisms (SNPs) associated with plasma levels of the detected miRNAs. After the application of a complete bioinformatics workflow on sequenced data to detect and quantify miRNAs, 120 miRNAs were found highly expressed in MARTHA plasma samples. Each of these miRNAs underwent a Genome Wide Association Study scan and were tested for association with 6,395,990 imputed (imputation criterion  $r^2 > 0.4$ ) SNPs with minor allele frequency greater than 0.05. Five SNP x miRNA association signals reached the pre-specified  $5 \cdot 10^{-8}$  threshold for declaring statistical significance. Two of them were cis effects involving hsa-miR-625-3p ( $p = 7.8 \cdot 10^{-16}$ ) and hsa-miR-941 ( $p = 1.1 \cdot 10^{-14}$ ) that had been previously reported in a miQTL study on whole blood. The remaining 3 associations were never reported trans miQTL effects. One miQTL effect was observed between a *CCSER1* coding SNP and hsa-miR-30e-3p ( $p = 1.0 \cdot 10^{-6}$ ). The two other miQTL associations involved hsa-miR-182-5p whose plasma levels were influenced by intronic SNPs in *KIRREL3* ( $p = 1.7 \cdot 10^{-6}$ ) and in *DOCK8* ( $p = 3.8 \cdot 10^{-6}$ ). Replication and in silico investigation of these 3 trans miQTL associations are ongoing.

**The influence of mitochondrial DNA variation on complex traits.** E.J. Grzeszkowiak<sup>1</sup>, D.W. Clark<sup>1</sup>, P.R.H.J. Timmers<sup>1</sup>, P.K. Joshi<sup>1</sup>, N. Pirastu<sup>1</sup>, J.F. Wilson<sup>1,2</sup>. 1) Centre for Global Health Research, Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Teviot Place, Edinburgh, UK; 2) MRC Human Genetics Unit, MRC Institute of Genetics & Molecular Medicine, University of Edinburgh, Edinburgh, UK.

Mitochondrial DNA (mtDNA) is one of the least studied parts of human genome, yet exhibits abundant genetic variation, some of which is structured among ethnic groups. MtDNA is involved in numerous rare Mendelian disorders and some research points to the influence of mtDNA on the regulation of lipid levels. However, the impact of mtDNA variation on complex traits remains largely unexplored. We have conducted an association study between mtDNA variation and a number of quantitative traits in 5 ethnicities comprising ~480,000 men and women. 265 markers have been used to infer haplogroups for each participant. ANOVAs were performed separately on each ethnic group for over 70 phenotypes spanning a wide range of health and anthropometric traits and then meta-analysed. Among many others, we detected a significant association with lifespan. We have also performed an mtWAS analysing all 265 genotyped markers as well as those we imputed using the haplogroup assignments. Our results suggest that mtDNA may play a significant and previously under-estimated role in complex traits and a further study utilising WGS and additional cohorts and ethnicities may be needed to determine if some of the population-specific associations are due to downstream variants whose frequencies differ among populations.

**The genetics of food and drink consumption and correlation with health-related traits.** *N. Pirastu<sup>1</sup>, E.J. Grzeszkowiak<sup>1</sup>, N. Taba<sup>2</sup>, C. McDonnell<sup>1</sup>, M.P Concas<sup>3</sup>, L. Repetto<sup>4</sup>, K. Kentistou<sup>1</sup>, A. Robino<sup>3</sup>, X. Shen<sup>1,4</sup>, T. Esko<sup>2,5</sup>, K. Fisher<sup>2</sup>, J.F. Wilson<sup>1,6</sup>.* 1) Centre for Global Health Research, Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Teviot Place, Edinburgh, EH8 9AG, Scotland; 2) Institute of Genomics, University of Tartu, Tartu, Riia 23b, 51010, Estonia; 3) Institute for Maternal and Child Health - IRCCS "Burlo Garofolo", Trieste, Italy; 4) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Nobels väg 12A, SE-171 77 Stockholm, Sweden; 5) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 6) MRC Human Genetic unit, Institute of Genetic and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, EH4 2XU, Scotland.

Several studies have shown that food and drink consumption have a considerable heritable component. With the exception of coffee and alcohol, identifying the genetic variants which are responsible has proven extremely difficult. Here, we conduct genome-wide association on consumption of coffee, alcohol, three genetically-determined food groups (meat, healthy foods and bread & cheese), adding salt to food and preferred drink temperature using food frequency questionnaire data from up to 334,162 subjects in UK Biobank. We identify 226 significant associations corresponding to 134 independent genomic loci, many of which are pleiotropic and 122 of which are completely novel. Several of the loci have been previously linked to numerous late-onset diseases, e.g. *HLA-DQA1*, *APOE*, *NEGR1*, *MC4R*, *GCKR* and *FTO*. Polygenic scores successfully predict food and drink consumption in the Estonian Biobank, validating our findings. Multivariate genetic regression suggests that dietary genetics shows strong genetic correlations with a spectrum of complex traits including obesity, cognition, cancer, personality and lifespan. Gene-set enrichment analyses reveal food choice genes to be preferentially upregulated in the brain and adipose tissue. Stratified LD-score regression shows significant correlation with brain areas involved in the reward system. Finally, clustering the genes previously associated with BMI based on their effects on food reveals groups of genes with specific dietary influences, giving new insights into their roles and the mechanisms underlying obesity and other diseases.

**Hepatic gene expression and DNA methylation associates with African ancestry: Uncovering the role of the genome in disease disparities in African Americans.** *C.S. Park<sup>1</sup>, Y. Xu<sup>2</sup>, Y. Zhong<sup>1</sup>, C. Alarcon<sup>1</sup>, T. De<sup>1</sup>, M.A. Perera<sup>1</sup>.* 1) Northwestern University, Chicago, IL; 2) University of Chicago, Chicago, IL.

African Americans (AAs) suffer disproportionately from many diseases and have major differences in hepatic drug metabolism and drug response compared to other populations. As an admixed population, AAs have varying proportions of African and European ancestry. To uncover whether ancestry may explain variabilities in gene expression and thus inform health disparities in AAs, we investigated whether hepatic gene expression and DNA methylation are associated with the degree of African ancestry. We performed genome-wide genotyping, RNA sequencing, and profiled the DNA methylation states of 60 AA-derived primary hepatocytes. In the 64 PharmGKB "very important pharmacogenes" – genes with extensive literature support for association to drug responses – we identified six genes, VDR ( $p = 0.041$ ), PTGIS ( $p = 0.030$ ), NR112 ( $p = 0.043$ ), ALDH1A1 ( $p = 0.0095$ ), ADH1B ( $p = 0.047$ ) and ADH1C ( $p = 0.045$ ), that were significantly associated with African ancestry. We replicated the association of Vitamin D Receptor (VDR) to African ancestry in an independent GTEx liver dataset, such that for every 1% increment in African ancestry, there is a corresponding 1.2% decrement in VDR gene expression. Genome-wide analysis identified 32 genes significantly associated with African ancestry ( $FDR < 0.05$ ). They include genes in coagulation and cardiovascular pathways that are dysregulated in diseases that disproportionately afflict AAs, including ALDH1A1, APOL1, GGT1, NPR2 and PTGIS. In our DNA methylation data, we identified 27,188 significant differentially methylated (DM) CpG sites (BH-adjusted  $p$ -value  $< 0.05$ ) corresponding to 1459 significant DM regions (BH-adjusted  $p$ -value  $< 0.05$ ) associated with greater African ancestry. Notably, and consistent with their gene expression profiles, VDR was identified as a PharmGKB gene that had higher methylated CpG sites with greater African ancestry while ALDH1A1, GGT1 and NPR2 had reduced methylation. Vitamin D is an exogenous hormone created by sun exposure or through diet, with established deficiencies in both Vitamin D and its bioactive metabolites in AAs. Consequently, VDR polymorphisms have been implicated in asthma, cardiovascular diseases and various cancer susceptibilities in AAs as well as peginterferon  $\alpha$ -2b response in hepatitis C. Likewise, APOL1 has been strongly associated with kidney disease exclusively in AAs. These findings suggest that ancestry may be as important a predictor of disease and drug response in AAs as known biomarkers.

**3446F****NAT2 genetic variants and toxicity related to anti-tubercular agents:**

**A systematic review and meta-analysis.** M. Richardson<sup>1</sup>, J. Kirkham<sup>1</sup>, K. Dwan<sup>2</sup>, D. Sloan<sup>3</sup>, G. Davies<sup>4</sup>, A. Jorgensen<sup>1</sup>. 1) Department of Biostatistics, University of Liverpool, United Kingdom; 2) Cochrane Editorial Unit, London, United Kingdom; 3) School of Medicine, University of St Andrews, United Kingdom; 4) Department of Clinical Infection, Microbiology and Immunology, University of Liverpool, United Kingdom.

**Background** Tuberculosis patients receiving anti-tuberculosis treatment may experience serious adverse drug reactions, such as hepatotoxicity. Genetic variants of the *NAT2* gene may increase the risk of experiencing such toxicity events. This systematic review and meta-analysis provides a comprehensive evaluation of the evidence base for associations between *NAT2* genetic variants and anti-tuberculosis drug-related toxicity. The scope of our review is wider than those previously conducted, as we considered associations between all *NAT2* genetic variants (including individual *NAT2* SNPs as well as acetylator phenotypes) and all anti-tuberculosis drug-related toxicity outcomes. Our review and meta-analysis therefore updates and adds to the existing evidence base on associations between *NAT2* genetic variants and anti-TB drug-related toxicity. **Methods** Our review was conducted in line with methods outlined in our protocol (PROSPERO number: CRD42017068448). We searched for studies in Medline, EMBASE, BIOSIS and Web of Science. We performed a qualitative quality assessment of each included study and calculated pooled effect estimates for each genotype on each outcome using meta-analyses. **Results** We included data from 39 distinct patient cohorts. The quality of included studies was variable, with many areas of concern. *NAT2* slow/intermediate acetylators were statistically significantly more likely to experience hepatotoxicity than rapid acetylators (OR=1.59, 95% CI 1.26–2.01,  $I^2=0\%$ ). We also meta-analysed data for six individual SNPs of the *NAT2* gene. For 590G-A and 857G-A, both heterozygous genotype (OR=1.30, 95% CI 1.06–1.59,  $I^2=0\%$  and OR=1.30, 95% CI 1.03–1.64,  $I^2=0.9\%$ , respectively) and homozygous mutant-type (OR=2.05, 95% CI 1.24–3.40,  $I^2=47.7\%$  and OR=1.99, 95% CI 1.02–3.91,  $I^2=11.3\%$ , respectively) significantly increased hepatotoxicity risk compared with homozygous wild-type. **Conclusions** *NAT2* acetylator status is significantly associated with the likelihood of experiencing anti-tuberculosis drug-related hepatotoxicity. To the best of our knowledge, no meta-analyses on individual SNPs of the *NAT2* gene have been published, therefore our results add to the existing knowledge base. We encountered many challenges in conducting our meta-analyses, particularly due to variability in reporting between individual studies. We outline recommendations for the future reporting of pharmacogenetics studies to enable high-quality systematic reviews and meta-analyses to be performed.

**The composite kernel association test (CKAT) for genetic biomarker analysis in pharmacogenetics studies.** J. Shen<sup>1</sup>, H. Zhang<sup>1</sup>, N. Zhao<sup>2</sup>. 1) Merck & Co., Inc., Kenilworth, NJ; 2) John Hopkins University, Baltimore, MD.

In Pharmacogenetics (PGx) studies, it is of substantial interest to discover novel genetic biomarkers that influence drug response so that personalized treatment strategies can be developed that maximize therapeutic efficacy and safety. Set-based approach, in which a group of SNPs (e.g., SNPs in a gene) are combined and tested for association with a phenotype, has gained much popularity in PGx studies. In this project, we develop the Composite Kernel Association Test (CKAT), a flexible and robust kernel machine based test, to test the joint effect between a SNP set and an outcome of interest (i.e., drug safety or efficacy response), considering both the genetic main effect and gene-treatment interaction effect for PGx studies. A score test is developed for hypothesis testing. We further develop an analytic p-value calculation procedure so that the computationally extensive procedures (i.e., permutation or perturbation) via simulation of the null distribution can be avoided. We evaluate the CKAT through extensive simulations and application to the gene-level association test of the reduced risk in *Clostridium difficile* Infection recurrence in patients treated with bezlotoxumab compared with placebo. We show that the proposed CKAT works well for PGx studies with relatively small sample size (i.e.,  $\leq 1000$ ), controls the type I error at genome-wide significance level, and is more powerful than existing approaches such as rareGE and MGME across multiple scenarios. Further, CKAT readily accommodates any types of kernels, and works for both continuous and binary outcomes.

**3448T****HCLC: A novel statistical method for phenome-wide association studies.**

X. Liang, Q. Sha, S. Zhang. Department of Mathematical Sciences, Michigan Technological University, Houghton, MI 49931.

The emergence of genetic data coupled to longitudinal electronic medical records (EMRs) offers the possibility of phenome-wide association studies (PheWAS) for disease-gene associations. In PheWAS, the whole phenome can be divided into numerous phenotypic categories according to the first three digits of the International Classification of Disease (ICD) code. Currently, statistical analyses for PheWAS is mainly univariate analysis, which tests the association between one genetic variant and one phenotype at a time. In this article, we derived a novel and powerful multivariate method, which we referred as HCLC, to test the association between a genetic variant with multiple phenotypes for each phenotypic category. The proposed method (HCLC) involves three steps. In the first step, we use the bottom-up hierarchical clustering method (HCM) to partition a large number of phenotypes into disjoint clusters within each category. In the second step, we apply the clustering linear combination method (CLC) to combine test statistics within each category based on the phenotypic clusters and obtain p-values from each phenotypic category. In the third step, we propose a large-scale association testing procedure with theoretical guarantees for false discovery rate (FDR) control under flexible correlation structures (Cai et al., 2015). We show that applying our new FDR-controlling procedure on the entire collection of hypotheses can control the rate of FD of associated genetic variants as well as the expected value of the average proportion of FD of phenotypic categories influenced by such variants. We perform extensive simulation studies to compare the performance of HCLC with that of other existing methods. The results show that our proposed HCLC method controls FDR very well and outperforms other methods we compared with.

**3449F****Reducing the blind spots in target validation, examples from UK Bio-**

**bank.** L.M. Yerges-Armstrong<sup>1</sup>, K. Song<sup>1</sup>, M.R. Nelson<sup>1</sup>, T. Johnson<sup>2</sup>, J.C. Whitaker<sup>2</sup>, R.A. Scott<sup>2</sup>. 1) GlaxoSmithKline, Collegeville, PA, USA; 2) GlaxoSmithKline, Stevenage, UK.

Deeply-phenotyped genetic resources like UK Biobank are enabling large-scale drug discovery efforts. While these efforts are accelerating new target identification, they can also be invaluable for target validation by using genetic variants to mimic pharmacological modulation of a drug target. While there are established examples of functionally validated, instrument variants which mimic the pharmacological perturbation of a drug target, such variants are exceedingly rare. Thus, increasing our ability to instrument genes would accelerate genetic target validation efforts. Here, we explore the potential of multi-SNP predictors of gene expression to provide an alternative source of target validation evidence. We evaluated 21 genes with low frequency predicted loss-of-function (pLOF) variants previously reported for association with phenotypes in UK Biobank (PMID: 29691411) to see if multi-SNP predictors of expression would recapitulate reported associations. Specifically, we used the PrediXcan method, applying an omnibus test of association across all tissues. 17 of the 21 genes replicated the reported association signal ( $p < 5 \times 10^{-6}$ ) despite the specific pLoF not being tested directly. We then extended our findings for each of these genes with a PheWAS of 157 quantitative and 2254 case-control traits. The multi-SNP predictor for *ENPEP*, for example, replicated association for both diastolic ( $p = 6 \times 10^{-6}$ ) and systolic blood pressure ( $p = 3.7 \times 10^{-6}$ ) and was also associated with atrial fibrillation ( $p = 6.5 \times 10^{-20}$ ). Further work to determine the utility and specificity of this approach is underway, this proof of concept demonstrates that instrumentation methods based on gene expression will reduce the blind spots in genetic target validation.

**3450W****Investigating fine-scale population structure in the UK biobank.** *J.P.*

*Cook, A.P. Morris.* Department of Biostatistics, University of Liverpool, Liverpool, United Kingdom.

The United Kingdom (UK) is a genetically diverse population with strong genetic differences between regions, which may adversely affect genome-wide association studies (GWAS) of complex traits if not accounted for in the analysis. Principal components (PCs), calculated from a genetic relatedness matrix (GRM), are routinely included as covariates in regression models to account for population structure in GWAS. Linear mixed models (LMMs), which account for population structure by including a random effect for the GRM, have also become commonly used in GWAS. UK BioBank provides an opportunity to examine fine-scale UK population structure in unprecedented detail, with the final release of genetic data consisting of ~500,000 individuals recruited from 23 centres. Easting and Northing (E&N) coordinates were collected for every participant at recruitment and birth, and genotypes were imputed up a combined reference panel from the Haplotype Reference Consortium, 1000 Genomes Project and UK10K Project. We performed regression analyses of E&N at birth, with and without adjustment for PCs, and using an LMM approach implemented in BOLT-LMM. Genome-wide inflation factors for N in regression analyses were extremely high without PC adjustment ( $\lambda=17.76$ ) and even when using 10 PCs ( $\lambda=4.25$ ). Residual inflation also remained after accounting for population structure in the LMM analysis ( $\lambda=1.76$ ). To allow for linkage disequilibrium (LD), we applied LD score regression and LD adjusted kinship analyses to the LMM results, but residual inflation remained: intercepts of 1.65 and 1.60 respectively. Variants mapping in *TLR1* showed the strongest signals of association with E&N genome-wide, including two variants previously associated with other asthma (rs4833095) and alcohol tolerance (rs4543123). We analysed rs4833095 with a self-reported asthma phenotype in UK BioBank including 40,020 cases and 336,697 controls. The PC unadjusted association ( $p=5.1 \times 10^{-13}$ ) strengthened when adjusting for population structure using either 10 PCs ( $p=5.9 \times 10^{-15}$ ) or a LMM ( $1.8 \times 10^{-13}$ ), demonstrating both the robustness of the association and the benefit of removing as much geographical confounding as possible. Our study has important implications for accounting for population structure in large scale GWAS performed in UK BioBank, and highlights the need for caution in interpreting association results from different analytical approaches.

**3451T****Genetic clusters and population stratification in the Estonian Biobank and the association with complex traits.** *K. Fischer<sup>1,5</sup>, N. Pervjakova<sup>1,2,3</sup>, S.E. Ojavee<sup>5</sup>, K. Läll<sup>1,5</sup>, M. Mändul<sup>1,5</sup>, A.P. Morris<sup>1,4</sup>, R. Mägi<sup>1</sup>.*

1) Estonian Genome Center, Institute of Genomics, University of Tartu, Tartu, Estonia; 2) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 3) Genomics of Common Disease, Division of Diabetes, Endocrinology and Metabolism, Department of Medicine, Imperial College London, UK; 4) Department of Biostatistics, University of Liverpool, Liverpool, UK; 5) Institute of Mathematics and Statistics, University of Tartu, Estonia.

It has been shown that principal components (PCs) derived from Multidimensional Scaling (MDS) analysis of the genetic relatedness matrix primarily reflect the geographic ancestry of an individual. Whilst PCs have been thought to be appropriate for accounting for population structure in genetically heterogeneous populations (e.g. across Europe), the availability of large-scale GWAS data in population biobanks offers the opportunity to investigate the utility of this approach to correct for fine-scale stratification and cryptic relatedness. We analysed 39,769 participants from the EGCUT cohort, genotyped with a range of Illumina arrays. The individuals are sampled from all counties of Estonia (the area of the country is 45000m<sup>2</sup> and with a population ~1.2 million). Only the data of ethnic Estonians (self-identified) was analysed. We calculated the first 250 PCs using 61,044 independent variants. First, we use K-means cluster analysis to demonstrate that genetically more similar clusters, on the basis of genetic PCs, can be associated with 18 distinct areas of Estonia, despite the small size of the country. As most of the first 250 PCs were significantly associated with the county of birth, we show that it is most efficient to use all of them in the k-means algorithm. Next, we tested the association of cluster membership, actual county of birth, and individual PCs with prevalent coronary heart disease (CAD, 3152 cases) and type 2 diabetes (T2D, 1691 cases). The first and third PC were significantly associated CAD and only the first one with T2D. Also the predicted cluster membership as well as the actual county of birth were associated with both diseases ( $p < 5 \times 10^{-5}$ ). While adjusting for the actual county of birth, the effect of PCs disappeared for both diseases, but the effect of cluster membership was still significant for T2D. Our results indicate that although PCs may help to adjust for population structure, a genetic cluster indicator may be more efficient in capturing the confounding due to geographic variation. However, to also account for cryptic relatedness, a mixed modelling framework with a random effect for the genetic relatedness matrix may still be optimal.

**3452F**

**Extensive fine-scale population structure in the UK Biobank.** *S. Hu<sup>1</sup>, G. Hellenthal<sup>2</sup>, J. Marchini<sup>1,3</sup>, D. Lawson<sup>4</sup>, S. Myers<sup>1,3</sup>.* 1) Department of Statistics, University of Oxford, Oxford, United Kingdom; 2) UCL Genetics Institute (UGI), University College London, London, United Kingdom; 3) Wellcome Center for Human Genetics, University of Oxford, Oxford, United Kingdom; 4) University of Bristol, Bristol, United Kingdom.

We developed and applied a novel, rapid, scalable statistical ancestry inference pipeline and applied this to the 500,000 UK Biobank samples. The approach breaks down the fine-scale ancestry of a single genome across 21 regions within the UK and Republic of Ireland, and 54 additional regions worldwide. This provides much greater spatial resolution (~70 miles) than existing approaches, distinguishing e.g. northern and southern parts of central England. Among UK-born participants (430,256 self-reported British), inferred UK ancestry was 96.15% vs. 3.85% for participants with non-UK ancestry. For 343,217 UK-born individuals possessing ≥95% UK ancestry, we compared their place of birth to their genetic ancestry breakdown. On average 28.82% of their ancestry derives from their area of birth, varying regionally from 16-46%. Overall, 30.1% of individuals mainly show ancestry (>50%) from a single region. For these people, this region matches their birthplace region fully 71% of the time (odds ratio 48 vs. random chance). Migration is complex: some regions exhibit limited migration. For example, individuals born in South Yorkshire have mean ancestry from South and North Yorkshire of 40.6% and 5.6% respectively. While for individuals born in North Yorkshire the mean ancestries are 14.6% and 16.2% respectively. Other regions, including London, show much higher levels of mixing: only 20.1% of London-born individuals mainly show ancestry from one region, and this is SE England for only 32% of these. Thus, despite recent population movements, substantial fine-scale population structure persists in the UK among the general population and country-wide, and this can be identified based on DNA information alone. Because our ancestry vectors predict (median  $r^2=0.80$ ) but are not predicted by (median  $r^2=0.49$ ) standard principle components, they might offer advantages in correcting for population stratification, particularly for rare variants, in phenotypic association testing. We identified particular mutations showing strong regional differences among UK ancestry regions, and many rare variants show geographic variability, with the maximal estimated frequency difference among regions being 74.74%.

**3453W**

**Existence and implications of ancestry-dependent phenotypic variance.** *S. Musharoff<sup>1</sup>, D. Park<sup>2</sup>, J. Galanter<sup>3</sup>, X. Liu<sup>4</sup>, S. Forsberg<sup>5</sup>, S. Huntsman<sup>6</sup>, C. Eng<sup>1</sup>, E.G. Burchard<sup>1,6</sup>, J.F. Ayroles<sup>5</sup>, N. Zaitlen<sup>1</sup>.* 1) Lung Biology, University of California, San Francisco, San Francisco, CA; 2) Encompass Bioscience Inc; 3) Genentech, South San Francisco, CA; 4) Department of Human Genetics, University of Chicago, IL; 5) Ecology and Evolutionary Biology and Lewis-Sigler for Integrative Genomics, Princeton University, Princeton, NJ; 6) Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA.

Genetic and environmental differences between worldwide populations produce concomitant variability in the distributions of complex phenotypes and disease prevalence. Studies of worldwide variability to date have focused on the relationship of ancestry and phenotypic mean. Here, we develop a novel framework, the ancestry double generalized linear model (ADGLM), to model phenotypic variance as a function of ancestry. Such ancestry-dependent variance is induced by gene-gene and gene-environment interactions, differential environmental distributions, and, as we show for the first time, differential selection. When applied to ~113K British individuals, ADGLM reveals ancestry (genetic PC1) is associated with the variance of 28 traits including BMI ( $p=1.0 \times 10^{-3}$ ), hemoglobin ( $p=7.8 \times 10^{-29}$ ), red hair color ( $p=1.3 \times 10^{-39}$ ), and skin pigmentation ( $p=1.6 \times 10^{-29}$ ). In ~3K Mexican and Puerto Rican individuals, admixture fraction is associated ( $p < 6.6 \times 10^{-4}$ ) with the variance of height, eczema, lung function, and asthma. Importantly, we show that such ancestry-variance associations can produce up to a three-fold difference in disease prevalence between populations while minimally affecting heritability. They may therefore partially account for the 2.8-fold difference in asthma prevalence between Mexicans (8%) and Puerto Ricans (22%) living in the United States. Given this observation of ancestry-dependent variance, we consider its implications for genetic association studies. In GWAS simulations with no genetic effect, linear regression with principal components (LR+PC) and linear mixed model association tests are miscalibrated at population-differentiated SNPs ( $\lambda_{GC}=1.56, 0.46$ ) while ADGLM is calibrated ( $\lambda_{GC}=1.06, 0.98$ ). When there is a genetic effect, ADGLM has up to 17% more power than LR+PC. This gain is observed in data from Mexicans and Puerto Ricans: ADGLM has more significant p-values than LR+PC at 10 of 11 known genetic associations for eczema, rash, rhinitis, skin pigmentation, tanning, and lung function, and ADGLM identifies two novel eczema and rash associations. Furthermore, ADGLM allows direct association testing of genotype and phenotypic variance and finds a novel SNP association with tanning variance ( $p=1.2 \times 10^{-8}$ ) in African-Americans. In conclusion, ancestry-dependent variance is prevalent in human populations and can bias association studies if ignored. Modeling this variance enables discoveries along an understudied axis of phenotypic variation and disease.

**3454T****Functional characterization of 3D-protein structures informed by human genetic diversity.** *I. Bartha<sup>1</sup>, M. Hicks<sup>2</sup>, J. di Iulio<sup>3</sup>, A. Telenti<sup>3</sup>, J.C. Venter<sup>4</sup>.*

1) Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland; 2) Human Longevity Inc. San Diego CA USA; 3) The Scripps Research Institute, San Diego, CA, USA; 4) J Craig Venter Institute, San Diego, CA, USA.

Sequence variation data of the human proteome can be used to analyze 3-dimensional protein structures to derive functional insights. We use human genetic variation from nearly 140,000 human exomes and genomes and 4,390 x-ray protein structures to model tolerance to amino acid changes in the 3D space of the human proteome. To understand variation in the structural proteome, we first identified 26,593 structures associated with 4,390 Uniprot entries that had x-ray crystal structures with a defined resolution and a minimum chain length greater than 10 amino acids. In total, we mapped 139,535 Uniprot features to the structures, and extracted a 3-dimensional context by defining a 5-Angstrom radius space for each feature. We identified 481,708 missense variants for these proteins from the analysis of 138,632 individuals' exomes. From these contextualized data, we constructed a model that describes functional constraints in three-dimensional protein structures. The strength of constraint (intolerance) was reflected in a 3-dimensional tolerance score (3DTS) that summarized the differences between observation and expectation in genetic variation at the level of 3D-sites. We confirmed the utility of structural intolerance data by comparing it to available deep mutational scanning data. The intolerance data correlated with deep mutational scanning functional readouts for PPARG, MAPK1/ERK, UBE2I, SUMO1, PTEN, CALM1, and CALM2 ( $r^2=0.23$  to  $0.81$ ). In conclusion, the increasing detail of the limits of protein diversity that can be gathered through large scale sequencing of the human population provides valuable information on the functional consequences and pathogenicity of genetic variants and offers new data on orthosteric, allosteric and additional functional sites that could be harnessed for drug development.

**3455F****A unified method for rare variant analysis of GxE interactions with application to GxSmoking interactions on obesity-related traits.** *E. Lim<sup>1</sup>, H. Chen<sup>2,3</sup>, C.T. Liu<sup>1</sup>.*

1) Department of Biostatistics, Boston University, Boston, MA; 2) Human Genetics Center, Department of Epidemiology, Human Genetics and Environmental Sciences, School of Public Health, University of Texas Health Science Center, Houston, TX; 3) Center for Precision Health, School of Public Health and School of Biomedical Informatics, University of Texas Health Science Center, Houston, TX.

Majority of single nucleotide polymorphisms (SNP) discovered by genome-wide association study only explain a small proportion of heritability, and thus much of the heritability is left unexplained. Gene-environment (GE) interactions, or the presence of rare variants may have substantial contributions in explaining missing heritability. Advanced technology in whole-genome sequencing has offered the opportunity to comprehensively investigate the genetic contribution, particularly rare variants, to complex traits. Many rare variants analysis have focused on jointly modeling the marginal effect, but the method to detect GE interactions, especially for rare variants, is underdeveloped. Identifying the modification effects of environmental factors on genetic risk poses a considerable challenge. To tackle this challenge, we developed a unified method in detecting GE interactions of a set of rare variants using generalized linear mixed effect model. The proposed method can accommodate both binary and continuous traits in related or unrelated sample. Under this model, genetic variants, sample relatedness and the GE interaction were modeled as random effects. We adopted a kernel-based method to leverage the joint information across the rare variants and implemented a variance component score test, which only requires fitting the model under the null hypothesis, and thus, reducing multiple testing and computational burden. Since the integrated quasi-likelihood function for binary traits contains high dimensional integral that is intractable, we use Laplacian method to approximate the integral and iteratively estimate our parameters with Fisher scoring algorithm. Our extensive simulation study shows that the proposed method maintains correct type I error and high power under various scenarios, such as differing the direction of main genotype effects and the number of variants in the model for both continuous and binary traits. We illustrated our method to test gene-based interaction with smoking on body mass index (BMI) or overweight ( $BMI \geq 25$ ) in 7188 Framingham Heart Study subjects and replicated the *CHRNA4* gene reported in previous large consortium meta-analysis of common SNP-smoking interaction. Our proposed set-based GE test is computationally efficient and is applicable to both binary and continuous phenotypes, while appropriately accounting for familial relationships.

**Enabling cost-effective multi-sample single cell RNA-seq studies via in-silico demultiplexing and doublet detection without external genotype data.** T.H. Yao, H.M. Kang. Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI.

The advent of massive parallel single-cell RNA sequencing (scRNA-seq) technologies dramatically enhances the resolution to understand how genetic and environmental factors alter transcriptomic profiles of individual cells and affect interactions between them. To accurately understand the effect of genetic and environmental variations on each cell, it is very important to rapidly escalate the scale of scRNA-seq studies, both experimentally and analytically. Recently, we developed an experimental workflow with a computation tool, demuxlet, to sequence single cell transcriptomes across multiple samples in a single library preparation by harnessing natural genetic variations. Our strategy reduces the per-cell and per-sample cost of scRNA-seq experiments by several folds while avoiding batch effects between multiplexed samples. Although our sample multiplexing strategy is rapidly becoming popular for large-scale scRNA-seq studies, the underlying statistical method, demuxlet, requires external genotypes to be collected, thus not applicable to circumstances such as model organisms or samples without separate DNA specimens available. Moreover, steps to collect, process, and impute the genotype data makes the multiplexing procedure less seamless and convenient than the standard scRNA-seq workflow. We develop a new method, freemuxlet, to demultiplex and to detect doublets from multiplexed scRNA-seq reads without requiring external genotypes. The major challenge in developing freemuxlet is that many pairs of droplets do not have enough overlapping reads, making pairwise distance between them uncertain. We define the distance between two droplets as Bayes Factors (BF) between the two hypotheses of sample origin to account for uncertainty. Multi-class clustering guided by hierarchical t-SNE followed by Gibbs sampling simultaneously estimates the consensus genotypes of each individual while deconvoluting the sample provenance of each droplet. We apply these methods to the 8-sample mixture dataset published in our previous study, and observed that 97% of droplets that were estimated as singlet using the original demuxlet (with external genotypes) have concordant sample deconvolution assignment with the Bayes Factor clustering results. Our results suggest that multiplexed scRNA-seq experiments can be more widely applied across a variety of species, sample conditions, and cell types much more seamlessly through freemuxlet.

**MMP3 gene variant is a promising biomarker for periodontal disease among Hispanics.** V. Navarrete<sup>1</sup>, I. Ramirez<sup>1</sup>, F.J. Estrada<sup>2</sup>, A.C. Perez<sup>2,3</sup>, E. Lira<sup>2</sup>. 1) Sección de Estudios de Posgrado e Investigación, Escuela Superior de Medicina, Instituto Politécnico Nacional. Plan de San Luis y Díaz Mirón s/n Casco de Santo Tomás 11340, Mexico; 2) Universidad Panamericana. Escuela de Medicina. Donatello 59, Ciudad de México, 03920, México; 3) Yale University School of Public Health, Laboratory of Epidemiology and Public Health. 60 College St, New Haven, CT, United States of America.

Genetic and environmental factors contribute to the development of periodontal disease (PD). In bioinformatics analyses, *MMP3* is a promising candidate gene associated with the development and prognosis of periodontitis. However, it remains unclear whether single nucleotide polymorphisms (SNPs) in this gene are associated with PD, especially among Hispanics. Hence, we performed a case-control study of 134 periodontitis cases and 134 controls from a referral center in Mexico City. All our cases were evaluated and selected by experienced DMDs based on current guidelines. Typical patients, with chronic periodontal disease, had evidence of supragingival and subgingival dentobacterial plaque, stone formation, gingival inflammation, pocket formation, loss of periodontal attachment, and loss of alveolar bone. We assessed a previously reported PD-associated polymorphism, rs679620 (top scoring SNP in bioinformatics analyses), by TaqMan probes on RT-PCR. Genotyping quality check, descriptive, univariate, and multivariate analyses were performed with PLINK v.1.9 and corroborated in R v.3.3.2. Our preliminary results indicate that allele T- (MAF = 0.35) compared to C-carriers have significantly ~61% lower odds of PD. Furthermore, there is a trend towards decreasing odds of periodontal disease on genotypic and trend test models. Taken all together, we propose that the rs679620 of *MMP3* might be a promising good prognosis biomarker for PD in Mexican population. Our results warrant further replication and validation in other race/ethnicities, especially of its predictive applicability in the DMD office setting.

**3458F****Two-phase sampling designs for post-GWA fine-mapping studies:**

**Optimality criteria.** *O. Espin-Garcia*<sup>1,2</sup>, *R.V. Craiu*<sup>3</sup>, *S.B. Bull*<sup>1,2</sup>. 1) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 2) Lunenfeld-Tanenbaum Research Institute, Sinai Health System, Toronto, Canada; 3) Department of Statistical Sciences, University of Toronto, Toronto, Canada.

Given typically modest genetic effect sizes, large-scale population studies are generally necessary to achieve genome-wide significance. These studies require careful design and budgeting. Post-GWAS analysis focuses on fine-mapping of targeted genetic regions, but as yet costs of next-generation sequencing remain prohibitively expensive for large studies. Two-phase sampling design and analysis is a cost-reduction technique that utilizes collected data during phase 1 GWAS (e.g. outcome, auxiliary variable) to select an "informative" (biased) subsample in phase 2 fine-mapping. The main goal is to make inference on a genetic variable that is costly and/or onerous to measure (e.g. sequencing data). In two-phase sampling designs less attention has been paid to determination of optimal study designs compared to effect estimation and hypothesis testing. To date, most of the work on optimal designs has focused on case-control studies, where for example, a "balanced" design has been claimed to be "near optimal". Strategies and tools that help researchers to select the (optimal) phase 2 subsample are not readily available beyond binary outcomes. Considering the effect size and haplotype distribution between a GWAS-auxiliary-variable and a sequence variant as inputs, we develop two approaches for optimal two-phase designs within the exponential family under a semiparametric maximum likelihood framework. One is based on analytic expressions for the variance-covariance matrix (VCM), and alternatively, another is based on a computational approach via a genetic algorithm for optimization of the phase 2 sampling space. We evaluate measures of statistical efficiency based on features of the VCM that have been proven useful to define optimality criteria in design of studies.

**3459W****Detection of genetic similarities using unsupervised random forest.**

*C.J.K. Fouodo*, *I.R. Koenig*. Institut für Medizinische Biometrie und Statistik, Universität zu Lübeck, Universitätsklinikum Schleswig-Holstein, Campus Lübeck, Lübeck, Germany.

Genome-wide association studies (GWAS) have in the past been successful in the identification of associations with well-defined phenotypes as well as in the establishment of supervised classification models based on univariable analyses. To perform multivariable genome wide analyses in GWAS data, classical statistical approaches like linear or logistic regression models are not suitable due to the high-dimensional nature of the data. As an alternative, random forest (RF) based approaches are known to be one of the more appropriate supervised machine learning methods for high dimensional multivariable data analysis. RF based approaches have been shown to be fast and to produce good predictive performances in high dimensional classification problems. Furthermore, the method can be extended to unsupervised learning analysis. Our aim is to apply an unsupervised random forest (URF) strategy to GWAS data to cluster individuals into genetically homogeneous subgroups. Incorporating a novel boosting approach, we further expect to obtain more stable clusters and improve the performance of the method provided each boosting iteration takes into account the result of the previous iterations. Clustering individuals according to their genetic similarities and without knowledge of a phenotype can allow us to discover novel subgroups of patients. The evaluation of our approach is demonstrated in an application to samples from the Pan-Asia SNP Consortium database with the objective to validate the derived clusters against the known ethnical background.

**Genetic risk scores for COPD: Identifying high risk individuals and understanding disease pathways.** P. Sakornsakolpat<sup>1,2</sup>, B.D. Hobbs<sup>1,3</sup>, M. Parker<sup>1</sup>, D. Prokopenko<sup>1</sup>, L.P. Hayden<sup>1</sup>, N. Shrine<sup>4</sup>, L.V. Wain<sup>4</sup>, M.D. Tobin<sup>4</sup>, E.K. Silverman<sup>1,3</sup>, M.H. Cho<sup>1,3</sup>. 1) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Department of Medicine, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand; 3) Division of Pulmonary and Critical Care Medicine, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 4) Department of Health Sciences, University of Leicester, Leicester, UK.

Chronic obstructive pulmonary disease (COPD) susceptibility is influenced by genetics. Identifying individuals at risk for COPD will impact public health and aid in the understanding of disease. We developed a genetic risk score for COPD by applying PRSice-2 to a case-control analysis in the UK Biobank (N=200,794), and applied this risk score to individuals in an independent cohort, COPDGene (N=6,760). We performed linkage disequilibrium (LD) clumping of the summary statistics from the UK Biobank and chose a P value threshold that best fitted to the training dataset of COPDGene. We included 15,155 genetic variants with  $P_{GWAS} < 0.0467$  in the risk score. We investigated the association of this risk score with various COPD-related phenotypes in the test dataset of COPDGene. The genetic risk score alone had an area under the curve (AUC) of 0.60 in predicting COPD case status ( $P=1.6 \times 10^{-12}$ ). The AUC of a model combining genetic risk score and clinical variables (age, sex, and smoking pack-years) was significantly larger than the AUC of a clinical model alone (0.77 vs 0.75, respectively;  $P=2.2 \times 10^{-16}$ ). This genetic risk score significantly predicted forced expiratory volume in one second ( $FEV_1$ ), ratio of  $FEV_1$  to forced vital capacity, % emphysema, % gas trapping, and severe COPD exacerbations ( $P < 0.05$ ). We also developed a functional risk score by imputing individuals' genetic data to gene expression using PrediXcan. We computed 186 functional risk scores from KEGG pathways, by aggregating imputed gene expression of genes within the same set. We identified significant associations at false discovery rate (FDR)  $< 10\%$  between the pentose phosphate pathway and four phenotypes (COPD,  $FEV_1$ ,  $FEV_1/FVC$ , airway wall area) with  $P < 1.1 \times 10^{-4}$ , as well as a gene set related to arrhythmogenic right ventricular cardiomyopathy (ARVC) and COPD exacerbation frequency ( $P < 6.2 \times 10^{-6}$ ). The latter gene set includes genes encoding desmosomal proteins; notably, an eQTL for desmoplakin (*DSP*) is associated with COPD in prior investigations. In conclusion, we demonstrated the utility of a genetic risk score to predict COPD and COPD-related phenotypes. An approach combining risk scores with gene expression implicates molecular pathways that may lead to further understanding of the disease.

**3461F**

**Sequential testing of multivariate phenotypes associated with SNP-sets by mixed model kernel statistics.** D.J. Schaid, J.P. Sinnwell, J. Chen. Health Sciences Research, Mayo Clinic, Rochester, MN.

Detecting genetic pleiotropy and understanding its causes can improve the biological understanding of a gene in multiple ways. Current statistical methods to evaluate the association of multiple traits with a set of SNPs (e.g., gene-level tests) are based on kernel statistics that test the null hypothesis that none of the traits are associated with a variant. Rejecting the null hypothesis does not provide information on which traits are associated with a set of SNPs. We developed a formal testing framework to determine which traits are associated with a set of SNPs, while accounting for correlations among the traits. Our methods are based on sequential testing with mixed models, starting with the usual null hypothesis that none of the traits are associated with a set of SNPs, using multivariate kernel statistics. If this hypothesis is rejected by a small p-value, we proceed by evaluating all possible ways of allowing one associated trait while testing the remaining traits, using a special kernel statistic. The maximum p-value from these tests is used as a summary p-value. If the maximum p-value is smaller than the nominal criterion (e.g., p-value  $< 0.05$ ), we continue onto the next sequential step of evaluating all possible ways of allowing two associated traits and testing the remaining traits, etc. By simulations, we illustrate that the Type-I error rate is well controlled, and illustrate power of our new methods. We illustrate how the sequential method is influenced by sample size, the number of traits, and the trait correlations. We apply the new methods to multivariate phenotypes to illustrate interpretation and benefits of our new approach. This strategy provides new ways to perform gene-level analyses for multiple traits while accounting for correlations among the traits.

**3462W**

**Incorporating genetic networks into case-control association studies with high-dimensional DNA methylation data.** *H. Sun, K. Kim.* Pusan National University, Busan, South Korea.

In human genetic association studies with high-dimensional gene expression data, it has been well known that statistical selection methods utilizing prior biological network knowledge such as genetic pathways and signaling pathways can outperform other methods that ignore genetic network structures in terms of true positive selection. In recent epigenetic research on case-control association studies, relatively many statistical methods have been proposed to identify cancer-related CpG sites and their corresponding genes from high-dimensional DNA methylation array data. However, most of existing methods are not designed to utilize genetic networks although methylation levels among linked genes in the networks tend to be highly correlated with each other. In this article, we propose new approach that combines independent component analysis with network-based regularization to identify outcome-related genes for analysis of high-dimensional DNA methylation data. The proposed approach first captures gene-level signals from multiple CpG sites using independent component analysis and then regularizes them to perform gene selection based on prior biological network information. In simulation studies, we demonstrated that the proposed approach overwhelms other statistical methods that do not utilize genetic network information in terms of true positive selection. We also applied it to the 450K DNA methylation array data of the four breast invasive carcinoma cancer subtypes from The Cancer Genome Atlas (TCGA) project.

**Co-localization analyses provide counterintuitive findings: Application to cystic fibrosis lung disease.** *F. Wang<sup>1,7</sup>, G. He<sup>2,7</sup>, J. Gong<sup>2</sup>, N. Panjwani<sup>2</sup>, B. Xiao<sup>2</sup>, F. Lin<sup>2</sup>, J. Avolio<sup>3</sup>, J.M. Rommens<sup>2,4</sup>, L. Sun<sup>1,5</sup>, L.J. Strug<sup>2,5,6</sup>.* 1) Department of Statistical Sciences, University of Toronto, Toronto, Canada; 2) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada; 3) Translational Medicine, Hospital for Sick Children, Toronto, Canada; 4) Respiratory Medicine, Hospital for Sick Children, Toronto, Canada; 5) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 6) Biostatistics Division, Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 7) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 7) These authors contributed equally to this work.

Genome-wide association study (GWAS) by the International Cystic Fibrosis (CF) Gene Modifier Consortium (ICFGMC) identified SNPs between *SLC6A14* and *AGTR2* on chromosome X as contributing to CF lung disease. In the same region, we conducted expression quantitative trait loci (eQTL) analysis using FastQTL with RNA-sequencing of human nasal epithelial cells from 63 CF Canadians enrolled in the ICFGMC. The *SLC6A14* eQTL p-values mirror the lung association pattern in the region, providing strong visual evidence that the *SLC6A14* expression mediates CF lung disease. Complications arise when we formally test the eQTL-GWAS co-localization. Associated SNPs at the *AGTR2/SLC6A14* locus span a 150kb region with high linkage disequilibrium (LD) and providing evidence of allelic heterogeneity. Detecting colocalization in the presence of high LD and/or allelic heterogeneity is challenging for several commonly used Bayesian approaches, such as COLOC and eCAVIAR, that estimate the posterior probability of co-localization under specific causal variation assumptions. COLOC assumes a single causal variant in both eQTL and GWAS, and the presence of allelic heterogeneity reduces the co-localization posterior probability. eCAVIAR can accommodate allelic heterogeneity, however the posterior probability of co-localization will be averaged across several variants in high LD, resulting in ambiguous colocalization conclusions. We recently developed iRegress, a Frequentist approach that assesses the pattern similarity between the GWAS and eQTL evidence through regression and incorporates a robust covariance estimator to account for LD. Although iRegress can accommodate allelic heterogeneity and LD, and shows benefit over the other methods in certain scenarios, high LD at the *SLC6A14/AGTR2* locus reduces the effective sample size limiting the power of testing the co-localization. Application of an intuitive sum of test statistics that compares the difference in averaged GWAS test statistics between eQTL SNPs and non-eQTL SNPs, accounting for LD through a mixture of chi-square distributions demonstrates strong evidence of co-localization ( $p\text{-value} = 9.5 \times 10^{-9}$ ) consistent with the visual pattern. Our findings suggest that no one method can accommodate all possible genetic architectures for co-localization analysis, and simple procedures can complement existing state-of-the-art methods to better understand mechanisms underlying GWAS loci.

**3464F**

**A general statistic to test an optimally weighted combination of common and/or rare variants in association studies.** *J. Zhang<sup>1</sup>, H. Chen<sup>2</sup>, B. Wu<sup>3</sup>, X. Wang<sup>1</sup>.* 1) Department of Mathematics, University of North Texas, Denton, TX; 2) Texas Academy of Mathematics & Science, University of North Texas, Denton, TX; 3) School of Public Health, University of Minnesota, Minneapolis, MN.

Both traditional genome-wide association study and next generation sequencing data analysis are increasingly used to interrogate the whole genome to comprehensively identify both common and rare disease variants in many large genetic studies. Rare variants generally have large effects though are hard to detect due to their low frequency. Currently, many existing statistical methods for rare variants association studies have employed a weighted combination scheme, which usually puts subjective weights or suboptimal weights based on some ad hoc assumptions (e.g. ignoring dependence between rare variants). In this study, we analytically derive optimal weights for both common and rare variants in a gene or pathway. We propose a General and novel approach to Test association between an Optimally Weighted combination of variants (G-TOW) in a gene or pathway and a continuous or dichotomous trait while easily adjusting for covariates. G-TOW is robust to the directions of effects of causal variants. We conduct extensive simulation studies to evaluate the performance of G-TOW. G-TOW has properly controlled type I error rates. Simulation results demonstrate that it is the most powerful test comparing with existing methods, when testing effects of either both rare and common variants or rare variants only. We also illustrate the effectiveness of G-TOW using the Genetic Analysis Workshop 17(GAW17) data.

**3465W**

**Predictive modeling of gene expression in admixed populations.** *A. V. Mikhaylova, T.A. Thornton.* Department of Biostatistics, University of Washington, Seattle, WA.

In recent years, several gene-based association methods, such as PrediXcan, have been developed. These methods provide valuable insight into relationships between genetic data and complex traits. However, PrediXcan models were trained on the Depression and Gene Network (DGN) and the Genotype-Tissue Expression (GTEx) subjects, the majority of which are of European descent. It is thus not clear how accurate the gene expression predictions would be in diverse populations. We use transcriptomic data from the GEUVADIS (Genetic European Variation in Health and Disease) RNA sequencing project and whole genome sequencing data from the 1000 Genomes project to compare a range of models from PrediXcan PredictDB and evaluate their predictive performance on one non-European (Yoruban) and four European populations. We show that predictive performance varies across populations, with the Yoruban (YRI) sample having the lowest correlations between the observed and predicted gene expression values, on average. To understand and quantify the level of transferability of prediction models, we perform a series of simulations using real genotype data and evaluate prediction accuracy in various settings: 1) where a training set and a test set come from populations with similar ancestries, 2) a training and a test set come from population with different ancestries, and 3) a test set consists of admixed subjects. Our findings indicate that predictive accuracy is lower when using a training set with ancestry different from the test set and, thus, demonstrate the importance of including more diverse samples in genetic studies. Finally, we propose a new approach of modeling gene expression that takes ancestry into account in order to improve prediction accuracy for admixed populations.

**3466T**

**The intersection of genetics and longitudinal survey data from the health and retirement study: A preliminary study of glaucoma.** *J.N. Cooke Bailey, T.G. Kinzy, N.K. Schiltz.* Population and Quantitative Health Sciences, Case Western Reserve University School of Medicine, Cleveland, OH.

Glaucoma is a leading cause of irreversible blindness worldwide; in the United States alone, over 2.7 million individuals are affected. Various risk factors for glaucoma are known and include age, race/ethnicity, genetics, and ocular measures. Despite numerous studies, molecular and environmental factors that contribute to glaucoma remain elusive. The University of Michigan Health and Retirement Study (HRS) is a longitudinal survey of a representative sample of Americans over the age of 50. Supported by the National Institute on Aging and the Social Security Administration, the HRS is designed to provide reliable data on the decisions, choices, and behaviors of people as they age and respond to changes in public policy, the economy, and health. The study obtains information every two years about income and wealth, health and use of health services, work and retirement, and family connections. Through its unique and in-depth interviews, the HRS provides an invaluable and growing body of multidisciplinary data that researchers can use to address important questions about the challenges and opportunities of aging. Because of its innovation and importance, the HRS has become the model and hub for a growing network of harmonized longitudinal aging studies around the world. Saliva was collected on half of the HRS sample each wave starting in 2006 and respondents were genotyped on the Illumina Human Omni2.5-Quad (Omni2.5) BeadChip at the NIH Center for Inherited Disease Research. We accessed survey results to evaluate prevalence of glaucoma in this dataset and performed a genome-wide association study (GWAS) adjusting for age, sex, and significant Principal Components (PC1-4). Of 8,245 genotyped individuals, 9.4% self-reported glaucoma. Respondents had a mean age of 76.55 (SD 7.50) and median age of 75.41 (IQR 70.75-81.50) and were 57.9% female (N=4775). A majority of respondents had genetic samples collected during the 2006 HRS year (N=4388, 53.22%; 2008, N=532, 6.45%; 2010, N=3325, 40.33%). Median time between genetic sample collection and survey assessment used was 2 years (IQR 2-6) with a majority assessed in 2012 (N=6369, 77.25%). A preliminary GWAS did not replicate known glaucoma loci and no variants attained genome-wide significance. Future analyses will subset respondents by race/ethnicity and evaluate genetic association with combinations of glaucoma and comorbidities. .

**3467F**

**Identifying hidden ancestries in publicly available summary genetic data.**

*A.E. Hendricks<sup>1</sup>, K. Koach<sup>1</sup>, M.M. Sorenson<sup>1</sup>, T. Dinh<sup>1</sup>, Y. Wu<sup>1</sup>, C.R. Gignoux<sup>2</sup>.*

1) Mathematical and Statistical Sciences, University of Colorado Denver, Denver, CO; 2) Colorado Center for Personalized Medicine, University of Colorado, Anschutz Medical Campus, Aurora, CO.

Recent summary level genetic data have enabled advancements in understanding the relationship between genetics, health, and disease. Summary test statistics from GWAS are particularly useful for secondary analyses (e.g. genetic correlation) and data dissemination. Publicly available databases of allele and genotype frequencies, such as the genome Aggregation Database (gnomAD), are rich resources for looking up potentially causal variants in studies of rare diseases and as controls in rare variant tests given new methods. However, these databases rely on allele frequencies, which are known to vary across global and local populations. Ancestries provided in the summary data are often broad (e.g. European, African, Asian) and do not include information on finer scale ancestries (e.g. British, Italian) or admixture patterns (e.g. African Americans within African summary groups). Lack of precise ancestry information can result in confounding in secondary or association analyses, and can contribute to variant misclassification in molecular diagnosis of rare diseases. To address this, we have developed a modified EM algorithm that estimates the proportion of finer scale ancestry within publicly available data (e.g. GWAS, genotype databases). Unlike traditional individual level ancestry estimation methods, our method only requires allele or genotype frequencies. We are able to accurately and precisely detect the underlying ancestry proportions across a wide variety of simulations. Specifically, we have sensitivity to detect ancestries that make up only 1% of the summary data. We further apply our method to the BRAVO allele frequencies from the Trans-Omics for Precision Medicine (TOPMed) and to gnomAD African and Latino groups identifying hidden ancestries not provided in the summary data. With applications to many publicly available data types, including GWAS summary data, our method has the ability to provide precise ancestry information for the increasing number of genetic resources. Increased precision of ancestry information will help to reduce inaccurate results due to unknown or hidden ancestries.

**KIBAG -- KIR genotype imputation with attribute bagging.** S. Khor<sup>1</sup>, X. Zheng<sup>2</sup>, A. Ishitani<sup>3</sup>, F. Azuma<sup>4</sup>, C. Pyo<sup>5</sup>, Y. Omae<sup>1</sup>, T. Yabe<sup>4</sup>, D. Geraghty<sup>2</sup>, K. Tokunaga<sup>1</sup>, *HLA & KIR Imputation Network (HKImp.net)*. 1) Department of Human Genetics, The University of Tokyo, Tokyo, Japan; 2) Department of Biostatistics, University of Washington, Seattle, WA, USA; 3) Nara Medical University, Kashihara, Nara 634, Japan; 4) Japanese Red Cross Kanto-Koshinetsu Block Blood Center, Tokyo, Japan; 5) Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, WA, USA.

Natural killer (NK) cells are essential in innate immunity and determine the outcome of antigen-specific responses. NK cell function based on the complex interactions mediated by membrane-bound and soluble gene products. NK cell activity is genetically modulated by differential expression of inhibitory and activating killer cell immunoglobulin-like receptors (KIR) that recognize HLA class I molecules. The high level of polymorphism of KIR genes together with their functional relation with HLA class I molecules suggest selection pressure driven by exposure to a wide variety of diseases. Indeed, long established KIR-HLA association has been revealed with HIV infection, hepatitis C infection, human papilloma virus (HPV) induced cervical cancer, psoriatic arthritis and type 1 diabetes. With the recent advancement of next generation sequencing (NGS) technology, KIR can now be characterized to high resolution including KIR copy number (CP), KIR A&B haplotypes and KIR allele. NGS based KIR typing remains a costly and laborious method to determine KIR types from a large cohort of individuals. Thus, we developed a new methodology named KIBAG (KIR Genotype Imputation with Attribute Bagging) which enable a rapid and inexpensive way to determine KIR typing from GWAS dataset. KIR typing of 726 Japanese individuals were performed using Scisco Genetics KIR typing kit and Miseq sequencing system. SNP information of these samples were determined using Affymetrix Axiom Japonica V1 and Japonica V2. Internal validation and external validation of KIR CP imputation were performed and an average accuracy of 97.9% and 95.7% were obtained respectively across 16 KIR genes. KIR with > 3 copies remains the most difficulties to impute due to the insufficiency of 3 copies carrying individual in the reference. Re-examination of GWAS with HLA class I associations or GWAS with SNP peaks in KIR region may reveal novel HLA-KIR associations. This work is part of the project of HKIMP.net (HLA & KIR Imputation Network) with the aim of providing population specific HLA & KIR imputation system to research community. KIR imputation system for a wide range of populations is currently undergoing.

**A novel association test for joint analysis of multiple phenotypes using conditional CUR.** Q. Sha, Z. Wang, X. Li, S. Zhang. Michigan Technological University, Houghton, MI.

Genome-wide association studies (GWAS) have successfully detected tens of thousands of SNP-trait associations. Earlier researches have primarily focused on association testing of genetic variants and some well-defined functions or specific phenotypic traits. Emerging evidence has shown that pleiotropy widely exists in complex human diseases. The joint analysis of multiple phenotypes within a cohort presents an attractive alternative to single phenotype analyses and may provide new insights into the etiology of human diseases. CUR matrix decomposition is a low-rank matrix approximation that uses only a small number of actual columns and/or actual rows from the original data matrix. Traditionally, CUR selects columns/rows that exhibit high statistical leverage on the best low-rank fit of the data matrix based on an "importance sampling" probability distribution. In this study, we demonstrate that the traditional CUR will not perform well in certain situations. We develop an innovative conditional CUR procedure that we refer to as cCUR to alleviate the intrinsic drawback of the traditional CUR in genetic association studies. We apply cCUR to jointly analyzing multiple correlated phenotypes. Extensive simulations as well as an analysis of COPDGene real dataset have been used to evaluate the performance of the proposed method. Our results demonstrate that the type I error rates of cCUR are well maintained under different scenarios and cCUR is either the most powerful test or comparable to the most powerful test among the existing methods we compared with. In addition, cCUR is able to detect more causal genetic variants in GWAS than the existing methods and is thus suitable for GWAS. .

**Leveraging allele-specific expression to refine fine-mapping for eQTL studies.** J. Zou<sup>1</sup>, F. Hormozdizadeh<sup>2</sup>, B. Jew<sup>3</sup>, S. Castejón<sup>4,5</sup>, J. Ernst<sup>6,7</sup>, J. Sul<sup>8</sup>, E. Eskini<sup>1,7</sup>. 1) Computer Science Department, University of California Los Angeles, CA; 2) Genetic Epidemiology and Statistical Genetics Program, Broad Institute of MIT and Harvard, Cambridge, Massachusetts; 3) Bioinformatics Interdepartmental Program, University of California, Los Angeles; 4) New York Genome Center, NY, USA; 5) Department of Systems Biology, Columbia University, NY, USA; 6) Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, California; 7) Department of Human Genetics, University of California, Los Angeles, California; 8) Department of Biological Chemistry, University of California, Los Angeles, California.

Many disease risk loci identified in genome-wide association studies are present in non-coding regions of the genome. These variants can affect complex traits by acting as expression quantitative trait loci (eQTLs) that influence expression of nearby genes. Therefore, identifying causal variants for gene expression is also important for elucidating the genetic basis of complex traits. However, detecting causal variants is challenging due to complex genetic correlation among variants known as linkage disequilibrium (LD) and due to the presence of multiple causal variants within a locus. Although several fine-mapping approaches have been developed to overcome these challenges, they may produce large sets of putative causal variants when true causal variants are in high LD with many non-causal variants. In eQTL studies, there is an additional source of information that can be used to improve fine-mapping called allele-specific expression (ASE) that measures imbalance in gene expression of two haplotypes in a diploid organism. It has also been shown that ASE is enriched in eQTLs, indicating that genetic variants which cause changes in total gene expression are also likely to cause ASE. In this work, we develop a novel statistical method that leverages both ASE and eQTL information to detect a minimal set of variants ("causal set") that contain the true causal variant with high probability. We illustrate through simulations and application to the Genotype-Tissue Expression (GTEx) dataset that our method identifies the true causal variants with higher specificity than an approach that uses only eQTL information. In the GTEx dataset, our method achieves a median reduction of 18% in the number of putative causal variants compared to the naïve approach which only uses eQTL information. Using orthogonal genome annotation, we also show that the SNPs in the causal sets computed are significantly enriched for functional elements compared to the SNPs excluded from the causal sets. While this method is not the first to combine ASE and eQTL data to identify cis-regulatory variants, it is unique in that it uses ASE and eQTL data to perform fine-mapping while taking LD and multiple causal variants into account. The majority of existing methods perform a test for each variant instead of modeling the entire locus. We show that using these statistics in our fine-mapping framework achieves a smaller median reduction rate compared to the statistics developed in our approach.

**An integrated analysis tool for big genomic data from biobanks.** H.C. Yang, M.C. Huang, C.W. Chen. Institute of Statistical Science, Academia Sinica, Taipei, Taiwan.

An integrated analysis of big genomic data from a biobank provides an unmet opportunity to study health-related issues but must face a challenge in batch effect. There is an urgent demand for analysis tools that can simultaneously adjust for batch effect and provide an unbiased analysis of allele frequency (AF), allelic imbalance (AI), loss of heterozygosity (LOH), long contiguous stretch of homozygosity (LCSH), and copy number variation or alteration (CNV/CNA). In this study, we extended our software ALICE (AF/LOH/LCSH/AI/CNV/CNA Enterprise) [1] by incorporating a new plate-based tiling array method to reduce batch effect. Local references for different types of chromosomal aberrations were generated based on local samples in the nearest neighbor plates to a sample to be examined, and then used to detect relative chromosomal aberrations. A parallel computing algorithm was implemented to increase computational efficiency. In addition, the results of our qPCR experiments for previous copy number validation were used to examine the performance of ALICE compared to PennCNV. We applied our batch effect reduction method to a large genomic dataset of 10,245 samples, genotyped with the Affymetrix TWB arrays, from the Taiwan Biobank Project. A dramatic reduction, 68.6% – 100.0% of the between-batch variation, was observed. The first draft of genomic maps of AF, AI, LOH/LCSH, and CNV/CNA in a Taiwan population and its three subpopulations (Minnan, Hakka, and Mainlanders) were established. The qPCR experiments showed ALICE outperformed PennCNV with regard to sensitivity in detecting copy number aberrations. In conclusion, ALICE with a user-friendly interface provides a powerful tool for an integrated analysis of big genomic data from biobanks. An integrated analysis tool for hybridization intensities and genotypes using new-generation population-optimized human arrays. *BMC Genomics* 17, 266.

**3472T****Hi-C deconvolution via joint modeling of bulk and single-cell Hi-C data.**

R. Huh<sup>1</sup>, Y. Yang<sup>2</sup>, Z. Hou<sup>2</sup>, J. Szatkiewicz<sup>2</sup>, Y. Li<sup>1,2,3</sup>. 1) University of North Carolina at Chapel Hill, Department of Biostatistics; 2) University of North Carolina at Chapel Hill, Department of Genetics; 3) University of North Carolina at Chapel Hill, Department of Computer Science.

Hi-C is a genome-wide ('all-against-all') variant of chromosome conformation capture technique, which measures spatial interactions important in providing information for gene regulation and 3D structure of the genome. Standard Hi-C data are generated from millions of cells, thus providing a population average measure of heterogeneous cells. When Hi-C samples are collected from different physiological states, observed differences in contact information are confounded by relative proportions of cell types among samples. Many deconvolution methods have been developed to address cellular heterogeneity in bulk RNA-seq data. However, to date, there are no deconvolution methods applied to Hi-C data. Here, we adopt a matrix decomposition based framework to estimate the proportions of each cell type in bulk Hi-C samples, which can be crucial in downstream analysis where, for example, differences in cellular composition across samples need to be adjusted. Recent developments in measuring single-cell Hi-C enable us to simulate bulk mixtures of Hi-C data to test the validity of our deconvolution method in estimating cell type proportions. In contrast to RNA-seq data, where gene expression levels are used to describe the cells, we leverage different levels of Hi-C measurements such as metrics for topologically associating domains, interchromosomal and intrachromosomal contacts, for profiling. We have performed extensive real data based simulations to demonstrate the power of our method. For one example, we mix HAP1 and HeLa (two different human cancer cell lines) single cells, at varying (10-90%) mixture proportions. For another example, we mix two mouse cell lines: Patski and MEF. Using interchromosomal contacts as our Hi-C metric, our method is able to closely replicate the simulated mixture weights. Absolute deviations of estimated proportions from the truth range from 0.001 to 0.09 for the human dataset and 0.024 to 0.092 for the mouse dataset. We aim to assess our deconvolution method using different levels of Hi-C metrics to provide the optimal solution for cell type proportions.

**3473F****Why cross-study common controls are hard---and what can we do about it?**

S. Buyske<sup>1</sup>, C. DeBoever<sup>2</sup>, A. Felsenfeld<sup>3</sup>, C.R. Gignoux<sup>4</sup>, X. Lin<sup>5</sup>, K.E. North<sup>6</sup>, M.A. Rivas<sup>7</sup>, T. Stephan<sup>3</sup>, NHGRI Genome Sequencing Program. 1) Statistics & Genetics Depts, Rutgers University, Piscataway, NJ; 2) Data4Cure, La Jolla, CA; 3) National Human Genome Research Institute, Bethesda, MD; 4) Colorado Center for Personalized Medicine, University of Colorado, Anschutz Medical Campus, Aurora, CO; 5) Dept of Biostatistics, T.H. Chan School of Public Health, Harvard University, Boston, MA; 6) Dept of Epidemiology & Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC; 7) Department of Biomedical Data Science, Stanford University, Stanford, CA.

Cross-study common controls for genetic association studies seem like a great idea---why not take advantage of the thousands of already sequenced subjects? However reality is more complicated than first appears. Issues related to common controls fall into two categories: subject selection and data. Within subject selection are many sub-issues including: How similar in genetic space are the cases and controls? Can standard tools (e.g., principal components) measure structure across the frequency spectrum? How about environmental design characteristics and secular trends? Studies also typically differ in sampling methods, which can have an impact on subject selection. For example, medical system biobanks tend to recruit patients who more frequently utilize healthcare systems compared to individuals in cohort studies. Even something as straightforward as sex ratio can affect study power. More fundamentally, what is a common control? Traditionally, controls are disease-specific, screened for the disease in question. On the other hand, common controls are much more likely to have to be considered as population-based controls, with unknown disease status (the effect on power depends on both disease and allele frequency). Furthermore, common controls may lack covariates generally used in the analysis of any particular trait, leaving researchers to consider the effect of disease prevalence in a putative pool of common controls. On the genotyping side, the use of common controls raises the specter of batch effects confounding the genetic-phenotypic association signal. Sequencing is not yet standardized to a point that such effects can be disregarded. How important are they and can statistical approaches reduce or eliminate them? For a researcher with study-specific cases and controls, as well as additional controls from a common controls resource, statistical methods fall into two approaches: 1) using just genotype calls, which allows one to consider if the study-specific controls differ from the common controls and weight accordingly, or 2) using read counts, which can be tested without calling genotypes. Many groups, including GSP and TOPMed, are making sequenced samples available for potential use as common controls, but their use requires careful consideration. Here, we provide recommendations based on initial discoveries from the GSP and other large data repositories to aid researchers in understanding the advantages and the caveats of leveraging common controls. .

**High dimensional stratified LD score regression.** *R. Cui<sup>1</sup>, T. Jones<sup>1</sup>, F-E. Eid<sup>1</sup>, Y. Reshef<sup>1,3</sup>, A. Bloemendal<sup>1</sup>, A. Price<sup>1,2</sup>, H. Finucane<sup>1</sup>.* 1) Broad Institute, Cambridge, MA; 2) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Cambridge, MA; 3) Department of Computer Science, Harvard University, Cambridge, MA.

Stratified LD score regression (S-LDSC, Finucane et. al. 2015) models the effects of functional annotations on per-SNP heritability, enabling us to gain insight into genetic architecture and disease biology. However, S-LDSC has so far only been applied to model fewer than 100 functional annotations simultaneously due to poor performance of ordinary least squares (OLS) when large number of features are involved. Here, we extend stratified LD score regression to accommodate a large number of functional annotations. We use the lasso shrinkage method and modified stochastic gradient descent to fit the data. We show in simulations using real genotypes and real annotations a dramatic increase in accuracy for estimating categorical contributions to SNP heritability (i.e., regression coefficients) under sparse prior. In a model with 690 annotations including cell type specific annotations from Roadmap Epigenomics Consortium and the GTEx project as well as annotations from the baselineLD model, we ran 1000 simulations in which the regression coefficients are assumed to be sparse. To compare lasso performance with OLS, we took the median over all simulations of the mean squared error of the regression coefficients for both methods. lasso showed a near 5 order of magnitude increase in accuracy when estimating categorical contributions than the traditional OLS method. We applied our method to GWAS summary statistics of Schizophrenia, LDL, and Rheumatoid Arthritis, with the same 690 annotations. To evaluate our method without knowledge of the true regression coefficients, we computed a weighted mean squared error in predicted chi-square statistics on a left-out chromosome. We compared five different methods: ordinary least squares (OLS), lasso, lasso+OLS, Ridge, Elastic Net, and a “mean estimator” in which we predict every chi-square statistic to be the mean of the observed chi-square statistics. We see an improved prediction accuracy for summary statistics with regularization, with OLS performing similarly to the mean estimator, and Elastic Net and lasso performing the best.

**A correction for sample overlap in genome-wide association studies in a polygenic pleiotropy-informed framework.** *M. LeBlanc<sup>1</sup>, V. Zuber<sup>2</sup>, WK. Thompson<sup>3</sup>, OA. Andreassen<sup>4</sup>, THE. Schizophrenia/Bipolar<sup>5</sup>, A. Frigessi<sup>6</sup>, BK. Andreassen<sup>6</sup>.* 1) Oslo Centre for Biostatistics and Epidemiology, Oslo University Hospital, Oslo, Norway; 2) MRC Biostatistics Unit, University of Cambridge; 3) Department of Psychiatry, University of California, San Diego; 4) Division of Mental Health and Addiction, Oslo University Hospital, Oslo, Norway; 5) Oslo Centre for Biostatistics and Epidemiology, University of Oslo and Oslo University Hospital, Oslo, Norway; 6) Department of Research, Cancer Registry of Norway, Oslo Norway; 7) Psychiatric Genomics Consortium.

**Background** There is considerable evidence that many complex traits have a partially shared genetic basis, termed pleiotropy. It is therefore useful to consider integrating genome-wide association study (GWAS) data across several traits, usually at the summary statistic level. A major practical challenge arises when these GWAS have overlapping subjects. This is particularly an issue when estimating pleiotropy using methods that condition the significance of one trait on the significance of a second, such as the covariate-modulated false discovery rate (cmfdr). **Results** We propose a method for correcting for sample overlap at the summary statistic level. We quantify the expected amount of spurious correlation between the summary statistics from two GWAS due to sample overlap, and use this estimated correlation in a simple linear correction that adjusts the joint distribution of test statistics from the two GWAS. The correction is appropriate for GWAS with case-control or quantitative outcomes. Our simulations and data example show that without correcting for sample overlap, the cmfdr is not properly controlled, leading to an excessive number of false discoveries and an excessive false discovery proportion. Our correction for sample overlap is effective in that it restores proper control of the false discovery rate, at very little loss in power. **Conclusions** With our proposed correction, it is possible to integrate GWAS summary statistics with overlapping samples in a statistical framework that is dependent on the joint distribution of the two GWAS.

**Epigenetics-prioritized imputation of gene expression identifies more tissue-specific disease genes.** *W. Liu<sup>1</sup>, M. Li<sup>2</sup>, W. Zhang<sup>2</sup>, G. Zhou<sup>1</sup>, X. Wu<sup>3</sup>, H. Zhao<sup>1,2,3</sup>.* 1) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 2) Department of Biostatistics, School of Public Health, Yale University, New Haven, CT; 3) Molecular Cell Biology, Genetics and Developmental Biology Program, Yale University, New Haven, CT.

With ever increasing data available from Genome-Wide Association Studies (GWAS) and transcriptome studies, many methods have been developed to identify disease-related genes by considering gene expression-mediated genetic effects on traits. However, most existing methods have not fully captured tissue-specific gene expression regulations, leading to loss of statistical power in identifications of disease-associated genes in relevant tissues. In this presentation, we propose a powerful and robust statistical method incorporating epigenetics signals to better prioritize biologically functional Single Nucleotide Polymorphism (SNPs) in gene expression level imputation and to better identify tissue-specific disease genes. Built on the assumption that SNPs with epigenetic signals are more likely to regulate the expression levels of their nearby genes, our method can more accurately predict gene expression levels by better identifying expression quantitative trait loci (eQTLs) and improve power to identify disease-related genes. To assess the performance of our method, we first evaluated the gene expression imputation accuracy via a 5-fold cross-validation in the whole blood tissue of the GTEx data. Compared with the commonly adopted elastic net model, our method achieved higher accuracies (mean value: 0.079 versus 0.019) across all genes ( $p < 2.2e-16$ , with a sample size of  $n=338$ ). Furthermore, when our method was applied to identify genes associated with schizophrenia (SCZ), type 2 diabetes, Alzheimer's disease and other complex traits, our method identified more (22.22% ~ 37.31%) disease-associated genes across all tissues than existing methods. More importantly, our method identified more genes (32.94% ~ 66.67%) in disease-associated tissues. For example, for SCZ, our method identified not only risk genes inferred in previous studies, but also novel genes, such as *PCDHA7*, which encodes a cell adhesion protein and plays an important role in establishing neuronal connections in brain, implying its potential role in schizophrenia. Besides, compared with PrediXcan, our method recalled more (138 versus 114) published risk genes. Overall, through integrating epigenetic information, our new method not only can better impute gene expression levels, but can also increase the statistical power to identify gene-trait associations both tissue-specifically and ubiquitously, providing novel insights in understanding complex traits mechanisms using multi-omics data.

**Estimating genetic effect size from top-ranking genome-wide association statistics to remedy the winner's curse.** *D. Zaykin<sup>1</sup>, O. Vsevolozhskaya<sup>2</sup>.* 1) National Institute of Environmental Health Sciences, NC; 2) University of Kentucky, KY.

Effect size estimates of genetic associations with diseases, such as odds ratios (ORs), tend to overstate their true values in whole genome studies due to selection of top-ranking loci. Various methods have been proposed for reducing this selection bias, known as the winner's curse phenomenon, but in the absence of *a priori* assumptions about the effect size distribution across loci in the genome, there is no remedy for the winner's curse: the bias cannot be eliminated, only reduced. To correct for selection bias during statistical analysis, it is therefore important to incorporate biological information about aspects of the effect size distribution, such as plausible frequency of truly associated variants in the genome and possible range of the effect size magnitude. The effect size distribution can be modeled naturally as a prior distribution in the Bayesian framework, but accurate specification of parameters for the prior distribution remains a challenge owing to sparsity of truly associated variants. Focusing on the  $\log(\text{OR})$  as a measure of effect size, we derive a posterior distribution for  $\log(\text{OR})$  utilizing only association statistics as summary of data. We model the prior as a mixture of two distributions, one for the bulk of non-associated loci, carrying effects of negligible magnitude, and the second one describing effect size distribution for associated loci, governed by the variance parameter to capture the spread of  $\log(\text{OR})$ . We develop a simple and powerful method for estimating the prior mixture distribution from the top ranking association statistics. In our approach, the fitted prior parameters are utilized to obtain a bias-corrected posterior estimator of  $\log(\text{OR})$ . We demonstrate efficiency of the proposed estimator, as well as its resistance to the winner's curse.

**VikNGS C++ Tool for sequence-based association testing enabling consortium research: Updates and applications.** Z. Baskurt<sup>1</sup>, S. Mastro-matteo<sup>1,3</sup>, J. Gong<sup>1</sup>, S.W. Scherer<sup>3,4</sup>, L.J. Strug<sup>1,2,3</sup>. 1) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada, Toronto, ON, Canada; 2) Biostatistics Division, Dalla Lana School of Public Health, University of Toronto, ON, Canada; 3) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 4) McLaughlin Centre and Department of Molecular Genetics, University of Toronto, ON, Canada.

The Variant Integrating Kit for NGS (VikNGS) is a C++ package designed for common and rare variant association analysis using sequence data generated across different study cohorts. Integrating sequencing data from different sources to increase sample size can improve power but can also introduce spurious association findings due to differences in uncertainty in genotype calls and unbalanced case-control sample sizes. A robust variance score statistic (RVS) that uses expected genotypes has been shown to control Type I error in case-control association studies when the cases and controls were sequenced using different read depths (rd). We generalized the RVS method to include multiple sequenced cohorts for quantitative trait analysis with covariate adjustment, as well as for the integration of an arbitrary number of sequenced cohorts. VikNGS enables power analysis to estimate sample size for study planning through a simple user interface, handles rare variant testing with linear or quadratic RVS classes of tests and any user-defined weights, e.g. SKAT, and provides a regular score test with genotype calls. To demonstrate the utility of VikNGS we consider a highly unbalanced case-control association study integrating three independently sequenced samples: 1) 101 samples with cystic fibrosis (CF) sequenced at 30x by Complete Genomics Inc, 2) 1927 samples without CF from the UK10K Consortium sequenced at an average rd of 6.5x, and 3) 379 European samples without CF from the 1000 Genomes Project Phase 1 sequenced at an average rd of 4x. We generated a multi-sample VCF file for chr 22 (no expected association with CF) and conducted association tests using 1) the generalized 3-group RVS method, 2) a method that uses expected genotypes but does not implement the RVS method and 3) the conventional score test using genotype calls. The generalized RVS approach is robust to unbalanced case-control designs and differential read-depth across the multiple cohorts. The other two tests produced many spurious associations. Quantitative trait analysis of lung function using the UK10K Consortium data and the generalized RVS demonstrate association at a CF lung disease modifier locus at chr 1, suggesting the CF modifier locus is relevant in the general population. VikNGS is a computationally efficient package that provides functionality for association analysis of WGS from multiple study groups through a user-friendly graphical interface.

**GASPOR: Detecting gene-level allele-specific expression in a population by RNA sequencing.** J. Fan<sup>1</sup>, J. Hu<sup>1</sup>, C. Xue<sup>2</sup>, M. Reilly<sup>2</sup>, R. Xiao<sup>1</sup>, M. Li<sup>1</sup>. 1) Department of Biostatistics, Epidemiology and Informatics, University of Pennsylvania, Philadelphia, PA; 2) Cardiology Division, Department of Medicine, Columbia University Medical Center, New York, NY.

Allele-specific expression (ASE) analysis, which quantifies the relative expression of two alleles in a diploid individual, is a powerful tool for identifying *cis*-regulated gene expression variations that underlie phenotypic differences among individuals. To understand the role of ASE in human diseases, we exploit allelic imbalance by RNA-seq, which provides allele-specific read counts at exonic SNPs distinguished by heterozygous sites. Existing methods for ASE detection report evidence of ASE in single individuals, in which the ASE is quantified for each SNP and a gene-level ASE is obtained by integrating effects across SNPs in the same gene for an individual. However, evidence of ASE is often shared across individuals. Failure to accommodate such shared information not only loses power, but also makes it difficult to interpret results across individuals. It is desirable to have a method that simultaneously models both multi-SNP and multi-individual information. However, ASE detection across individuals is challenging because the data often include some individuals that are heterozygous for the unobserved *cis*-regulatory SNP and others that are homozygous for the *cis*-regulatory SNP, leading to heterogeneity in ASE as only those heterozygous for the *cis*-regulatory SNP will show evidence of ASE, whereas those homozygous individuals will have balanced expression. To simultaneously model gene-level ASE across individuals and to account for such heterogeneity, we develop GASPOR, a mixture model of two binomial distributions with subject-specific random effect to account for correlation of multiple SNPs within the same gene. GASPOR is able to detect gene-level ASE under one condition and differential ASE between two conditions (e.g., pre- vs post-treatment). Extensive simulations show that GASPOR performed consistently well under a variety of scenarios, and was substantially more powerful than individual-based ASE detection methods. We further applied GASPOR to RNA-seq data in the Genetics of Evoked Response to Niacin and Endotoxemia Study, and identified genes showing strong evidence of differential ASE pre- vs post-LPS stimulation, which were missed by existing methods. To the best of our knowledge, GASPOR is the first method for gene-level ASE detection in a population. With the growing popularity of RNA-seq, we believe GASPOR will be well-suited for various ASE studies for human diseases. An R package of GASPOR will be available.

**3480W****Fast and robust ancestry inference using principal component analysis.**

*D. Zhang, R. Dey, S. Lee.* Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Population stratification (PS) is a major confounder in genome-wide association studies (GWAS) and can lead to false positive associations. To adjust for PS, principal component analysis (PCA)-based ancestry prediction has been widely used. This approach first performs PCA on the reference samples with detailed ancestry information and then uses the reference sample PCA results to predict the PC scores of the study samples. Simple Projection (SP) and Augmentation-Decomposition-Transformation (ADP), such as LASER and TRACE, are popular methods for predicting PC scores. However, they are either biased or computationally expensive. For example, the predicted PC scores from SP can be biased toward NULL. On the other hand, since ADP requires running PCA separately for each study sample on the augmented dataset, its computational cost is high. To address these problems, we propose two alternative approaches, Adjusted Projection (AP) and Online ADP (OADP), and have implemented them in our genoPCA software. Using random matrix theory results, AP asymptotically estimates and adjusts for the bias of SP. OADP uses online singular value decomposition, which can greatly reduce the computation cost of ADP. We carried out extensive simulation studies to show that these alternative approaches are unbiased and that the computation times are 10-100 times faster than ADP when 2000 reference samples are used. We also applied our approaches to 500,000 study samples from the UK biobank data with 2,500 samples from the 1000 Genomes data as the reference. AP and OADP required 16 and 92 CPU hours, respectively, while the projected computation time of ADP is 1,933 CPU hours. Furthermore, when we only used the European reference samples in the 1000 Genomes to infer sub-European ancestry, SP clearly showed bias, unlike the proposed approaches. By using AP and OADP, we can infer ancestry and adjust for PS in GWAS robustly and efficiently.

**3481T****Kernel association test for rare copy number variants using CNV intensity profiles.** *A. Brucker<sup>1</sup>, W. Lu<sup>1</sup>, R.M. West<sup>1</sup>, J. Szatkiewicz<sup>2</sup>, J.-Y. Tzeng<sup>1</sup>.* 1) NC State University, Raleigh, NC; 2) UNC Chapel Hill, Chapel Hill, NC.

Copy number variants (CNVs) are the gain or loss of DNA segments in the genome that can vary in dosage and length. Rare CNVs have been shown to be associated with phenotypes including cancers and psychiatric disorders. Recent studies have shown that kernel-based tests are a useful tool for assessing the aggregate effect of rare CNVs on phenotypes, due to their ability to capture between- and within-locus etiological heterogeneity. To perform a kernel association test, a CNV locus needs to be defined so that similar variants in a single locus correspond to similarity in profiles. Then collapsing methods are applied to summarize similarity across all loci and a kernel is constructed. There is nuance in the choice of locus with which the "locus"-specific effects are retained during aggregation, and current work has suggested that different locus definitions can lead to different relative performance depending on the underlying effect patterns. In this work, we propose a new kernel-based test that does not require a definition of locus but makes use of the alignment of CNV profiles performed in standard CNV data processing. This test has power to detect associations driven by CNV dosage, length, and dosage-length interactions. In a variety of simulation settings the proposed test shows comparable and improved power over existing approaches. A real data analysis will examine the performance of the test applied to known gene pathways for data from the Psychiatric Genomics Consortium.

**Enrichment of survey responses by genetic community within a large genetic genealogy database.** *E.P. Sorokin<sup>1</sup>, K.A. Rand<sup>1</sup>, J.M. Granka<sup>1</sup>, A. Girshick<sup>1</sup>, L. Nguyen<sup>1</sup>, J. Byrnes<sup>1</sup>, K. Noto<sup>1</sup>, E.L. Hong<sup>1</sup>, K.G. Chahine<sup>2</sup>, C.A. Ball<sup>1</sup>.* 1) Ancestry.com DNA, LLC, San Francisco, CA; 2) Ancestry.com DNA, LLC, Lehi, UT.

The increased scale of human genetic cohorts has empowered the elucidation of cryptic population structure, often through the detection of regions of identity-by-descent. Our analysis, coupled with community detection algorithms across a network of AncestryDNA customers who consented to research, has yielded a portrait of the fine-scale population structure within post-colonial America, including genetic communities of European, African, East Asian, South Asian, Middle Eastern and Oceanian ancestry. In addition to rich metadata stemming from historical records and other genealogical sources, we sought to determine whether additional sources of data could elucidate cultural or other factors underlying the formation or maintenance of this population structure. To further understand patterns within and across genetic communities, we collected survey responses from a subset of AncestryDNA customers. Here, we examine the distributions of these survey responses by genetic communities and characterize their community-specific prevalence. We also perform association analyses with certain traits and directly genotyped SNPs. We show that some traits have distinct patterns across fine-scale population structure and we also contribute to the replication and identification of loci associated with certain traits. .

**3483W**

**Imputed gene associations identify replicable *trans*-acting/target gene pairs and suggest a larger *trans* than *cis* contribution to complex trait architecture.** *H.E. Wheeler<sup>2,3</sup>, S. Ploch<sup>1</sup>, A.N. Barbeira<sup>4</sup>, H.K. Im<sup>4</sup>.* 1) Dept of Biology, Loyola University Chicago, Chicago, IL; 2) Dept of Computer Science, Loyola University Chicago, Chicago, IL; 3) Dept of Public Health Sciences, Loyola University Chicago, Maywood, IL; 4) Section of Genetic Medicine, Department of Medicine, University of Chicago, Chicago, IL.

Genetic variation contributes to complex trait variation through regulation of gene expression. Much progress has been made in uncovering local *cis*-acting expression quantitative trait loci (eQTLs), but distal *trans*-acting eQTLs have been more difficult to identify and replicate. Here, we apply PrediXcan to map *trans*-acting genes, rather than SNPs. We compared results between the discovery Framingham Heart Study (FHS, n=4838) and the replication Depression Genes and Networks (DGN, n=922) whole blood cohorts. We used *cis*-acting models built in the Genotype Tissue Expression (GTEx) Project whole blood cohort to predict gene expression in FHS and DGN. Examining the correlations between predicted and observed gene expression of gene pairs on different chromosomes, 124 pairs were significantly correlated in FHS, with an expected true positive rate ( $\pi_1$ ) of 0.70 in DGN. To determine if combining predicted expression across tissue models could improve our ability to detect *trans*-acting/target gene pairs, we used the multivariable regression approach called MultiXcan, which accounts for correlation among predicted expression levels across 44 GTEx tissues. When we applied MultiXcan to the FHS data, we discovered 3657 *trans*-acting/target gene pairs, a dramatic increase compared to the single tissue whole blood model. Although the expected true positive rate of the multi-tissue model was lower ( $\pi_1=0.43$ ) than the single tissue model, the absolute number of replicate gene pairs was much higher. Thus, our *trans*-MultiXcan model increases power to detect *trans*-acting gene pairs >10-fold, indicating shared *cis*-eQTL allow us to leverage multiple tissues to detect more *trans*-acting effects. Pathway analysis of replicated MultiXcan gene pairs revealed the *trans*-acting genes are enriched in transcription and nucleic acid binding pathways and target genes are enriched in transcription factor binding sites and highly conserved motifs, indicating that our method identifies genes of expected function. We found that MultiXcan *trans*-acting and target genes are more heritable than other expressed (background) genes. Using height as a representative complex trait, *trans*-acting gene associations with height are more significant than target and background gene associations in both UK Biobank (n=500,131) and the GIANT Consortium (n=253,288), consistent with a larger contribution of *trans*-acting effects than *cis*-acting effects to complex traits.

**Discovery of novel hepatic eQTLs in African Americans: Disparities in precision medicine.** Y. Zhong<sup>1</sup>, Y. Xu<sup>2</sup>, T. De<sup>1</sup>, A. Alarcon<sup>1</sup>, CS. Park<sup>1</sup>, BM. Lec<sup>1</sup>, MA. Perera<sup>1</sup>. 1) Northwestern University, Chicago, IL; 2) University of Chicago, Chicago, IL.

Genetic regulation of gene expression through eQTLs has been studied in a variety of treatment conditions and tissue types. However, the catalog of eQTLs needs to be expanded to be inclusive of other minority populations. Importantly, population-specific eQTLs promise to provide mechanistic insight of transcriptome regulation within and across populations. Liver is a critical organ for the understanding of drug metabolism, as well as diseases such as coagulopathies and metabolic disorders. Both of these broad disorders show disparities in morbidity, mortality and response to drug therapy between African Americans (AAs) and non-African populations. In the GTEx project, only 15 individuals of African ancestry comprised the liver eQTL mapping of 449 individuals, making extrapolation of this more diverse population under-powered and not representative of the larger AA population. Here, we performed the first eQTL mapping in AA hepatocytes and identified 28,855 significant gene-SNP pairs corresponding to 387 eGenes and overlapped identified eQTLs with GTEx liver eQTLs (v.7) results. While there was a significant correlation of effect sizes of common eQTLs, we observed a large number of eQTLs (9,655) and eGenes (145) were unique to AA hepatocytes. We found larger allele frequency differences between African and European populations for AA-specific eQTLs compared to common eQTLs, suggesting differences in allele frequency underlie population-specific eQTLs. Given the scarcity of exon QTLs data available, we identified 3,190 exon QTLs corresponding to 150 eExons. Surprisingly, 101 eExons do not belong to identified eGenes, suggesting mapping exon QTLs may reveal additional regulatory events related to differential transcript expression. We next characterized the functional properties of AA hepatic eQTLs. AA eQTLs cluster primarily near the transcriptional start site as compared to other cis regions. Using CaVEMaN, we identified 5% of lead SNPs with larger than 0.6 probability of being a causal variant. Finally, we built a PrediXcan model that predicted hepatic transcriptome (852 reliable genes) with AA genotype and found a moderate correlation (spearman  $\rho = 0.13$ ) of prediction accuracy when compared with GTEx European liver model. Together, this is the first comprehensive study that characterizes the genetic regulation of gene expression in AA hepatocytes, revealing population-specific regulation of eQTLs with implications for disease genomics and pharmacogenomics.

**Robust and powerful analysis of gene-environment interactions using polygenic risk scores in case-control studies.** N. Chatterjee<sup>1,2</sup>, A. Meisner<sup>1</sup>. 1) Department of Biostatistics, Johns Hopkins School of Public Health, Baltimore, MD; 2) Department of Oncology, Johns Hopkins School of Medicine, Baltimore, MD.

**Background** Assessment of gene-environment interactions is critical for understanding disease etiology, developing models for risk prediction, and evaluating the impact of lifestyle interventions by genetic background. Despite the availability of powerful methods and large datasets, investigations of gene-environment interactions have led to very limited findings to date, possibly due to weak effects of individual SNPs. Use of polygenic risk scores (PRS), overall or possibly grouped by pathways, can be a powerful strategy for detecting global patterns of interactions across many genetic variants. **Methods** Motivated by the power of the case-only design for the efficient analysis of single SNP gene-environment interactions, we consider retrospective approaches to the analysis of PRS in case-control studies. We show that under the assumptions of normality of the PRS and independence between the PRS and the environmental risk factor (E), relative risk interaction parameters can be estimated by performing a linear regression analysis of PRS on E in a sample of cases. Furthermore, if genotype data are available on a sample of subjects representative of the population, information on the mean of the PRS can be used to estimate the main effect of the PRS in the underlying disease risk model. Further extensions are considered to account for population stratification and gene-environment dependence, the latter of which could be modeled using a PRS associated with E. **Results** Simulation studies indicate the efficiency of the case-only method is similar to that of a full cohort study with a comparable number of cases and is about twice that of a standard logistic regression analysis of a case-control study with an equal number of cases and controls. We observe similar efficiency of the method in the analysis of gene-environment interactions and breast cancer risk in the UK Biobank cohort study and simulated case-control studies within this cohort. Results from additional simulation studies and analyses investigating the effects of population stratification and gene-environment dependence will be presented. **Conclusion** Case-only and other retrospective methods have the potential to greatly enhance the power of gene-environment interaction analysis based on PRS in case-control studies. However, careful consideration is needed to avoid bias due to population stratification and gene-environment associations.

**Reconstruction of patterns of cryptic relatedness and identification of the resulting shared genomic segments in a large electronic health record-linked DNA biobank.** *H-H. Chen, L.E. Petty, J.E. Below.* The Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville, TN.

In regionally ascertained samples it is common to enroll individuals that are cryptically related to one another; when genetic data are available for the sample, these cryptic relationships can be discovered and utilized in epidemiologic and genetic analyses. Specifically, the number and length of shared genomic segments can be used to estimate the relatedness between individuals, reconstruct pedigrees, trace population history, and even map disease genes. The Vanderbilt DNA biobank (BioVU) has collected DNA samples from over 280,000 participants with linked electronic health records from Vanderbilt University Medical Center. Characterization of full pedigree reconstruction, distant relatedness, and shared genomic segment detection in all 280,000 participants is on-going, however, in preliminary analyses, we estimated relatedness, reconstructed pedigrees, and identified shared segments in a subset of 6,551 individuals from BioVU genotyped on the Illumina Multi-Ethnic Global Array (MEGA), using 815,371 variants. Shapeit2 was applied to estimate each individual's haplotype, and then GERMLINE was performed to identify the shared segments between all pairs of participants who shared segments identical-by-descent (IBD). We then reconstructed pedigrees using PRIMUS and determined pair-wise relatedness using ERSAs and PADRE. In our preliminary investigation, the average shared segment length is 4.538 cM, and among individuals who shared at least one segment, the mean number of shared segments is 2.054. The maximum number of shared segments observed was 62. We identified 42 first-degree relatives (parent-offspring or siblings), 28 second-degree relatives, and 83 third-degree relatives. 941 pairs were related at 4<sup>th</sup> or 5<sup>th</sup> degree, 1,284 pairs were related at 6<sup>th</sup> or 7<sup>th</sup>, and over 48% of pairs were estimated to be related at 8<sup>th</sup> or 9<sup>th</sup> degree. These results highlight the complex and significant patterns of unreported relatedness captured in regionally ascertained biobanks, a finding that has important consequences for future epidemiologic and genetic analyses, as well as providing an untapped avenue for IBD-based disease-gene discovery.

**Exome-chip association study of refractive error in U.S. Caucasians.** *D.D. Lewis<sup>1</sup>, J. Ishika<sup>1</sup>, T. Alexander<sup>1,2</sup>, A.M. Musolf<sup>1</sup>, D. Stambolian<sup>3</sup>, J.E. Bailey-Wilson<sup>1</sup>.* 1) Computational and Statistical Genomics Branch, National Human Genome Research Institute, Baltimore, MD; 2) National Institute of Arthritis and Musculoskeletal and Skin Diseases, Bethesda, MD; 3) Department of Ophthalmology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Refractive error occurs when light fails to properly focus on the retina of the eye. In the case of myopia, the light is focused in front of the retina, causing blurry distance vision. Myopia is defined in terms of refractive error (RE), a quantitative trait measured in Diopters (D), such that individuals with RE of -0.5D or more negative generally require glasses to correct their vision. Individuals with high myopia (RE < -6D) are vulnerable to ocular complications later in life. Consequently, great efforts have been undertaken to identify and understand the mechanisms underlying the development and progression of myopia. Some environmental exposures contribute to risk and genome-wide association studies (GWAS) and linkage studies have identified loci underlying the distribution of refractive error and influencing the risk of myopia. However, few causal variants have been definitely identified and a large proportion of the variation in refractive error remains unexplained. Therefore, this study aims to determine whether rare variants may account for some of the variation of refractive error. Here we present results of a single-variant association test for a quantitative trait, refractive error, in 1562 control individuals from the Age-Related Eye Disease Study (AREDS). After quality control, close to 100,000 variants were analyzed and EMMAX single-marker analysis identified 18 rare variants that were genome wide significant ( $p < 5 \times 10^{-6}$ ). Interesting candidate variants were found in genes *NIPSNAP2*, *TSSK3* and *IDH1*. One study identified a role for *IDH1* in bovine eyes, where the enzyme protein fulfills the criteria for a corneal epithelial crystallin, which may be involved in maintaining corneal epithelial transparency. We are extending the analysis to gene-based tests and will present these results.

**3488F****Robust region-based test for unbalanced case-control phenotypes.** Z.Zhao<sup>1,2</sup>, L. Fritsche<sup>1,2</sup>, M. Zawistowski<sup>1,2</sup>, C. Brummett<sup>3</sup>, G. Abecasis<sup>1,2</sup>, S. Lee<sup>1,2</sup>.

1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI; 3) Department of Anesthesiology, University of Michigan Medical School, Ann Arbor, MI.

In Biobank data analysis, most binary phenotypes from Electronic Health Records (EHR) have unbalanced and often extremely unbalanced case-control ratios (1:10 or 1:100, respectively), which can cause inflation of type I error rates. Recently, a saddlepoint approximation (SPA) based single variant test has been developed to provide an accurate and scalable method to test for associations of such phenotypes. For gene or region-based multiple variant tests, a few methods exist which adjust for unbalanced case-control ratios; however, these methods are either less accurate when case-control ratios are extremely unbalanced or not scalable for large data analyses. Here we propose SKAT/SKAT-O type region-based tests, where the single-variant score statistic is calibrated based on SPA and Efficient Resampling (ER). Our method also utilizes a small number of resampling to estimate higher moments of overall test statistics, which can further calibrate association p-values. Through simulation studies, we show that the proposed method can both adjust for covariates and provide well-calibrated p-values. In contrast, the unadjusted approach has greatly inflated type I error rates (200 times of exome-wide  $\alpha=2.5 \times 10^{-6}$ ) when case: control ratio was 1:99. In the application to the Michigan Genomics Initiative (MGI), we show that the proposed method can control type I error rates even for traits with a very small number of cases and a large number of controls (e.g. Breast cancer: 1160 cases and 15473 controls; Gout: 449 cases and 17644 controls; and Primary hypercoagulable state: 168 cases and 16401 controls).

**3489W****Haplotype-based GRMs complement SNP-based GRMs in a regional heritability analysis of complex traits.** R.F. Oppong<sup>1</sup>, P. Navarro<sup>2</sup>, C.S. Haley<sup>2,3</sup>,S. Knott<sup>1</sup>. 1) Institute of Evolutionary Biology, The University of Edinburgh, Edinburgh, United Kingdom; 2) MRC IGMM, The University of Edinburgh, Edinburgh, United Kingdom; 3) The Roslin Institute and Royal Dick School of Veterinary Studies, The University of Edinburgh, Edinburgh, United Kingdom.

We have proposed and implemented a genome-wide analytical method that analyses blocks of genomic regions using a regional GREML model. The novelty in our method is that genomic regions in our data are defined naturally by recombination hotspots drawn from a reference human genome and we use a regional GREML model that fits a haplotype-based GRM. We compared this model to a regional GREML model that fits a SNP-based GRM. We hypothesise that the haplotype-based model will complement conventional SNP-based GREML methods by capturing regions in the genome contributing to the phenotypic variation that the SNP-based methods fail to capture. This can arise where there are causative variants associated with individual haplotypes but not in linkage disequilibrium with individual SNPs. This scenario is particularly likely for relatively newly-arisen and rarer variants. We tested this hypothesis in a simulation study involving 20,000 individuals in which we simulated 20 replicates each of two types of phenotypes with SNPs and three types of phenotypes with haplotypes as the effect variants. The results show that the two models are very specific to the type of marker effect they can capture; – the haplotype-based model can specifically target haplotype effects which are mostly missed by SNP-based analysis and vice versa. These results, therefore, support the hypothesis that haplotype-based GREML models will complement SNP-based GREML models. In conclusion, the use of haplotype-based GREML regional heritability models in the analysis of real data is of interest as these models can identify causal effects when the variance is explained by haplotype-associated variants that cannot be detected using other analytical models.

**Kids First Data Resource Center: Advancing genetic analyses of structural birth defects and childhood cancer.** *D.M. Taylor*<sup>1,2</sup>, *S. Volchenboum*<sup>3,4</sup>, *A. Heath*<sup>1</sup>, *Y. Zhu*<sup>1</sup>, *L. Graglia*<sup>3</sup>, *B. Furner*<sup>3</sup>, *J. Lilly*<sup>1</sup>, *P. Raman*<sup>1</sup>, *B. Farrow*<sup>1</sup>, *T. Patton*<sup>1</sup>, *A. Resnick*<sup>1</sup>, *Gabriella Miller Kids First Data Resource Center.* 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, Perelman School of Medicine, The University of Pennsylvania, Philadelphia PA; 3) Center for Research Informatics, The University of Chicago, Chicago, Illinois; 4) Department of Pediatrics, Biological Sciences Division, The University of Chicago, Chicago, Illinois.

Structural birth defects and childhood cancers share a common context of altered developmental biology. Numerous studies have provided clear evidence that children with certain structural birth defects or developmental disorders have an increased risk of developing cancer during childhood. Moreover, it is also known that various structural and developmental defects often co-occur independent of known syndromes, providing complex phenotypes of developmental defects that appear to share a common genetic basis. A better understanding of genetic variation within and across a disparate set of developmental and cancer phenotypes, genes, and pathways could spur advancements in prevention, detection, and therapeutics to improve outcomes for affected children and families. The NIH Common Fund's Gabriella Miller Kids First Pediatric Research Program (GMKF) is a collaborative initiative focused on providing large-scale clinically-annotated genomic data for pediatric cancer and structural birth defect cohorts, including trio germline whole genome sequencing (WGS) and tumor WGS and RNA-seq. The GMKF Kids First Data Resource Center (DRC, <https://kidsfirstdrc.org/>) is charged with empowering collaborative research and discovery through integration of GMKF cohorts and external data. The Kids First Data Resource Portal (DRP) is a first-of-its-kind international repository for GMKF cohorts and data discovery environment, which will facilitate data release to the community through the dbGAP application and data use agreement process. As of 2017, there are 23 GMKF cohorts funded for sequencing (15 structural birth defects and 8 pediatric cancers). Approximately 8,000 WGS patient samples and phenotypes will be available at the launch of the Kids First DRC portal in June 2018, and 25,000 WGS will be available by early 2019, making the Kids First DRP one of the largest pediatric data resources of its kind. We present preliminary summarization analyses, including of phenotype and genotype data across available cohorts. Germline genomic summaries include *de novo* events, rare variant frequencies, affected genes and any relationships to cancer mutation data. Phenotype summaries include information content and cross-cohort relationships through ontological analysis. We show how the Kids First DRP can help investigators at all levels access and analyze the Kids First cohort data.

**Refining fine-mapping: Effect sizes and regional heritability.** *C. Benner*<sup>1,2</sup>, *A. Havulinna*<sup>1,3</sup>, *V. Salomaa*<sup>2</sup>, *S. Ripatti*<sup>1,2,4</sup>, *M. Pirinen*<sup>1,2,5</sup>. 1) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 2) Department of Public Health, University of Helsinki, Helsinki, Finland; 3) National Institute for Health and Welfare, Helsinki, Finland; 4) Broad Institute of MIT and Harvard, Cambridge, USA; 5) Helsinki Institute for Information Technology HIIT and Department of Mathematics and Statistics, University of Helsinki, Helsinki, Finland.

Recent statistical approaches have shown that the set of all available genetic variants explains considerably more phenotypic variance of complex traits and diseases than the individual variants that are robustly associated with these phenotypes. However, an ultimate goal in genetics research is to narrow down the polygenic regional heritability into individual causal variants contributing to heritability. Because rapidly increasing sample sizes constantly improve fine-mapping of causal variants, it is useful to routinely estimate how much phenotypic variance the detected causal variants explain for each region. We have therefore extended the FINEMAP software to estimate the effect sizes and regional heritability under the probabilistic model that assumes a handful of causal variants per each region. Using the UK Biobank data to simulate genomic regions with only a few causal variants, we demonstrate that FINEMAP provides higher precision and enables more detailed decomposition of regional heritability into causal variants than the variance component model implemented in BOLT or the fixed-effect model implemented in HESS. Using data from 51 serum biomarkers and four lipid traits from the FINRISK study, with a broad spectrum of genome-wide heritability levels, we estimate that FINEMAP captures on average 24% more regional heritability than the variant with the lowest P value alone and 20% less than BOLT. As an example where both FINEMAP and BOLT give a similar estimate of about 70% regional heritability, we study in detail the association between the *PON1* gene and Paraoxonase 1 levels. Our simulations suggest how an upward bias of BOLT and a downward bias of FINEMAP could together explain the observed difference between the methods. We conclude that FINEMAP provides a computationally efficient framework to deduce a variant-level picture of the regional genetic architecture and expect that these new features prove useful as the accuracy of fine-mapping constantly increases with rapidly growing sample size in the era of biobank-scale data.

**A regression-based framework for large-scale integration of pathway knowledge in GWAS.** S. Bhattacharjee, S. Biswas, S. Pal. National Institute of Biomedical Genomics, Kalyani, West Bengal, India.

Traditional unbiased Genome-wide Association Studies (GWAS) have successfully identified thousands of genetic polymorphisms (SNPs) to be associated with various complex traits. However, GWAS are under-powered to detect all associated variants due to a huge multiple-testing burden; particularly true for variants with lower frequency or weaker effects. There is recent interest in conducting prioritized analysis of GWAS using SNP-level functional annotations and some rigorous statistical methods have been developed to enable incorporation of SNP-level knowledge. Another, very rich source of biological knowledge exists in the form of gene-level functional annotations (e.g. pathways). Pathway enrichment analysis, occasionally used after a GWAS, can help in the interpretation of findings; but does not by itself improve the power of detecting additional novel loci. It is imperative to use knowledge of pathways/networks a-priori to 'inform' the genome-wide search. Here, we develop a statistical method to enable a prioritized genome-wide scan using knowledge from a very large number of gene-level annotations (e.g. pathways from a pathway database). Our method is computationally efficient and scalable for routine use with large number of annotations. It takes as input p-values of SNPs from a GWAS and re-weights them optimally with pathway information utilizing a flexible framework based on regularized logistic regression. We demonstrate using simulations and real GWAS data on Type-2 Diabetes, Coronary Artery Disease etc., that such a 'pathway-guided GWAS' can indeed gain substantial power over unbiased GWAS, specifically when the associated SNPs map to genes that cluster into a few biological pathways. Unlike most prioritization tools using FDR, our method maintains global false-positive rates at the same stringency as in a usual GWAS (i.e.  $p < 5 \times 10^{-8}$ ). We have created an R package 'GKnowMTest' (Genomic Knowledge-guided Multiple Testing) for flexible incorporation of gene-level knowledge into GWAS. Further, we have extended our method to allow large number of SNP-level functional annotations retaining the computationally simple regression-based framework. In conjunction with knowledge from pathways, we are using SNP-level knowledge including histone marks, transcription factor binding and regulation of gene expression in tissues to prioritize GWAS and assess the gains in power of detecting associated loci.

**3493T**

**Revisiting the genome-wide significance threshold.** Z. Chen, M. Boehnke, B. Mukherjee. Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Genome-wide association studies (GWAS) have successfully yielded reproducible results by using a P-value threshold of  $5 \times 10^{-8}$  to classify association results as genome-wide significant. However, this threshold was proposed a decade ago, before the advent of newer experimental and imputation strategies that now allows us to study many more common and low-frequency variants. In this study, we revisit the P-value threshold of  $5 \times 10^{-8}$  with empirical and simulation analysis and compare that decision rule to two other metrics for controlling multiple hypotheses testing: the Benjamini-Hochberg-Yekutieli (BHY) procedure and Bayesian false-discovery probability (BFDP). We applied various threshold and decision rules to a series of GWAS with sequentially growing datasets from the Global Lipids Genetics Consortium (GLGC) and evaluated the performance of these metrics in detecting noteworthy signals from the most recent GWAS results in 2013 assuming the latest GWAS represents "true signals". In addition, we re-estimate a genome-wide significance threshold using a permutation procedure suggested by Dudbridge and Gusnanto (2008) but with a simulated dataset at the size and scale of more recent GWAS with much higher marker density. For the fixed P-value metric, compared to a threshold of  $5 \times 10^{-8}$  a less stringent threshold of  $5 \times 10^{-7}$  gains on average 6 additional true discoveries and controls the empirical false-discovery rate (FDR) between 6 and 17%. BHY and BFDP, which seeks to directly control the FDR, did not produce consistently better empirical FDRs than the fixed P-value metric and are more complex to use. Applying these methods to testing multiple traits simultaneously (e.g. three lipid traits together) lowered the empirical FDR by an average of 5.6% when compared to the combined univariate tests. To estimate a genome-wide significance threshold, we will permute phenotypes for 6,000 samples and ~9.5 million variants from the most recent UK Biobank study on body mass index and repeat the procedure 1,000 times. We then calculate the effective number of independent tests at multiple marker densities using the minimum P-values and extrapolate to full saturation of the whole-genome by fitting a Monod function.

**3494F**

**Efficient and accurate estimation of genotype odds ratios in biobank-based unbalanced case-control studies.** *R. Dey, S. Lee.* Biostatistics, University of Michigan, Ann Arbor, MI.

In genome-wide association studies (GWASs), genotype odds ratios (ORs) quantify the effects of the variants on the binary phenotypes, and calculating the genotype ORs for all of the markers is required for several downstream analyses. Calculating genotype ORs in a genome-wide scale is computationally challenging, especially when analysing large-scale biobank data, which involves performing thousands of GWASs phenome-wide. Since most of the binary phenotypes in biobank-based studies have unbalanced (case:control = 1:10) or often extremely unbalanced (case:control = 1:500) case-control ratios, the existing methods cannot provide a scalable and accurate way to estimate the genotype ORs. The traditional logistic regression provides biased OR estimates in such situations. Although the Firth bias correction method can provide unbiased OR estimates, it is not scalable for genome-wide or phenome-wide scale association analyses typically used in biobank-based studies, especially when the number of non-genetic covariates is large. On the other hand, the saddlepoint approximation-based test (fastSPA), which can provide accurate p values and is scalable to analyse large-scale biobank data, does not provide the genotype OR estimates as it is a score-based test. Here, we propose a scalable method using the fastSPA approach, to accurately estimate the genotype ORs, adjusting for non-genetic covariates. Comparing to the Firth method, our proposed method reduces the computational complexity by  $O(k^3)$ , where  $k$  is the number of non-genetic covariates. Our method is  $\sim 10$ x faster than the Firth method when sample size is 20000, and 10 non-genetic covariates are being adjusted for. Through extensive numerical simulations and real data examples, we show that the proposed method is both scalable and accurate in estimating the genotype ORs in genome-wide or phenome-wide scale.

**Harmonizing genetic ancestry and self-identified race/ethnicity (HARE) for genome-wide association study in the Million Veteran Program.** *H. Fang<sup>1</sup>, Q. Hu<sup>2</sup>, J. Huang<sup>3,4</sup>, S. Damraue<sup>5,6</sup>, J. Honerlaw<sup>4,7</sup>, T. Assimes<sup>1,8</sup>, J. Lynch<sup>9</sup>, P. Wilson<sup>2</sup>, C. O'Donnell<sup>3,4</sup>, S. Pyarajan<sup>3,4</sup>, M. Gaziano<sup>1,7</sup>, S. DuVal<sup>10</sup>, K. Cho<sup>3,4,7,10</sup>, P. Tsao<sup>1,8</sup>, K. Chang<sup>5,6</sup>, Y. Sun<sup>2,11</sup>, H. Tang<sup>1</sup>* on behalf of the VA Million Veteran Program. 1) Stanford University, Stanford, CA; 2) Emory University, Atlanta, GA; 3) Harvard Medical School, Boston, MA; 4) Veterans Affairs Boston Healthcare System, Boston, MA; 5) Corporal Michael Crescenz VAMC, Philadelphia, PA; 6) Perlmutter School of Medicine, University of Pennsylvania, Philadelphia, PA; 7) Massachusetts Veterans Epidemiology and Research Information Center (MAVERIC), Boston, MA; 8) Palo Alto VA Health Care System, Palo Alto, CA; 9) VA Informatics and Computing Infrastructure, Salt Lake City VA, Salt Lake City, UT 84148; 10) Brigham and Women's Hospital, Boston, MA; 11) Atlanta VA Health Care System, Atlanta, GA.

**Background:** Minorities are underrepresented in many epidemiologic studies and biorepository programs to date. Large-scale, multi-ethnic cohorts, such as the Million Veterans Program (MVP) provide unprecedented opportunities to elucidate genetic factors influencing complex traits and disease risks in minority populations. Among 350,000 MVP participants, 25% represent ethnic minorities. Genetic diversity of these cohorts present new challenges to analysis and interpretation. We considered the definition and utility of race/ethnicity categories in the context of multi-ethnic GWAS studies. **Method:** We have developed a semi-supervised machine learning algorithm, which integrates race/ethnicity information from survey data, electronic health records (EHR), and ancestry inferred from genetic variation. The output variable is termed Harmonized Ancestry and Race/Ethnicity (HARE). Using simulated and real phenotypes, we investigate the statistical power of identifying ethnicity-specific trait loci. **Results:** Among participants whose self-reported race/ethnicity information was ambiguous or incomplete, over 95% were assigned to one of four HARE groups (Hispanics, non-Hispanics White, non-Hispanics Black, and non-Hispanics Asian). On the other hand, of participants with self-reported race/ethnicity information, less than 0.2% had conflicting HARE information. Through simulations, we demonstrated that stratifying by HARE achieved greater power in identifying population-specific trait loci than an un-stratified analysis of the entire MVP cohort. For height, numerous ethnicity-specific loci were identified in HARE-stratified analysis, which cannot be identified by simply analyzing all individuals together and adjusting for principal components. **Conclusion:** HARE enhanced population-specific genetic association analyses by increasing sample sizes and improving interpretability. It offers a practical approach to leverage the genetic diversity in a multi-ethnic cohort, and enables meaningful joint analyses across such cohorts.

**Genotype-covariate correlation and interaction disentangled by a whole-genome multivariate reaction norm model.** *S.Hong Lee<sup>1</sup>, G. Ni<sup>1</sup>, J. Van der Werf<sup>2</sup>, X. Zhou<sup>1</sup>, E. Hyppönen<sup>1</sup>, N. Wray<sup>3</sup>.* 1) University of South Australia, Adelaide, SA, Australia; 2) University of New England, Armidale, NSW, Australia; 3) University of Queensland, Brisbane, Queensland, Australia.

The genomics era has brought useful tools to dissect the genetic architecture of complex traits. We propose a reaction norm model (RNM) to tackle genotype-environment correlation and interaction problems in the context of genome-wide association analyses of complex traits. In our approach, an environmental risk factor affecting a trait of interest (e.g. BMI) can be a phenotype modeled as a continuous covariate (e.g. smoking quantity) that is itself regulated by genetic as well as environmental factors. Hence, a correct model for the genetic component of the trait of interest would need to account for its interaction with the covariate as well as its correlation with the genetic component underlying the covariate. A multivariate RNM allows the modelling of the relation between the genotype (G) and the covariate (C), so that their correlation (association) and interaction (effect modification) can be jointly modelled (genotype-covariate correlation and interaction, GCCI). We demonstrate using simulation that the proposed multivariate RNM better performs than the current state-of-the-art methods that ignore G-C correlation and generate an inflated signal for interactions. Deflated p-values are also observed in a real data example on detecting BMI-smoking interaction when BMI-smoking correlations are not properly modelled. We also show using simulation that the estimated residual variances from genomic restricted maximum likelihood (GREML) or linkage disequilibrium score regression (LDSC) can be inflated in the presence of interaction, implying that the currently reported SNP-heritability estimates from these methods should be interpreted with caution. Correspondingly, real data analyses demonstrate that the estimated residual variance of BMI from GREML is significantly higher than a RNM fitting multiple covariates (smoking and neuroticism) jointly (p-value = 1.57E-04). We conclude that it is essential to account both for interaction and correlation when dissecting the genetic architecture of complex traits, and that the failure to do so may lead to substantial bias in estimated variance components of interaction, as well as the estimated SNP-heritability.

**3497F**

**A meta-analysis method to detect pleiotropic loci of correlated traits.**

*C.H. Lee<sup>1,2</sup>, H. Shi<sup>3</sup>, P. Bogdan<sup>4,5</sup>, H. Lee<sup>6</sup>, E. Eskin<sup>4,7</sup>, B. Han<sup>1,2</sup>.* 1) Department of Medicine, Seoul National University College of Medicine, Seoul, Republic of Korea; 2) Department of Convergence Medicine, University of Ulsan College of Medicine, Seoul, Republic of Korea; 3) Bioinformatics Interdepartmental Program, University of California, Los Angeles, California, USA; 4) Department of Human genetics, University of California, Los Angeles, Los Angeles, California, USA; 5) Department of Pathology and Laboratory Medicine, University of California, Los Angeles, Los Angeles, California, USA; 6) Department of Biochemistry and Molecular Biology, university of Ulsan College of Medicine, Seoul, Republic of Korea; 7) Department of Computer Science, University of California, Los Angeles, Los Angeles, California, USA.

Genome-wide association studies have identified many genetic risk loci, some of which have been found to be associated with multiple complex traits. Identifying these pleiotropic loci can be valuable because they can be potential drug targets to control the cause of comorbid conditions. Recent studies have conducted cross-phenotype meta-analyses using summary statistics of readily accessible large-scale consortium data. In this study design, it is reasonable to assume that the pleiotropic loci may have differing effect sizes to multiple traits. Therefore, the use of random effect meta-analysis model assuming heterogeneity can be more suitable for identifying novel loci than the use of ordinary fixed effect meta-analysis model. The difficulty of this cross-phenotype meta-analysis is that the model should optimally account for both the genetic correlations for each pair of the traits as well as the environmental correlations due to the cryptic relatedness or the overlapping samples. Here, we developed a novel random effects model meta-analysis framework which is optimized for detecting pleiotropic loci. Using the linkage disequilibrium information from the reference data and the summary statistics of the diseases, our framework can distinguish the genetic and environmental correlations. Then, we use this information to maximize the statistical power for identifying pleiotropic loci. We applied our framework to analyze seven autoimmune disease data obtained from published results. In this analysis we confirmed associations at 210 known genes to autoimmune conditions and identified novel pleiotropic associations at five loci: *BCL2L11*(2q13, p=4.18E-8), *RPL13AP21*(12q13.11, p=2.45E-8), *NEURL4*(17p13.1, p=1.95E-8) and 2 intergenic variants including: rs9852014(3q21, p=2.06E-28) and rs1464446(3q24, p= 7.42E-10). We anticipate that our framework can help identifying pleiotropic loci with heterogeneous effects in cross-phenotype meta-analysis. .

**3498W****Prioritizing variants and reducing false positive associations in GWAS.**

K. Lin, A. Auton, 23andMe Research Team. 23andMe, Mountain View, CA.

With the deeper coverage of sequencing technology, a significant number of new rare variants are identified and tested for associations with phenotypes in genome-wide association studies (GWAS). The conventional genome-wide significance threshold  $5 \times 10^{-8}$  is based on the estimated number of independent common variants. However, rare variants are in low linkage-disequilibrium with common variants, thus applying the same significance threshold to rare variants is guaranteed to increase false positives as there are much more rare than common variants. Studies have suggested using more stringent thresholds for rare variants; however, there is no consensus on the appropriate threshold as it depends on the number of rare variants included in the studies. Without estimating the number of independent variants, the naive solution of assuming all rare and common variants are independent and utilizing Bonferroni correction leads to an extremely conservative test. Alternatively, controlling for false discovery rate (FDR) is known to be not as conservative as Bonferroni correction, and therefore it could be well-suited to reduce false positives while maintaining desirable power. Independent Hypothesis Weighting (IHW; Ignatiadis et.al. 2016) is an approach to control FDR and can incorporate covariates to prioritize variants to improve power. Here, we employed IHW to re-analyze GWAS results. With controlling for FDR, we supplied functional categories and allele frequency as covariates to IHW. We aimed to answer two questions: (1) if applying IHW can remove false positive signals due to inappropriate threshold and retain true signals, and (2) if applying IHW can identify additional new signals. Applying IHW to various disease phenotypes, we observed that IHW suggested to down-weight rare variants and up-weight common variants. This is intuitive as in general GWAS have more power to detect associations for common variants; down-weighting rare variants leads to reduced false positive signals and retaining true signals from common variants. In addition to up-weighting common variants, IHW also suggested to up-weight coding variants; for example, protein-truncating variant rs34358 was sub-significant in the original type 2 diabetes GWAS (p-value:  $1.5e-06$ ) and became significant (q-value: 0.00071) after applying IHW. Together, these results suggest that controlling for FDR and prioritizing functional variants can reduce false positives and further improve power for GWAS.

**3499T****Probabilistic fine-mapping of transcriptome-wide association studies.**

N. Mancuso<sup>1</sup>, G. Kichaev<sup>2</sup>, H. Shi<sup>2</sup>, M. Freund<sup>3</sup>, A. Gusev<sup>4</sup>, B. Pasaniuc<sup>1,2,3</sup>. 1) Dept of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California, Los Angeles, CA 90024; 2) Bioinformatics Interdepartmental Program, University of California, Los Angeles, CA 90024; 3) Dept of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA 90024; 4) Dana-Farber Cancer Institute, Boston, MA 02215.

Transcriptome-wide association studies (TWAS) using predicted expression have identified thousands of genes whose locally-regulated expression is associated to complex traits and diseases. In this work, we show that linkage disequilibrium (LD) among SNPs induces significant gene-trait associations at non-causal genes as a function eQTL weights used in expression prediction. Here, we introduce FOCUS, a probabilistic framework that models the induced correlation among TWAS signals to assign a probability for each gene to be causal while controlling for pleiotropic SNP effects and unmeasured causal mechanisms. Our approach yields credible-sets of genes containing the causal gene at a nominal confidence level (e.g. 90%) that can be used to prioritize genes for functional assays. In detail, we model the distribution of TWAS statistics using a multivariate Gaussian distribution parametrized by LD, eQTL weights, and causal gene effect sizes. We control for bias from pleiotropic SNP effects by including an intercept term that models the average SNP effects tagged by predicted expression. Importantly, to allow for genes without prediction models in the relevant tissue (either due to QC or low power in eQTL studies), we leverage recent work demonstrating that eQTLs are shared across tissues and include prediction models from proxy tissues for such genes. To account for missing causal molecular mechanisms, we include the null model as a possible outcome in the credible set. We validate our approach through extensive simulations starting from real genotype data and find that FOCUS is accurate under a variety of trait architectures, with only a slight decrease in performance when proxy tissues are used. When causal mechanisms are absent, we find FOCUS prioritizes the null model in most simulations, despite nearby significant genes. To illustrate FOCUS's performance in real data, we re-analyzed TWAS results for lipids. Using 90%-credible sets, FOCUS prioritizes a single gene at 61/75 risk regions for HDL, LDL, triglycerides, and total cholesterol. FOCUS finds several genes with well-studied functional impact on HDL and LDL are highly ranked using our method. For example, *GALNT2* and *SORT1* genes were ranked with marginal posterior probabilities  $>0.95$ . Overall, FOCUS prioritizes genes with well-characterized functional impact and while accounting for confounding when predicted expression is unlikely to explain observed genetic risk.

**Power and sample size calculations for genetic association studies in the presence of genetic model misspecification.** *C.M. Moore<sup>1,2</sup>, S. Jacobson<sup>2</sup>, T.E. Fingerlin<sup>2</sup>*. 1) Division of Biostatistics and Bioinformatics, National Jewish Health, Denver, CO; 2) Center for Genes, Environment and Health National Jewish Health, Denver, CO.

When analyzing data from large-scale genetic association studies, such as data generated from targeted or genome-wide resequencing studies, it is common to assume a single genetic model, such as dominant or additive, for all tests of association between a given genetic variant and the phenotype. However, for many variants, the chosen model will result in poor model fit and may lack statistical power due to model misspecification. This potential genetic model misspecification is particularly important when genetic variants identified in one race or ethnic background are further investigated and tested in other races or ethnic groups. Multiple degree of freedom tests, sometimes called 'genotypic' tests, do not assume a particular genetic model and therefore offer more flexibility in modeling the relationship between genotype and phenotype. While the flexibility of these tests is appealing, they are often not used in practice for multiple reasons, including ease of application using popular analysis software. In addition, it is often assumed that the test lacks power due to small numbers of subjects homozygous for the minor allele and the extra degrees of freedom used in testing. Multiple degree of freedom tests are less powerful than tests from a correctly specified 1-degree of freedom genetic model, but can be more powerful than an incorrectly specified model, depending on the sample size, minor allele frequency, and the true underlying genetic model. We have developed an open-source software program ("genpwr") that performs power and sample size calculations under mis-specification of the genetic model (for example using a dominant test, when the true genetic model is recessive). The package allows for dichotomous or continuous phenotypes, adjustment for covariates, and gene x environment interactions. Understanding the impact of model misspecification on power and detectable effect sizes can aid in study design and in the development of appropriate analysis plans that maximize power to detect a range of true underlying genetic effects. In particular, these calculations can help identify when a multiple degree of freedom test may be advantageous given 1) the wide range of sample sizes now available and 2) the varying level of certainty in the appropriate genetic model, especially across race and ethnic groups. We illustrate how we used these methods in the development of an analysis plan for a resequencing study in idiopathic pulmonary fibrosis.

**Drugs for specific diseases tend to target genes whose expression is causally linked to those diseases.** *S. Rüeger<sup>1,2</sup>, E. Porcu<sup>2,3</sup>, Z. Kutalik<sup>1,2</sup>*. 1) Institute of Social and Preventive Medicine, Lausanne University Hospital, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland.

While GWASs alone are limited to SNP-trait associations, in combination with gene expression QTLs via Mendelian randomization (MR) studies they have the potential to pinpoint key causal genes for diseases. Our MR analysis provided 603'404 causal effect estimates (of which 5'009 are significantly non-zero) between whole blood expression of 15'985 genes and 43 traits/diseases), which were combined with known drug target genes using the Drugbank.ca database. For this, we developed a score to quantify for each drug-trait pair how well the drug targets correspond to the set of genes causally implicated for the given trait. For 15 diseases (among the 43 traits) we compiled a curated list of known treatments, 309 *disease-specific drugs* in total. First, for a given disease, we compared the score of drugs known to treat that disease to that of all other drugs, and found that disease-specific drugs score significantly ( $P < 0.05$ ) higher for 6 out of 15 diseases, with depressive symptoms and schizophrenia showing the clearest separation ( $P = 8 \times 10^{-6}$  and  $P = 6 \times 10^{-4}$ , respectively). Second, for each drug we calculated the rank of its score with the disease for which it is clinically used relative to the scores with the other 42 traits. We found that for 54 out of 309 drugs the score for the relevant disease ranked in the top five (out of 43). Notably, certain drugs for fasting insulin, HDL, LDL (Mifepristone, Saxagliptin, Niacin, Ezetimibe) ranked first. Given these promising findings, our drug-disease score could provide guidance for repositioning existing drugs to off-target diseases.

**Genetic and genomic stability across lymphoblastoid cell line expansions.** L. Scheinfeldt<sup>1</sup>, K. Hodges<sup>1</sup>, J. Pevsner<sup>2</sup>, D. Berlin<sup>1</sup>, N. Turan<sup>1</sup>, N. Gerry<sup>1,2</sup>. 1) Coriell Institute for Medical Research, Camden, NJ; 2) Kennedy Krieger Institute, Baltimore, MD; 3) Advanced BioMedical Laboratories, Cinnaminson, NJ.

Lymphoblastoid cell lines (LCLs) are a valuable resource to the genetics and genomics communities primarily due to their ability to provide a renewable source of DNA. Other common applications include studies of gene expression and gene regulation, drug metabolism, immunology, cell biology, and more recently in the development of iPSCs. Previous work has characterized variant stability in transformed cultures and across culture passages. Our objective was to extend this work to evaluate single nucleotide polymorphism and structural variation across cell line expansions. Our study included DNA extracted from whole blood, transformed cell lines, and several generations of expansions sampled from six research participants. In total, 29 LCLs were successfully established and sequentially expanded three times, and 118 DNA samples and 11 technical replicates were processed for analysis on the Affymetrix Human SNP Array 6.0. PennCNV was used to call CNVs from the B allele frequencies, log R ratios, and signal files for each sample set of autosomal chromosomes. Single nucleotide variation was stable between DNA and expanded cell lines (ranging from 99.90% to 99.98% concordance). Structural variation was less consistent across expansions (median 33% concordance) with a noticeable decrease in later expansions. These results are most applicable to genome-wide association studies (GWAS). By design, GWAS gain statistical power to detect modest disease risk effect sizes with increased sample sizes. One way in which GWAS can increase sample sizes is to leverage existing clinical samples and biorepositories that offer DNA extracted from LCLs. Our results support this strategy and suggest that SNPs can be reliably measured from LCL DNA. More caution should be taken in studies that are focused on the accurate measurement of germline structural variation in culture given the documented changes in CNV loci across LCL transformation, passaging, and expansion.

**Gene hunting with hidden Markov model knockoffs.** M. Sesia<sup>1</sup>, C. Sabatti<sup>1,2</sup>, E. Candès<sup>1</sup>. 1) Department of Statistics, Stanford University, Stanford, CA; 2) Department of Biomedical Data Science, Stanford University, Stanford, CA.

Modern scientific studies often require the identification of a subset of explanatory variables. Several statistical methods have been developed to automate this task, and the framework of knockoffs has been proposed as a general solution for variable selection under rigorous type-I error control, without relying on strong modeling assumptions. In this paper, we extend the methodology of knockoffs to problems where the distribution of the covariates can be described by a hidden Markov model. We develop an exact and efficient algorithm to sample knockoff variables in this setting and then argue that, combined with the existing selective framework, this provides a natural and powerful tool for inference in genome-wide association studies with guaranteed false discovery rate control. We apply our methodology to datasets on Crohn's disease and some continuous phenotypes.

**LabWAS: Study designs and novel findings from a meta-analysis of quantitative lab values from independent health systems.** *J.S. Weinstock<sup>1</sup>, J. Goldstein<sup>2</sup>, M. Zawistowski<sup>1</sup>, L. Bastarache<sup>3</sup>, D.B. Larach<sup>4</sup>, L.G. Fritsche<sup>1</sup>, C.M. Brummett<sup>4</sup>, S. Kheterpal<sup>4</sup>, G.R. Abecasis<sup>1</sup>, J.C. Denny<sup>3,5</sup>.* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI; 2) Department of Pathology, Northwestern Memorial Hospital, Chicago, IL; 3) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 4) Department of Anesthesiology, University of Michigan Medical School, Ann Arbor, MI; 5) Department of Medicine, Vanderbilt University Medical Center, Nashville, TN.

Electronic Health Record (EHR) systems have enabled discovery of novel associations across a rich collection of phenotypes. In contrast to phenotypes measured exclusively for research, EHR derived phenotypes are influenced by unique properties of the host health system. Recruitment mechanisms, which vary across biobanks, are likely to affect which participants are included and the nature of the measurements. The diversity of disparate health systems makes analyses across multiple EHR systems challenging, which is especially true for laboratory measurements, which may differ in measurement protocols. We performed a meta-analysis of GWASes of 66 quantitative laboratory measurements across two independent health systems: the Michigan Genomics Initiative (MGI) from Michigan Medicine and BioVU from Vanderbilt University. Participants in MGI were recruited through surgical encounters at Michigan Medicine, and 37,412 blood samples were genotyped. The BioVU cohort was recruited on patient check-in during outpatient encounters, and 20,515 genotyped blood samples were used for this analysis. The size of individual GWASes varied by the frequency of those laboratory measurements. We restricted analysis to unrelated individuals of European ancestry. Meta-analyses used the intersection of 798,338 SNPs genotyped in both studies. After aligning GWAS analysis protocols, we systematically examined different study design choices in parallel to study the impact of analysis decisions on GWAS results. We examined laboratory measurement context and the consequences of different health state covariates in analysis. We also performed GWASes based on a subset of measurements that were recorded in outpatient contexts, to assess the tradeoff of sample size and phenotype fidelity. For example, for glucose, we observed the health state covariates to reduce power in known loci in both systems. We observed heterogeneity in these effects across laboratory phenotypes – for red blood cell counts, using only outpatient values improved power in BioVU, but reduced power in MGI. We produced a set of best analysis practices for performing GWASes on most common laboratory traits in EHR systems. We found that taking the mean of lab measurements, applying an inverse normal transformation, excluding disease covariates, and using all measurements in all contexts to be a useful default practice. The results of our meta-analyses are browsable at a public web portal, [pheweb.sph.umich.edu:5004](http://pheweb.sph.umich.edu:5004).

**Bivariate logistic Bayesian LASSO for finding genetic association with two correlated phenotypes.** *X. Yuan.* University of Texas at Dallas, Richardson, TX.

Often multiple correlated outcomes are collected in health-related studies. However, typically each outcome is analyzed separately. In genetic association studies, joint modeling of multiple traits (phenotypes) can utilize the correlation amongst them and thereby be more powerful and insightful. Also, rare variants are currently a major focus of genetic research as a key to missing heritability. A recent method named logistic Bayesian LASSO (LBL) can detect rare haplotype variants associated with a single binary phenotype. Here we extend LBL to jointly model two correlated binary traits. Our proposed bivariate LBL model uses a latent variable to induce correlation between the two outcomes. To compare the bivariate LBL with the univariate LBL, we simulate two binary traits using a probit model with varying correlation between the two traits. We consider a number of settings, in which a rare haplotype is associated with one or both traits with same or different directions of effects. Our results show that the bivariate LBL performs better or similar to univariate LBL in most settings. It has most gain in power when there is a high positive correlation between the traits and the effects of the associated haplotype on the two traits are of opposite directions.

**3506F**

**Implications of post-colonial demographic structure on interpretations of association analyses.** *M. Zhang<sup>1</sup>, J.M. Granka<sup>1</sup>, E.P. Sorokin<sup>1</sup>, K.A. Rand<sup>1</sup>, S. Hateley<sup>1</sup>, K. Noto<sup>1</sup>, E.L. Hong<sup>1</sup>, K.G. Chahine<sup>1</sup>, C.A. Ball<sup>2</sup>*. 1) AncestryDNA, San Francisco, CA; 2) AncestryDNA, Lehi, UT.

Recent work has highlighted the need to evaluate the impact of fine-scale population structure on association analyses. Despite thousands of high-powered genome-wide association studies (GWAS), only about one-fifth of all studies include individuals of non-European descent. It is understood that GWAS conducted in European populations are not always generalizable to non-European populations, and that continental population structure is an important factor to consider. However, in the age of regionally-run genomic studies, it remains unclear whether fine-scale population structure, particularly more recent within-continental structure, contributes to bias in the interpretation of GWAS results. We identify regional fine-scale structure, within continental ethnicity groups, in a subset of over one million AncestryDNA customers who have consented to research. Such regional United States population structure, identified to relate to post-colonial demography during the last several hundred years, is generally undetectable in a principal component analysis (PCA), although regional allele frequency variation at the single-variant level still exists. To explore whether this variation plays a role in association analyses, we examine the regional distribution of polygenic risk scores (PRS) calculated from previously-identified variants in the GWAS catalog for various well-studied phenotypes. To account for continental population structure, we examine PRS distributions using variants that have been identified in the same continental population. While observed differences occur primarily across continental groups and only some regional groups, in some cases these differences could suggest residual confounding due to within-continental population structure. It is unclear whether the observed differences can be attributed to true differences in disease risk, or whether they are solely an artifact of generalizing GWAS results to other, unstudied populations. Even when considering very recent time scales, small frequency differences may impact GWAS conclusions and interpretations -- particularly in the transferability of results to similar, but unstudied, populations. This work highlights the fundamental need to understand the generalizability of GWAS results through the lens of both continental, and within-continental, population structure, particularly in large-scale analyses.

**On set-based association tests: Insights gained from a regression, based on summary statistics.** *Y. Zhao<sup>1</sup>, L. Sun<sup>1,2</sup>*. 1) Department of Statistical Sciences, University of Toronto, Toronto, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada.

Set-based tests that jointly analyze a group of variants have been applied in various settings, including rare variants analysis. In each case, myriad tests have been proposed with competing and sometimes conflicting claims in terms of method performance. We developed a unifying regression framework based on summary statistics. We show that existing tests such as burden, SKAT and SKAT-O can be derived as a special case from this new architecture. Moreover, the regression framework provides a straightforward way to account for any inherent correlations between the variables in a set. Subsequently, we propose new test statistics that are SKAT-O-like, but without the apparent 'optimal' weighting. Under mild conditions, we show that the asymptotic distribution of the new test statistics are Chi-square distributed, and we provide accurate p-value calculation for finite samples with respect to the number of variables analyzed in a set. Focusing on rare variants analysis and through extensive simulation studies, we show that the proposed method is often, but not always, more powerful than SKAT-O across a number of alternative scenarios. In addition, the summary statistics-based regression framework is easy to implement, and it provides a principled way for additional improvements such as incorporating available genomic information for data integration. Finally, previous tests designed for PhewWAS, Polygenic Risk Score (PRS), PrediXcan or TWAS can also be re-examined through this new lens.

**3508T**

**Statistical power in GWAS revisited: Sample size, genetic relatedness, and gene-by-environment interactions.** A. Ziyatdinov<sup>1</sup>, J. Kim<sup>1</sup>, P. Kraft<sup>1</sup>, H. Aschard<sup>1,2</sup>. 1) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; 2) Centre de Bioinformatique, Biostatistique et Biologie Intégrative (C3BI), Institut Pasteur, Paris, France.

Genome-wide association studies (GWAS) have identified thousands of genetic associations for complex diseases and heavily relies on increasing the sample size. Recent analyses of biobank-scale genetic data suggest: (i) inclusion of genetically related individuals empowers GWAS (Loh *et al.*, 2017); (ii) the wealth of collected environmental exposures has potential to uncover gene-by-environmental interactions (Young *et al.*, 2016). However, quantification of GWAS power - the non-centrality parameter (NCP) of an association test, which is proportional to the sample size ( $n$ ) and the variance explained by genetic variant ( $q^2$ ) - holds only for unrelated individuals. Here, we first expand it by incorporating individual relationships by linear mixed model. We next consider gene-by-environment interactions, where interaction effect on trait is tested in the presence of marginal genetic effect. Consider a set of related individuals, which relatedness is expressed by the kinship matrix ( $K$ ), and association between outcome ( $y$ ) and genotype ( $g$ ) is evaluated by linear mixed model. For a given phenotypic variance-covariance matrix ( $V$ ), we show that the non-centrality parameter for marginal association test can be approximated as  $NCP_{rel} = \text{tr}(V^{-1}\Sigma_g)$ , where  $\text{tr}$  is the trace operator and  $\Sigma_g$  is the covariance matrix of genotypes. For families we have  $V = [h^2K + I]$  and  $\Sigma_g = q^2K$ , that results in  $NCP_{rel} = \text{tr}([h^2K + I]^{-1}K)q^2$ . That means  $NCP_{rel} \leq NCP$ , i.e. for the same sample size, power is expected to decrease as relatedness between individuals increases – which was previously shown analytically only for sib-pairs in (Visscher *et al.*, 2008). Further, we consider testing for fixed effect gene-by-environment interaction in related individuals. We have derived  $NCP_{rel+int} = \text{tr}(V^{-1}\Sigma_{int})$ , where  $\Sigma_{int}$  is the covariance matrix in distribution of the interaction variable. For families we have  $V = [h^2K + I]$ ,  $\Sigma_{int} = q^2w^2K_{int}$ , where  $w^2 = f(1-f)$  and  $f$  is the frequency of binary exposure.  $K_{int}$  is a matrix derived from  $K$  and depends on realization of exposure in a given study. We argue that  $K_{int}$  is different from the matrix recently proposed in (Sul *et al.*, 2016). We validated all results by simulations. Our formulas have a range of implications. For testing marginal genetic effect, one can quickly assess the power in studies involving related individuals. Because of the potential gain in power for testing gene-by-environment interaction, the formula will allow optimization of the study design of related individuals.

**Joint analysis of multiple phenotypes using a clustering linear combination method based on hierarchical clustering.** X. Li, Q. Sha, S. Zhang. Department of Mathematical Sciences, Michigan Technological University, Houghton, MI.

Emerging evidence suggests that a genetic variant can affect multiple distinct, but possibly correlated phenotypes, especially in complex human diseases. Individual phenotype analyses are generally less informative and underpowered to uncover the genetic variants underlying complex traits and diseases. The joint analysis of multiple phenotypes may offer new insights into the disease etiology. In this paper, we develop an innovative method for joint analysis of multiple phenotypes using a hierarchical clustering approach followed by a clustering linear combination method. We have named this method the HCCLC method. The proposed method consists of two consecutive steps: the Hierarchical Clustering (HC) and the Clustering Linear Combination (CLC). The HC step partitions the phenotypes into a small number of clusters. The phenotypes within each cluster strongly correlate with each other, while phenotypes between clusters are significantly less likely to be correlated. The CLC method is then adopted to test the association between a genetic variant of interest and multiple phenotypes. This is done by combining individual test statistics, while taking advantage of the natural grouping information of phenotypes. Extensive simulation studies together with a COPDGene real data analysis have been used to assess the applicability of our proposed method. Our simulation results demonstrate that the type I error rates of HCCLC are well maintained in different realistic settings. HCCLC either outperforms all other methods or has statistical power that is very close to the most powerful method we have compared it with. In addition, our real data analysis shows that HCCLC is an appropriate test for genome-wide association studies (GWAS).

**Heritability estimates in admixed populations from Greenland.** *G. Athanasiadis, A. Albrechtsen.* Section for Computational and RNA Biology, Department of Biology, Copenhagen University, Copenhagen, Denmark.

Standard restricted maximum likelihood (REML) methods for complex trait heritability estimates in human populations require that samples are unrelated and un-admixed. As a result, smaller non-European cohorts cannot benefit entirely from the methodological advancements that produce reliable heritability estimates in large European cohorts. In light of the above, we used three Greenlandic cohorts ( $N = 4,824$ ) and an extensive simulation setup to investigate how REML-based heritability estimates are affected by a high degree of relatedness in the sample, as well as by recent admixture. We also propose specific heritability estimate guidelines for setups similar to ours. Finally, we also applied our model of choice to a number of quantitative traits from our Greenlandic cohorts and report considerable genetic components for many of them.

**RSSp: An effective method for estimating the heritability of polygenic traits using GWAS summary statistics.** *N.W. Knoblauch<sup>2</sup>, X. He<sup>1</sup>.* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Committee on Genetics, Genomics and Systems Biology, University of Chicago, Chicago, IL.

Genome-wide association study (GWAS) summary statistics are the most universal statistical tool for describing the relationship between genetic variants and a trait of interest in a population. As dozens of large-scale GWAS have demonstrated, the variants most significantly associated with a particular phenotype often explain only a small amount of the heritability of that trait, a reality that has pushed researchers to look towards the full distribution of marginal phenotype/genotype associations to better understand genetic architecture. Unfortunately, linkage disequilibrium (LD) distorts the observed relationship between genotype and phenotype, and must be accounted for when analyzing GWAS summary statistics. With an estimate of LD, often obtained from an out-of-sample reference panel, it is possible to account for the distortionary effect of LD on GWAS summary statistics when estimating heritability. Regression with Summary Statistics (RSS) (Zhou and Stephens 2017) is a Bayesian statistical framework for obtaining multivariate regression estimates using univariate estimates and a correlation (LD) matrix. We have developed an implementation of RSS tailored for heritability estimation for highly polygenic traits, and we call our method RSSp. To assess RSSp's effectiveness, we simulated effect sizes for hundreds of traits under a range of narrow-sense heritability values using real genotype data from the Genetics of Recurrent Early-Onset Depression (GENRED) cohort ( $N=1902$ ), as well as the Wellcome Trust Case-Control Consortium cardiovascular disease cohort ( $N=4686$ ). We then performed GWAS on these simulated traits, and estimated heritability using a held out set of samples as a reference LD panel. LD was estimated using either the sample correlation or using a regularization technique called LDshrink, which uses a genetic map to regularize LD estimates. Comparing our heritability estimates obtained using RSSp to heritability estimates using LD score regression, the most popular method for estimating heritability from summary statistics, two things are especially noteworthy. First, RSSp heritability estimates compare favorably to estimates from LD score regression. RSSp had a relative RMSE of 0.34, a 44 percent improvement over LD score regression (RMSE=0.60), and a 52 percent improvement over LD score regression fit without an intercept term (RMSE=0.70). Second, RSSp heritability estimates are improved by using LDshrink (RMSE=0.34 vs RMSE=0.44).

**3512F****Reliable heritability estimation in admixed populations using covariate-adjusted LD score regression.**

X. Li<sup>1,2</sup>, Y. Luo<sup>1,2</sup>, J.M. Mercader<sup>2,3</sup>, J. Florez<sup>2</sup>, H.K. Finucane<sup>2</sup>, S. Raychaudhuri<sup>1,2</sup>, *The SIGMA Type 2 Diabetes Consortium*. 1) Medicine-Brigham and Women's Hospital, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 3) Diabetes Unit and Center for Genomic Medicine, Massachusetts General Hospital, Boston, MA.

To date, the majority of genome-wide association studies (GWAS) have been performed in Europeans, but recent studies are now including additional populations, including admixed populations. Genetic heritability ( $h_g^2$ ) is an essential measurement to understand the polygenic traits. However, current methods used to measure  $h_g^2$  based on GWAS are designed for homogeneous populations, and may not work for admixed populations. Here, we introduce covariate-adjusted LD score regression (cov-LDSC) that can be applied to admixed GWAS when estimating  $h_g^2$ . LD score regression (LDSC) is a family of methods that takes advantage of the linear relationship between  $\chi^2$  statistics and the linkage disequilibrium (LD) to measure  $h_g^2$  (Bulik-Sullivan, et al., 2015). This linear relationship still holds in admixed populations; however, the LD measured by LDSC is often inflated by counting the admixture-LD, especially for population specific SNPs. We first demonstrate that the LDSC leads to deflated  $h_g^2$  in admixed population. We simulated genotypes of 10,000 admixed samples with msprime (J. Kelleher, et al., 2016) using demographic history inferred from 1000 Genome. We then developed three simulation scenarios for evaluation: (1) different total  $h_g^2$ ; (2) different degrees of polygenicity in simulated traits and (3) different percentages of ancestral proportions. We found that LDSC systematically underestimated  $h_g^2$  due to inflations in LD score estimates; for example, for a 40% heritable trait in a 50% admixed population, LDSC yields an estimate of 32%, whereas cov-LDSC provides an unbiased point estimate. Next we implemented cov-LDSC where we correct inflation in LD scores by regressing out genome-wide covariates such as principal components at each SNP. Applying cov-LDSC to these same simulations, we observed that it yields robust  $h_g^2$  estimates in all scenarios. We also simulated different phenotypes based on real genotypes of 8,214 Mexican individuals from the SIGMA cohorts (The SIGMA Type 2 Diabetes Consortium, 2014), who have in average 60% Native American and 40% European ancestry. Again, cov-LDSC yields unbiased  $h_g^2$  estimates, compared to LDSC. We thus conclude, through extensive studies based on both simulated and real genotypes, that cov-LDSC can yield reliable  $h_g^2$  estimates in admixed GWAS. Cov-LDSC can be applied on GWAS summary statistics without raw genotype access and has the potential to be extended to measure partitioned heritability efficiently in admixed populations.

**3513W****Extending SNP-based heritability analysis: How many variants show strong effect in a GWAS.** F. Takeuchi, N. Kato. Research Institute, National Center for Global Health and Medicine, Shinjuku-ku, Tokyo, Japan.

In SNP-based heritability analyses, the allele substitution effects of causal variants are modeled to follow a zero-mean normal distribution, whose variance represents the heritability. One topic unstudied so far is the proportion of SNPs showing strong associations in a GWAS, which is large for lipids and small for BMI and height. In terms of probability distribution, the proportion corresponds to the tail-heaviness, which characterizes a distribution independently of the variance. Without understanding that proportion, we cannot calculate the power of a GWAS, which is the expected number of loci to be discovered. To address those topics, we modeled the allele substitution effects of single SNPs by the  $t$ -distribution, which can adjust tail-heaviness by the degrees-of-freedom parameter. We extended the Popcorn program, which analyzes GWAS summary statistics and estimates heritability in a population and genetic correlation between two populations of different ancestries. Using the observed parameters, we simulated possible distribution of SNP effect-size. GWAS datasets for blood pressure, lipids, type 2 diabetes, BMI and height in East Asian or European-ancestry populations were analyzed. The estimated heritability ranged 0.07–0.31, and the genetic correlation ranged 0.77–0.99. The degrees of freedom were ~3 for lipids, ~5 for BMI, and ~4 for other traits, indeed indicating heavy tail for lipids. Using simulation, we computed the power of GWAS under various sample sizes. The extension of SNP-based heritability analysis by adopting  $t$ -distribution enabled the modeling of the spectrum of associations in a GWAS and power calculation. The source code is available from <https://github.com/fumi-github/Popcorn-t>.

**Heritability and genetic correlation analysis of biobank data.** *Y. Wu, S. Sankararaman.* UCLA, Los Angeles, CA.

SNP heritability, i.e. the proportion of phenotypic variance explained by SNPs, and genetic correlation are important parameters in efforts to understand the genetic architecture of complex phenotypes as well as in the design and interpretation of genome-wide association studies. Attempts to estimate SNP heritability as well genetic correlations among complex phenotypes attributable to genome-wide SNP variation data have motivated the analysis of large datasets as well as the development of sophisticated tools to estimate heritability and genetic correlation in these datasets. Linear Mixed Models (LMMs) have emerged as a key tool for heritability and genetic correlation estimation where the parameters of the LMMs, i.e., the variance components, are related to the heritability attributable to the SNPs analyzed and genetic correlations across phenotypes. Likelihood-based inference in LMMs, however, poses serious computational burdens. We propose a scalable randomized Method-of-Moments (MoM) estimator of SNP heritability and genetic correlations in LMMs. Our method, RHE-reg, leverages the structure of genotype data to obtain runtimes that are sub-linear in the number of individuals (assuming the number of SNPs is held constant). We perform extensive simulations to validate the accuracy and scalability of our method. RHE-reg can compute the heritability and genetic correlations on the UK biobank dataset consisting of 430,000 individuals and 460,000 SNPs in 3 hours on a stand-alone computing machine. We used RHE-reg to estimate heritability and genetic correlations for all 60 traits in the UK Biobank.

**Relatedness disequilibrium regression estimates heritability without environmental bias.** *A.I. Young<sup>1,2,3</sup>, M.L. Frigge<sup>1</sup>, D.F. Gudbjartsson<sup>1,4</sup>, G. Thorleifsson<sup>1</sup>, G. Bjornsdottir<sup>1</sup>, P. Sulem<sup>1</sup>, G. Masson<sup>1</sup>, U. Thorsteinsdottir<sup>1,5</sup>, K. Stefansson<sup>1,5</sup>, A. Kong<sup>1,3,4</sup>.* 1) deCODE genetics/Amgen Inc., Reykjavik 101, Iceland; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, U.K; 3) Big Data Institute, Li Ka Shing Centre for Health Information and Discovery, University of Oxford, Oxford, UK; 4) School of Engineering and Natural Sciences, University of Iceland, Reykjavik 101, Iceland; 5) Faculty of Medicine, University of Iceland, Reykjavik 101, Iceland.

Heritability measures the relative contribution of genetic inheritance (nature) and environment (nurture) to trait variation. Estimation of heritability is especially challenging when genetic and environmental effects are correlated, such as when indirect genetic effects from relatives are present. An indirect genetic effect on a proband (phenotyped individual) is the effect of a genetic variant on the proband through the proband's environment. Examples of indirect genetic effects include effects from parents to offspring, which occur when parental nurturing behaviours are influenced by parents' genes. Indirect genetic effects from parents to offspring and between siblings have been shown to be substantial for educational attainment. We show that existing methods for estimating heritability, including GREML methods based on SNP sharing between distant relatives, can be severely biased by indirect genetic effects. We introduce a novel method for estimating heritability that does not exhibit such bias: relatedness disequilibrium regression (RDR). RDR removes environmental bias by exploiting variation in relatedness due to random Mendelian segregations in the probands' parents. We show mathematically and in simulations that RDR estimates heritability with negligible bias due to environment in almost all scenarios. We use a sample of 54,888 Icelanders with both parents genotyped to estimate the heritability of 14 traits, including height (55.4%, S.E. 4.4%), body mass index (BMI) (28.9%, S.E. 6.3%), and educational attainment (17.0%, S.E. 9.4%). We find evidence that existing identity-by-descent based methods severely overestimate heritability for educational attainment, height, BMI, and age at first child in women. We find evidence that GREML methods overestimate heritability for height, age at first child in women, and educational attainment. We find that GREML estimates of the heritability of educational attainment are inflated by a factor of around 1.7, consistent with the estimated magnitude of indirect genetic effects from parents and siblings. Furthermore, without genotype data on close relatives of the proband - such as used by RDR - our results show that it is impossible to remove the bias due to indirect genetic effects. Unfortunately, large datasets including many close relative pairs are currently rare. We therefore argue that greater efforts to collect such data will be essential for understanding genetic causation and the nature of nurture.

**SOS: Are genotype-based association tests robust to departure from Hardy-Weinberg equilibrium?** L. Zhang<sup>1</sup>, L. Sun<sup>1,2</sup>. 1) Department of Statistical Sciences, University of Toronto, Toronto, Canada, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada.

Though the exact origin of the argument is debatable, it is agreed that genotype-based association tests are robust to the departure from Hardy-Weinberg equilibrium (HWE), or not sensitive to Hardy-Weinberg disequilibrium (HWD). Indeed, empirical evidence appears to support this statement, particularly in studies using unrelated individuals. But how about related individuals? Linear mixed model (LMM) has become the most popular method for family-based association studies. The covariance structure of the phenotype is partitioned into a weighted sum of correlation structure due to genetic relatedness (or kinship coefficient) and shared environmental effect, where the weight is usually referred as 'heritability'. We show theoretically that if the causal SNP(s) are in HWD in the founders, the kinship coefficient matrix no longer captures the true relatedness structure between the genotypes in the related individuals. Thus, LMM may not be robust to the departure from HWE. Consider the simplest sib-pair design and assume the genotypes of the (unrelated) parents are in HWD but not available, the genotypes of the siblings can be shown to be in HWE; a textbook example demonstrating that HWE can be achieved after one single generation of random mating. However, we can also show theoretically that when it comes to association analysis, HWD in the founder generation affects the result through the covariance structure between the sibling genotypes. When heritability is known, based on literature, our simulation studies show that the empirical type 1 error rate can get as high as 10% at a 5% significance level. When heritability is estimated internally by LMM, type 1 error is well controlled but the estimated heritability is then biased. In practice, the problem occurs only if the true causal variants depart from HWE considerably and the sample consists mostly of related individuals. However, as we move beyond low-hanging fruit and continue to struggle with the missing heritability issue, our findings can be impactful. Furthermore, we propose an alternative approach to family-based association studies that is robust to the departure from HWE and remains powerful in the absence of HWD.

Identifying the genes and pathways that drive GWAS signal in noncoding regions remains a major challenge in deriving clinically relevant meaning from GWAS. Methods that partition SNP-heritability by genomic annotation (e.g., stratified LD score regression) can identify regulatory regions enriched with SNP effects of large magnitude; these methods assume that all allelic effects have mean 0 in the population and variances that depend on their annotation profiles. While useful, functional enrichment is limited in interpretability as it cannot elucidate specific biological mechanisms – e.g., the effect of increased binding of a given transcription factor (TF) on trait. In contrast, methods for estimating the effects of molecular mechanisms on trait (i.e., signed LD profile regression) model the expectation of allelic effects on trait as functions of their effects on the mechanism of interest while assuming the variances of the allelic effects are equal. Here, we propose MV-reg (Mean Variance REGression): a generalized framework for integrating QTLs or any allele-specific annotation with GWAS to estimate both the magnitude and direction of effect of a molecular mechanism (e.g., TF binding or gene expression) on a complex trait. Continuing with the TF binding example, MV-reg models both the expectation and variance of allelic effects on trait as functions of their effects on TF binding, and estimates the genome-wide effects of altered binding on both the mean and variance to identify trait-relevant TFs. We show via simulations that MV-reg produces unbiased estimates of the effects of TF binding on trait, and can use the estimated effects of TF binding on variance to prioritize TFs with equal mean effects. Lastly, we apply MV-reg to estimate the effects of 1370 TFs on BMI and LDL, and find a total of 8 TFs with significant nonzero effects (FDR < 0.1), 1 of which affects both traits. Our results are consistent with known biology; e.g., we find that increased binding of RORA1 (involved in lipid metabolism) and IPF1 (a transcriptional activator of insulin) are associated with higher BMI, and increased binding of AGL2 (involved in glycogenolysis) is associated with both higher BMI and lower LDL. We find an additional 9 TFs with nonzero effects on BMI or LDL (1 of which has effects on both) that do not pass the threshold for significance but show increased evidence for association due to their statistically significant effects on decreasing the allelic variances.

**Finding rare variants of large effect using identity-by-descent mapping.** S. Shringarpure, D. Hinds, V. Vacic, S. Pitts, R. Gentleman, A. Auton, 23andMe Research Team. 23andMe Inc, Mountain View, CA., USA.

With the availability of large cohorts, there is now increased potential for discovering rare variant associations in various phenotypes. However, due to limited imputation accuracy for rare variants, GWAS studies are not well-powered to discover rare variant associations. We demonstrate the utility of identity-by-descent (IBD) mapping methods to discover rare associations using simulations and application on data from 23andMe research participants. We performed extensive simulations examining the power of IBD mapping to detect rare associations as a function of rare variant frequency, effect size, disease prevalence and sample size. We find that IBD mapping can discover associations rarer than 0.5% in frequency, which cannot be detected using GWAS on imputed data. We applied our method on consented research participants from the 23andMe cohort and analyzed 200 phenotypes. Typically, we observe far fewer associations than GWAS, however, we see that discovered associations are rarer and have much larger effect sizes than typical GWAS associations. For instance, in an association analysis for morningness in individuals of Ashkenazi ancestry (11,625 cases, 11,509 controls), we find 2 large-effect rare haplotype clusters in regions previously reported as having common variant associations for chronotype [1], sleep disturbances [2], and insomnia [3], along with 2 novel haplotype clusters. In an association analysis for gout in Ashkenazi Jews, we find an association overlapping *ALDH16A1* (OR=5.7, P=6e-12, Freq=0.55%). WGS data from an individual in the associated cluster shows a rare missense mutation (rs150414818) in *ALDH16A1*. This variant has been previously reported for association with gout in Icelandic populations, where it is more common in frequency (1.9%) and has a weaker reported effect (OR=3.12). In addition to these associations, we find a number of rare variant associations in gene-phenotype combinations where common variant associations have previously been reported, as well other novel associations. These results suggest that IBD mapping can be used to find rare associations that may not be discovered through GWAS. **Prenatal diagnostics of congenital anomalies in assisted reproduction pregnancies: Population-based data from the Czech Republic.** A. Sipek Jr<sup>1,2</sup>, V. Gregor<sup>1,3</sup>, A. Sipek Sr.<sup>1,3,4</sup>, J. Klaschka<sup>5,6</sup>, M. Malys<sup>7</sup>, J. Jirova<sup>8</sup>. 1) Department of Medical Genetics, Thomayer Hospital, Prague, Czech Republic; 2) Institute of Biology and Medical Genetics, First Faculty of Medicine, Charles University, Prague, Czech Republic; 3) Department of Medical Genetics, Pronatal Sanatory, Prague, Czech Republic; 4) Institute of Biology and Medical Genetics, Third Faculty of Medicine, Charles University, Prague, Czech Republic; 5) Institute of Computer Science of the Czech Academy of Sciences, Prague, Czech Republic; 6) Institute of Biophysics and Informatics, First Faculty of Medicine, Charles University, Prague, Czech Republic; 7) National Institute of Public Health, Prague, Czech Republic; 8) Institute for Health Information and Statistics, Prague, Czech Republic.

**Introduction:** The proportion of children born after the use of assisted reproduction techniques is increasing worldwide. In the Czech Republic there were 3.65% children born after assisted reproduction in 2015. Various studies have confirmed higher incidence of selected groups of congenital anomalies among the assisted reproduction children. We are presenting first results of Czech population-wide study focusing the spectrum of congenital anomalies diagnosed during prenatal diagnostics among assisted reproduction pregnancies. **Methods:** Data were obtained from the official medical registries run by the Institute of Health Information and Statistics of the Czech Republic, namely National Registry of Congenital Anomalies and the National Registry of Assisted Reproduction. Those registries are run by the government, have population-wide coverage and the registration process is compulsory by the law. All cases of congenital anomalies (Q00-Q99 codes of ICD-10 classification) that were diagnosed prenatally among assisted reproduction pregnancies were further analyzed. Time period: 2007-2015. **Results:** During the selected time period, there were 538 cases of assisted reproduction pregnancies diagnosed with different types of anomalies. During the same time period, there were 1.012.375 children born in the Czech Republic (among those there were 29.899 = 2.95% assisted reproduction children). Most of those anomalies were part of chromosomal aberration syndromes (numerical and structural): 332 cases (61.7%). Among the non-syndromic cases – the most common were the anomalies of the central nervous system: 71 cases (13.2%), followed by the anomalies of the urinary tract (54 cases = 10.0 %), hearth defects (50 cases = 9.3 %) and gastrointestinal/abdominal wall anomalies (39 cases = 7.3%). **Discussion and conclusion:** The distribution of anomalies diagnosed in assisted reproduction pregnancies resembles the distribution of anomalies prenatally diagnosed in spontaneous conception pregnancies. The current limitations in different registries databases connection (incomplete data in healthy controls) do not allow us to provide exact statistical evaluation of this difference right now, but this issue will be overcome in the next stage of this project. **Acknowledgements:** Supported by Ministry of Health of the Czech Republic, grant nr. AZV 17-29622A and RVO project: "Thomayerova nemocnice – TN, 00064190". .

**Machine learning of causal biological networks with the principle of Mendelian randomization.** *M.B. Badsha, E.A. Martin, A.Q. Fu.* Department of Statistical Science, Institute of Bioinformatics and Evolutionary Studies, Center for Modeling Complex Interactions, University of Idaho, Moscow, ID 83844-1104.

Although large amounts of genomic data are available, it remains a challenge to reliably infer causal relationships among molecular phenotypes (such as gene expression). It is even harder to learn a causal network of many phenotypes. Correlation (or association) is often used as a proxy of a potential causal relationship, but similar levels of correlation can arise from different causal mechanisms. However, a genetic variant (e.g., an expression quantitative trait loci; or eQTL) associated with one of the two genes can help break the symmetry and determine the direction of the edge between genes. This is the rationale behind the Principle of Mendelian Randomization (PMR), which assumes that the alleles of a genetic variant are randomly assigned to individuals in a population, analogous to a natural perturbation experiment and therefore achieving the goal of randomization. We present MRPC, which learns a causal biological network efficiently and robustly from integrating genotype and molecular phenotype data, in which directed edges indicate causal directions. MRPC is the first machine learning algorithm that incorporates the PMR in classical algorithms for learning causal graphs in computer science (bioRxiv, 171348; arXiv, 1806.01899). MRPC performs a large number of statistical independence tests to determine whether an edge should be retained. It implements an online false discovery rate (FDR) control method that controls the overall FDR when the total number of tests is unknown beforehand. We demonstrate through simulation that MRPC achieves higher recall, precision and stability than existing general-purpose network inference methods (such as those implemented in R packages pcalg and bnlearn) and methods using the PMR (e.g., CIT, one of the most popular PMR-based method, and findr, a more efficient version of CIT). We applied MRPC to the GEUVADIS data to distinguish direct and indirect targets among multiple genes associated with expression quantitative trait loci (eQTLs). We also constructed a causal network for frequently altered cancer genes, using the copy number variation (CNV) and gene expression data from ER+ breast cancer patients in the TCGA consortium. From the cancer gene network, we further identified six modules of CNVs and genes that are enriched for distinct biological processes or pathways.

Multi-instrumental variable (IV) MR approaches utilize multiple single nucleotide variants (SNVs) as IVs to infer causality of an exposure with an outcome. Recently, we detected widespread horizontal pleiotropy in causal relationships inferred from MR among complex traits and diseases. As a result, there may be significant heterogeneity in the effects of IVs in MR, suggesting that single-IV MR approaches that account for heterogeneity of causal effects may be more appropriate than multi-IV MR in the context of horizontal pleiotropy. We conducted single IV MR for 82 GWAS traits (39 exposures and 82 outcomes) totaling 140,887 tests. We compared causal relationships inferred through single-IV MR with analogous results from multi-IV MR tests (implemented in MR-PRESSO), which included detection of horizontally pleiotropic outliers. We compared outlier and non-outlier SNVs in the context of their contributions to pleiotropy, as measured by a recently developed score that assesses pleiotropy for a given SNV through the total magnitude of its effect across traits ( $P_m$ ) and through its number of associations ( $P_n$ ). Across all exposure-outcome pairs, a total of 1,096 SNVs were significant for the single-IV MR test at a globally-corrected threshold ( $P < 0.05/\text{total tests}$ ,  $3.55 \times 10^{-7}$ ), 1,892 were identified as outliers, and 530 were both MR-significant and outliers. Outlier SNVs had a significantly greater mean pleiotropy score ( $P_m + 6.0$ ,  $P = 2.65 \times 10^{-27}$ ;  $P_n + 13.47$ ,  $P = 3.88 \times 10^{-32}$ ) than non-outliers. Of 3,157 exposure-outcome pairs, 325 had at least one significant single-IV MR variant and therefore evidence for causality. In comparison, out of 129 relationships that were significant for the multi-IV MR test, 84 had a SNV that was also significant for the single-IV MR test. In conclusion, single- and multi-IV MR are complementary methods; though 84 causal relationships were identified by both methods, 241 and 45 relationships were identified by only single- or multi-IV MR, respectively. Single-IV MR has added utility when pleiotropy and heterogeneity are present. For example, lack of significance in single-IV MR for the known causal relationships between both triglycerides (TG) and LDL-C, and coronary artery disease (CAD) due to opposite directions of effect for a given SNV (e.g. rs174546) reveals it to be a likely ineffective drug target for CAD. Therefore, single-IV MR has the potential to inform drug discovery in ways in which multi-IV MR cannot.

**Bayesian variable selection for Mendelian randomization.** *A. Gkatzionis, P.J. Newcombe.* MRC Biostatistics Unit, University of Cambridge, Cambridge, United Kingdom.

Mendelian randomization is the use of genetic information to assess the existence of a causal relationship between a risk factor and an outcome of interest. A Mendelian randomization analysis relies on a set of genetic variants (SNPs) that are strongly associated with the risk factor, and only associated with the outcome through their effect on the risk factor. Nowadays, SNPs associated with a risk factor can be obtained through large consortia genome-wide association studies (GWAS). The results reported by such studies, typically a list of univariate associations between SNPs and the risk factor, can be used to perform variable selection among a set of candidate SNPs. The JAM algorithm (Joint Analysis of Marginal summary statistics, Newcombe, Conti and Richardson, 2016) is a Bayesian model search algorithm recently proposed for this task. JAM uses a reversible-jump MCMC procedure to perform SNP selection based on GWAS summarized data. It accounts for genetic correlations and can be parallelized to analyse large numbers of SNPs simultaneously. We discuss the use of JAM for Mendelian randomization. In this context, we propose an extension that augments the JAM posterior with a loss function in order to penalize SNPs having a pleiotropic effect on the outcome. The performance of the new algorithm is illustrated with simulated and real data.

**Accounting for confounding in Mendelian randomization using genome wide summary statistics.** *J. Morrison, N. Knoblauch, J. Marcus, X. He, M. Stephens.* Human Genetics, University of Chicago, Chicago, IL.

Genome wide association studies (GWAS) have discovered trait associated variants for a wide array of phenotypes including clinically relevant traits such as disease status and intermediate molecular traits such as gene expression and metabolite levels. This wealth of data provides an opportunity to test hypotheses about the causal relationships between traits using Mendelian randomization (MR) and related methods. Current methods towards this goal rely on the assumption that pleiotropy is rare, that is, it is unusual for a single variant to effect multiple biological functions. However, recent research suggests this assumption is false. Many variants discovered via GWAS have strong signals of association with multiple, sometimes seemingly unrelated, traits while studies of gene regulation have uncovered variants that regulate the expression of many genes. A natural consequence of wide-spread pleiotropy is confounder driven genetic correlation. For example, if gene A is causally associated with disease susceptibility but gene A and gene B share some of their regulatory variants, gene B will appear to be "genetically correlated" with the disease. We propose a new method (Causal Analysis Using Summary Effect Estimates; CAUSE) that can accommodate multiple forms of pleiotropy including genetic variants acting on a shared confounder. We first apply our method to identifying relationships between pairs of complex traits. We demonstrate that CAUSE can recover known causal relationships (for example a causal effect of LDL cholesterol on coronary artery disease) and is able to identify several instances where correlation between traits is induced by substantial but incomplete sharing of genetic factors (for example between height and LDL cholesterol) leading to spurious signals using other methods. We also present an application to identifying genes with expression levels causally linked to Crohns disease. This analysis identifies both known Crohns genes and makes several new but plausible discoveries.

**Leveraging genome-wide significant loci to increase the power of S-LDSC to detect enrichment.** *K. Tashman<sup>1,2</sup>, A. Ganna<sup>1,2</sup>, B.M. Neale<sup>1,2</sup>, H.K. Finucane<sup>1,2</sup>.* 1) Stanley Center, Broad Institute, Cambridge, MA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Richard B. Simches Research Center Boston, MA.

Stratified LD Score Regression (S-LDSC; Finucane et al. 2015 Nat Genet) is a powerful tool to detect whether disease heritability is enriched in a functional annotation. S-LDSC is currently well-powered to detect enrichment for annotations with signal spread throughout the genome. However, it removes outlying single nucleotide polymorphisms (SNPs) such as those found in genome-wide significant loci, leaving potentially informative signal on the table. Here, we show that by explicitly modeling the signal found in top loci, we can increase the power of S-LDSC to detect enrichment. Specifically, we introduce a method for pathway analysis that combines S-LDSC with INRICH (Lee et al. 2011 Bioinformatics), a gene set enrichment tool that utilizes signal from top loci to test for enrichment of genes from a given pathway in a disease. To leverage signal from both S-LDSC and INRICH, we run both methods, excluding the loci used by INRICH when running S-LDSC, and we meta-analyze the p-values from the INRICH and S-LDSC results using Fisher's method. We applied our method in a pathway analysis of asthma using publicly available summary statistics from the UK Biobank and 6,166 pathways from KEGG and MSigDB provided with the INRICH software. While zero pathways passed FDR<0.05 with S-LDSC alone or with INRICH alone, our combined method identified 59 pathways with FDR<0.05, including gene sets as small as 5 genes; the identified pathways included many immune-related pathways and the top three most enriched pathways were ST-Interleukin-13, JAK-STAT signaling and Biocarta-TOB1. For this analysis, we created an open-source cloud-based pipeline that allows parallelized S-LDSC analyses. Utilizing this pipeline we were able to compute LD scores for 6,166 gene sets in less than two hours; we have released these LD scores publicly. Our work shows that incorporating signal from top loci can increase the power of S-LDSC. We plan to continue to evaluate and apply our method, and to extend it to enrichment of arbitrary functional annotations.

**Robust method for inferring genetic relationship across studies without compromising privacy.** *X. Zhao<sup>1</sup>, L. Franciolini<sup>2,3</sup>, D. MacArthur<sup>2,3</sup>, G. Abecasis<sup>1</sup>.* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI, USA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 3) Broad Institute of MIT and Harvard, Cambridge, MA, USA.

Reference datasets of human genetic variation are critical resources for functional interpretation of putative disease-causing variants by, for example, helping separate genomic positions and regions that are mutation intolerant from others where variation is more common. Although variant summaries like allele frequencies and quality metrics are often shared, through resources like dbSNP and ClinVar, or custom browsers like gnomAD and BRAVO, the underlying individual level data is typically more restricted. Without this information, it can be difficult for researchers to evaluate overlap between different data sources when attempting to aggregate information across them. Here, we propose a privacy-preserving protocol for identifying duplicates and close genetic relatives across variation datasets. Our method does not require disclosure of individual identities when checking for overlap between two datasets. The method works by combining a cryptographic technique, homomorphic encryption, with the robust relationship inference method implemented in KING (Manichaikul et al., 2010). Homomorphic encryption allows addition and multiplication on encrypted data to get encrypted results, which, when decrypted, match the results of calculations performed on the original unencrypted data. By developing a simple algorithm that relies on these operations, we construct a framework under which kinship coefficients can be obtained without disclose any genetic information between studies. Through simulations, we show that our method successfully encrypts genetic data and decrypts kinship coefficient results. We were able to correctly infer all duplicates and almost all (99%) 1st degree relatives with 2% false positive pairs. Our performance is identical to using KING with the original unencrypted genotypes. Our protocol also scales well in computing time and is protected from possible attacks. Then we applied our technique to federate genetic variants from the Trans-Omics for Precision Medicine (TOPMed) web browser with those in the Genome Aggregation Dataset (gnomAD) browser. Between 62,784 TOPMed Freeze65k samples and 138,632 gnomAD samples, we identified 5,568 pairs of duplicates and 2,269 pairs of 1st degree relatives. Securely identifying related samples will control for relatedness in federation of reference datasets when they have data sharing barriers. It will help with providing a reliable large-scale resource for clinical interpretation of genetic variants.

**Identifying associations between genetic variants and microbiome community diversity using kernel methods.** *M.C. Wu.* Fred Hutchinson Cancer Research Center, Seattle, WA.

Understanding genetic influences on microbiome composition is important both because the microbiome can serve as an intermediate trait and because such knowledge enhances our understanding of how inter-individual differences in composition may be innate. Community level analysis, wherein overall microbiome profiles across all taxa is assessed for association with outcomes (beta diversity analysis), is a standard mode of analysis in microbiome studies due to its ability to detect subtle, concerted shifts in microbiome composition. However, little has been done on community level analysis within the context of genetic studies. Standard distance-permutation based approaches do not work well in genetic studies due to high dimensionality, computational expense of permutation, and poor capture of features of genetic data. Therefore, we propose a novel framework for community level analysis in relation to groups of genetic variants, e.g. in a region, gene, or pathway within the kernel machine testing framework. The kernel machine is commonly used already for analyzing genetic data (through the SKAT method) and has also been applied to community level analysis in microbiome studies (through the MiRKAT method). Exploiting existing work, we embed microbiome community composition in a kernel matrix which captures ecologically relevant structure. Similarly, genetic variants (or possibly a single variant) are embedded within a kernel matrix. Then association between the kernelized data is measured through a generalized measure of multivariate correlation called the kernel RV (KRV) coefficient. Using finite sample or asymptotic null distributions for the KRV, we can quickly and analytically calculate p-values for the association between composition and genetic variation. Novel statistical strategies are proposed to enable covariate adjustment and to accommodate related individuals. Simulations and data applications demonstrate that the proposed strategy correctly controls type I error while maintaining excellent power, even in the presence of confounders or genetic relatedness.

**FinnGen: Towards a comprehensive catalogue of genomes and major health events for 500,000 Finnish residents.** *J. Karjalainen<sup>1,2,3</sup> on behalf of the FinnGen Consortium.* 1) Broad Institute, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Institute for Molecular Medicine Finland, Helsinki, Finland.

FinnGen is a public-private partnership project that was initiated in August 2017 and aims to combine genome and national health register data from up to 500,000 Finnish individuals. It uses the unique resource of national health care registers that cover health information of every resident for their entire life span. Data freezes are produced in increments of 50,000 individuals every 6 months. At present, we have completed the first data freeze with 52,425 genotyped individuals. By the time of ASHG we will have doubled the sample to 100,000. Compared to other large scale biobank projects like the UK Biobank, FinnGen is enriched for several diseases including late onset diseases like Alzheimer's disease (n=1,459). We continue to prioritize sample collection from specialty clinics to increase the number of late onset diseases. We designed a custom genotyping array containing 837,899 markers. The common variant imputation backbone consist of 548,494 markers optimized for imputation. Additionally, to enable studying variants not captured well by imputation, we identified rare (< 0.5%) missense and protein truncating variants (PTV) from 19,778 exome-sequenced Finns and added all 60,093 PTVs and 137,996 non-singleton missense variants on the array. Chip genotyped individuals were further imputed with a population-specific high-coverage (>30x) WGS-based imputation reference panel, consisting of 3,775 individuals and 17M variants. The Finnish population isolate provides benefits to identify rare and low-frequency variants relevant to disease susceptibility. We performed phenome-wide association scans for 16.8 million imputed variants across 807 clinical endpoints (n cases>100) using 39,000 non-related Finnish participants. We used the logistic saddlepoint approximation method to control for false positives caused by case-control imbalance and low allele frequencies when using conventional regression methods. We identified 651 independent loci with genome-wide significant associations in 302 clinical endpoints. In PTV burden analysis we confirmed known associations with *MYOC* and glaucoma, and *CHEK2* and all cancers combined (strongest associations to breast and prostate cancers). A meta-analysis with UKBB using the same phenotypes is ongoing. In addition, we developed web-based reporting and visualization tools to explore the association results together with previous genetic findings that include data from UKBB and the GWAS catalog, and pharmacological data.

**3528W****Polygenicity varies with allele frequency and functional category due to negative selection.**

*L.J. O'Connor<sup>1,2</sup>, A. Schoech<sup>1</sup>, F. Hormozdiazari<sup>1</sup>, S. Gazal<sup>1</sup>, N. Patterson<sup>3</sup>, A.L. Price<sup>1,3</sup>.* 1) Department of Epidemiology, Harvard TH Chan School of Public Health, Boston, MA; 2) Program in Bioinformatics and Integrative Genomics, Harvard Graduate School of Arts and Sciences, Cambridge, MA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge.

Common diseases and complex traits are highly polygenic. This polygenicity could reflect negative selection, if large-effect SNPs are prevented from becoming common in the population; we refer to this phenomenon as *flattening*. Here, we quantify the effects of flattening by comparing polygenicity across allele frequencies and functional annotations. We introduce a new definition of polygenicity, the *effective number of associated SNPs* ( $M_e$ ); in the special case of no LD,  $M_e$  is inversely proportional to the kurtosis of causal effects, and under a point-normal model it equals the number of causal SNPs. We introduce a method, stratified LD fourth moment regression (S-LD4M), to estimate  $M_e$  for subsets of SNPs by regressing squared chi-square statistics on LD fourth moments (sums of  $r_{ij}^4$ ). We confirmed that S-LD4M produces robust estimates of  $M_e$  in realistic simulations. We applied S-LD4M to 32 diseases and complex traits (avg N=403k). Polygenicity varies widely across traits (mean  $\log_{10} M_e=3.36$ , s.d. 0.64); brain-related traits are especially polygenic, e.g.  $\log_{10} M_e=4.28$  (s.e. 0.06) for schizophrenia. Approximately 25% of sparsity (excess kurtosis) was explained by functional annotations in the baseline-LD model (Gazal et al. 2017 Nat Genet). Comparing the polygenicity (per-SNP  $M_e$ ) of common (MAF>5%) vs. low-frequency (MAF>0.5%) SNPs, we determined that common SNPs are 4.2 (s.e. 0.7) times more polygenic than low-frequency SNPs. We compared polygenicity across functional categories, determining that polygenicity enrichment is very nearly equal ( $r^2=0.95$ ) to heritability enrichment; for example, SNPs in conserved regions are approximately 13x enriched in units of both  $h^2$  and  $M_e$ . This concordance implies that heritability enrichment predominantly reflects differences in the number of associations rather than their magnitude, probably due to a selection threshold. It suggests that significant GWAS loci represent a mixture of SNPs with deleterious effects on weakly selected genes and SNPs with subtle regulatory effects on strongly selected genes; though the former are more tractable, the latter may provide more insight. Indeed, among fine-mapped IBD GWAS loci (Huang et al. 2017 Nature), 13/30 putative causal genes implicated by fine-mapped regulatory variants were LoF intolerant, vs. 0/6 genes implicated by coding variants ( $p=0.003$ ). Our findings underscore the profound effect of negative selection on the genetic architecture of complex traits.

**3529T****A robust unified test for Hardy-Weinberg equilibrium in arbitrarily structured populations.**

*A. Kwong, H.M. Kang, The Trans-Omics for Precision Medicine Program.* University of Michigan, Ann Arbor, MI.

Hardy-Weinberg Equilibrium (HWE) has long been an important metric to evaluate the quality of variant calls. Deviations from HWE can be caused by many factors, including population structure and genotyping error. For samples arising from similar ancestries, in the absence of population structure, the chi-squared and exact tests for HWE are routinely used in variant quality control. To account for population structure for samples from discrete, non-overlapping populations in HWE tests, subpopulations can first be tested separately, then test statistics can be combined across subpopulations using Stouffer's method. When a set of samples arise from a more continuous spectrum of ancestries, then these traditional tests are unable to control Type I errors. As genetic studies contain samples of increasing diversity and admixture, this will become an increasingly prevalent problem for variant quality control. To address these issues, we propose the Robust Unified Test for Hardy-Weinberg Equilibrium, which uses both a score test and a likelihood ratio test with individual-level adjustments for ancestry. Our method allows the joint computation of ancestry-adjusted HWE statistics, without the need to split samples into stratified subpopulations, by using individual-specific allele frequencies for each sample at each variant, based on ancestry summary statistics. We tested our method against the chi-square test, exact test, and Stouffer's method in both simulated data and variants from the Trans-Omics Precision Medicine (TOPMed) Program, and show that when samples contain population structure, our method was better at controlling Type I errors than the chi-square and exact tests, with more power to detect deviation from HWE after adjusting for population structure when compared to Stouffer's method. For example, when testing 338,722 low-quality variants with high Mendelian discordance in chromosome 20 in TOPMed, our method found 196,962 variants to significantly deviate from HWE at  $p<10^{-6}$ , compared to 114,381 variants using the exact test. When testing 18,380 high-quality variants present in both the Omni2.5 array and HapMap3 site lists, our method found only 325 significant variants, compared to 6,754 using the exact test. In summary, we have developed a powerful and flexible method well-suited for variant quality control in modern genetic studies with samples arising from diverse ancestries.

**3530F****Spatially-dense 3D facial heritability and genetic correlations in a heterogeneous sample.** *J. Li<sup>1,2</sup>, J.D. White<sup>3</sup>, K. Indencleef<sup>4</sup>, H. Hoskens<sup>5,6</sup>, A. Ortega Castrillon<sup>1,2</sup>, A. Zaidi<sup>3</sup>, R.J. Eller<sup>6</sup>, S. Walsh<sup>6</sup>, M.D. Shriver<sup>3</sup>, P. Claes<sup>1,2,7</sup>.*

1) Medical Imaging Research Center, MIRC, University Hospitals Leuven, Leuven, Belgium; 2) Department of Electrical Engineering, ESAT/PSI, KU Leuven, Leuven, Belgium; 3) Department of Anthropology, Penn State University, University Park, Pennsylvania, USA; 4) Department of Neurosciences, Experimental Otorhinolaryngology, KU Leuven, Leuven, Belgium; 5) Department of Human Genetics, KU Leuven, Leuven, Belgium; 6) Department of Biology, Indiana University-Purdue University Indianapolis, Indianapolis, IN, USA; 7) Murdoch Childrens Research Institute, Melbourne, Victoria, Australia.

The human face is a complex trait with a strong genetic component. Though facial heritability and the genetic correlation between different facial features have been estimated in numerous studies, most of the methods used rely on a strong assumption of population homogeneity in either a family-based or a population-based designs. We propose a mixed linear model (MLM) to estimate the genetic contributions to facial variation in a sample composed of a heterogeneous combination of populations. The additive genetic variation is decomposed into fixed and random effect components, consisting of the multivariate genomic background (PCA) and the pairwise genomic relationships between individuals adjusted for population heterogeneity and admixture, respectively. Rather than using population allele frequencies, the adjusted genomic relationships are obtained using individual-specific allele frequencies that are estimated from a logistic regression between genotypes and the multivariate genomic background. Finally, the narrow-sense heritability is defined in terms of the proportion of variance explained by the two components. We present the narrow-sense heritability of facial shape calculated from 3D facial images and genotype data of 2,882 unrelated individuals of varying ancestries. First, we estimated the narrow-sense heritability of univariate pairwise distances between 7,160 quasi-landmarks representing facial shape in a spatially-dense arrangement. The highest heritability was observed for the distance between the nasion and the zygion, 65.07%. In addition, we estimated the narrow-sense heritability and the pairwise genetic correlations of all quasi-landmarks as multivariate three-dimensional variables. The narrow-sense heritability of multivariate quasi-landmarks ranged from 13.74% (around the chelion) to 54.05% (the chin). Finally, we performed a hierarchical segmentation of facial shape based on the genetic correlation between quasi-landmarks, grouping them into modules that are internally well-integrated. The resulting genetic correlation-driven facial segmentation shows remarkable overlap with the facial prominences in early embryonic development: frontonasal prominence, maxillary prominence, and mandibular prominence. Our results suggest a promising future for genetic studies of facial shape phenotypes learned from genetic correlations in a heterogeneous sample.

**3531W****Accounting for sub-phenotyping in rare variant association tests.** *E. Genin<sup>1</sup>, O. Bocher<sup>1</sup>, A. Saint Pierre<sup>1</sup>, H. Perdry<sup>2</sup>, G. Marenne<sup>1</sup>.* 1) UMR1078, Inserm, Université de Brest, EFS, CHU Brest, Brest, France; 2) UMR669, Inserm, Université Paris Sud, Paris, France.

Technological advances have made genome sequencing a reality and opened up new possibilities to explore genetic disease architecture and test the role of rare variants in common diseases. Investigators have access to the integrality of the genetic information and the challenge now is to understand the phenotypic consequences of these different genetic variants. For that purpose, it could be of interest to go beyond the classical binary disease model of cases and controls and refine the trait under study by sub-phenotyping to take into account for example disease severity, age of onset or any other relevant information that could be important in the disease etiology. Indeed, most common human diseases show clinical and phenotypic heterogeneity that could underlie genetic heterogeneity and it might thus improve power of association tests to identify relevant patient subgroups. Many tests have been proposed for rare variant association testing, either with quantitative phenotypes or with binary phenotypes but there is no test for rare variant association that allows a sub-grouping of patients. In this work, we propose extensions of rare variant burden tests that address this issue of sub-phenotyping. We have developed a multinomial logistic extension of two popular rare variant association tests, CAST and WSS and implemented them in an R package. Through extensive simulations, we show that accounting for phenotype heterogeneity of patients could largely improve the power of rare variant association tests, and, as expected, this is especially true under scenarios where genetic heterogeneity between subgroups is important. Interestingly, in the absence of genetic heterogeneity, we find that the power loss from separating cases into subgroups is rather limited and the cost/benefit balance is strongly in favor of using information on sub-phenotypes. We also illustrate this advantage on some real data examples where we show the benefit of sub-phenotyping cases. The tests developed and the simulation framework are implemented in an R package available on Github. This package makes it possible for investigators to run the tests on their data but also to perform simulations under different scenarios using information from GnomAD or their own information on rare variants found in different genes.

**A survey of integrating age-at-onset genetics for predicting the age-specific disease risk.** C. Tian, D. Hinds, 23andMe Research Team. 23andMe, Mountain View, CA.

Human disease is characterized by marked genetic heterogeneity, which has important implications for gene discovery. In particular, evidence suggests distinct genetic susceptibility between early-onset and late-onset diseases. In this study, we demonstrated that stratifying on age-at-onset information collected in the case-control studies could lead to the discovery of novel genetic risk factor so-called modifiers of age-at-onset, despite reduced sample size. For example, two distinct missense variants in *SERPINA1* were associated with high cholesterol in young adults and elderly people, respectively, while variants in *HDAC5* and *CTNND2* were significantly associated with high cholesterol in young adults only. This degree of heterogeneity on age-at-onset also has important implications for development of personalized genetic assessment. As a result, we should include modifiers of age-at-onset into the predictive modeling to increase predicting accuracy, especially for earlier onset diseases. Currently, genetic risk scores (GRS), derived mainly from case-control GWAS, have been used for predictive modeling of many complex disease risks. This approach is considered clinically suboptimal for assessing an age-dependent disease where a subset of "controls" will become "case" over time. Scientists are trying to extend the work by integrating genetics within a survival-analysis-epidemiology framework to derive a polygenic hazard score (PHS) and hope to use it to inform both whether and when to order screening tests. Some preliminary work has been done for Alzheimer's disease and prostate cancer. Here we carefully investigated the Cox survival model for age-specific risk prediction and provided some practical guidance on incorporating age-at-onset genetics into disease risk prediction. When using the survival model, one thing to consider is that the baseline hazard estimates derived from GWAS samples cannot be used directly, especially for senior individuals. We evaluated methods for deriving population-based incidence rate estimates. Previous study showed that simple inclusion or exclusion of future cases in each risk set induced an under- or over-estimation bias in the regression parameters, respectively. A weighted Cox model that weights subjects according to age-conditional probabilities of developing the disease in the source population may provide less biased estimation.

**Importance of protected statistical testing and replicate number in RNA-sequencing studies.** R.Z. Blumhagen<sup>1</sup>, C.M. Moore<sup>1</sup>, B.E. Vestal<sup>1</sup>, C.D. Langefeld<sup>2</sup>, T.E. Fingerlin<sup>1</sup>. 1) Center for Genes, Environment and Health, National Jewish Health, Denver, CO; 2) Wake Forest School of Medicine, Medical Center Boulevard, Winston-Salem, N.C.

When more than two groups are of interest in RNA-Seq studies, it is common practice to perform all pairwise comparisons between groups to identify differentially expressed genes. Using this approach without proper adjustment for multiple comparisons increases false positive associations. As RNA-Seq studies become more complex, including multiple groups, conditions and time points, the number of pairwise tests grows. To reduce false positive associations, we examine the use of a likelihood ratio test (LRT) as the first step before evaluation of the pairwise comparisons, consistent with other protected testing approaches. We first give results from a simulation study comparing the statistical testing properties of the LRT gate-keeping approach to the pairwise comparison (PC) approach, where a gene is called differentially expressed if at least one pairwise test is significant. We then apply the two methods to real datasets. We simulated RNA-Seq data using a negative binomial model with mean and variance distributions derived from a clinical dataset with a range of parameters for group number, number of replicates per group and proportions of differentially expressed genes. As expected, PC had higher type 1 error and false discovery rates (FDR) than the LRT in all scenarios. For example, in a simulation including 7 groups with 5 replicates each and  $\alpha=0.001$ , PC had 50.1 times (95% CI: 41.5-61.7) the nominal type 1 error compared to 10.0 times for the LRT (95% 5.2-15.3). Under the alternative of 10% differentially expressed genes with a 2-fold change, PC had 4.6 times (95% 4.2-5.0) the expected FDR compared to 2.4 times for the LRT (95% CI: 1.9-2.8). Despite having lower FDR than the PC approach, the LRT also exhibited inflated FDR for small numbers of replicates. The inflation worsened as the number of study groups increased, illustrating the importance of replicate number within each experimental group. In a simulation including 5 groups, increasing the replicates from 3 to 5 in each group reduced the FDR inflation from 3.3 times to 2 times. In summary, when comparing RNA-Seq expression between more than two groups, the LRT reduces false positives and better controls FDR compared to evaluating all pairwise comparisons. This approach is also more powerful than using a correction for the number of pairwise tests. Further, we recommend careful consideration of the number of replicates within each group to reduce false discoveries.

**Classification of cell type from single-cell RNA sequencing data by deep neural networks.** C. Lou, G. Hu, W. Chen, D. Stambolian, M. Li. University of Pennsylvania, Philadelphia, PA.

Recent advances in single-cell RNA-seq (scRNA-seq) have made it possible to systematically characterize cell types by gene expression. Knowledge of cell types is important in the pursuit of precision medicine. Current approaches for cell type classification often perform poorly when the differences of cell types are subtle. As scRNA-seq becomes increasingly popular, more and more scRNA-seq data have been generated. It is appealing to incorporate these data to inform cell type classification when new data become available. Supervised learning using neural networks is suited perfectly for this purpose. To evaluate the performance of this approach, we focus on 9,515 bipolar cells generated from mice retina using 10x Genomics platform. We choose bipolar cells due to their large number of subtypes, and the availability of well characterized subtypes from a previously published study (Shekhar et al. 2016), which includes ~24,000 bipolar cells generated using DropSeq. Using the Shekhar data as a gold standard, we classify our 9,515 bipolar cells using two different methods. The first approach is a semi-supervised clustering method, which involves aligning data from our bipolar cells with the Shekhar data and then clustering using the Louvain-Jaccard algorithm to find clusters that correspond to those identified by Shekhar. The second approach is supervised learning using neural networks in which the model parameters are estimated using the Shekhar data as the training dataset. The trained neural network is then applied to our bipolar cells to assign cell types. With the semi-supervised clustering, we identify 15 different bipolar cell subtypes whose gene expression profiles correspond to those in Shekhar. Using neural networks with one hidden layer and 100 nodes, we also identify 15 different bipolar cell subtypes, of which 77% have concordant cell type assignments with the semi-supervised clustering method. When increasing the number of hidden layers and the number of nodes per layer, the concordance rate increases further. Since the two scRNA-seq datasets were generated using different platforms, our results suggest that deep neural networks are a robust approach for supervised learning of cell type classification. We are currently applying this approach to a larger scRNA-seq dataset that involves ~100K single cells from mouse retina. We anticipate that this analysis will yield a comprehensive cellular map for bipolar cells in the mouse retina.

**3535T**

**Robust adjusted profile likelihood ratios for the analysis of differential gene expression.** L. Zhong<sup>1,2</sup>, G. He<sup>1,2</sup>, L.J. Strug<sup>1,2</sup>. 1) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 2) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada.

RNA Sequencing (RNA-Seq) experiments generate read counts that provide a measure of gene expression. RNA-Seq can then be used, for example, to determine which genes show differences in expression in Cystic Fibrosis patients with low versus high lung function. Popular approaches for differential gene expression analysis include edgeR and DESeq2. Although count data is routinely modeled using a Poisson distribution, the RNA-Seq data does not in general satisfy the Poisson distributional assumption of equal mean-variance. EdgeR and DESeq2 therefore assume a negative binomial distribution for the read counts to model the overdispersed mean-variance relationship for biological replicates and estimate the gene-specific dispersion level for the downstream testing procedure. The negative binomial distribution assumes a quadratic variance function, yet more general patterns for over/under-dispersion could be observed, potentially missing important genes. We propose a general solution to measure gene expression differences for any variance pattern using robust adjusted profile likelihood inference. Poisson regression is used to model the relative abundance, with the estimated effective library size used as an offset term for normalization. Simulation under a variety of scenarios demonstrates that the profile likelihood ratio for the differential gene expression parameter, after a data-driven robust adjustment for departures from the Poisson mean-variance assumption, can reliably detect which genes display differential expression. Findings are compared to analyses using conventional approaches. In RNA-Seq of nasal epithelia from 64 patients with Cystic Fibrosis, we identify 15 differentially expressed genes associated with lung function, adjusted for study site, gender and immune cell contamination. We provide a flexible approach to gene expression analysis that can accommodate over or under dispersion, any mean-variance relationship, is applicable to categorical or quantitative conditions of interest and complex experimental designs. Support intervals and novel graphics provide accessible genome-wide interpretations.

**Deconvolution of bulk tissue cell type proportions from single-cell RNA-seq.** X. Wang, J. Park, K. Susztak, M. Li, N. Zhang. University of Pennsylvania, Philadelphia, PA.

The characterization of cell types within intact bulk tissue and the estimation of their proportions play an important role in human disease studies. Many clinical and population-based transcriptomic studies use bulk RNA sequencing (RNA-seq) from intact tissues, where the average gene expression across cells in the tissue is measured. Since many tissues are heterogeneous at the cellular level, failure to control for cell type differences may mask the underlying cell-type specific contributions to disease, and sometimes, may even produce false positive results due to confounding from cell type proportions. Deconvolution of cell type proportions from bulk tissue gene expression data, is difficult, especially when the underlying cell types are unknown. Recent advances in single-cell RNA sequencing (scRNA-seq) has paved the way for exploring cellular heterogeneity and allows for the identification of novel cell types and better characterization of known cell types. However, scRNA-seq is still costly, and furthermore, is not well suited for the quantification of cell type proportions in a tissue, because the cell dissociation and isolation steps of the scRNA-seq procedure are biased, leading to over-representation or under-representation of certain cell types. Although progress has been made on the bulk RNA-seq deconvolution problem, all existing methods ignore the cross-subject heterogeneity in gene expression and rely heavily on pre-selected marker genes. Our analysis of multiple scRNA-seq datasets suggests that cross-subject heterogeneity is not ignorable. To overcome these limitations, here we present MuSiC (Multi-Subject Single Cell deconvolution), to estimate cell type proportions with a data-driven scheme to automatically weigh genes rather than pre-selecting markers with arbitrary cutoff. The weight is determined by the cross-subject cell-type specific gene expression variance as well as the technical noise of the bulk RNA-seq data. MuSiC clearly outperforms known methods in several real datasets. Comparing cell type compositions between normal and type 2 diabetes (T2D) individuals, MuSiC detected significant negative correlation between T2D and beta cell proportions, which is missed by other existing methods. MuSiC can successfully detect rare cell types in mouse kidney by hierarchical structure, which grouped similar cell types together and find signals of chronic kidney disease missed by other methods.

**Impact of genotype imputation on genome-wide meta-analysis: To aggregate or to eliminate?** E.F. Acar. The Centre for Phenogenomics, The Hospital for Sick Children, Toronto, Ontario, Canada.

Genotype imputation is a technique extensively used in genome-wide association studies (GWAS), as well as in their meta-analysis. The impact of imputation on testing genetic associations in a single GWAS has been addressed in the literature and a number of imputation-based test procedures have been proposed. However, the consequences of including imputation-based GWAS results in a meta-analysis remain largely unexplored. In this work, we consider both fixed and random effects models to evaluate the accuracy and efficiency of imputation-based meta-analysis results under different levels of genotype imputation accuracy. Simulation results reaffirm that meta-analysis boosts the power of detecting genetic associations compared to individual study results. However, the power deteriorates with increasing uncertainty in imputed genotypes. To control the contribution of imputation-based studies, we propose a reweighing scheme based on genotype imputation accuracy. Our approach achieves a better detection power relative to the traditional approaches, and improve the validity and reliability of imputation-based meta-analysis results.

**A method to estimate the sampling variance of genotype principal components and residual confounding due to incomplete capture of population structure.** C. Chen<sup>1,2</sup>, D. Palmer<sup>1,2</sup>, J. Bloom<sup>1,2</sup>, D. Chen<sup>1,2</sup>, K. Tashman<sup>1,2</sup>, C. Churchhouse<sup>1,2</sup>, B. Neale<sup>1,2</sup>, A. Bloemendaal<sup>1,2</sup>. 1) Medical and Population Genetics Program and Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA.

Principal component analysis (PCA) is widely applied to genotype data to identify population structure and control for its confounding effect in genome-wide association studies (GWAS). Patterson, Price & Reich (PLoS Genet 2006) applied results from random matrix theory to show that in a structured sample, for population differentiation below a threshold depending on the sample size and number of markers, PCA fails to detect the signal. Real data with linkage disequilibrium require an estimate of the effective number of independent markers, for which this work includes a moments-based estimator. We observe the latter to be highly unstable and often poorly calibrated, and propose an alternative robust estimator based on the eigenvalues of the genetic relationship matrix. The threshold phenomenon for each principal component (PC) depends on its corresponding eigenvalue. We extend previous work to fully characterize the eigenvalues for population structures including clines and admixture, generalizing the models of Balding & Nichols (Genetica 1995) and Pritchard, Stephens & Donnelly (Genetics 2000). We establish that the eigenvalues depend only on the population differentiation parameters and the covariance of the admixture distribution. Further, for each eigenvalue above the threshold, we combine our robust estimator with existing theory to estimate the magnitude of differentiation the corresponding PC attempts to capture. Below the signal-detection threshold, a PC is essentially uncorrelated with the true direction of differentiation; even above the threshold, however, the correlation may be only partial. We estimate this correlation, also in terms of the corresponding eigenvalue. Finally, we predict the correlation for other samples from the same population with the same markers, yielding a critical sample size below which the correlation drops to zero. We validate all these estimators through extensive simulations and downsampling experiments on multiple datasets. Our results imply that using sample PCs as covariates in GWAS may incompletely control for population stratification. We investigate the degree to which study results may be affected, considering both binary and continuous traits under various stratification scenarios. We provide a straightforward software implementation of our method together with some practical recommendations.

**3539F**

**General retrospective mega-analysis framework for rare variant association tests.** Y. Chiu<sup>1</sup>, L. Chien<sup>2</sup>. 1) National Health Research Institutes, Zhunan, Miaoli 35053, Taiwan; 2) Center for Fundamental Science, Kaohsiung Medical University, Kaohsiung 80708, Taiwan.

We proposed a retrospective mega-analysis framework for gene- or region-based multimarker rare variant association tests. Our proposed mega-analysis association tests allow investigators to combine longitudinal and cross-sectional family- and/or population-based studies. This framework can be applied to a continuous, categorical or survival trait. In addition to autosomal variants, the tests can be applied to conduct mega-analyses on X-chromosome variants. Tests were built on study-specific region- or gene-level quasi-score statistics and, therefore, do not require estimates of effects of individual rare variants. We used the generalized estimating equation approach to account for complex multiple correlation structures between family members, repeated measurements, and genetic markers. While accounting for multilevel correlations and heterogeneity across studies, the test statistics were computationally efficient and feasible for large-scale sequencing studies. The retrospective aspect of association tests helps alleviate bias due to phenotype-related sampling and type I errors due to misspecification of phenotypic distribution. We evaluated our developed mega-analysis methods through comprehensive simulations with varying sample sizes, covariates, population stratification structures, and study designs across multiple studies. To illustrate application of the proposed framework, we conducted a mega-association analysis combining a longitudinal family study and a cross-sectional case-control study from Genetic Analysis Workshop 19.

**A flexible linear mixed model for estimating heritability of categorical phenotypes.** *G. Darnell<sup>1</sup>, N. Mukherjee<sup>2</sup>, S. Mukherjee<sup>2,3</sup>, B. Engelhardt<sup>4</sup>.* 1) Lewis-Sigler Institute, Princeton University, Princeton, NJ; 2) Department of Statistics, Duke University, Durham, NJ; 3) Department of Mathematics, Computer Science, Duke University, Durham, NJ; 4) Department of Computer Science, Center for Machine Learning and Statistics, Princeton University, Princeton, NJ.

Heritability of human complex traits such as disease risk have long been estimated using models based on principles of quantitative genetics. However, many traits like age-related macular degeneration, schizophrenia, and autism cannot be naturally represented on a continuous scale or with binary values, and have complex diagnosis patterns that are typically represented with a category-based system. Even traits that are inherently binary and have a monogenic basis can trigger an effect on related non-binary traits through variation in population gene expression levels [Barbeira, 2018]. It is crucial for understanding the genetic architecture of complex traits to estimate genetic correlations among traits that are represented on heterogeneous scales. Many sources of data that include important signal but were previously underused, including responses to survey questionnaires such as that of the UK Biobank, are categorical in nature. We developed a flexible probabilistic framework that estimates heritability of, and the degree of pleiotropy between, categorical traits that does not require any recoding of the phenotype to a continuous, ordinal, or binary scale. Our model is based upon the multivariate generalized linear mixed model, and extends this framework further to be able to partition variance in categorical traits. Simulated trait studies show that our model is highly accurate and robust in recovering heritability and pleiotropy relative to current approximations of these estimates of heritability. We apply our framework to the UK Biobank data, which contains categorical survey responses and disease stages, covariates such as age, sex, and BMI, and genetic marker information in order to estimate the underlying heritability of categorical traits. In these data, we gain insights into the degree to which complex traits have a common genetic basis, and we can begin to uncover the pleiotropic effects of regulatory mechanisms.

**Sparse canonical correlation analysis (sCCA) significantly improves power of cross-tissue transcriptome-wide association studies (TWAS).** *H. Feng<sup>1,2</sup>, B. Pasaniuc<sup>3,4</sup>, M. Major<sup>3,4</sup>, P. Kraft<sup>1,2</sup>.* 1) Program in Genetic Epidemiology and Statistical Genetics, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, United States of America; 2) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, United States of America; 3) Department of Human Genetics, University of California Los Angeles, Los Angeles, California, United States of America; 4) Department of Pathology and Laboratory Medicine, University of California Los Angeles, Los Angeles, California, United States of America.

TWAS test the association between imputed gene expression and an outcome, which relies on accurate estimation of genetic effects on gene expression and suffers from low power at small eQTL sample sizes or when data from relevant tissues is not available. Genetic regulation of expression is similar across tissues for many genes, therefore cross-tissue TWAS tackles these issues by leveraging eQTL data across multiple tissues. Here, we use sCCA to integrate data across tissues and build a new feature (i.e. a cross-tissue weighted average of expression values with high genetic correlation, which can be used to identify heritable genes and as an intermediate trait in TWAS analyses) and show that sCCA-TWAS outperforms traditional TWAS. We simulated gene expression data from 22 tissues using empirical cross-tissue correlation patterns from GTEx, assuming different genetic correlation patterns across tissues, and simulate GWAS summary statistics assuming expression levels in a single tissue are associated with outcome, and compared sCCA-TWAS to single-tissue TWAS; cross-tissue TWAS adjusting for multiple testing with Bonferroni and Generalized Berk-Jones (GBJ); and summarizing cross-tissue expression patterns using Principal Component Analysis (PCA). All methods control the Type I error both when there is no genetic effect on expression or when expression is not associated with outcome. When expression drives trait, sCCA-TWAS had the greatest power to detect a gene associated with outcome, even when the causal expression trait was not directly measured: e.g. when gene expression explains 2% of the variability in outcome and the GWAS sample size is 20,000, the average power difference between sCCA and single-tissue, multi-tissue, and PCA approaches was 0.23, 0.26, and 0.40. The large gain in power is likely due to sCCA cross-tissue features being more likely to be significantly heritable than single-tissue or PC expression features (2.78x, and 3.72x respectively). Our results suggest that aggregating eQTL data across multiple tissues using sCCA can improve the specificity and sensitivity of TWAS. We also present a comparison of these approaches applied to multiple large, publicly available GWAS of complex traits.

**Improving gene expression prediction accuracy in transcriptome-wide association studies.** *J. Fryett<sup>1</sup>, A.P. Morris<sup>2</sup>, H.J. Cordell<sup>1</sup>.* 1) Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, United Kingdom; 2) Department of Biostatistics, University of Liverpool, Liverpool, United Kingdom.

Transcriptome-wide association studies (TWAS) are a popular approach for integrating genome-wide association study (GWAS) data and gene expression data to investigate the role of gene expression in complex traits. In this method, gene expression values (attributable to genetic regulation) are first predicted from SNP genotype data, and then tested for association with a trait of interest. The power of this approach to identify expression-trait associations depends partially on gene expression prediction accuracy. Here, we use genotype and blood expression data from the Geuvadis project with 10-fold nested cross-validation to examine and compare the ability of seven statistical approaches (Ridge regression, LASSO, Elastic net with alpha pre-set to 0.5, Elastic net with alpha determined by cross-validation, a Bayesian Sparse Linear Mixed Model (BSLMM), the Best Linear Unbiased Predictor (BLUP) and Random Forest) to predict gene expression from SNP data. Overall, we find that expression of most genes cannot be predicted accurately using SNP genotype data. However, approximately 2% of genes showed reasonable prediction accuracy (cross-validation  $R^2 > 0.3$ ), representing a set of genes where the TWAS approach may have power to detect associations. We also observe that the sparse statistical models (LASSO, Elastic net, BSLMM) predict expression marginally more accurately than polygenic models. Through an application to GWAS data for type 1 diabetes from the Wellcome Trust Case Control Consortium, we find that all seven methods perform similarly at detecting associations. We also investigate the effects of sample size, ancestry and tissue specificity on prediction accuracy. We find that prediction accuracy is consistently reduced when fewer samples are used to train the gene expression prediction models, or when populations of different ancestries are used to train the prediction models and to test them. Finally, by training gene expression prediction models using data from developing brains, we find that prediction accuracy is reduced when the tissues used to train and to test the models are different. We conclude that TWAS prediction accuracy can be improved through the use of sparse statistical models, larger sample sizes, and by using data of appropriate ancestry and tissue. This may lead to improved ability to detect associations with the TWAS approach.

**Mapping multiple complex and omics trait-associations using summary statistics from correlated or independent samples.** *K.J. Gleason<sup>1</sup>, F. Yang<sup>2</sup>, L.S. Chen<sup>1</sup>.* 1) Dept. of Public Health Sciences, The University of Chicago, Chicago, IL; 2) Dept. of Biostatistics and Informatics, Colorado School of Public Health, Aurora, CO.

To date, genome-wide association studies (GWAS) have identified more than 60 thousand unique SNP-trait associations, but the functional mechanisms underlying many of these associations remain unknown. The analysis of the joint associations of a SNP to complex trait(s) and omics-phenotypes (e.g., mRNA expression, DNA methylation, and protein abundance) has the potential to elucidate mechanisms underlying known associations or to reveal novel relationships between genetic variants and complex traits. In this work, we propose an integrative genomics approach for mapping multi-trait associations using summary statistics from correlated, overlapping or independent samples, and develop an R package: "primo." Different from existing literature, primo can analyze the joint associations of more than three sets of summary statistics. Primo estimates the probability that a SNP is associated with any arbitrary combination (e.g. at least 1, at least 2, some but not others, or all) of traits and omics-phenotypes of interest. Empirical false discovery rates are estimated and controlled through permutation of test statistics. We first applied primo to identify multi-omics QTLs in tumor samples from TCGA in breast tissues, and ovary tissues, separately. We joint analyzed the eQTL, meQTL, and pQTL summary statistics, and have identified multiple genes with e-me-pQTLs, several of which were known to be cancer-related. We further integrated the three breast tissue QTL sets with summary statistics from a breast cancer GWAS, and identified several breast-cancer-risk-associated SNPs that were also multi-omics QTLs. Those results illustrated that some SNPs, in particular those in non-coding regions, may affect cancer risks and other complex traits via certain omics phenotypes. In another integrative analysis by primo, we estimated broad sharing (~73%) of eQTLs between tumor breast tissues from TCGA and normal breast tissues from GTEx. Similar sharing (~78%) was estimated in the analysis of ovary tissues. Finally, we used primo to assess pleiotropy by integrating molecular QTL summary statistics with results from GWAS of multiple complex traits. SNPs identified by primo to be associated with multiple diseases and omics phenotypes highlight possibly shared mechanisms that underlie disease processes. The package is freely available for download at <https://github.com/kjgleason/primo>.

**A semi-supervised approach for predicting cell type/tissue specific functional consequences of non-coding variation using massively parallel reporter assays, with applications to complex trait genetics.** Z. He<sup>1</sup>, L. Liu<sup>2</sup>, K. Wang<sup>2</sup>, I. Ionita-Laza<sup>2</sup>. 1) Dept of Neurology, Stanford University, Stanford, CA; 2) Dept of Biostatistics, Columbia University, New York, NY; 3) Dept of Statistics, Columbia University, New York, NY; 4) Raymond G. Perleman Center for Cellular and Molecular Therapeutics, Children's Hospital of Philadelphia, PA.

Predicting the functional consequences of genetic variants is a challenging problem, especially for variants in non-coding regions. Projects such as ENCODE and Roadmap Epigenomics make available various epigenetic features, including histone modifications and chromatin accessibility, genome-wide in over a hundred different tissues and cell types. In addition, recent developments in high-throughput assays to assess the functional impact of variants in regulatory regions (e.g. massively parallel reporter assays, CRISPR/Cas9-mediated in situ saturating mutagenesis) can lead to the generation of high quality data on the functional effects of selected variants. We propose here a semi-supervised approach, GenoNet, to jointly utilize experimentally confirmed regulatory variants (labeled variants), millions of unlabeled variants genome-wide, and more than a thousand cell type/tissue specific epigenetic annotations to predict functional consequences of non-coding genetic variants. Through the application to several experimental datasets, we demonstrate that the proposed method significantly improves prediction accuracy compared to existing functional prediction methods at the tissue/cell type level, but especially so at the organism level. Importantly, we illustrate how the GenoNet scores can help in fine-mapping at GWAS loci using as example a leading schizophrenia risk locus flanking *MIR137*, and in the discovery of disease associated genes through an integrative analysis of lipid phenotypes using a MetaboChIP dataset on 12,281 individuals. The ability to infer cell-type specific functional elements that regulate target genes will greatly enhance our understanding of what genes contribute to cellular identity and cell lineage differentiation, and better prioritize non-coding variants from GWAS or NGS in the contexts of the cell types that are relevant to the disease under study. It also allows the design of functional genomics experiments that target specific subsets of non-coding regions based on the cell type under study. As more systematic and comprehensive lists of experimentally validated variants become available across a large number of tissues and cell types over the next few years, semi-supervised methods like GenoNet can be used to provide increasingly accurate functional predictions for variants genome-wide and across a variety of tissues and cell types.

**A universal and nearly optimal permutation testing approach and an application to association analysis of quantitative traits in whole-genome sequencing studies.** J. Hecker<sup>1</sup>, I. Ruczinski<sup>2</sup>, M. Cho<sup>3,6</sup>, H. Loehlein Fier<sup>4</sup>, D. Prokopenko<sup>5,6</sup>, E. Silverman<sup>3</sup>, B. Coull<sup>1</sup>, C. Lange<sup>1,3</sup>. 1) Harvard T. H. Chan School of Public Health, Boston, MA; 2) Bloomberg School of Public Health, Baltimore, MD; 3) Brigham and Women's Hospital, Boston, MA; 4) University of Bonn, Bonn, Germany; 5) Massachusetts General Hospital, Boston, MA; 6) Harvard Medical School, Boston, MA.

While permutation-based approaches are ideal tools to address statistical issues related to association testing in whole-genome sequencing (WGS) and other large-scale genomic studies (e.g. potential violations of asymptotic distribution assumptions, non-normality of phenotypes, design imbalances), the actual application of such approaches is usually prohibitive due to the computational burden or the restriction to specific scenarios and test statistics. Whereas current approaches use approximations of the permutation distribution or are based on adaptive heuristic criteria to reduce the number of permutations that are computed, we propose here a framework for permutation testing that is based on sequential testing theory and directly tests the permutation-based p-value against a pre-specified significance level. This allows for the rigorous control of both error probabilities, type 1 and 2 error, and is nearly optimal in terms of the number of expected permutations. Our framework can be applied to arbitrary association test statistics for which permutation testing can be implemented, e.g. association tests for single variants or regions in WGS studies. In an application to a WGS study for a quantitative trait of lung function, we illustrate the performance of our approach and its practical implementation for single variant analysis. Given the moderate, additional computational burden, permutation-based testing might be considered the first choice of analysis in many large-scale genetic/genomic studies where the limitations of asymptotic theory could invalidate the findings of the statistical analysis.

**Comparison of Mendelian randomisation and Bayesian network approaches for causal inference.** *R. Howey, H.J. Cordell.* Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom.

Mendelian randomisation (MR) is a popular method for inferring the causal relationships between variables in genetic studies. Results from genome-wide association studies often generate genetic variants that are associated with an intermediate trait. These variants can then be used as instrumental variables to investigate if the intermediate trait has a causal influence on another (outcome) trait. However, a valid instrumental variable must satisfy certain conditions, in particular, that there are no direct relationships between the instrumental variable and the outcome variable or any other potential confounders. An alternative approach for inferring the causal direction between two variables is with the use of Bayesian networks (BN), which have no such explicit causal assumptions and benefit from using more than three variables in an analysis. We compare MR and BN using simulated data in a four variable model where X is (usually) causal on Y and G and Z are instrumental variables for X and Y respectively. We consider MR analyses using G or Z as an instrumental variable and BN analyses using only G or Z as well as both G and Z. We consider three different models: (i) a model with no confounding variables; (ii) a non-genetic confounding model, where a variable influences both X and Y, and (iii) a genetic confounding model, where G influences Y via an additional intermediate variable. Our results show that for models (i) and (ii) BN showed comparative power to MR and that the use of both instrumental variables with BN showed greater power than using either separately. Receiver operating characteristic (ROC) curves were considerably better for BN than MR. The non-genetic confounder model did not unduly affect either the MR or BN analyses. The genetic confounder model caused problems for both MR and BN. For MR with G as an instrumental variable there was a huge inflation in type I error due to the instrumental variable assumption not holding. BN analysis type I error was well controlled when no effect from X to Y was present but the type I error was moderately inflated when there was a causal effect from Y to X and G was the only instrumental variable. We have shown that while MR is easy to perform and widely understood, BN offers an alternative approach with some advantages over MR such as better ROC curves, ability to utilise more variables and less adverse effects when confounding is present.

**Controls: How large is too large? A survey of methods for optimal subsampling in large-scale case-control studies.** *Y. Jiang, C. Tian, D. Hinds, 23andMe Research Team.* 23andMe, 899 West Evelyn Ave, Mountain View, CA.

Large-scale case-control studies provide unparalleled opportunities to advance the understanding of the genetic architecture of complex diseases. One emerging challenge of analyzing such enormous datasets is that the number of controls collected is substantially larger than the number of cases for most of the phenotypes, particularly rare diseases. 23andMe's case-control cohorts are close to the general population-based cohorts, where the control-to-case ratios are over 100 for many of the collected phenotypes. Currently, existing methods include all available controls in the analyses. This approach not only demands huge computational resources, but without proper adjustment, it can also lead to significantly inflated type I error rate induced by the imbalanced case-control ratio. In this study, we examined the hypothesis that gains in power are marginal after control-to-case ratio reaches a certain threshold for fixed sample size and allele frequency, and we attempted to identify the saturate ratio. We focused on investigating strategies that deliberately sample a subset of controls to lower the computational burden and reduce the imbalance ratio, which can improve power in certain scenarios. Even though a few subsampling methods have been proposed, the best practice to select controls remains to be elucidated. Propensity score and coarsened exact matching are commonly used methods in social sciences. We adopted these strategies and selected various proportions of samples to include in a GWAS. Our results showed that for most diseases, once the control-to-case ratio reaches 10, the selected sub-sample GWAS can recover the hits of GWAS using the full database. However, some studies have argued that the estimation is inconsistent if the model is not correctly specified. "Local case-control" sampling and "A-optimal" sampling use a post-hoc analytic adjustment to improve the biased pilot estimate, which provides a consistent estimation. The pilot fit, however, introduces tremendous computational cost for large-scale GWAS study where millions of SNPs are tested. Using 23andMe's dataset of over 3 million consented research participants, we use empirical evidence to systematically evaluate and discuss the usage of multiple subsampling strategies. We provide practical guidelines for control selection across different disease prevalence, minor allele frequency, and computational speed.

**An analysis of the genetic overlap of 20 complex traits under a non-in-finitesimal model.** R.D. Johnson<sup>1</sup>, H. Shi<sup>2</sup>, K. Burch<sup>2</sup>, B. Pasaniuc<sup>2,3,4</sup>, S. Sankararaman<sup>1,2,3</sup>. 1) Dept of Computer Science, University of California, Los Angeles, CA 90024; 2) Bioinformatics Interdepartmental Program, University of California, Los Angeles, 90024; 3) Dept of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA 90024; 4) Dept of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California, Los Angeles, 90024.

Quantifying the shared genetic component of two complex traits can elucidate the genetic basis underlying the comorbidity of various traits. Large-scale genome-wide association studies conducted for thousands of traits have provided a catalog of genetic variants that are implicated across multiple traits. Current methods that quantify the genetic overlap between a pair of traits through GWAS association data either assume an infinitesimal model where every SNP is causal or relax this assumption but restrict the number of causal SNPs due to computational constraints. We previously introduced UNITY (Unifying Non-Infinitesimal Trait analysis), a flexible, unifying framework that quantifies the overlap between two traits through GWAS summary association data. UNITY calculates the proportion of shared causal SNPs between two traits, as well as the proportion of causal SNPs that are specific to each trait. UNITY makes minimal assumptions where we do not assume every SNP is causal, also called the non-infinitesimal model. Additionally, our inference does not restrict the number of inferred causal variants a priori, thus allowing for a variety of genetic architectures. In this work, we used UNITY to systematically quantify the proportion of trait-specific and shared causal variants between 380 pairs of complex traits through publically available GWAS summary statistics. We show that traits that were believed to be extremely polygenic actually only contain a small fraction of the genome to be causal. For example, our analysis of height showed that <5% of the genome is estimated to be causal, thus motivating the use of methods that do not impose the infinitesimal assumption.

**Leveraging variance QTLs in a twins cohort identifies epistatic interactions influencing gut microbiome composition.** A.R. Marderstein<sup>1,2</sup>, E.R. Davenport<sup>3</sup>, C.V. Van Hout<sup>4</sup>, A.G. Clark<sup>3,4</sup>. 1) Tri-Institutional Program in Computational Biology & Medicine, Cornell University/Weill Cornell Medicine, Ithaca/New York, NY; 2) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 3) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY; 4) Regeneron Genetics Center, Tarrytown, NY.

Efficiently identifying epistatic (GxG) and genotype-by-environment (GxE) interactions in humans remains an important challenge. Since exhaustive all-pairwise interaction testing involves  $n(n-1)/2$  tests (for  $n$  SNPs), it is computationally intensive and the multiple test correction severely limits statistical power. To address this gap, we screened for genetic associations with the variance of a phenotype (vQTLs), which can be caused by both gene x gene (GxG) and genotype x environment (GxE) interactions. Screening for vQTLs involves just  $n$  tests, so it provides a powerful inroad to discovering genetic interactions by nominating loci as promising candidates for an interaction. In our study, we first used simulations to demonstrate that two variants affecting the mean of a phenotype through an interaction are also likely to be associated with the single-SNP stratified phenotypic variances. We then applied our method in a sequential approach to identify epistatic interactions impacting gut microbiome composition in >2000 individuals from the TwinsUK cohort. First, we performed a *two-step squared-residual linear mixed model* approach to identify genome-wide associations (1.1 million SNPs) with the variances of 945 bacterial relative abundances. Second, to discover novel GxG interactions, we tested significant vQTL loci with all other variants using mean-based interaction models with robust Huber-White standard errors. This robust standard error approach better maintains the genomic inflation factor across phenotypes in comparison to a default standard error approach ( $\lambda_{GC, Normal}: \mu=1.20, \square=0.14; \lambda_{GC, Robust}: \mu=1.02, \square=0.02$ ). We discovered 252 genome-wide significant interactions ( $P < 5 \times 10^{-8}$ ) across the 945 microbial phenotypes, including a study-wide significant host genetic interaction ( $P < 4.7 \times 10^{-11}$ ) impacting Clostridiales abundances. This interaction is between an intergenic eQTL for three nearby genes in the bitter taste receptor family (*TAS2R3*, *TAS2R4*, *TAS2R5*) and another intergenic SNP in LD with an active regulatory region located 75 kb upstream of the *APOB*, which has been previously linked with LDL levels ( $P = 10^{-182}$ ). This interaction was also genome-wide significant with 29 other taxa within the Clostridiales order, including taxa in the Ruminococcaceae and Lachnospiraceae families. Our results demonstrate that vQTLs provide a practical and powerful approach to discovering GxG and GxE interactions in human genome-wide association studies.

**Estimating differential networks in microbiome data: Penalized precision matrix estimation in a multinomial model.** *K. McGregor<sup>1,3</sup>, A. Labbe<sup>2</sup>, C.M.T. Greenwood<sup>3</sup>*. 1) McGill University, Montreal, Quebec, Canada; 2) HEC Montreal, Montreal, Quebec, Canada; 3) Lady Davis Institute for Medical Research, Jewish General Hospital, Montreal, Quebec, Canada.

The microbiome is the collection of microorganisms colonizing the human body, and plays an integral part in human health. A growing trend in microbiome analysis is to construct a network to estimate the level of co-occurrence between different taxa. Current methods do not facilitate investigation into how these networks change with respect to some phenotype. We propose a model to estimate network changes with respect to a binary phenotype. The counts of individual taxa in the samples are modelled through a multinomial distribution whose probabilities depend on a Gaussian random effect term. A sparse precision matrix over all the random effect terms determines the co-occurrence network among taxa. The model fit is obtained and evaluated using Monte Carlo methods. The performance of the model has been evaluated through an extensive simulation study, and has been shown to outperform existing methods in terms of estimation of network parameters. We also demonstrate an application of the model to estimate changes in the murine intestinal microbial network topology with respect to macrolide exposure. A new method to approximate the posterior distribution will be introduced to fit the model without the computational burden of Monte Carlo sampling.

**A selection operator for summary association statistics reveals allelic heterogeneity of complex traits.** *Z. Ning<sup>1</sup>, Y. Lee<sup>2</sup>, P. Joshi<sup>3</sup>, J. Wilson<sup>3,4</sup>, Y. Pawitan<sup>1</sup>, X. Shen<sup>1,3</sup>*. 1) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Nobels vag 12A, SE-171 77 Stockholm, Sweden; 2) Department of Statistics, Seoul National University, Seoul 151747, South Korea; 3) Center for Population Health Sciences, Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Old Medical School, Teviot Place, Edinburgh, EH8 9AG, Scotland, United Kingdom; 4) MRC Human Genetics Unit, MRC Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, EH4 2XU, Scotland, United Kingdom.

In recent years, as a secondary analysis in genome-wide association studies (GWAS), conditional and joint multi-variant analysis (GCTA-COJO) has been successful in discovering additional association signals within detected loci. This suggests that many loci mapped in GWAS harbor more than a single causal variant. We develop a penalized selection operator (SOJO) within each mapped locus, based on LASSO regression derived from summary association statistics. We show that SOJO achieves better variable selection accuracy and prediction performance. Our empirical results indicate that human height is not only a highly polygenic trait, but also has high allelic heterogeneity within its established hundreds of loci. An R package named "sojo" is made to implement this method.

## 3552W

**MRMix: A mixture model approach to robust and efficient Mendelian randomization analysis.** G. Qi, N. Chatterjee<sup>1,2</sup>. 1) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Department of Oncology, Johns Hopkins School of Medicine, Baltimore, MD.

**Background:** Many commonly used methods for Mendelian Randomization (MR) analysis rely heavily on the assumption that genetic correlations across risk-factors and health outcomes mainly arise from underlying causal relationships. Some recent methods are more robust to the violation of this assumption, but they can lack efficiency and can still be susceptible to bias if a large majority of the genetic variants violate the assumption. **Methods:** We consider a “working model” to describe the bi-variate effect-size distribution of SNPs across  $X$  and  $Y$  using a normal mixture model (MRMix) that assumes the existence of only a fraction of SNPs which are valid instruments, i.e. they have only direct effect on  $X$ , while other SNPs can have both direct and indirect effects or have no effects at all. Under this model, the residual of the form  $\beta_x - \theta\beta_y$  - here  $\beta_x$  and  $\beta_y$  denote the total effect of a SNP on  $X$  and  $Y$ , respectively, and  $\theta$  is the putative causal effect - has a mixture normal distribution with an enriched point mass at 0 only at  $\theta = \theta_0$ , the true value of the causal effect. Based on this observation, we propose a simple method for estimating the causal effect  $\theta_0$  through a grid-search procedure to maximize the probability concentration of observed residuals  $\beta_x - \theta\beta_y$  at the “null” component of a two-component normal mixture model. **Results:** Simulation studies showed that MRMix provides nearly unbiased or/and substantially more robust estimates of causal effects compared to alternatives under various scenarios. Further, the studies showed that MRMix is sensitive to direction and can achieve much higher efficiency (up to 3–4 fold) relative to a non-parametric mode based ratio estimator that is found to be comparably robust. We applied the proposed methods for conducting MR analysis using largest publicly available datasets across a number of risk-factors and health outcomes. Notable observations include confirmation of negative relationship between genetically determined BMI and the risk of breast cancer; a strong detrimental effect of BMI on the risk of major depressive disorder; no causal effect of HDL on coronary artery disease; detrimental effect of higher level of HDL on the risk of breast cancer; and positive effect of higher level of LDL on bone mineral density. Results from more large-scale MR analyses will be presented at the meeting. **Conclusion:** MRMix provides a robust and efficient method for estimation of causal effects in two-sample MR analysis.

## 3553T

**Genotype imputation using the pBWT.** S. Rubinacci, J. Marchini<sup>1,2</sup>. 1) Department of Statistics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Wellcome Center for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom.

Genotype imputation is the process of predicting genotypes that have not been typed in a sample of individuals. We have developed two new methods that aim to reduce the memory requirements and speed of the IMPUTE model. Firstly, we have implemented a new version of the IMPUTE v4 method that uses a reference panel stored in a positional Burrows-Wheeler Transform (pBWT) data structure. This approach conditions on all the haplotypes in a reference panel. When using the Haplotype Reference Panel (HRC) with 64,812 haplotypes this new method reduces the memory by 75% compared to IMPUTEv4, with a corresponding modest increase in compute time of 23%. Secondly, we have developed a new version of IMPUTE that very quickly selects a small subset of haplotypes to condition on. As the reference panel grows we expect to find an ever smaller set of good conditioning haplotypes. By adopting this idea we aim to develop a method that has sub-linear scaling in reference panel size. Again we use a pBWT data structure for the reference panel and insert each sample haplotype into this structure in order to identify locally best matching haplotypes. This operation has complexity independent of the reference panel size. The method then uses the selected haplotypes as conditioning states within the IMPUTE model. We have tested our method using the HRC chromosome 20 reference panel and compared the results to IMPUTE v4. We imputed genotypes into 10 individuals of European ancestry, based on genotypes on Illumina 1M-Duo3\_C genotyping array, and compared the results to genotypes derived from high-coverage sequencing. Imputation was carried out in windows of 5Mb. Our method has a parameter  $L$  indicating the maximum number of possible copying states to add at each marker, and we have used values of  $L=1,8,12,25$  for each window, and this results in an average of 115, 503, 777 and 1,623 copying states respectively. Our method is more than 10x faster than IMPUTE v4, with almost identical memory requirements for every value of  $L$  tested. The new copying state selection takes only 0.56% of the time of an imputation task and produces the same accuracy as IMPUTE v4. For example, for imputed variants with frequency 0.1% IMPUTE v4 and our new method with  $L=12$  produce mean imputation  $r^2$  of 0.67 and 0.68 respectively. With  $L=1$   $r^2=0.63$ , highlighting that closest matches in the pBWT data structure contain a lot, but not all of the relevant information. .

**Accounting for cryptic relatedness across families between subjects with no genotype data.** *M. Saad<sup>1</sup>, E. Ullah<sup>1</sup>, E.M. Wijsman<sup>2,3</sup>*. 1) Qatar Computing Research Institute, Doha, Qatar; 2) Department of Biostatistics, University of Washington, Seattle, WA, USA; 3) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA, USA.

Complex traits continue to provide challenges for identifying disease-risk genes. Whole genome sequencing has become inexpensive and fast. This provides opportunities for investigation of rare variation. In the search for disease-associated rare variation, family-based designs have again become common, because rare, highly-penetrant genotypes can segregate in pedigrees. Association testing is often used to identify variants of interest. When related subjects are included in the sample, a kinship matrix must be used to account for relatedness between subjects. Relationships may be known from the pedigree structures, or can be inferred using observed genotypes. For subjects without genotype data, however, no approach is able to infer relatedness between subjects in different pedigrees. Pedigree-based imputation increases the sample size and thus association power, and also provides genotype probabilities in subjects without genotype data. When phenotypes for such subjects exist, including them in the analysis adds information for detecting association between genotypes and phenotype. However, knowing the relationship between such subjects and the remaining subjects, especially across pedigrees, is crucial to control the type 1 error. We propose a solution for inferring cryptic relatedness between subjects with completely missing genotype data. We use GIGI to estimate the probabilities of missing genotypes, and incorporate them in an Expectation-Maximization approach to estimate the kinship coefficients. Through simulation, our approach succeeds in inferring many types of relationships with relatively high confidence. It yields average kinship estimates of 0.19, 0.1, and 0.05 for underlying kinships of 0.25, 0.125, and 0.0625, respectively, for subjects without genotype data.

**Enrichment analysis in genome-wide association studies through modelling of effect-size distribution in relation to annotations and genomic propensity scores.** *A. Saha<sup>1</sup>, Y. Zhang<sup>1</sup>, N. Chatterjee<sup>1,2</sup>*. 1) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 2) Department of Oncology, School of Medicine, Johns Hopkins University, Baltimore, MD.

**Background** Heritability enrichment analyses in genome-wide association studies (GWAS) are commonly used to gain understanding of the contributions of various population genetic and functional genomic characteristics of the genome on trait variation. Assessment of the effect-size distribution (ESD) associated with genome-wide panel of SNPs in relationship to annotation information can provide more detailed insights into the genetic architecture of complex traits. The effort to disentangle contributions of different annotations, however, can be complicated by their complex interrelationships. **Method** We assume a normal-mixture model for the ESD with varying variance component parameters to allow for clusters of SNPs with distinct effect-sizes. We allow the SNP annotations to influence the ESD through the underlying mixing probabilities in a log-linear modelling framework. Under the proposed model, we show that the distribution of summary-statistics of GWAS markers can be approximated by an alternative normal-mixture form with the mixing probabilities depending on the probability distribution of number of SNPs from different clusters the GWAS markers tag. Further, in this representation, the variance component parameters depend on weighted LD-scores with weights depending on local annotation information. We propose utilizing the model to characterize enrichment by each individual annotation, while adjusting for others through underlying "genomic propensity scores", which could be constructed based on simple regression modelling among the annotations themselves. **Results** We applied the proposed method for the analysis of publicly available GWAS summary statistics across a wide variety of traits together with the annotation information available from various databases. Preliminary analyses show that the method can identify evidence of negative selection, i.e., inverse relationship between effect-sizes and minor allele frequencies, across a wide variety of traits. Further, it identifies evidence of strong enrichment for certain annotations like transcription start site and conserved region. Results from more detailed analysis by individual traits, annotations and underlying cell-type context will follow. **Conclusion** Modelling of effect-size-distribution in relationship to genomic annotations and underlying propensity scores can provide novel insights into genetic architecture of complex traits.

**High-definition likelihood inference for heritability and genetic correlation using GWAS summary statistics.** X. Shen<sup>1,2,3</sup>, Z. Ning<sup>1</sup>, Y. Pawitan<sup>1</sup>. 1) Karolinska Institutet, Stockholm, Sweden; 2) Sun Yat-sen University, Guangzhou, China; 3) University of Edinburgh, Edinburgh, United Kingdom.

**Motivation:** In the past three years, LD Score Regression has been an influential technique, allowing estimation of heritability and genetic correlation using only GWAS summary statistics. LD Score Regression was also reported to be able to distinguish polygenicity from population structure in a GWAS study. However, the definition of LD score only uses part of the linkage disequilibrium information, thus the current LD Score Regression method has a limited efficiency of estimation. **Results:** In order to improve LD Score Regression as a method based on a “low-definition” likelihood (LDL) function, we develop a full high-definition likelihood (HDL) model that accounts for substantially more information in the LD structure. Simulation studies show that HDL has about 7 times efficiency compared to LD Score Regression, e.g. for genetic correlation estimation. With this, HDL is able to report accurate heritability and genetic correlation estimates with much smaller standard errors, identifying more genetically correlated complex traits. With the full likelihood method, bootstrap implementation is avoided so that computational efficiency is also improved. **Conclusion:** The HDL method, as a full likelihood model of summary association statistics and LD structure, substantially improves the accuracy of heritability and genetic correlation estimation. Some other remaining issues of LD Score Regression can also be solved directly when the full likelihood is considered.

**A statistical framework to quantify shared genetic variability in *de novo* mutations for complex diseases.** Y. Shi<sup>1</sup>, Q. Lu<sup>2</sup>, SC. Jin<sup>3</sup>, X. Zeng<sup>3</sup>, W. Dong<sup>3</sup>, B. Li<sup>4</sup>, J. Warren<sup>1</sup>, R. Lifton<sup>3,4</sup>, M. Brueckner<sup>3</sup>, H. Zhao<sup>1,5</sup>. 1) Department of Biostatistics, Yale School of Public Health, New Haven, CT, USA 06511; 2) Department of Biostatistics and Medical Informatics, University of Wisconsin-Madison, Madison, WI, USA 53792; 3) Department of Genetics, Yale University, New Haven, CT, USA 06510; 4) Laboratory of Human Genetics and Genomics, Rockefeller University, New York, USA 10065; 5) Program of Computational Biology and Bioinformatics, Yale University, New Haven, CT, USA 06510.

Damaging *de novo* mutations (DNMs) in protein-coding genes are known to be critically involved in the etiology of many developmental diseases. In particular, exome sequencing studies of thousands of proband-parent trios have identified a large number of causal genes for congenital heart disease (CHD) and autism spectrum disorder (ASD). These results suggested substantial contributions of DNMs – 10~15% of CHD and ASD diagnoses can be explained by pathogenic DNMs. Interestingly, a substantial fraction of genes were enriched for DNMs in both CHD and ASD, hinting at shared genetic pathways. However, these results were obtained in hypothesis-driven analyses using huge samples. It is therefore of practical interest to develop a powerful framework to quantify shared genetics using DNM data of two diseases and search for common pathways while adjusting for other factors contributing to mutation rate (e.g. gene length and sequence context). In this project, we introduced a hierarchical Poisson model to jointly model DNM counts in two diseases and quantify shared DNM effects via an enrichment correlation (EC) metric. We have implemented both frequentist and Bayesian methods for parameter inference and demonstrated the effectiveness of our method using extensive simulations. We then applied our method to real DNM data from 1,213 CHD trios and 2,508 ASD trios acquired from denovoDB. We identified strong significant correlation between loss-of-function (LoF) DNM counts of CHD and ASD (EC=0.38; 95% credible interval=[0.22, 0.50]). As a positive control, we randomly partitioned 1,213 CHD trios into two equal-sized subsets and our method identified a strong correlation (EC=0.61; 95% credible interval=[0.39, 0.90]) in LoF DNMs. We also repeated the analysis in a control dataset (N=1,789) and did not observe significant correlation (EC=-0.03; 95% credible interval=[-0.31, 0.21]). Additionally, we tested correlation of CHD and ASD using 546 genes in the chromatin remodeling pathway – a key pathway for both CHD and ASD. LoF EC between CHD and ASD was further amplified (EC=0.70 [0.38, 0.91]) in this pathway. In summary, our method provides a novel, robust metric to quantify correlation in DNM enrichment between diseases. This new method has the potential to be widely used in future DNM studies to systematically screen for shared genetic components.

**Joint analysis of GWAS summary statistics in East Asians and Europeans provides insights into population-specific and shared causal variants of complex traits.** *H. Shi<sup>1</sup>, K. Burch<sup>1</sup>, R. Johnson<sup>2</sup>, M. Freund<sup>4</sup>, G. Kichaev<sup>1</sup>, N. Mancuso<sup>3</sup>, A. Manuel<sup>5</sup>, N. Dong<sup>6</sup>, B. Pasaniuc<sup>1,2,4</sup>.* 1) Bioinformatics Interdepartmental Program, University of California Los Angeles, Los Angeles, CA; 2) Dept of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA; 3) Dept of Computer Science, University of California Los Angeles, Los Angeles, CA; 4) Dept of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA; 5) Dept of Biology, Florida International University, Miami, FL; 6) Dept of Biomedical Engineering, Boston University, Boston, MA.

Trans-ethnic genetic studies have been shown to improve detection of trait-associated loci and fine mapping of causal variants (Morris, *Genet Epidemiol*, 2011; Kichaev, *Am J Hum Genet*, 2016). However, although GWAS risk regions are largely replicated across different continental populations, whether the replication is due to shared causal variants or different causal variants that impact the same genes remain unclear. Here, we introduce POSC, a Bayesian approach to both estimate genome-wide proportion of population-specific/shared causal variants and identify individual SNPs that are population-specific/shared from GWAS summary statistics, while accounting for linkage disequilibrium (LD) of the two continental populations. In detail, POSC performs inference in two stages. In the first stage, POSC estimates the genome-wide prior probability that a SNP is population-specific/shared using all SNPs regardless of their statistical significance. In the second stage, POSC quantifies posterior probability of each of these SNPs to be population-specific/shared using the prior obtained in the first stage. We show through extensive simulations that POSC yields approximately unbiased estimates of genome-wide proportions of population-specific/shared causal variants, and robustly infers individual population-specific/shared causal variants. We apply POSC on GWAS summary statistics data of 9 complex traits and diseases in East Asians (Kanai et al., *Nat Genet*, 2018) and Europeans (average  $N_{EAS} = 94,621$ ,  $N_{EUR} = 103,507$ ). Across all analyzed traits, on average, 84% (82%) of the causal variants in East Asians (Europeans) are also causal in the other population, and 16% (18%) of the causal variants are specific to East Asians (Europeans). The large fraction of shared causal variants is in concordance with the high trans-ethnic genetic impact correlation ( $R_g = 0.85$  on average) of these traits (Brown et al., *Am J Hum Genet*, 2016). Next, we find that genomic regions having GWAS-significant associations in only one population, on average, show a 2.8X enrichment of shared causal variants than expected from the prior, providing evidence that GWAS-significant associations not present in GWAS studies in other populations are likely in part due to different LD structures. Finally, we show that regions surrounding genes specifically expressed in trait-relevant tissues (Finucane et al., *Nat Genet*, 2018) harbor a disproportionate amount of both shared and population-specific causal variants.

**Enhanced case-control association analyses leveraging family history.**

*C.R. Solis-Lemus<sup>1</sup>, S.T. Fischer<sup>1</sup>, E.J. Leslie<sup>1</sup>, D. Ghosh<sup>2</sup>, D.J. Cutler<sup>1</sup>, M.P. Epstein<sup>1</sup>.* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Biostatistics and Informatics, Colorado School of Public Health, Aurora, CO.

Standard methods for case-control association studies of rare and common variation often treat disease outcome as a dichotomous phenotype. However, both theoretical and experimental studies have demonstrated that cases with a family history of disease can be enriched for risk variation relative to sporadic cases. Likewise, controls with a family history of disease can harbor more risk variation than controls without such history. Assuming family-history information is available, this observation motivates the idea of replacing the standard dichotomous outcome variable in case-control studies with a more informative outcome variable that distinguishes cases and controls with and without family history. Potential options for enhanced outcome variables include ordinal categorical variables and conditional means from liability-threshold models. We explore both options to create modified association tests for common and rare variation that leverage family-history information. Preliminary results suggest that leveraging family-history information via ordinal categorical variables can greatly improve power in rare-variant association tests compared to standard dichotomous modeling of disease phenotypes that ignore such information. We further illustrate our methods using GWAS and NGS data from a genome-wide study of craniofacial defects.

**Building multi-predictor models of quantitative phenotypes from the Trinity Student Study with tiled regression.** A.J.M. Sorant<sup>1</sup>, J.A. Sabourin<sup>1</sup>, C.M. Justice<sup>1</sup>, L.C. Brody<sup>2</sup>, J.E. Bailey-Wilson<sup>1</sup>, A.F. Wilson<sup>1</sup>. 1) Computational and Statistical Genomics Branch, National Human Genome Research Institute, NIH, Baltimore, MD, USA; 2) Gene and Environment Interaction Section, National Human Genome Research Institute, NIH, Bethesda, MD, USA.

The Trinity Student Study obtained DNA and metabolite measurements from blood samples provided by a cohort of healthy Irish college students, as well as health and lifestyle information from questionnaires [Molloy et al. 2016]. After data cleaning, 757,533 genotypes were available for analysis on 2232 individuals. Imputation of the genotyped data resulted in a set of 2,350,763 imputed genotypes. Significant results of genome-wide association studies have been published for several quantitative phenotypes including methylmalonic acid concentration (MMA) [Molloy et al. 2016] and serum vitamin B12 concentration (SB12) and holo-transcobalamin (HoloTC) [Velkova et al. 2017]. Previous results were determined with simple linear regression (SLR) analyses (single-marker tests) with imputed genotypes. Because of linkage disequilibrium, single-marker studies may pick up many associations which might or might not be due to a single causal effect. In the present study, tiled regression (TR), which combines variable selection with a staged approach [Wilson et al., 2009], was used to form a multiple linear regression (MLR) model, determining combinations of predictors that jointly and independently contribute to the variation in each phenotype. Although the selected model may include a correlated predictor rather than a causal one, multiple predictors chosen from the same region can indicate multiple causal effects. Another difference is that significance, as measured by an SLR p-value, may be different from that representing its significance in an MLR model. As in the previous studies, a  $\log_{10}$ -transformed version of each phenotype, adjusted for age and sex, was analyzed, initially with raw genotypes. Tiled regression analysis was performed using TRQUANT v. 0.3 [Sorant et al., 2017], with stepwise selection criteria  $10^{-5}$ ,  $10^{-6}$  and  $10^{-7}$  at the tile, chromosome and genome-wide stages, respectively. With one exception, each variant reported as significant in the previous results either was included in the final selected MLR model or a nearby one was. (The exception was significant only at a suggestive level in the original analysis.) In some cases, additional variants, sometimes but not always from the same regions, were also found to jointly and independently contribute significantly to the model. Interactions among variants selected at the genome-wide stage were also considered, but they did not improve on the main effects model.

**Heterogenous effects linear mixed model improves whole genome association testing in multi-ethnic populations: Applications to the TOPMed and PAGE Consortia.** T.A. Thornton<sup>1</sup>, M.P. Conomos<sup>1</sup>, S.G. Gogarten<sup>1</sup>, A.P. Reiner<sup>2</sup>. 1) Biostatistics, University of Washington, Seattle, WA., Select a Country; 2) Epidemiology, University of Washington, Seattle, WA., Select a Country.

Whereas genetic studies of complex traits have primarily examined populations of European ancestry, recent studies, such as the Trans-Omics for Precision Medicine (TOPMed) program and the Population Architecture using Genomics and Epidemiology (PAGE) study, have generated an abundance of whole-genome genotyping and sequencing data from multi-ethnic populations for complex trait mapping. These data offer an unprecedented opportunity for the identification of novel rare and common genetic variation underlying phenotypic diversity among populations, as well as the potential to provide new insights into health disparities of minority populations for many complex diseases. However, beyond the obvious computational issues of analyzing millions of genetics variants from whole-genome data in tens of thousands of individuals, there are substantial statistical challenges for complex trait mapping in multi-ethnic samples with heterogenous genomes from a variety of study designs. Linear mixed models (LMMs) have been shown to be a powerful and effective approach for genome-wide association testing in samples with population structure, family structure, and/or cryptic relatedness. Existing LMM implementations, however, have largely been used and evaluated in relatively homogenous European populations. We demonstrate that widely used LMM implementations, such as GCTA, EMMAX and GEMMA, can fail when applied to samples from multi-ethnic populations because these methods do not appropriately model heterogenous variances of traits across multi-ethnic. To address the shortcomings of existing LMM methods, we developed HEMMAT (heterogenous effects mixed model association test) for genetic association testing of quantitative traits in multi-ethnic populations. In applications using real genotype and phenotype data from the multi-ethnic TOPMed and PAGE studies, we demonstrate that HEMMAT provides a significant improvement, in terms of both type-1 error and power, over existing LMM approaches for complex trait mapping in multi-ethnic populations.

**Genome-wide priors for gene prioritization.** *E. Weeks<sup>1</sup>, J. Ullirsch<sup>1,2</sup>, K. Tashman<sup>1</sup>, J. Engreitz<sup>1</sup>, H. Finucane<sup>1</sup>.* 1) Broad Institute of MIT and Harvard, Cambridge, MA; 2) Harvard T.H. Chan School of Public Health, Boston, MA.

Identifying causal genes for complex traits remains one of the biggest challenges in the post-GWAS era. For the vast majority of GWAS associated loci, the identity of the causal gene(s) driving the association is unknown. One approach to begin to understand the underlying causal mechanisms behind these loci is via gene prioritization methods such as colocalization methods or methods that use enhancer-promoter interaction data. Here, we propose a gene prioritization method that leverages genome-wide enrichments of gene features such as cell-type specific gene expression, pathways, and protein-protein interaction networks. When computing the prioritization score for a gene, we leave out the GWAS summary statistics for the chromosome containing the gene, which makes the results of our method ideal for combining with other methods that use locus-specific data. Specifically, we envision that our method can be integrated into other gene prioritization methods as a way of assigning priors to genes for being causal. In this way, we expect to be able to combine our broader genome-wide approach with locus-specific methods to more accurately predict the causal genes for complex traits. Our method consists of two steps: first, we assign a prior probability of being causal to each gene using the GWAS summary statistics for the trait of interest. Second, we update our prior using the gene features in a regularized weighted logistic regression framework. The output of our model is, thus, biologically informed probabilities for every gene that it is causal for a given phenotype computed without using the GWAS data at the locus containing the gene. We apply our method to summary statistics from 73 complex traits and 593 gene features derived from several publicly available sources of gene expression data. We evaluate our results by correlating the output probabilities with our prior probabilities and show that our method has a significant correlation for 67 out of 73 phenotypes ( $P < 0.05/73$ ). For two traits, inflammatory bowel disease and white blood cell count, we more rigorously evaluate our results using a set of gold standard genes with fine-mapped coding variants. For inflammatory bowel disease, the mean score was 0.0603 for our gold standard genes and 0.0518 for all other genes ( $P = 2.5 \times 10^{-6}$ ). For white blood cell count, we saw a more modest difference with a mean score of 0.0585 for our gold standard genes and 0.0518 for all other genes ( $P = 1.8 \times 10^{-6}$ ).

**3563F**

**Simulation study of double FDR method on LD block structure in GWAS.** *J. Xu, D. Mehrotra.* BARDS, Merck & Co., North Wales, PA 19454, PA.

P-value threshold after multiplicity correction is critical in genome wide association study (GWAS) to call out true signals while controlling false positives. The current well accepted threshold is  $5 \times 10^{-8}$ , which aims to control 5% family wise error rate (FWER) using Bonferroni method assuming one million independent SNPs. This threshold has been broadly applied in GWAS field given its simplicity. However, the between SNP correlation structure has not been considered and FWER is much more restricted than false discovery rate (FDR). In this simulation study, we propose applying double FDR method on linkage disequilibrium (LD) block structure. This method yields much higher power than  $p < 5 \times 10^{-8}$  while controlling FDR at 5%.

**3564W**

**Dimension reduction and remedy for multicollinearity of DNA sequencing data using the lasso based clustering.** Y.J. Yoo. Dept Mathematics Education, Seoul National University, Seoul, South Korea.

For genetic association analysis based on multiple SNP regression using high density DNA sequencing data, multicollinearity can be a serious issue. We propose an algorithm to reduce the dimension of the sequencing data by selecting a clusters in multicollinearity and replacing the cluster with by principal components. In this algorithm, we first detect SNPs causing multicollinearity based on variance inflation factor (VIF). SNP variable with highest VIF over a threshold value is clustered with certain SNPs selected by lasso regression of the highest VIF SNP on the rest of SNP variables. The SNPs forming a cluster which are in multicollinearity are replaced by principal components explaining most of the variability caused by these SNPs. This procedure continues in greedy manner until the highest VIF of update variables are below the threshold. We applied the method to 1000 Genomes Project data and found that the degrees of freedom are reduced to 7~80% based on the threshold options. Through simulation study, we investigated how the power of multi-marker tests constructed from multiple SNP regression is affected by this dimension reduction procedure. We found that Wald test can gain power by this procedure, and linear combination (LC) test and multiple linear combination (MLC) test which is a hybrid test between Wald and LC test yielded similar power with the results using entire SNP variables.

**3565T**

**Thresholding Fisher's p-value combination method (TFisher) for set-based genetic association studies.** H. Zhang<sup>1</sup>, Z. Wu<sup>2</sup>. 1) Merck & Co., Inc., Kenilworth, NJ; 2) Worcester Polytechnic Institute, Worcester, MA.

Genetic association studies have successfully identified many genetic variants that associate with complex traits and diseases. It is believed that grouping the individual effects of multiple variants may yield extra insight into the complex diseases. Many p-value combination methods have been developed to detect the overall effect of a set of genetic variants, e.g. Fisher's p-value combination method and its derivatives like truncated product method. We propose a unified family of statistics, called TFisher, with general p-value thresholding and weighting schemes in which a soft-thresholding scheme is shown to have optimal statistical power for signal detection in a large variety of signal patterns. Analytical calculation of the p-value for arbitrary correlation structure is given. When prior information of signal pattern is unavailable, an omnibus test, oTFisher, is proposed to provide robust results. Simulations evidence the accuracy of calculation and validate the theoretical advantages of the soft-thresholding method. The TFisher tests are applied to analyzing a whole exome sequencing data of amyotrophic lateral sclerosis, as well as Genetic Factors for Osteoporosis Consortium (GEFOS) using summary statistics. The proposed methods have been implemented into an R package TFisher and published on the CRAN <https://cran.r-project.org/package=TFisher>.

**3566F**

**Genetic mapping of human diseases using gene damage scores.** X. Zhu<sup>1</sup>, S. Gustafsson<sup>2</sup>, W. Wong<sup>1,3</sup>, E. Ingelsson<sup>4,5</sup>, J. Zou<sup>2,6,7</sup>. 1) Department of Statistics, Stanford University, Stanford, CA; 2) Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University, Sweden; 3) Department of Biomedical Data Science, Stanford University, Stanford, CA; 4) Department of Medicine, Division of Cardiovascular Medicine, Stanford University School of Medicine, Stanford, CA; 5) Stanford Cardiovascular Institute, Stanford University, Stanford, CA; 6) Department of Computer Science, Stanford University, Stanford, CA; 7) Department of Electrical Engineering, Stanford University, Stanford, CA.

Genetic scores that aggregate information from multiple variants have proven successful for understanding the role of genetic variation in complex traits (e.g. Purcell et al, 2009; Gamazon et al, 2015). Here we considered a "Gene Damage Score" (GeneDS) that quantifies total mutational damage of a gene in an individual. Specifically, we defined GeneDS of an individual for a target gene as the minor allele sum of all functional variants in this gene, weighted by variant-level deleterious metrics. In this work, we selected functional variants as SNPs predicted to cause moderate-to-severe damage (including various mutations from missense to stop-gain), and used CADD scores (Kircher et al, 2014) as variant weights. To test the utility of GeneDS for mapping diseases, we conducted a whole genome-phenome association scan of 16,080 genes and 745 diseases on 337,536 unrelated individuals of European ancestry within UK Biobank. We correlated GeneDS of each gene with diagnosis of each disease via logistic regression, controlling for age, gender and genotype-based principal components. Our large-scale analysis illustrates multiple advantages of GeneDS in association studies when compared to conventional methods. First, GeneDS association signals are almost independent, since correlations between GeneDS of nearby genes are much smaller than linkage disequilibrium between nearby SNPs. Second, unlike variant-based methods, GeneDS output can be directly used in gene set enrichment analyses, which may yield additional biological insights. Third and perhaps most importantly, in contrast to most gene-based tests, GeneDS provides an interpretable direction of effect for the observed associations, which may help elucidate the mode of action for a therapeutic target gene. As a proof of concept, increased damage in *SCN1A* was associated with reduced risk in epilepsy ( $z=-3.92$ ,  $FDR<0.1$ ); this negative correlation is consistent with the fact that *SCN1A* is the target of four different approved blockers for epilepsy. Finally, although defining GeneDS requires individual-level genotypes, GeneDS-based association analyses can be performed on GWAS summary statistics. This feature greatly facilitates replication studies. For example, we identified a positive association between GeneDS of *HGFAC* and coronary artery disease risk ( $z=6.98$ ,  $FDR<0.1$ ) in UK Biobank, and then replicated this finding ( $z=2.67$ ) using external summary data from the CARDIoGRAMplusC4D consortium (Nikpay et al, 2015).

**A Bayesian mixture model to accommodate multiple sources of uncertainty into transcriptome-wide association studies.** J.D. Rosen<sup>1</sup>, Y. Li<sup>1,2,3</sup>. 1) Department of Biostatistics, University of North Carolina, Chapel Hill, NC 27599; 2) Department of Genetics, University of North Carolina, Chapel Hill, NC 27599; 3) Department of Computer Science, University of North Carolina, Chapel Hill, NC 27599.

In the past several years various methods have been proposed for exploring associations between genes and complex traits. Sometimes referred to as transcriptome-wide association studies (TWAS), these methods share a common framework: training of a predictive model of gene expression based on eQTL data, prediction of gene expression using GWAS data for which gene expression values are unavailable, and finally using these predicted values to perform an association analysis with desired phenotypes. These methods largely differ in the predictive model employed. However most still use point estimates from their respective predictive models without considering various sources of uncertainty. These include uncertainty in SNP effect estimates in the predictive model, uncertainty in gene expression, and uncertainty in the genotype measurement (typically from imputation). We propose a predictive Bayesian mixture model to address some of these issues. Similar to the previously reported BayesR methodology, the use of a mixture model addresses the issue of multiple markers that contribute small effects to genetic variation. Early simulation studies have demonstrated predictive performance gains, measured by squared correlation, over other methodologies. For example, we observe a 15.3% relative increase in predictive performance over elastic net as implemented in PrediXcan. Uncertainty due to imputation, quantified by estimated  $R^2$ , is incorporated into the distribution for each specific SNP, which has the effect of demanding increasing evidence of having a non-zero coefficient with decreasing imputation quality. Furthermore, the use of Gibbs sampling allows for straightforward calculation of both (unbiased) mean and variance of SNP effects, facilitating the use of a multiple imputation framework for association analysis to improve power and validity. Preliminary analyses of actual data reveal multiple genes associated with blood cell related traits.

**2665T****Natural selection at the Adenylate cyclase 3 (*ADCY3*) gene.** *I. Yoshiuchi*<sup>1,2</sup>.

1) Diabetes, Medicine, and Genetics, Yoshiuchi Medical Diabetes Institute, Ikoma, Nara, Japan; 2) Diabetes and Medicine, Yoshiuchi Medical Diabetes Family Clinic, Ikoma, Nara, Japan.

Diabetes and obesity cause serious complications including cardiovascular disease, and become the global health burden in the world. Diabetes is strongly associated with obesity. There are highly heritabilities of diabetes and obesity. According to the thrifty gene hypothesis, natural selection for diabetes- and obesity-related genes is important during feast and famine because such genes control glucose and fat levels. Loss of function variations in the Adenylate cyclase 3 (*ADCY3*) gene are associated with obesity and type 2 diabetes. Mutations in *ADCY3* cause monogenic severe obesity. *ADCY3*-deficient mice showed severe obesity, impaired insulin sensitivity, reduced physical activity and hyperphagia. Here, we aimed to uncover evidence of selection at *ADCY3*. We performed a three-step method to detect selection at *ADCY3* using the 1000 genome population and HapMap population data. We used Wright's F-statistics as a measure of population differentiation, the long-range haplotype (LRH) to test extended haplotypes, and the integrated haplotype score (iHS) to detect selection at *ADCY3*. We observed high population differentiation at one *ADCY3* height-adjusted BMI-associated SNP using Wright's F-statistics. The LRH and the iHS also showed evidence for selection at *ADCY3*. These findings provide evidence for natural selection at *ADCY3*. Further discoveries are warranted on the evolution of obesity- and type 2 diabetes-associated genes.

Hábitat, Universidad Tecnológica del Chocó, Quibdó, Chocó, Colombia.

The ChocoGen research project was initiated to facilitate genomic studies of the predominantly Afro-Colombian population of Chocó, a state located on Colombia's Pacific coast. The project aims to (1) characterize the genetic ancestry of the population of Chocó, and (2) explore the relationship between ancestry and genetic determinants of health in the region. We compared genome-wide patterns of genetic ancestry for Chocó to six other admixed American populations, with an emphasis on a Mestizo population from the neighboring state of Antioquia. Chocó shows mostly African genetic ancestry (76%) with a nearly even split between European (13%) and Native American (11%) fractions, whereas Antioquia has primarily European ancestry (75%), followed by Native American (18%) and African (7%). Sample donors from Chocó self-identify as having more African ancestry than can be genetically inferred, as opposed to what we previously found for Antioquia, where individuals tend to overestimate levels of European ancestry. Despite the clear differences between Chocó and Antioquia at the level of continental ancestry, the two populations show overall patterns of subcontinental ancestry that are highly similar. When the subcontinental ancestral origins within Africa, Europe and the Americas are considered jointly, the populations of Chocó and Antioquia were found to be most closely related, to the exclusion of the other admixed American populations that we analyzed, pointing to a shared genetic legacy that underlies a common, unifying identity that binds the country. We investigated the role that genetic ancestry plays in the epidemiology of type 2 diabetes (T2D) for these two Colombian populations. Chocó has significantly higher predicted genetic risk for T2D compared to Antioquia, and the elevated predicted risk for T2D in Chocó is correlated with higher African ancestry. Despite its elevated predicted genetic risk, the population of Chocó has a three-times lower observed T2D prevalence than Antioquia, indicating that environmental factors better explain differences in T2D outcomes for Colombia. However, Chocó has substantially lower socioeconomic status (SES) than Antioquia, which is unexpected given that low SES is widely considered to be an environmental risk factor for T2D. Our exploration of the dietary and lifestyle factors that characterize low SES in Chocó illustrates how poverty can divergently manifest as a T2D protective factor in Colombia.

Although Tibetans are considered well adapted to high altitude, whether there is a limit of elevation they can live has not been tested. Tibetans have lower hemoglobin (Hb) levels compared with lowlanders moving to high altitude, which is considered a protection from overproduction of red cells (polycythemia), a condition that increases the risk of heart attack, stroke, and fetal loss during pregnancy. To detect if there is a turning point of changes of physiological traits with altitude, we collected Hb data from nearly 9,000 Tibetans, representing 20 geographic populations living in different elevations from 2,227m to 5,018m. The results indicated a clear turning point at the elevation of 4,500m where the Hb level and polycythemia incidence went up dramatically. We proposed that the elevation of 4,500m marks the altitude limit for Tibetans where the protective blunting effect on hemoglobin disappears.

**High throughput pipeline for HLA typing identifies >800 novel alleles in populations from Africa.** T. Porter<sup>1,2</sup>, M.O. Pollard<sup>1,2</sup>, A.J. Mentzer<sup>3</sup>, A. Dillthey<sup>4</sup>, C. Pomilla<sup>1,2</sup>. 1) Global Health and Populations, Human Genetics, The Wellcome Sanger Institute, Cambridge, United Kingdom; 2) Department of Medicine, University of Cambridge, Cambridge, United Kingdom; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, United Kingdom; 4) Institut für Medizinische Mikrobiologie und Krankenhaushygiene, Universitätsklinikum Düsseldorf.

The HLA Diversity in Africa Project aims to characterise the diversity of the HLA region amongst a wide variety of ethnic groups across Africa. Current HLA panels and reference databases are limited in data from diverse global populations, and are predominately European centric, limiting their utility in providing a global resource for characterising genetic diversity in this region. Our aim is to overcome this by providing a freely available resource (in the form of an imputation panel) to facilitate disambiguation of clinical types and help understand the role of the HLA region in response to infection, auto-immune disease and vaccine response in African and non-African populations. We present the largest African high resolution HLA panel to date. To this end, through extensive research and development, we have developed a robust and efficient high throughput pipeline using commercially available PCR primers to target HLA genes for PacBio sequencing for typing the Class I and Class II loci of 431 samples (4741 amplicons) from 19 ethno-linguistic groups across Africa, highlighting the utility of the pipeline for clinical applications. We show that our pipeline exceeds conventional sanger based typing approaches in accuracy and resolution of typing, at comparable cost. We also report more than 800 novel alleles discovered and validated using our pipeline, across the allele frequency spectrum. By sequencing the full length of these alleles we are able to distinguish them from highly homologous European alleles. These accurate high resolution types provide a rich resource for imputation, potentially improving power to discover associations within the MHC to facilitate HLA linked disease research. This also provides an important resource for disambiguation of clinical types obtained using sanger based technology (SBT). In summary, here, we present an optimised workflow for high resolution HLA typing among African populations using long-read sequencing approaches. Our pipeline allows inference of high levels of HLA diversity among populations across Africa, providing a resource for medical genetics and for better clinical HLA typing in global populations.

**2669F****Different selected mechanisms attenuated the inhibitory interaction of KIR2DL1 with C2' HLA-C in two indigenous human populations in Southern Africa.**

The functions of human natural killer (NK) cells in defense against pathogens and placental development during reproduction are modulated by interactions of killer cell immunoglobulin-like receptors (KIR) with HLA-A, -B and -C class I ligands. Both receptors and ligands are highly polymorphic and exhibit extensive differences between human populations. Indigenous to Southern Africa are the KhoeSan, the most ancient group of modern human populations, who have highest genomic diversity worldwide. We studied two KhoeSan populations, the Nama pastoralists and the #Khomani San hunter-gatherers. Comprehensive next-generation sequence analysis of *HLA-A*, *-B* and *-C* and all *KIR* genes identified 248 different *KIR* and 137 *HLA class I*, which assort into ~200 haplotypes for each gene family. All 74 Nama and 78 #Khomani San studied have different genotypes. Numerous novel *KIR* alleles were identified, including three arising by intergenic recombination. On average, KhoeSan individuals have 7-8 pairs of interacting *KIR* and HLA class I ligands, the highest diversity and divergence of polymorphic NK cell receptors and ligands observed to date. In this context of high genetic diversity, both the Nama and the Khomani San have an unusually conserved, centromeric *KIR* haplotype that has arisen to high frequency and is different in the two KhoeSan populations. Distinguishing these haplotypes are independent mutations in *KIR2DL1*, that both prevent *KIR2DL1* from functioning as an inhibitory receptor for C2' HLA-C. The relatively high frequency of C2' HLA-C in the Nama and the #Khomani San appears to have led to natural selection against strong inhibitory C2-specific *KIR*.

**2670W****Ancient and modern admixture enhanced the interactions of HLA class I with killer cell immunoglobulin-like receptors in East Asian populations.**

R. of China; 7) Frederick National Laboratory for Cancer Research (FNLRCR), Frederick, MD.

Natural killer (NK) cells are white blood cells essential for controlling human infection, cancer and fetal development. NK cell functions are modulated by interactions between inhibitory killer cell immunoglobulin-like receptors (*KIR*) and HLA-A, -B and -C molecules expressed on tissue cells. Both gene families are highly polymorphic; the *KIR* locus (chromosome 19q13.4) varies in gene number and sequence, and *HLA* (chromosome 6p21) are the most polymorphic human genes. All *HLA-C* alleles encode a *KIR* ligand and contribute to reproduction and immunity. In contrast, only some *HLA-A* and *-B* alleles encode *KIR* ligands and they are focused on immunity. By targeted high-resolution analysis of *KIR* and *HLA-A*, *-B* and *-C* genes, we show the Chinese Southern Han are significantly enriched for interactions between inhibitory *KIR* and HLA-A and -B. This enrichment has substantial input from population admixture, from both ancient and modern humans, who contributed multiple *HLA class I* and *KIR* haplotypes. Consequently, over 80% of Southern Han *HLA* haplotypes encode more than one *KIR* ligand. Complementing the high number of *KIR* ligands, the *KIR* locus combines a high frequency of genes expressing potent inhibitory *KIR*, with low frequency of those expressing activating *KIR*. The centromeric region of the *KIR* locus encodes strong and conserved inhibitory HLA-C specific receptors, and the telomeric region provides a high number and diversity of inhibitory HLA-A and -B specific receptors. We identified two *KIR* telomeric region haplotypes that have duplicated *KIR3DL1/S1* as present both in archaic humans and Southern Han. In all these characteristics, the Southern Han represent other East Asians, whose NK cell repertoires are thus enhanced in quantity, diversity and effector strength, likely through natural selection for resistance to endemic viral infections.

**VarCount: Automated *in trans* variant calling reveals novel epilepsy genes and selection patterns between populations.** A. Cox<sup>1,2</sup>, F. Grady<sup>2</sup>, G. Velez<sup>2</sup>, V. Mahajan<sup>3</sup>, P. Ferguson<sup>2</sup>, A. Kitchen<sup>2</sup>, B. Darbro<sup>2</sup>, A. Bassuk<sup>2</sup>. 1) Yale School of Medicine, New Haven, CT; 2) University of Iowa, Iowa City, IA; 3) Stanford University, Palo Alto, CA.

Compound heterozygotes (CH) occur when different mutations at the same locus on both maternal and paternal chromosomes produce a recessive trait. It is suspected that undetected compound heterozygosity explains a significant portion of missing heritability for diseases and other phenotypes. Here we present the tool VarCount for the quantification of mutations at the individual level. We used VarCount to characterize homozygous and CH variants in the Epi4k epilepsy cohort and in the 1000 genomes participants. In Epi4k, we found enrichment for rare, CH mutations in six genes, including three involved in neuronal growth and development. PRTG, TNC and MACF1 are potential novel recessive epilepsy genes. Comparing the 1000 genomes superpopulations, we found significant differences in several genes, including immune response genes. NWD1 modulates androgen receptor signaling and is up-regulated in prostate cancer so recessive mutations may contribute to cancer development in African men. Mutations in the virus inhibitor APOBEC3B are enriched in East Asians, reflective of host-virus coevolution. SSC5D mutations are enriched in Africans, indicating that recessive mutations were selected against during global migrations and possibly as a factor of diet. Our results highlight that compound heterozygous mutations should be considered in sporadic epilepsy. Our findings also suggest that selection on recessive mutations occurred during the establishment of global populations, and the resulting genetic differences reflect host-virus co-evolution and underlie susceptibility to diseases like prostate and cervical cancer. .

**Improved pathogenic variant localization using a hierarchical model of sub-regional intolerance.** T.J. Hayeck<sup>1,2</sup>, N. Stong<sup>1</sup>, C.J. Wolock<sup>1</sup>, B. Copeland<sup>1</sup>, S. Kamalakaran<sup>1</sup>, D. Goldstein<sup>1</sup>, A. Allen<sup>1,3</sup>. 1) Institute of Genomic Medicine - Columbia University, New York, NY; 2) Department of Biostatistics - Columbia University, New York, NY; 3) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC, USA.

Different parts of a gene can be of differential importance to development and health. This regional heterogeneity is also apparent in the distribution of disease mutations which often cluster in particular regions of disease genes. The ability to precisely estimate functionally important sub-regions of genes will be key in correctly deciphering relationships between genetic variation and disease. Previous methods have had some success using standing human variation to characterize this variability in importance by measuring sub-regional intolerance, i.e., the depletion in functional variation from expectation within a given region of a gene. However, the ability to precisely estimate local intolerance was restricted by the fact that only information within a given sub-region is used, leading to instability in local estimates, especially for small regions. Here, we overcome that limitation by borrowing information across genes using a Bayesian hierarchical model. We fit the model using standing human variation comprised of 123,136 individuals found in the genome Aggregation Database (gnomAD). We show that our approach stabilizes estimates, leading to lower variability and improved predictive utility. Specifically, using pathogenic mutations from ClinVar we show that our approach more effectively identifies regions enriched for pathogenic variants and are able to show significant correlations between sub-region intolerance and the distribution of pathogenic variation in disease genes, with AUC up to 0.86 for de novo missense variants in Online Mendelian Inheritance in Man (OMIM) genes. This later result immediately suggests that considering the intolerance of regions in which variants are found may improve diagnostic interpretation within exons. We also illustrate the utility of integrating regional intolerance into gene-level disease association tests with a study of known disease genes for epileptic encephalopathy.

**2673W****Functional validation of missense variants in *VMAT1* reveals evolutionary trajectory of human psychology.** *D. Sato<sup>1</sup>, Y. Ishii<sup>1</sup>, T. Naga<sup>2</sup>, M. Kawata<sup>1</sup>.*

1) Department of Ecology and Evolutionary Biology, Tohoku University, Sendai, Miyagi, Japan; 2) Department of Biomolecular Sciences, Tohoku University, Sendai, Miyagi, Japan.

*VMAT1*, which encodes vesicular monoamine transporter 1, regulates the transport of monoamine into neuronal synaptic vesicles, and several functional mutations in *VMAT1* have been reported to date. Among them, Thr136Ile belongs to a luminal loop domain, which interacts with G protein, and has been known to upregulate the monoamine transport and to affect our psychological conditions and/or psychiatric disorders, such as anxiety and bipolar disorders. In our previous study from evolutionary perspective (Sato & Kawata, in revision), it was estimated that the 136Ile had emerged later in modern humans and has been subject to strong selective pressure recently. Moreover, we found that this polymorphism does not exist in other mammals including the other great apes (they have monomorphic 136Asn instead), and that the substitution from the 136Asn to the 136Thr had been under positive selection in the archaic human lineage. Thus, it is quite interesting to investigate how the functional mutations have affected our psychology and personality traits during the human evolution. In the present study, we compared the functional differences among the 136Asn/Thr/Ile using fluorescent false neurotransmitters (FFNs), which act as fluorescent substrates of VMAT, to visualize the uptake of neurotransmitters. Plasmids encoding YFP-tagged VMAT1 were transiently transfected into HEK293T cells, and cells were then incubated with FFN206 for an hour. After washing, the fluorescence intensity of FFNs was quantified by a fluorescent microscope (with the ImageJ software) and a microplate reader. We also quantified the fluorescence intensity of YFP to estimate the expression level of YFP-VMAT1. The result showed that the uptake of FFNs in cells expressing the 136Asn or the 136Ile of VMAT1 was greater than that of the 136Thr. This suggests that the efficiency in monoamine transport had once decreased in the archaic human lineage but has increased again in recent ages. In summary, our study presents an unusual pattern of evolution of monoaminergic pathways in humans, suggesting the unique evolution of human psychology.

**2674T****Understanding the hidden complexity of Latin American population isolates.**

Ruiz-Linares<sup>9,10</sup>, G. Bedoya<sup>11</sup>, N. Freimer<sup>3</sup>, K. Lohmueller<sup>1,2</sup>, Costa Rica/Colombia Consortium for Genetic Investigation of Bipolar Endophenotypes.* 1) Department of Human Genetics, University of California Los Angeles, Los Angeles, CA; 2) Department of Ecology & Evolutionary Biology, University of California Los Angeles, Los Angeles, CA; 3) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA; 4) Department of Psychiatry and Biobehavioral Sciences, Semel Center for Informatics and Personalized Genomics, University of California Los Angeles, Los Angeles, CA; 5) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 6) Icahn Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY; 7) Department of Biomedical Data Science, Stanford University, Stanford, CA; 8) Department of Statistics, Stanford University, Stanford, CA; 9) Ministry of Education Key Laboratory of Contemporary Anthropology and Collaborative Innovation Center of Genetics and Development, Fudan University, Shanghai; 10) Aix-Marseille Univ, CNRS, EFS, ADES, Marseille, France; 11) Genética Molecular (GEN-MOL), Universidad de Antioquia, Medellín, Colombia.

Most population isolates examined to date were founded from a single ancestral population. Consequently, there is limited knowledge about the demographic history of admixed population isolates. Here we investigate genomic diversity of recently admixed population isolates from Costa Rica and Colombia and compare their diversity to a benchmark population isolate, the Finnish. These Latin American isolates originated during the 16<sup>th</sup> century from admixture between a few hundred European males and Amerindian females, with a limited contribution from African founders. We examine whole genome sequence data from 449 individuals, ascertained as families to build multigenerational pedigrees, with a mean sequencing depth of coverage of approximately 24X. We find that Latin American isolates have increased genetic diversity relative to the Finnish. However, there is an increase in the amount of identity by descent (IBD) segments in the Latin American isolates relative to the Finnish. The increase in IBD segments is likely a consequence of a very recent and severe population bottleneck during the founding of the admixed population isolates. Furthermore, the proportion of the genome that falls within a long run of homozygosity (ROH) in Costa Rican and Colombian individuals was significantly greater than that in the Finnish, suggesting more recent consanguinity in the Latin American isolates relative to that seen in the Finnish. Lastly, we found that recent consanguinity increased the number of deleterious variants found in the homozygous state, which is relevant if deleterious variants are recessive. Our study suggests there is no single genetic signature of a population isolate.

**2675F**

**Ancient DNA sequencing shows population heterogeneity of Neolithic Central China.** C. Li<sup>1</sup>, J. He<sup>2</sup>, X. Zhang<sup>3</sup>, F. Wu<sup>2</sup>, X. Zhang<sup>1</sup>, B. Feng<sup>2</sup>, P. Underhill<sup>4</sup>, C. Zhang<sup>5</sup>, C. Wu<sup>6</sup>, F. Tang<sup>2</sup>, B. Su<sup>1</sup>, H. Zhao<sup>3</sup>, X. Wu<sup>2</sup>, Y. Pang<sup>2</sup>, Y. Huang<sup>2,6</sup>. 1) Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming, Yunnan, China; 2) Biodynamic Optical Imaging Center (BIOPIIC), School of Life Sciences, Beijing Advanced Innovation Center for Genomics, Peking University, Beijing 100871, China; 3) School of Archaeology and Museology, Peking University, Beijing 100871, China; 4) Department of Genetics, Stanford University, Stanford, CA94305, USA; 5) Institute of Oil and Gas, Peking University, Beijing 100871, China; 6) Peking-Tsinghua Center for Life Sciences, College of Engineering, Peking University, Beijing 100871, China.

Ancient human DNA sequences are highly desired for providing concrete evidence for a better reconstruction of the past life, especially the genetic relationship and interaction among prehistoric populations. Most recently, genome-wide sequencing data of an Upper Paleolithic human of East Asia has been successfully analyzed, whereas only one mitochondrial genome sequence of Neolithic human is reported to provide a genetic link to southern China as well as insights concerning early Austronesian expansion. Nuclear genome information of Neolithic human in East Asia, especially the central China which is one of the main hubs of the development of civilization in human history, has been still deficient for a long time due to the scarcity of samples and their unfavorable preservation environments, limiting our understanding of human genetic relationships and interactions in that period. We used high-throughput sequencing to study ancient DNA samples from the remains of 41 Neolithic human individuals, excavated from a 5,000-y-old secondary burial site in Baligang M13, China. The majority of these samples contained no more than 0.1% of endogenous human DNA, thus we explored various protocols to construct sequencing libraries from these poorly preserved aDNA samples from such a mass burial. We developed various nucleic acid probe-mediated approaches to enrich the mtDNA and obtained 13 complete MT genome sequences which clearly ruled out a direct maternal relationship between any two individuals, predicting the post-matriarchal structure of the late Neolithic society in China. The relatively diversified haplogroup types imply these Neolithic humans living in the Central Plain of China already a mixture of distantly related ethnic and genetic groups rather than a small population derived from a single founder. Furthermore, the quality of DNA from a petrous bone is feasible to detect a few single nucleotide variations associated with haplogroup sites in chromosome Y, helping us to unravel a close genetic relationship of the Neolithic Baligang M13 individuals to present people in China and East/Southeast Asia, and suggesting the consistence between paternal and maternal phylogeny as well. The genomic interrogation of this Neolithic burial facilitates our understanding of 5,000-y-old prehistoric culture in central China. .

**2676W**

**Unique and conserved gene pool provides higher risk of rare genetic disorders in populations of Jammu and Kashmir-India.** S. Sharma<sup>1</sup>, E. Rai<sup>2</sup>, A. Angural<sup>1</sup>, A. Sapolia<sup>1</sup>, S. Razdan<sup>2</sup>, K.K. Pandita<sup>3</sup>. 1) Human Genetic Research Group, School of Biotechnology, Shri Mata Vaishno Devi University, Katra, Jammu, India; 2) Neurology Clinic, Bhagwati Nagar, JAMMU, India; 3) Health Clinic, H. No. 62, Lane 11, Swam Vihar, Muthi, JAMMU, India.

Jammu and Kashmir (J&K) is the North most State of India, located in Himalayan region and geographically isolated. It is anticipated that this region has acted as corridor to various invasions and migrations, to and from mainland India, Eurasia or northeast Asia but underrepresented in any of the study so far in literature. The isolated gene pool of the region on one had provides Uniqueness to the population groups of the region, at the same time various endogamous and consanguineous practices provide higher risk of genetic diseases in the populations. These disorders are predominantly rare, poorly understood and most often remain uncharacterized or patients are misdiagnosed due to lack of specific clinical resources. Understanding the basics of inheritance is essential in such cases as it helps to figure out the plausibility of a disorder as an inherited or genetic disease. Though identification and characterization of such disorders is complicated, Next generation Sequencing has come up as a tool in recent times and is of great help. We have devised a "Bottom UP" approach and clubbed it with NGS/WES, as an affective method in understanding uncharacterized Mendelian Disorders in the region. It may be of great help especially in developing countries and regions like J&K where such disorders remain undiagnosed/misdiagnosed due to lack of specialized testing. We have collected huge number of highly extended families representing various rare genetic disorders and trying to elucidate the genetic cause and biology of the diseases in these families with this approach.

**Reconstructing the peopling of old world south Asia: From modern to ancient genomes.** *N. Rai<sup>1</sup>, K. Thangaraj<sup>2</sup>*. 1) Ancient DNA Laboratory, Birbal Sahni Institute of Palaeosciences, Lucknow, Uttar Pradesh, India; 2) Centre for Cellular and Molecular Biology, Hyderabad, Telangana, India.

South Asia was one of the first geographic regions to be peopled by modern humans after their African exodus. Today, the diverse ethnic groups of South Asia comprise an array of tribes, castes, and religious groups, who are largely endogamous and have hence developed complex, multi-layered genetic differentiation. From such a complex structure, several questions have stood out from the research of our group and others that are only beginning to be resolved using modern sequencing techniques and targeted sampling of populations and archaeological specimens. Here, for the first time we have used ancient genomics approach to understand the deep population ancestry of Indian Sub- continent. Despite the rich sources available of modern Indian populations, success from ancient DNA specimens in the subcontinent have been limited. We have successfully analysed several museum samples and fresh excavation from the different part of India which provides us a wonderful opportunity to be able to relate these modern populations genetically with those in the past and build complex models of population mixture and migration in India. Using ancient genomics data from the human remains who have lived about 4-5 thousand years before present in North West and South of India, we are trying to understand the population history of Iron age people and their genetic relation with the North West of Indians and Iranian Farmers. Furthermore, we are providing a solid Genetic evidence that substantiates archaeological and linguistic evidence for the origins of Dravidian languages and the language of the Indus valley people.

**Reconstructing the health landscape of a medieval hospital cemetery: A holistic interdisciplinary approach.** *C.L. Scheib<sup>1,2</sup>, A.W. Wohms<sup>3</sup>, X. Ge<sup>4</sup>, J.S. Bates<sup>2</sup>, P. Maheshwari-Aplin<sup>2</sup>, B. Haines<sup>2</sup>, S.A. Inskip<sup>2</sup>, J. Dittmar<sup>2</sup>, C. Cessford<sup>2</sup>, B. Mulder<sup>2</sup>, A.A. Rose<sup>2</sup>, M. Metspalu<sup>1</sup>, T.C. O'Connell<sup>2</sup>, P. Mitchell<sup>2</sup>, J.T. Stock<sup>5</sup>, J.E. Robb<sup>2</sup>, T. Kivisild<sup>1,2</sup>*. 1) University of Tartu, Tartu, Estonia; 2) University of Cambridge, Cambridge, United Kingdom; 3) University of Oxford, Oxford, United Kingdom; 4) University of Manchester, Manchester, United Kingdom; 5) University of Western Ontario, London, Ontario, Canada.

Established for the care of the poor and infirm, with the exception of pregnant women, lepers, the wounded, crippled and insane, the assemblage of 400 internments (c. 1204-1511) from the Hospital of St. John, Cambridge, provides a laboratory for testing osteological/aDNA methods and for understanding the health and diseases of a broadly representative British medieval population as it experienced the spread of Black Death from continental Europe during 1347 – 1349. Four hundred skeletons from the cemetery site were assessed for osteological traits and paleopathology. A subset was sampled for isotopic and ancient DNA (aDNA) analysis and compared to a time-transect of sites in the local area. DNA was extracted from teeth, built into double-stranded Illumina-compatible libraries and sequenced on the NextSeq500 75-cycle single-end platform. The raw libraries were screened in collaboration with the Jena Max Planck Institute for the Science of Human History using MALT. Surprisingly, though the cemetery's prime usage overlaps the main plague period, no skeletons ( $n = 86$ , 0%) tested positive for the presence of *Y. pestis* in the teeth, while a contemporaneous site less than 500 meters away contained at least 5 individuals ( $n = 26$ , 19%) whose teeth tested positive for *Y. pestis* aDNA. In line with the charter, within the St. John Hospital cemetery, no signs of active *M. leprae* infection (osteologically or aDNA) were found; however, osteological evidence of possible *M. tuberculosis* infection is abundant (post-cranial remains are currently being extracted and screened for pathogen aDNA) as well as a number of trauma. Ancient DNA scans did, however, find evidence of opportunistic infections, pneumonia and septicemia, more indicative of 'diseases of the elderly' that effect immunocompromised individuals in today's hospital settings and analyses of the human genome provide insight into heritable disease risk present in the population. By combining the aDNA with dietary isotopic information and skeletal analysis, this collection provides a valuable experiment in holistic Bioarchaeology and an opportunity to explore the relationships between diet, culture, and heritable disease risk on the discovery and expression of heritable and communicable disease in the archaeological record.

**2679W****Multi-omics approach to elucidating the C57BL mouse substrains.** Y.

*Ren, A. Palmer.* University of California, San Diego, San Diego, CA.

Since C.C. Little initially generated the C57BL inbred strain in the 1920's, the inbred substrain C57BL/6 (B6) became the most frequently used mouse strain in biomedical research. B6 mice are used in a wide variety of research areas including cardiovascular biology, developmental biology, diabetes and obesity, genetics, immunology, neurobiology, and behavioral research. The popularity of B6 inbred mice led to the establishment of many colonies at different vendors and academic institutions around the world. Once a new B6 substrain is established, spontaneous mutations will arise in both the original colony and the new colony, and a subset of those mutations will spread through the colony by genetic drift and become fixed. The longer individual substrains are separated from each other, the greater the number of genetic differences between them. These genetic differences can lead to significant phenotypic and gene expression differences. A number of studies have reported these phenotypic differences among the C57BL/6 substrains, especially related to several behaviors and tolerance for glucose, alcohol, and drugs. In order to characterize the substrain differences, we have performed whole-genome sequencing and RNA-sequencing on 9 commonly used B6 substrains and 5 commonly used B10 substrains. This has led to the discovery of many substrain specific accumulated mutations (SSAM), substrain specific accumulated gene expression (SSAGE), and cis-regulatory elements (CRE) that are important for any research using B6 substrains.

**2680T****Visualization of population structure history with Scale-Invariant Geometric Data Analysis (SIGDA).** M. Robinson, A. Zimmer, T. Farrah, D.E.

*Mauldin, N.D. Price, L. Hood, G. Glusman.* Institute for Systems Biology, Seattle, WA.

We present exploratory data analyses and visualizations of single nucleotide variants (SNVs) from the 1000 Genomes cohort on the most relevant dimensions of population history: time, population structure, and chromosomal position. We demonstrate that our algebraic method, Scale-Invariant Geometric Data Analysis (SIGDA), provides the following improvements over a principal components analysis (PCA, often applied to population structure through EIGENSTRAT) of the same SNV data: 1. Like canonical correlation analysis (CCA), a leading method for contingency table analysis, SIGDA maps individuals (rows in the data matrix) and SNVs (columns) against population structures on the same scale. In contrast, PCA is only designed to map individuals on the coordinate axes; SNVs are analyzed in very different, incompatible coordinates, and are rarely visualized in a population structure analysis. 2. Due to the common coordinate system, SIGDA provides intuitive visualizations of SNVs as markers of population structure by allele frequency, a proxy for allele age. Visualization of an individual's alleles illustrates their individual population history against the background of genotypes in the cohort. SNV coordinates from SIGDA can also be visualized against their chromosomal positions, providing a visualization of an individual's population history along each chromosome in a manner similar to chromoPainter. 3. Using a resampling strategy, we show that SIGDA identifies more robust elements of population structure than PCA does on the same data. 4. In an analysis of the entire 1000 Genomes cohort, SIGDA robustly identifies population structures among the South Asian (SAS) populations which are only observed by PCA when the cohort is restricted to the SAS sub-cohort. This reflects the fact that PCA is more affected than SIGDA by within-cohort differences in effective population size. Importantly, these analyses reflect the algebraic structure of the data, independent of any population genetic model, and we anticipate that future work will allow hypothesis testing of population size, mutation rates, migration rates, and selection coefficients in an algebraic statistics context. Finally, SIGDA is a generic exploratory data analysis method; it provides unique advantages for analysis gene expression data, contingency tables, and has applications across all of data science. This work is supported by NIH 1U54EB020406 and the MJ Murdock Charitable Trust.

**Detecting polygenic signals and molecular mechanisms of adaptation to local environments.** *F. Luca<sup>1</sup>, A. Findley<sup>1</sup>, D. Witonsky<sup>2</sup>, R. Pique-Regi<sup>1</sup>.* 1) Wayne State University, Detroit, MI; 2) University of Chicago, Chicago, IL.

Human migration led to the settlement of population groups in varied environmental contexts worldwide. The extent to which adaptation to local environments has shaped human genetic diversity is a longstanding question in human evolution. Recent studies have suggested a role for archaic human introgression in modern human adaptation to environmental pressures such as pathogen load. With a few notable exceptions, most tests for polygenic adaptation in humans have relied on SNP associations with organismal-level phenotypes, commonly measured in GWAS. However, functional genomic studies have demonstrated that variation in gene expression across individuals and in response to environmental perturbations is a main mechanism underlying complex trait variation. Here we consider gene expression response to *in vitro* treatments as a molecular phenotype to identify genes and regulatory variants that played an important role in adaptations to local environments. We apply Berg and Coop's test for polygenic adaptation to 52 populations in the Human Genome Diversity Panel and we test for selection on eQTLs for genes differentially expressed. We first validate our approach using Crohn's disease as an example: we consider differentially expressed genes between healthy and diseased ileal tissue samples and show that selection on eQTLs from GTEx for these genes mimics the signal observed when considering SNPs associated with Crohn's disease in GWAS. We then expand to eQTLs for genes differentially expressed in a panel of 52 cellular environments, resulting from 5 cell types and 35 treatments, including hormones, vitamins, drugs, and environmental contaminants. We find evidence of polygenic adaptation for response to the antibacterial triclosan in vascular endothelial cells and iron in PBMCs (FDR = 5%). We then investigated if Neanderthal introgression in the human genome may have contributed to adaptation to local environments through gene regulatory changes. Considering the same set of eQTLs and gene expression responses as described above, we found an enrichment for genes regulated by Neanderthal SNPs in genes differentially expressed in response to 16 treatments, including dexamethasone, caffeine, and vitamin D. These findings expand the set of environments where archaic introgression may have contributed to modern human adaptations to local environments.

**Self-reported race/ethnicity as a function of genetic ancestry in the Kaiser Permanente (KP) Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort.** *Y. Banda<sup>1</sup>, D. Ranatunga<sup>2</sup>, C. Schaefer<sup>3</sup>, N. Risch<sup>1,2,3</sup>.* 1) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 2) Kaiser Permanente Northern California Division of Research, Oakland, CA; 3) Department of Epidemiology and Biostatistics, University of California, San Francisco, CA.

In a vast number of epidemiological and genetic association studies of disease phenotypes, ethnic origin has been shown to be associated with the phenotypes. In most biomedical research studies, either self-reported race/ethnicity or genetic ancestry data, or both, is used for ethnic origin assessment. Preference of proxy depends on the type of analysis being conducted and the nature of the question being addressed. Of particular importance is the self-identification of individuals with mixed genetic ancestry, in terms of how many and which race/ethnicity categories are endorsed. We analyzed the correspondence between self-reported race/ethnicity and genetic ancestry in a sample of 97,671 individuals who are participants in the KP GERA cohort. Genetic ancestry was determined from a set of 43,988 SNPs from GWAS arrays. We focused on individuals who had at least 5% genetic ancestry from more than one continent, and calculated the rate of self-identification with a particular race/ethnicity group as a function of genetic ancestry. We observed that rates of self-identification as African American, East Asian or Latino rise dramatically with a modest amount of African, East Asian and Native American genetic ancestry, respectively. By contrast, the rate of self-identification as White rises only when the European genetic ancestry is very high. This indicates that the majority of people who are genetically mixed, even those with primarily European genetic ancestry, self-identify with the minority ancestral group. We also examined the rate of endorsing more than one race/ethnicity category. Here we observed a difference between those with more recent admixture (e.g. in the parental or grandparental generation) versus older admixture, with the more recently admixed individuals being more symmetric in their self-reported race/ethnicity and endorsing more than one category. These results reflect multiple social and political factors, including social homogeneity, migration, mating patterns, and historical considerations of genetically admixed individuals in a majority white population. These results also have implications for the interpretation of self-reported race/ethnicity covariates in epidemiologic studies.

**Study of Touch DNA in simulated situations with computer keyboards for forensic purposes.** *F.T. Goncalves, D.O Francisco, C. Fridman.* Universidade de Sao Paulo Faculdade de Medicina, Sao Paulo, Sao Paulo, Brazil.

In a crime scene, partial fingerprints can be used to obtaining genetic profiles based on genomic polymorphisms, assisting the elucidation of criminal investigations. Variables may interfere with the obtaining of profiles, as the type of the surface where the biological material was deposited. This study aimed to analyze the feasibility of obtaining STR profiles from fingerprints left on computers keyboards. Eight simulated experiments were conducted in pairs with four women and one man in two different keyboards. Each keyboard were used daily by a woman (primary donor) and then were manipulated during five minutes by the secondary donor (a woman or a man). The genetic material provided from the keyboards were collected with the double swab method and the DNA was extracted by two different methodologies: Swab Solution (Promega Corporation) and DNA IQ (Promega Corporation). The samples were quantified and then amplified by multiplex PCR using the kit for Human Identification *PowerPlex® Fusion System* (Promega Corporation) that contain 24 STR markers. Results showed that the recovery of the genetic material deposited on the substrate was higher when a man was present in the mixture, independent of the extraction method. Besides, in all experiments the profile predominant in the mixture was provided by the primary donor. Stochastic effects were observed in all profiles, impairing the determination of the real number of donors present in the samples. Therefore, our group has been working to improve these results and assist the elucidation of cybercrimes.

**Systematic detection of conserved and divergent brain proteins during human evolution.** *G. Dumas<sup>1,2,3,4</sup>, S. Malesys<sup>1,2,3,4</sup>, T. Bourgeron<sup>1,2,3,4</sup>.* 1) Institut Pasteur, Human Genetics and Cognitive Functions Unit, Paris, France; 2) CNRS UMR3571 Genes, Synapses and Cognition, Institut Pasteur, Paris, France; 3) University Paris Diderot, Sorbonne Paris Cité, Human Genetics and Cognitive Functions, Paris, France; 4) Centre de Bioinformatique, Biostatistique et Biologie Intégrative (C3BI, USR 3756 Institut Pasteur et CNRS), Paris, France.

The human brain organization differs from that of other primates, but the mechanisms accounting for its evolution remain unclear. Using a systematic analysis of all protein-coding genes in non-human primates and in hominins such as Neanderthal, we confirm that brain-related genes are among the most conserved genes of the human genome. Although brain diseases are expectedly enriched in highly conserved genes, we also highlight several genes associated with neurodevelopmental conditions such as micro/macrocephaly, autism or dyslexia that display a high degree of coding-sequence divergence during primate evolution. These genes involved in key processes of cortical and cerebellar development might have played roles in the specificity of the brain of modern humans. This resource is available online and can be used to estimate the degree of evolution of a single gene or a set of genes.

**Feeding behaviors determine acidic chitinase mRNA levels in mammalian and poultry stomachs.** F. Oyama<sup>1</sup>, A. Kashimura<sup>1</sup>, A. Kikuchi<sup>1</sup>, H. Masuda<sup>1</sup>, R. Miyahara<sup>1</sup>, Y. Hiruma<sup>1</sup>, S. Wakita<sup>1</sup>, M. Ohno<sup>1</sup>, M. Sakaguchi<sup>1</sup>, Y. Sugahara<sup>1</sup>, E. Tabata<sup>1,2</sup>. 1) Department of Chemistry and Life Science, Kogakuin University, Hachioji, Tokyo 192-0015, Japan; 2) Research Fellow of Japan Society for the Promotion of Science (DC1)Koujimachi, Chiyoda-ku, Tokyo 102-0083, Japan.

Chitin, a linear  $\beta$ -1, 4-linked polymer of *N*-acetyl-D-glucosamine (GlcNAc), is the second most abundant polysaccharide in nature and functions as a major structural polymer in many organisms. Recently, we reported that acidic chitinase (Chia) is highly expressed in mouse, chicken and pig stomach tissues and that it can digest chitin in the respective gastrointestinal tracts (GIT). However, the gene expression and enzymatic activity level in other mammals are still unknown. Chia mRNA expression levels were much lower in bovine (herbivores) and dog (carnivores) than those in mouse, pig and chicken (omnivores) stomachs. Moreover, the chitinolytic activities of recombinant bovine and dog Chia enzymes were slightly but significantly lower when compared with those of mouse, pig and chicken Chia. Thus, feeding behavior seems to be directly linked to Chia expression levels as well as chitinolytic activity of the enzyme in the particular animals. .

Lactase persistence (LP) is a recent adaptive trait in humans and has evolved mainly in populations that practice milk production. Prior studies of African populations have identified novel common variants in intron 13 of the *MCM6* gene (a known candidate enhancer region for *LCT*) associated with LP primarily in pastoralists. While these variants account for a large proportion of the phenotypic variance, there may be additional polymorphisms that contribute to the LP trait. To test this hypothesis, we resequenced 555bp of intron 13 of *MCM6*, in ~1,500 African individuals from diverse populations in Ethiopia, Tanzania and Botswana. We also genotyped these same individuals using the Illumina Omni 5M SNP array, and integrated our sequencing data with the 5M genotype data to detect signatures of selection. In addition, we performed the lactose tolerance test for a subset of ~450 individuals. Based on our analyses, we identified for the first time the presence of the C-14010 and G-13915 variants in the Hadza hunter-gatherers from Tanzania. We also observed the G-13915 variant in the Burunge and Maasai populations from Tanzania, which has never previously been reported. Furthermore, we confirmed the presence of the G-13907 and the G-13915 alleles in Ethiopia. In addition, we detected a strong association between LP and genomic regions on several chromosomes in the Maasai pastoralists based on Fisher's Exact Test, suggesting candidate regions that might contribute to LP in this population. Overall, this large-scale study offers new insights into the genetic basis and evolutionary history of LP in Africa.

**Evolutionarily conserved genes regulating hypoxia tolerance.** D. Zhou<sup>1</sup>, J. Xue<sup>1</sup>, Y.H. Hsiao<sup>1</sup>, T. Stobdan<sup>1</sup>, G.G. Haddad<sup>1,2,3</sup>. 1) Dept. of Pediatrics, University of California San Diego, La Jolla, CA; 2) Dept. of Neuroscience, University of California San Diego, La Jolla, CA; 3) The Rady Children's Hospital, San Diego, CA.

Hypoxia represents a critical element in the pathogenesis of many human diseases, such as ischemic stroke, myocardial infarction and solid tumors. Understanding the mechanisms regulating hypoxia tolerance or susceptibility is essential in developing effective strategies for medical interventions. In this regard, we have generated a hypoxia-tolerant *Drosophila melanogaster* strain through laboratory-directed evolution over >300 generations and analyzed the whole genomes of these flies. Due to the fact that the environmental conditions can be well controlled in the laboratory evolution experiments, the main variable in our experiments is the level of oxygen, which constitutes the only selection pressure applied. Therefore, these hypoxia-tolerant flies are a powerful model to delineate the mechanisms regulating hypoxia responses, and not a mixture of stressors. In parallel, we took advantage of the natural evolution of humans at different high altitude regions of the world and analyzed the whole genomes of Ethiopian and Andean highlanders. Through a comparative genomic approach, we obtained a group of evolutionarily conserved genes (28 human genes/23 *Drosophila* homologs) that are potentially involved in regulating hypoxia tolerance in human highlanders and the hypoxia-tolerant flies. Indeed, we confirmed the role of a subset of these candidate genes as regulating hypoxia tolerance experimentally. We discovered that ubiquitous knock-down of the expression of genes (Dm/Human), i.e., *gm/GATA3*, *Mkk4/MAP2K4*, *pyd/TJP1*, *RapGAP1/RAP1GAP2* and *shep/RBMS3*, dramatically enhanced hypoxia tolerance *in vivo* in *Drosophila*. These mechanisms have a strong potential to be translated into novel targets for developing therapeutic strategies to treat hypoxia-related diseases.

**Detecting adaptive introgression in human populations without knowledge of the archaic samples.** A. Akbari, V. Bafna. UC San Diego, La Jolla, CA.

**Motivation.** Most approaches that capture signatures of selective sweeps in population genomics data do not identify the specific mutation favored by selection. We recently proposed a method in Nature methods (Akbari et al. 2018), iSAFE (for "integrated selection of allele favored by evolution"), that enables researchers to accurately pinpoint the favored mutation in a large region. iSAFE revealed a specific genomic pattern in some putative targets of the selective sweep, including EDAR1 and LCT loci, that cannot be explained by hard/soft Selective Sweep (SS), or even multiple selective sweeps. Here, we show that Adaptive Introgression (AI) or Adaptation on a Recombination Suppressor (ARS) mechanism (like chromosomal inversion) can create such a pattern in the population. We present a novel method, based on properties of iSAFE, to accurately infer the favored haplotype and label the target region whether it is neutral, SS, AI, or ARS. This method does not require, archaic samples, knowledge of demography, the phenotype under selection, or functional annotations of mutations. **Method.** The iSAFE method can accurately pinpoint the favored mutation in a large region (~5 Mbp) by using a statistic derived solely from population genetics signals. iSAFE treats each mutation as a binary classifier, i.e. carriers and non-carriers. Therefore, if two mutations are fully linked they get exactly the same iSAFE score regardless of their chromosomal position in the target window. This enables us to easily infer the favored haplotype. We use length and number of mutations on the favored haplotype to estimate the branch length of the favored haplotype and separate SS, AI, and ARS. Finally, we use an extension of the coalescent theory to infer the divergence time of the human population and, possibly unknown, archaic hominin in the AI cases. **Result.** We validated our method with extensive simulations and also on known examples of AI in the human population, like EPAS1 in Tibetans highlanders. The results, on both simulations and real data, are very accurate and promising. We also found some novel loci in all populations of 1000 genome projects that are predicted, with a high confidence, to be Adaptive Introgression from a possibly unknown archaic hominin.

**De novo mutation rates from 1465 ancestrally diverse trios highlight rapid founder population changes and inter-ancestral conservation in mutational processes.** M.D. Kessler<sup>1</sup>, J. Perry<sup>1</sup>, M. Daya<sup>2</sup>, N.L. Heard-Costa<sup>3</sup>, B. Cade<sup>3</sup>, H. Wang<sup>3</sup>, J. Ziniti<sup>3</sup>, S. Datta<sup>4</sup>, S.T. Weiss<sup>5</sup>, K. Barnes<sup>6</sup>, S. Redline<sup>3</sup>, V. Ramachandran<sup>7</sup>, A. Johnson<sup>8</sup>, R. Mathias<sup>9</sup>, J. O'Connell<sup>10</sup>, X. Tian<sup>2</sup>, B. Mitchell<sup>1</sup>, J.G. Wilson<sup>6</sup>, D.A. Nickerson<sup>2</sup>, S. Zoellner<sup>8</sup>, S. Browning<sup>3</sup>, G. Abecasis<sup>9</sup>, R. Hernandez<sup>10</sup>, T.D. O'Connor<sup>1</sup>, TOPMed Consortium. 1) University of Maryland Baltimore, Baltimore, MD; 2) University of Washington, Seattle, WA; 3) Harvard Medical School, Boston, MA; 4) National Heart, Lung and Blood Institute's The Framingham Heart Study, Framingham, MA; 5) Boston University School of Medicine, Boston, MA; 6) University of Mississippi Medical Center, Jackson, MS; 7) University of Houston Clear Lake, Houston, TX; 8) University of Colorado Denver, Denver, CO; 9) University of Michigan, Ann Arbor, MI; 10) University of California San Francisco, San Francisco, CA.

*De novo* Mutations (DNMs), or mutations that appear in an individual despite not being seen in their parents, are an important source of genetic variation whose impact is relevant to studies of human evolution, demography, and disease. Utilizing the largest high-coverage human whole genome sequencing dataset to date as part of the Trans-Omics for Precision Medicine (TOPMed) program, we directly estimate and analyze DNM counts, rates, and spectra from 1465 trios across an array of diverse human populations. We find a weak but significant positive correlation between genome-wide heterozygosity and DNM count ( $R^2=0.005$ ,  $P<0.02$ ), though we do not find significant differences in DNM rate between individuals of European, African, and Latino ancestry. When we explore the intersect of DNMs and ancestral segments within admixed populations, we do not find significant differences in DNM accumulation rates between ancestral origins. However, interestingly, we do find significantly fewer DNMs in Amish individuals compared with other Europeans, even after accounting for parental age and sequencing center (Amish mean = 54.78, European mean = 59.15,  $p$ -value < 0.005). Specifically, we find significant reductions in the number of A→G/ T→C mutations in the Amish that seem to underpin their overall reduction in DNMs ( $p$ -value < 0.015). Given the lack of local differences in DNM rate seen across ancestrally distinct genomic segments, and that the correlation between heterozygosity and DNMs is too weak to explain the degree of difference in DNMs seen between the Amish and other Europeans, these data suggest that either environmental variables or uncommon genetic elements have led to a reduced accumulation rate of DNMs in the Amish.

**2690F**

**Human prehistoric demography revealed by polymorphic pattern of CpG transitions.** X. Liu. Human Genetics Center, University of Texas School of Public Health, Houston, TX.

**Background:** Thanks to the advance of archaeological and genetic studies of human populations, we have learned a lot about our own prehistoric demographic events, including the out-of-Africa migration and the eventual distribution throughout the continents. However, many details are still missing and under hot debate. One missing yet important piece of the puzzle is when and how human populations expand during the Holocene, especially around the time of Neolithic Revolution. **Materials and Methods:** We inferred demographic histories from 1 to 40 thousand years ago (kya) for 20 population samples from the 1000 Genomes Project phase 3 dataset, using a newly developed model-flexible method called Stairway plot with 36 million non-coding CpG sites genome-wide. Simulation studies were conducted to test the robustness of the inference, and 4 independent population samples were used to verify some of our findings. **Results:** Our results show many population growth events likely due to the Neolithic Revolution (i.e. shifting from hunting and gathering to agriculture and settlement): Han Chinese experienced a dramatic ~10 fold population growth around 8 kya to 12 kya; some South European and South Asian populations also began their long-term population growth around 10 kya but in a more gradual fashion; British and Western European populations began their takeoff around 6-7 kya. The potential agriculture-associated population growth of Luhya in Webuye, Kenya (LWK) came relatively late (no earlier than 3 kya) compared to other African populations, in contrast to the assumption that they are the direct descendants of Bantu-speaking immigrants from West Africa. We also observed several population growth events dated before the introduction of agriculture. **Conclusion:** In this study, we estimated detailed recent human demographic prehistories using a model-flexible approach with the observed polymorphic pattern of CpG transitions. Those prehistories help to shed light on the origins of different populations and the impact of agriculture on human demography. As an exploratory study, our results can be used not only for testing existing hypotheses, as we demonstrated, more importantly they provide new findings and hypotheses for future studies.

**Full genome sequencing of Native American ancestry individuals reveals adaptation to high altitude in the Andes.** *M. Muzzio<sup>1</sup>, A. Dobbyn<sup>2</sup>, J.M.B. Motti<sup>3</sup>, M.C. Yee<sup>4</sup>, S. Kohli<sup>2</sup>, K. Slivinski<sup>2</sup>, M.R. Santos<sup>1</sup>, V. Ramallo<sup>1</sup>, E.L. Alfaro<sup>5</sup>, J.E. Dipierri<sup>5</sup>, G. Bailliet<sup>1</sup>, C.M. Bravi<sup>1</sup>, E.E. Kenny<sup>2</sup>.* 1) IMBICE CONICET UNLP, La Plata, Buenos Aires, Argentina; 2) Mount Sinai School of Medicine, New York, EEUU; 3) CONICET - Laboratorio de Ecología Evolutiva Humana, NEIPHA-FACSO-UNCPBA; 4) Stanford University, California, EEUU; 5) INECHOA (Instituto de Ecorregiones Andinas) UNJu-CONICET. Instituto de Biología de la Altura; Universidad Nacional de Jujuy, San Salvador de Jujuy, Jujuy, Argentina.

**We carried out Whole Genome Sequencing to 4X coverage on blood samples from 14 high-altitude Andean individuals and 11 low-altitude Chaqueño individuals with over 90% Native American ancestry on the Illumina HiSeq2500 platform. We called variants using a pooled analysis in GATK, implementing Unified Genotyper (UG) as the variant calling method. We identified samples with high missingness rates and re-ran the GATK pipeline excluding these individuals, leaving us with 13 highlanders and 9 lowlanders for all subsequent analyses. After filtering, we had a total of 5,232,922 variants remaining. We annotated our variants for genic and functional status with ANNOVAR. FST statistics were calculated using vcftools. The resulting FST statistics were winsorized, and p-values were generated for the resultant exponentially distributed statistics in R. We used DEPICT (Data-driven Expression-Prioritized Integration for Complex Traits) to conduct gene set prioritization and tissue enrichment analyses. We used input variants at multiple FST FDR thresholds (0.01, 0.1, 1 and 5%) and ANNOVAR annotations. At an FDR threshold of 0.01 percent, we identified four genomic regions that are highly differentiated between the low and high altitude populations and a number of genes in these regions could potentially be relevant in the response to high altitude hypoxia. Expanding the analysis to include windows at an FDR threshold of 0.02 percent, we identified an additional nine genomic regions, one of which has previously been implicated in a study of Chronic Mountain Sickness in an Andean population. Finally, in order to gain further biological insights from our high FST variants, we conducted tissue and gene set enrichment analyses using DEPICT. Taking variants at an FST FDR threshold of 1 percent, using all nonsynonymous/stoploss/stopgain variants as input, the tissue enrichment analysis shows the most significant (nominal P-value FDR<5%) enriched tissue to be fetal blood. Taking variants at an FST FDR threshold of 5 percent, again using all nonsynonymous/stoploss/stopgain variants as input, the tissue enrichment analysis shows the three most significantly enriched tissues to be fetal blood, esophagus, and blood, and the most significant enriched gene sets to include multiple lung and oxygen-related processes, such as reactive oxygen species metabolic process (GO:0072593), abnormal vascular endothelial cell physiology (MP:0004003), and superoxide metabolic process (GO:0006801)..**

**Distribution of local ancestry and evidence of positive selection in Brazilian individuals.** *R. Secolin<sup>1,5</sup>, A. Mas<sup>2</sup>, L.R. Araújo<sup>2</sup>, F.R. Torres<sup>1</sup>, T.K. Araujo<sup>1</sup>, M.L. Santos<sup>1</sup>, C.S. Rocha<sup>1,5</sup>, B.S. Carvalho<sup>3,5</sup>, F. Cendes<sup>4,5</sup>, I. Lopes-Cendes<sup>1,5</sup>, D. Comas<sup>2</sup>.* 1) Department of Medical Genetics, School of Medical Sciences, University of Campinas, Campinas, São Paulo, Brazil; 2) Departamento de Ciências Experimentais e de la Salud, Institute of Evolutionary Biology (CSIC-UPF), Universitat Pompeu Fabra, Barcelona, Spain; 3) Department of Statistics, Institute of Mathematics, Statistics and Scientific Computing, University of Campinas, Campinas, São Paulo, Brazil; 4) Department of Neurology, School of Medical Sciences, University of Campinas, Campinas, São Paulo, Brazil; 5) Brazilian Institute of Neuroscience and Neurotechnology (BRAINN), Campinas, São Paulo, Brazil.

**Background:** Admixed populations can be used to identify causal variants related to disease due to the creation of local ancestry tracts across the genome. Although local ancestry information is available for admixed American populations, it is still poorly explored in Brazilian individuals. **Objective:** To describe the distribution and to identify deviations of local ancestry across the genome in a Brazilian sample. Furthermore, if significant deviations in local ancestry are found we aim to further explore the issue by searching for signals of recent natural selection and the possibility of association with disease. **Methods:** We evaluated 264 individuals obtained within the scope of the Brazilian Initiative on Precision Medicine (<http://bipmed.org/>) and compared with the 1000 Genome Project database. Genotyping calling was performed by Genome-Wide Human SNP Array 6.0 platform. We processed the data and evaluated population structure by principal components using PLINK 1.9 software. Global and local ancestry was estimated by ADMIXTURE and RFMIX algorithm, respectively. We identified haplotype inversion events by the *invClust* package in R. We tested ancestry tracts for positive selection using five neutrality statistics combined into a Fisher combined score. **Results:** As expected, Brazilian sample presented a high proportion of South European ancestry, followed by West sub-Saharan African and Native American ancestries. However, local ancestry revealed a decreased European ancestry proportion followed by an excess of Native American ancestry on chromosome 8p23.1. We demonstrated that this deviation is due to haplotypes created by inversion events. Interestingly, Brazilian non-inverted haplotypes were found to be more similar to Native Americans than European haplotypes, different from what was observed for other admixed American populations. We also found signals of recent positive selection on chromosome 8p23.1. **Discussion:** We observed that one gene (*PPP1R3B*) located within the locus at 8p23.1 is related to diet and have already been associated with type 2 diabetes and obesity, which strengthens the positive selection hypothesis. Our results reinforce the need to study additional American admixed populations, avoiding extrapolated conclusions from one to another. Moreover, we show that individual local ancestry can be used to obtain relevant information about the risk of human diseases. Supported by: CEPID-BRAINN FAPESP, and BEPE-PD-FAPESP, São Paulo, Brazil.

**Genetic differentiation and population structure of five endogamous groups of Punjab (North-West India): An analysis of *Alu* insertion and restriction site polymorphisms.** G. Singh<sup>1,2,3</sup>, H. Singh<sup>2</sup>, A.J.S. Bhanwer<sup>2</sup>. 1) Panjab University, Chandigarh, India; 2) Guru Nanak Dev University, Amritsar; 3) Wildlife Institute of India, Dehradun.

The state of Punjab on the North-West Frontier of India has served as a main corridor for all the major invasions into India, particularly of Indo-Europeans. It resulted in the mixing of foreign gene pool into the local population. The present study was designed to explore the genetic diversities and affinities among the five major endogamous groups using autosomal markers. A total of 1021 unrelated samples belonging to Baniyas, Brahmins, Jat Sikhs, Khatri and Scheduled Castes were genotyped for four Ins/Del (*ACE*, *APO*, *PLAT*, *D1*) and six restriction fragment length polymorphisms [*ESR* (*PvuII*), *LPL* (*PvuII*) *T2* (*MspI*) and three *DRD2* (*Taq1A*, *Taq1B*, *Taq1D*)]. All the loci were found to be polymorphic among the studied populations. The average heterozygosity among the studied populations is fairly substantial ranging from 0.3816 in Baniyas to 0.4311 in Scheduled Castes. The genetic differentiation among studied populations ranged from 0.0418-0.0022 for the *PLAT* and *Taq1A* loci, respectively, with an average value being 0.0136. Phylogenetic analysis revealed that Baniyas and Khatri are genetically closest to each other. The Jat Sikhs are genetically close to Brahmins and are distant from the Baniyas. The Jat Sikhs, Baniyas, Brahmins and Khatri are genetically very distant from the Scheduled Castes. Overall, a uniform allele frequency distribution pattern and low level of genetic differentiation was observed in the studied population groups indicating that genetic drift might have been small or negligible in shaping the genetic structure of North-West Indian Populations. .

**Mutation rate estimation with three-way identity by descent.** X. Tian, B.L. Browning, S.R. Browning. University of Washington, Seattle, WA.

We present a new method for mutation rate estimation based on segments of identity by descent (IBD) shared among multiple individuals. The IBD segments arise from common ancestry within the past few thousand years. Therefore, compared to inter-species comparison, our method avoids the potential confounding of mutation rates in humans with those in other closely related species. Our method uses the sharing of IBD segments among three individuals to estimate the mutation rate while controlling for genotype error, hence our method is more robust than parent-offspring trio analysis to genotype errors. Our method is applicable to sequence data with or without close relatives. We demonstrate the accuracy of our method in simulated data under various demographic models and observe that our approach is robust to substantial levels of genotype error. We apply the method to estimate the mutation rate in [how many] individuals from the Framingham Heart Study who were sequenced by the NHLBI TOPMed project (data obtained through dbGaP accession phs000974.v2.p2). We obtain an estimate of  $1.18 \times 10^{-8}$  mutations per basepair per generation with a 95% confidence interval of  $[1.12 \times 10^{-8}, 1.25 \times 10^{-8}]$ . Our estimate is consistent with previous estimates based on parent-offspring trio analysis, but has a tighter confidence interval because it is based on many more meioses.

**Identifying the genetic and environmental determinants of gene expression variation in Africans.** D.E. Kelly<sup>1</sup>, R. Ma<sup>1</sup>, N.G. Crawford<sup>1</sup>, Y. Ren<sup>1</sup>, R.A. Rawlings-Goss<sup>1</sup>, G.R. Grant<sup>1</sup>, M. Yeager<sup>2</sup>, S. Chanock<sup>3</sup>, A. Ranciaro<sup>1</sup>, S. Thompson<sup>1</sup>, J.B. Hirbo<sup>4</sup>, W. Beggs<sup>1</sup>, T.B. Nyambo<sup>5</sup>, S.A. Omar<sup>6</sup>, D.O. Meskel<sup>7</sup>, G. Belay<sup>7</sup>, C.D. Brown<sup>1</sup>, H. Li<sup>1</sup>, S.A. Tishkoff<sup>1</sup>. 1) University of Pennsylvania, Philadelphia, PA; 2) National Institutes of Health, Division of Cancer, Bethesda, MD; 3) Frederick National Laboratory for Cancer Research, Frederick, MD; 4) Vanderbilt University, Nashville, TN; 5) Muhimbili University of Health and Allied Sciences, Salaam, Tanzania; 6) Kenya Medical Research Institute, Nairobi, Kenya; 7) Addis Ababa University, Addis Ababa, Ethiopia.

Gene regulation plays a predominant role in human evolution and complex traits, and high throughput methods are making the measurement of expression variation routine. However, studies to date have failed to capture the breadth of global genetic and environmental diversity by focusing primarily on Western individuals of European descent. Studies of Africans, who harbor the most genetic variation in the world and are exposed to a diversity of environmental variables and diets, are necessary to complete our understanding of how evolution has shaped human genetic and phenotypic diversity. To identify genetic and environmental contributors to gene expression variation in whole blood we have collected RNA sequencing data from 171 individuals representing 9 diverse East African populations. Differential expression analyses uncover genes correlated with ancestry and environmental variables, while cis-eQTL mapping identifies genetic variants contributing to gene expression variation in these samples. The majority of identified eQTLs replicate in Europeans, and those that fail to replicate are enriched for variants that are at moderate frequency in Africa and are low frequency or monomorphic in Europe. Integrating allele frequency differentiation and scans of natural selection, we identify candidate genes and pathways that may have undergone positive selection in these populations, including genes related to liver function in pastoralist populations. This study represents one of the most diverse study of gene expression in Africans to date, providing insights into the impact of adaptation on human gene expression and highlighting the need to extend genomics studies to non-European populations.

**Genomes of 175 Mongolian individuals reveal population specific genetic architecture and genetic relationship with other human populations.**

X. Guo<sup>1,6</sup>, H. Bai<sup>2,4</sup>, N. Narisu<sup>3</sup>, T. Lan<sup>1,6</sup>, Q. Wu<sup>4</sup>, B. Burenbatu<sup>4</sup>, H. Zhou<sup>5</sup>, Y. Yin<sup>1,6,7</sup>. 1) BGI, Shenzhen, Guangdong, China; 2) 1. School of Life Science, Inner Mongolia University for the Nationalities, Tongliao 028000, China; 3) 4. Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD 20892, USA; 4) Affiliated Hospital of Inner Mongolia University for the Nationalities, Tongliao 028000, China; 5) College of Life Science, Inner Mongolia Agricultural University, Hohhot 010018, China; 6) 3. Laboratory of Genomics and Molecular Biomedicine, Department of Biology, University of Copenhagen, DK-2100 Copenhagen, Denmark; 7) 17. School of Life Science and Biotechnology, Dalian University of Technology, Dalian 116024, China.

Approximately 10 million Mongolians currently reside in Mongolia, Northern China, Russia and other neighboring countries. Mongolians played important roles in early human dispersal, like the peopling of the New World, and in the shaping of recent Eurasians, such as the expansion of Mongol Empire. Mongolians are the typical nomadic people and have population specific traditional dietary, which leads to prevalence of related traits/diseases, such as BMI, hypertension, Type 2 Diabetes and so on. However, this interesting ethnic group is still under-studied. In this study, we aim to explore the genetic architecture of the population and their relationship to other ethnic groups in neighboring regions. To address this, blood samples from 175 Mongolians representing 6 ethnic tribes across northern China and Mongolia were sampled. Genomic DNA was extracted and the whole genome was sequenced to an average depth of 22x on Illumina HiSeq2000 platform. We characterized 15.2 million single nucleotide polymorphisms (SNPs), of which 3.9 million (25.8%) are novel when compared against the 1000 Genomes Project (1000G). Using the SNP data, we constructed a high-quality genetic variation reference panel for Mongolians. Our new reference panel fills an important gap between the East Asians and Admixed Americans provided by the 1000G and significantly improves our ability to impute missing genotypes. Although Mongolians most resemble East Asians genetically, however, from the clustering analysis, we observed the evidence of strong population stratification among tribes, and variance among Mongolians exceeds that of other East Asian populations. The structure analysis and patrilineal/matrilineal analysis also showed higher population diversity than other East Asian groups. Demography inference indicated diverse demographic histories among the Mongolian tribes, which approximately correlates with the current population structure. Pairwise estimation of separation time indicates Mongolians and other East Asians separated 7-13 kya but Horchin, whereas the tribes of Mongolians started to differentiate much later. Incorporating our results with the 1000G reveals shared alleles between Finns and Mongolians/Siberians, suggesting the extensive gene flow throughout northern Eurasian populations. Finally, through phylogenetic relationships, we highlight that North, East, and Southeast Asian populations are more aligned with each other than these groups are with South Asian and Oceanian populations. In summary, genomic data and the haplotype panel of Mongolians presented here will be a valuable resource for identifying population specific genetic causes of diseases in Central/North Asia, and exploring human evolutionary scenarios throughout Asia.

**2697W**

**Genetic missense variants at the *EGLN1* locus associated with high-altitude adaptation in Tibetans are rare in Andeans.** *E.S. Lawrence<sup>1</sup>, E.C. Heinrich<sup>1</sup>, L. Wu<sup>1</sup>, F.C. Villafuerte<sup>2</sup>, T.S. Simonson<sup>1</sup>, C.A. Ramirez<sup>2</sup>, A.M. Coel<sup>3</sup>, G.L. Cavalleri<sup>3</sup>.* 1) Medicine, UC San Diego, La Jolla, CA; 2) Facultad de Ciencias y Filosofía, Universidad Peruana Cayetano Heredia (UPCH), Lima, Peru; 3) Department of Molecular & Cellular Therapeutics, Royal College of Surgeons in Ireland, Dublin, Ireland.

High-altitude populations have been challenged by chronic hypoxia for many generations and demonstrate some of the most rapid evolution observed in humans. Genome-wide scans have brought to light numerous hypoxic-response candidate genes that are associated with distinct traits in these populations. One example is *EGLN1*, which shows signals of selection in Tibetan and Andean populations and has been linked to hemoglobin concentration in Tibetans living at high altitude. *EGLN1* encodes the hypoxia-inducible factor (HIF) prolyl hydroxylase 2 (PHD2) protein, which serves as an oxygen-sensitive regulator of HIF transcription factor activity. We determined the frequencies of these adaptive Tibetan alleles in Quechua Andeans residents at high altitude (4,350 m) in addition to individuals of Nepali ancestry resident at sea level. The rs186996510 minor C allele previously found at high genotypic frequency in Tibetans (N=26) (G/G: 0.15; G/C: 0.08; C/C: 0.77) (Lorenzo, et al. 2014), was absent in our Andean cohort (N=106) (G/G: 1.00) and rare among our Nepali cohort (N=17) (G/G: 0.82; G/C: 0.06; C/C: 0.12). The minor G allele of rs12097901 was also found at lower genotypic frequencies in Andeans (C/C: 0.76; C/G: 0.22; G/G: 0.02) and Nepalese (C/C: 0.65; C/G: 0.24; G/G: 0.12) compared to Tibetans (G/G: 0.81; G/C: 0.19; C/C: 0.00). These results suggest that adaptation involving *EGLN1* in Andeans involves different mechanisms than those described in Tibetans. The precise Andean adaptive variants remain to be determined.

**2698T**

**Tankyrase: A promising target to investigate high altitude adaptation/maladaptation.** *M. Miglani<sup>1,2</sup>, M. Rain<sup>2</sup>, M.A.Q. Pasha<sup>2</sup>, A. Vibhuti<sup>1</sup>.* 1) SRM UNIVERSITY, SONEPAT, India; 2) CSIR-IGIB, NEW DELHI.

Telomeres are prone to damage by the ROS produced due to oxidative stresses encountered at high altitude (HA). Tankyrase (TRF-1 interacting ankyrin-related ADP-ribose polymerase) acts as a positive regulator of telomere length as it performs post translational modification during DNA damage. It thus could be an important marker with respect to HA adaptation or maladaptation. The present study investigated the plausible roles of genetic polymorphism of tankyrase gene and its level as a biochemical in three well-defined groups, namely High altitude pulmonary edema-patients (HAPE-p), HAPE-free sojourners (HAPE-f) and healthy highlanders (HLs) comprising 200 samples, each. Genotyping was performed using PCR-RFLP and the protein level was estimated using ELISA and correlations between genotype/allele with protein levels were analysed. Three tankyrase SNPs, rs7015700, rs12541709& rs11991621 were genotyped. The heterozygote rs7015700GA was prevalent in HLs than HAPE-f, hence it may contribute towards adaptation. Tankyrase rs11991621GA also exhibited increased prevalence in HLs over HAPE-f. For both SNPs, heterozygotes were found to be strongly prevalent in HLs over HAPE-f & HAPE-p. HLs have the highest telomere length followed by HAPE-f and HAPE-p ( $p < 0.05$ , HLs v/s HAPE-r; HAPE-p v/s HAPE-r). In a correlation analysis between the heterozygotes and the telomere length, the greater length was observed in HLs than the patients. This phenomenon also suggests that the telomere effect could be multifactorial. HAPE-p had significantly decreased and HLs had marginally reduced concentration of tankyrase as compared to HAPE-f ( $p \leq 0.05$ ). For genotypic & allelic correlations with tankyrase levels, rs7015700GA genotype contributed towards higher levels ( $p < 0.05$ ) in HAPE-f and rs11991621G allele contributed towards higher levels ( $p < 0.05$ ) in HAPE-p. These results suggest that perhaps telomere length is more regulated by telomerase enzyme than the tankyrase. Our findings suggest that Tankyrase levels are high in HAPE-f which is attributed to their role in maintenance of telomere length hence this gene becomes vital to study adaptation/maladaptation at HA. .

**Low-frequency variant functional architectures reveal strength of negative selection across coding and non-coding annotations.** S. Gazal<sup>1,2</sup>, P.-R. Loh<sup>2,3</sup>, H.K. Finucane<sup>2</sup>, A. Ganna<sup>2,4,5</sup>, A. Schoech<sup>1,2,6</sup>, S. Sunyaev<sup>2,3,7</sup>, A.L. Price<sup>1,2,6</sup>.

1) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 3) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts, USA; 4) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 5) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital, Boston, Massachusetts, USA; 6) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; 7) Department of Biomedical Informatics, Harvard Medical School, Boston MA, USA.

Common variant heritability is known to be concentrated in variants within cell-type-specific non-coding functional annotations, with a limited role for common coding variants. However, little is known about the functional architecture of low-frequency variants, which are disproportionately impacted by negative selection. Here, we partitioned the heritability of both low-frequency ( $0.5\% \leq \text{MAF} < 5\%$ ) and common ( $\text{MAF} \geq 5\%$ ) variants in 40 UK Biobank traits (average  $N = 363\text{K}$ ) across a broad set of coding and non-coding functional annotations, employing an extension of stratified LD score regression with the baseline-LD model (Finucane et al. 2015 *Nat Genet*, Gazal et al. 2017 *Nat Genet*) to low-frequency variants that produces robust results in simulations. We determined that non-synonymous coding variants explain  $17 \pm 1\%$  of low-frequency variant heritability ( $h_{\text{ir}}^2$ ) versus only  $2.1 \pm 0.2\%$  of common variant heritability ( $h_{\text{c}}^2$ ), and that regions conserved in primates explain nearly half of  $h_{\text{ir}}^2$  ( $43 \pm 2\%$ ). Other annotations previously linked to negative selection, including non-synonymous variants with high PolyPhen-2 scores, non-synonymous variants in genes under strong selection, and low-LD variants, were also significantly more enriched for  $h_{\text{ir}}^2$  as compared to  $h_{\text{c}}^2$ . Cell-type-specific non-coding annotations that were significantly enriched for  $h_{\text{c}}^2$  of corresponding traits tended to be similarly enriched for  $h_{\text{ir}}^2$  for most traits, but more enriched for brain-related annotations and traits. For example, H3K4me3 marks in brain dorsolateral prefrontal cortex explain  $57 \pm 12\%$  of  $h_{\text{ir}}^2$  vs.  $12 \pm 2\%$  of  $h_{\text{c}}^2$  for neuroticism, implicating the action of negative selection on low-frequency variants affecting gene regulation in the brain. By performing forward simulations at parameter settings consistent with our UK Biobank results, we confirmed that the ratio of low-frequency variant enrichment vs. common variant enrichment primarily depends on the mean selection coefficient of causal variants in the annotation, enabling us to quantify the strength of negative selection across annotations. Furthermore, we used this ratio to predict the effect size variance of causal rare variants ( $\text{MAF} < 0.5\%$ ) in each annotation, informing their prioritization in whole-genome sequencing studies. Our results provide a deeper understanding of low-frequency variant functional architectures and guidelines for the design of association studies targeting functional classes of low-frequency and rare variants.

**Heritability of language and associations with population demography.**

N. Telis<sup>1</sup>, H. Arbel<sup>1</sup>, E.P. Sorokin<sup>1</sup>, M. Zhang<sup>1</sup>, J.M. Granka<sup>1</sup>, E.L. Hong<sup>1</sup>, K.G. Chahine<sup>2</sup>, C.A. Ball<sup>1</sup>. 1) Ancestry.com DNA LLC, San Francisco, CA; 2) Ancestry.com DNA LLC, Lehi, UT.

Language and population structure are intricately connected by human culture. Past studies have found that while language can roughly mirror population genetic patterns, the two diverge, likely because of the relative fluidity and recency of linguistic change. By using a large cohort with rich pedigree information, we are able to examine the relationship between genetics and exceptionally recent linguistic patterns by comparing reported language with reported grandparental language. We characterize the heritabilities of different languages by comparing persistence of reported grandparent language with reported language in their grandchildren. To further explore the connection between recent genetic history and linguistics, we also compare the ethnicity assignments of grandchildren who did and did not maintain their grandparents' languages. We identify connections between recent linguistic retention and subtle genetic differences in subpopulations of language speakers, and use language to further understand subtle population structure arising even within populations sharing language as recently as 2 generations ago.

**Demographic inference with sequential Monte Carlo methods reveals large European back-migration in the Late Pleistocene.** C.B. Cole<sup>1</sup>, D. Henderson<sup>1</sup>, S.J. Zhu<sup>2</sup>, G. Lunter<sup>1</sup>. 1) Wellcome Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Big Data Institute, University of Oxford, Oxford, Oxfordshire, United Kingdom.

**Background:** Mutations within human genomes can be informative about our species' demographic history, and are shaped by a complex mix of migration and admixture events as well as population size changes. Existing methods to infer demography from mutations differ in the approximations made in order to make inference tractable, resulting in a range of compromises between resolution and range the type of demographic events that can be inferred. **Methods:** We explore the use of sequential Monte Carlo techniques applied to the Sequentially Markovian Coalescent (SMC<sup>2</sup>) to infer demographics from whole genome sequencing data. The approach is asymptotically exact, and since Ancestral Recombination Graphs (ARGs) are explicitly simulated, and has the ability to infer directional migration rates between populations. Complex and increasingly realistic models are straightforward to investigate as inference is fundamentally based on simulation. **Results:** Here we analyze the genomes of ancestrally African and non-African individuals using a two-island model with migration. We detect a large migration event from ancestral European individuals back to Africa approximately 50 to 70 thousand years ago. Simulation experiments support this interpretation, and reject scenarios lacking a strong back-migration pulse. We also find that modelling European and African populations jointly with back-migration explains a previously unexplained deep ancestral high diversity signal in single-population analyses of African samples, and shows better alignment of the two population's inferred population sizes through time, with an inferred split time that is closer to the accepted dating of the out-of-Africa event. **Conclusion:** As the fossil record and genetics continue to illuminate a complex out-of-Africa event, additionally powerful and exact methods are needed to describe the demographic histories of particular groups and individuals. Here we introduce a new method for demographic inference from whole-genome data, and show that migrations back to Africa may have played a more substantial role in shaping the genetic diversity of some African populations than previously realised.

**Host genetic control of the microbiome in wild primates.** R. Blekhan<sup>1</sup>, L. Grieneisen<sup>1</sup>, M. Dasari<sup>2</sup>, T. Gould<sup>1</sup>, J.R. Bjork<sup>2</sup>, J.-C. Grenier<sup>2</sup>, V. Yotova<sup>3</sup>, D. Jansen<sup>2</sup>, N. Gotte<sup>4</sup>, J.A. Gilbert<sup>4</sup>, L. Barreiro<sup>3</sup>, J. Tung<sup>5</sup>, E. Archie<sup>1</sup>. 1) University of Minnesota, Minneapolis, MN; 2) University of Notre Dame, Notre Dame, IN; 3) Université de Montréal, Montreal, Québec, Canada; 4) University of Chicago, Chicago, IL; 5) Duke University, Durham, NC.

Variation in gut microbiome composition—defined as the identity and abundance of different bacterial taxa—is linked to key health outcomes in humans and other vertebrates. Variation in the gut microbiome is affected by many environmental factors, but host genetics also has a significant impact on the microbiome. Understanding the relative roles of genetic and environmental factors is a central goal in human disease research. However, it is often difficult to disentangle genetic from environmental effects because relatives often use the same resources and have similar diets. Here, we identified components of the gut microbiome that are associated with host genetics—i.e. heritable microbes—controlling for changes in the host's physical and social environments over time. Specifically, we used an unprecedented dataset of >10,000 microbiome profiles collected over 14 years from a well-studied population of wild savannah baboons (*Papio cynocephalus*) with available host genetic relatedness data. We found that gut microbial composition changes over time and across environments. Specifically, the overall microbiome community composition was affected by baboon social group membership, collection year, and hydrologic season. Controlling for these fluctuations in the physical and social environment, we identified several heritable common bacterial taxa, such that more related individuals had more similar bacterial abundances. Heritable taxa included Christensenellaceae and Rikenellaceae, bacterial families that are also highly heritable in humans, suggesting that common host genetic mechanisms may control microbiome composition across primates. Finally, the relative abundance of heritable taxa changes over time within individuals, emphasizing the importance of longitudinal studies to account for temporal and environmental effects in shaping gut microbial composition. To summarize, we present the first analysis of host genetic control of the gut microbiome in non-human primates, indicating that microbiome heritability is affected by fluctuating environment, and suggesting that heritable microbial taxa may be shared across primate species.

**Patterns of positive selection inferred across the Pacific.** *S. Kaewert<sup>1</sup>, G. Wojcik<sup>2</sup>, E. Sorokin<sup>2</sup>, J. Homburger<sup>2</sup>, C. Quinto-Cortés<sup>4</sup>, A. Ioannidis<sup>5</sup>, J. Portillo<sup>6</sup>, J. Rodriguez<sup>4</sup>, K. Auckland<sup>6</sup>, A. Severson<sup>3</sup>, J. Blanc<sup>7</sup>, G. Belbin<sup>8</sup>, S. Oppenheimer<sup>9</sup>, T. Parks<sup>8</sup>, M. Phipps<sup>8</sup>, K. Robson<sup>8</sup>, E. Kenny<sup>8</sup>, A. Hill<sup>8</sup>, A. Mentzer<sup>6</sup>, C. Bustamante<sup>2</sup>, A. Moreno-Estrada<sup>4</sup>, C. Gignoux<sup>1,10</sup>.* 1) Colorado Center for Personalized Medicine, University of Colorado, Aurora, Colorado, USA; 2) Department of Biomedical Data Science, Stanford University, Stanford, CA; 3) Department of Genetics, Stanford University, Stanford, CA; 4) National Laboratory of Genomics for Biodiversity, Irapuato, Guanajuato, Mexico; 5) Computational and Mathematical Engineering, Stanford University, Palo Alto, CA; 6) University of Oxford, United Kingdom; 7) University of California, Davis, Davis, CA; 8) Icahn School of Medicine at Mount Sinai, New York, NY; 9) Monash University, Malaysia; 10) Department of Biostatistics and Informatics, University of Colorado, Aurora, Colorado, USA.

The unique prehistory of the settlement of the Pacific was a complex demographic event involving numerous migrations and exposure to a wide variety of environmental pressures on new islands. These pressures include the unique disease dynamics present in isolated, high-density populations with intermittent contact. However, the region of Oceania has been understudied in human genetics. Leveraging the data from the new Oceanian Genome Variation Project (OGVP), involving 980 individuals from 88 populations measured on the MEGA platform at over 1.7M sites along the genome, we used a combination of haplotype-based (iHS, nSI, xp-EHH) and differentiation (Fst, SPA) statistics to infer patterns of positive selection unique to regions across the Pacific. The uniquely detailed populations of OGVP allow for hierarchical evidence of selection acting on populations, specific regions, or Oceania as a whole compared to mainland Asia. Enrichment analysis of top selection hits show significant enrichment in genes associated with antigen processing and presentation (Melanesia, Micronesia, Solomon Islands, Southeast Asia), cytokine production (Melanesia and Southeast Asia), cellular defense response (Mainland East Asia, Melanesia, Solomon Islands, Micronesia, Republic of Palau and part of Papua New Guinea), viral process (Coastal Papua New Guinea) and response to interferon-gamma (French Polynesia and Tuvalu)(all FDR < 0.08). These results suggest that disease has played a critical role in the settlement of Oceania. Finally, as recently established, we extend linear mixed effects models to test for significant effects of selection associated with latitude and longitude in a GWAS framework, finding associations with immune genes IL6R (FDR=0.001), IL20RA (FDR=0.004), and C1QA, B, C (FDR=0.003) as well as a general enrichment for genes associated with cellular defense response (FDR=0.03). These results, combined with the relatively low effective population size in the region, suggest that infectious disease has provided a strong selective pressure throughout Oceania.

**2704T**

**A pharmacogenomic variation database of Chinese population based on whole genome sequencing.** *J. Guo, R. Guo, N. Qu, M. Jian, X. Liu.* BGI-Shenzhen, Shenzhen, Guangdong, China.

**Background:** Genetic variations in drug-related genes are responsible for up to 40 percent of individual drug response differences. Previous studies have underlined the importance of rare single nucleotide variants in pharmacogenes which approximately contribute 30-40 percent of functional variability. However, a comprehensive view of pharmacogenetic profiling in Chinese population is lacking. **Methods:** A cohort of 968 healthy independent Chinese individuals covering 30 administrative divisions were recruited. Whole genome sequencing was performed on BGISEQ 500 platform with 100-bp paired-end reads. **Results:** Overall, we have identified 175,283 variants in 229 pharmacogenes that encode 138 phase I and phase II drug metabolizing enzymes, 51 transporters, 40 drug targets and regulators. The majority were single nucleotide variants, and the ratio of transition (Ti, n= 104005) and transversion (Tv, n= 48344) was close to two, which was consistent with the ratio across the whole genome. The total number of variants were normalized by the length of the corresponding gene, yielding 16.7 variants per kbp on average, among them, *CYP2D6* and *SULT1A1* genes had the most variants, which were 43.6 and 43.3 variants per kbp respectively while *UGT1A7* and *UGT1A9* seemed to be most conserved with 1.8 variants per kbp only. In the current study, there were 81383 novel variants discovered compared to dbSNP Build 150 and 119349 variants were firstly reported in east Asian population in comparison with phase III 1000 genome project. Bioinformatics analysis revealed that 53.5 percent (n=93750) of variants were singletons, 10.3 percent were doubletons, and 14.6 percent were rare with minor allele frequency no more than 0.01, and only 21.6 percent were common variants with minor allele frequency more than 0.01. Most of the variants (94.4 percent) were located in the intron region as expected. The composition analysis of exonic variants showed that only 16 percent were synonymous, 30 percent were missense mutations and 50 percent were in UTR which might have functional effects. **Conclusion:** Based on whole genome sequencing technique, our study developed so far, the most comprehensive pharmacogenomic variation dataset in Chinese population. These data could be useful resource for accurate analysis of pharmacogenetic genotyping incorporating not only common and known variants but also rare functional variants to facilitate personalized medicine. .

**The evolution of TLR7 and TLR8 in yellow fever virus endemic areas.** *N. Torosin, L.A. Knapp.* Anthropology Dept, University of Utah, Salt Lake City, UT.

In Misiones, Argentina, howler monkey populations (*Alouatta guariba clamitans*) and (*Alouatta caraya*) were devastated first in 1965, and then in 2008-2009, by Yellow Fever Virus (YFV). Unlike humans and other South American monkeys, howler monkeys are highly susceptible to YFV and die within a week after infection. To better comprehend the relationship between immune function and genetic variation in *Alouatta*, we identified and sequenced two innate immune genes that identify YFV, known as Toll-like receptors (TLR7 and TLR8). Study subjects (N = 41) were from one of three categories: 1) alive prior to the outbreak, 2) died from the virus, or 3) survived the outbreak along with their progeny. No reference genome exists for *Alouatta*, therefore we first performed *de novo* sequencing for one individual of each species and then used Ampliseq to execute targeted sequencing of the genes of interest for the remaining samples. Using these data, along with genetic data previously collected from *Alouatta palliata mexicana* and published primate immune gene sequences, optimal maximum likelihood models of sequence evolution were identified, and phylogenetic trees were created. We compared the allele frequencies of innate immune genes TLR7 and TLR8 from pre-YFV outbreak, post-YFV outbreak, and YFV affected howler individuals using Fishers exact test. Frequencies of twenty-one variants in TLR7 and nine variants in TLR8 were statistically significant between the three groups, suggesting that some TLR variants may provide individuals with better resistance to YFV than others. Our results are valuable for identifying underlying genetic variation that affects susceptibility not only to YFV, but potentially to other single stranded RNA viruses.

**2706W**

**The genetic structure and demographic history of Mexicans of African descent.** *M.C. Ávila-Arcos<sup>1</sup>, S. Ramachandran<sup>1</sup>, A. Moreno-Estrada<sup>2</sup>, M.W. Feldman<sup>3,4</sup>, C.D. Bustamante<sup>3</sup>.* 1) International Laboratory for Human Genome Research, UNAM. Querétaro, Mexico.; 2) Laboratorio Nacional de Genómica para la Biodiversidad, CINVESTAV-IPN, Irapuato, Guanajuato, Mexico; 3) Center for Evolutionary, Computational and Human Genomics, Stanford University, Stanford, CA, USA; 4) Department of Biology, Stanford University, Stanford, CA, USA.

Despite having received 200,000 Africans during the slave trade, no study in Mexico has focused on the characterization of the African genetic ancestry of its Afro-descendant population. In this study we worked together with Afro-Mexican communities to characterize their genetic ancestry using dense genome-wide genotyping. The dataset consists of 380 self-identified Afro-descendants, indigenous and mestizo population from three Mexican states. To complement the genome-wide genotype data, we collected genealogical, self-identification and phenotypes such as skin pigmentation, height, weight, hip to waist ratio and hemoglobin. Genotype data revealed that up to 50% of the genetic ancestry of some individuals is of African origin, with the remaining being mainly of indigenous origin. By exploring local ancestry and admixture patterns in this population, as well as correlations between the genetic ancestry, self-identification and phenotypes; we have characterized aspects of their demographic history and some trends of public health relevance. Lastly, since Afro-Mexicans currently suffer from poverty, discrimination, lack of recognition as a vulnerable minority, and limited access to health services, this study contributes to their appreciation as part of Mexico's mosaic of diversity and will hopefully set the stage for health interventions.

**Reconstructing the history of the Native American populations from Brazilian coast.** *T. Hünemeier<sup>1</sup>, M. Castro-Araújo<sup>1</sup>, A. Mas<sup>2,4</sup>, K. Nunes<sup>1</sup>, M.C. Bortolin<sup>1</sup>, F.M. Salzano<sup>2</sup>, A. Pereira<sup>3</sup>, D. Comas<sup>4</sup>.* 1) Genetics and Evolutionary Biology, University of São Paulo, Brazil; 2) Department of Genetics, Federal University of Rio Grande do Sul, Porto Alegre, Brazil; 3) Laboratory of Genetics and Molecular Cardiology, Heart Institute (InCor), University of São Paulo Medical School Hospital, São Paulo, Brazil; 4) Institut de Biologia Evolutiva, Universitat Pompeu Fabra, Barcelona, Spain.

When Portuguese first arrived at Northeast Brazilian coast around 500 years ago, the first native population with whom they made contact were the Tupiniquins. After the Conquest, a reduction of 95% in the autochthonous population is estimated to have happened due to the introduction of European infectious diseases, slave trade and warfare. In 1876 the total population of Tupiniquins decayed to just 55 individuals, and they were declared extinct soon after. However, in the middle of the XX century some admixed individuals were culturally identified as belonging to the Tupiniquin group. Although these group is considered culturally related to the extinct Tupiniquin population, they do not speak any native language and there is no clear evidence whether this community is genetically related to the extinct tribe of the Conquest time or another autochthonous population resulting from the admixture of different people belonging to the Tupí and Jean groups (the two main Brazilian autochthonous linguistic stocks), such as the Guarani people that has lived in the same region during the last century. Here we investigated the genomic origins of this self-declared Tupiniquin group by studying their extant population (n=50) as well as other native populations geographically and linguistic related to them (n=133). We also used the Tupiniquin to try elucidated the dispersion these group along Brazilian coast around 2000 years before present. Our results showed that the individuals self-declared as Tupiniquin presented a Native American ancestry not closely related to any other Brazilian Native extant population, and so could be the only living representatives of the coastal Tupí branch, representing genetically the populations that were extinct after the Conquest.

**How genetic disease risks can be misestimated across global populations.** *M. Kim, J. Lachance.* Georgia Institute of Technology, North Ave NW, Atlanta, GA 30332.

Accurate assessment of health disparities requires unbiased knowledge of genetic risks in different populations. Unfortunately, most genome-wide association studies use genotyping arrays and European samples. Here, we integrate whole genome sequence data, GWAS results, and computer simulations to examine how genetic disease risks can be misestimated. We find that genetic disease risks are substantially overestimated for individuals with African ancestry. These patterns hold for multiple disease classes (e.g., cancer, gastrointestinal, morphological, and neurological diseases). A contributing factor to this bias is that existing genotyping arrays are enriched for SNPs that have higher frequencies of ancestral alleles in Africa. By simulating GWAS with different study populations, we find that non-African cohorts yield disease associations that have biased allele frequencies and that African cohorts yield disease associations that are relatively free of bias. We also find empirical evidence that genotyping arrays and SNP ascertainment bias contribute to continental differences in risk allele frequencies. Because of these causes, polygenic risk scores can be grossly misestimated for individuals of African descent. Importantly, continental differences in risk allele frequencies are only moderately reduced if GWAS use whole genome sequences and thousands of cases and controls. Finally, our study demonstrates continental differences in allele frequencies also depend upon SNP age. Comparisons between uncorrected and corrected genetic risk scores reveal the benefits of taking into account whether risk alleles are ancestral or derived. This demonstrates that evolutionary history can influence predictions of complex traits, including polygenic disease risks. In sum, our results imply that caution must be taken when extrapolating GWAS results from one population to predict disease risks in another population.

**The impact of genetic admixture and natural selection on driving population differences in East Asia.** S. Xu. CAS-MPG Partner Institute for Computational Biology, Shanghai, Shanghai, China.

Genetic admixture in human, the result of inter-marriage among people from different well-differentiated populations, has been a common phenomenon throughout the history of modern humans. Understanding of population admixture dynamics is important not only to mapping human complex traits/diseases but also to other applications, such as elucidating population history and detecting natural selection signatures. By analyzing the genomes collected from several East Asian populations together with many present-day and ancient human genomic data, we propose that gene flow (recent population admixture and ancient genetic introgression), as an evolutionary driving force and also an under-investigated one, played an important role in shaping human genetic diversity and population adaptive divergence in East Asia.

**Fine-scale population structure of European Land's end: Genetics of North Western France and the Loire River.** C. Dina<sup>1</sup>, J. Gienza<sup>1</sup>, I. Alves<sup>1</sup>, M. Karakachoff<sup>1</sup>, A. Saint-Pierre<sup>2</sup>, P. Lindebaum<sup>1</sup>, E. Svensson<sup>3</sup>, E. Charpentier<sup>1</sup>, K. Rouault<sup>4</sup>, E. Baron<sup>1</sup>, S. Bonnaud<sup>1</sup>, T. Ludwig<sup>5</sup>, S. Lecointe<sup>1</sup>, C. Berthelier<sup>1</sup>, E. Gallic<sup>4</sup>, A. Charpentier<sup>1</sup>, C. Férec<sup>2</sup>, H. Le Marec<sup>1</sup>, R. Olaso<sup>6</sup>, S. Chatel<sup>1</sup>, V. Meyer<sup>6</sup>, A. Boland<sup>6</sup>, M. Jakobsson<sup>3</sup>, P. Darlu<sup>5</sup>, J.-J. Schott<sup>1</sup>, J.-F. Deleuze<sup>6</sup>, E. Génin<sup>2</sup>, R. Redon<sup>1</sup>. 1) l'institut du thorax, INSERM, CNRS, UNIV Nantes, CHU Nantes, Nantes, France; 2) UMR 1078 Génétique, Génomique fonctionnelle et Biotechnologies, Inserm, Université de Brest, EFS, CHU Brest, Brest, France; 3) Department of Evolutionary Biology, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden; 4) Université de Rennes; 5) CNRS/ MNHN/ Université Paris Diderot, UMR 7206 Eco-anthropologie et ethnobiologie; 6) Centre National de Recherche en Génomique Humaine - CNRGH DRF - CEA, Evry France.

Characterising the genetic structure of human populations provides insight into demographical history and informs research on disease association studies. In this study, we examine the fine-scale genetic structure of French Brittany, Anjou, Poitou and Maine. This Peninsula spans from continental area to a final edge called Finistère ("end of Lands") with Loire River as the only physical barrier, covering 60 000km<sup>2</sup> and extending 470 km from west to east. Combining array genotypes, whole genome sequence, surname and genealogy distribution data and ancient DNA we characterize the fine-scale population structure of this area and identify relation with history. **Methods Results** We genotyped 3500 individuals with grandparents born in northwestern France on Axiom™ PMRA. A subset of 400 individuals, together with 4 local medieval individuals, were sequenced whole genome using Illumina Ten X. Principal Components are highly correlated with geographical coordinates ( $p < 2e-16$ ). Genetic distances are highly correlated with surname-based and genealogy distances (Mantel test,  $r = 0.8$  and  $r=0.3$ ). Analysis based on haplotype structure, using "chromosome painting", confirmed this fine-scale structure. The initial division occurs between North and South of Loire, the second one reflects historical border of Brittany. At the finest level, we obtained 79 clusters with more than ten individuals (154 in total) revealing more detailed structure. We observed a pattern of gradual increase of average runs of homozygosity towards the end of the Brittany, with local historically interesting hotspots. Consistently, higher levels of IBD sharing appeared in Brittany, increasing towards the cape. Using IBD sharing, we were able to identify the recent exponential growth in effective population size already seen in European populations but subgroups may have followed different trajectories in the last 25 generations. The WGS SFS confirmed the previous observations and showed a decrease in singletons in Brittany, with a westwards gradient, reflecting stratification or smaller effective population size. **Conclusion** We here report existence of a fine-scale structure across western France, with evidence of distinct demographic histories between subpopulations. To our knowledge this is the first observations of a coincidence of geographical and historical limits with genetic barriers at such a small geographical level in Europe. We are presenting results combining a large variety of information .

The settlement of Oceania represents a uniquely structured, final chapter in the historical founding events of the human species. Resolving the detailed sequences of islands settled and dates of settlement requires careful attention to both haplotype and genetic drift based methodologies. These must be developed within a framework that accounts for the confounding effects of subsequent waves of complex admixture (Melanesian and European). We will present methodologies for analyzing these island populations that we have developed across two different large studies (the Oceanian Genome Variation Project: 980 individuals from 88 populations genotyped at 1.7M sites and a eastern-Pacific dataset comprising 500 individuals from 20 populations genotyped at 700k sites). We introduce an algorithm for graph reconstruction based on combining directionality measures with dissimilarity measures, a method for dating settlement based on haplotypes, and a PCA-like matrix completion-based method for visualizing ancestry-specific patterns of population differentiation. Based on these new methods we will present new findings about the origin and timing of specific migrations, including strong evidence for a complex pre-European admixture event between Polynesians and Native Americans.

**An initiative for genetic data collection from underrepresented countries and populations.** K.F. McManus, M. Moreno, J. Kim, K. Bryc, J. Mountain, . 23andMe Research Team. 23andMe, San Francisco, CA.

It is well-known that currently available human genetic data do not adequately represent the breadth and depth of the world's diversity. The lack of genetic research on people of diverse ancestries greatly limits a comprehensive understanding of genetic variation in *Homo sapiens*, as well as hinders understanding of genetic disease risk in populations underrepresented in genetic research. 23andMe's Global Genetics Project, launched in 2018, seeks to genotype individuals with four grandparents from large populations throughout the world that are underrepresented in genetic research. This initiative follows our 2016-17 African Genetics Project, which enrolled over 1,100 people with four grandparents from certain African countries, including hundreds of samples from each of Ethiopia, Somalia and Sudan. Over the next few years, we aim to enroll 6,000 participants representing 62 countries in regions including central, western and southeastern Asia; northern, western and southern Africa; Oceania; and Central and South America. Consenting participants, who are recruited from the US, are asked to provide a saliva sample and complete a survey about their family's birthplaces, cultural affiliations and languages. These data will be used for a variety of ancestry and health research projects. For ancestry research, they will be used to improve understanding of population structure, diversity and migrations throughout the world. They will be used to further health research in underrepresented populations by exploring models of disease risk in these populations.

**Identification and characterization of *AluYRa1* exonization event in cynomolgus macaque genome.** H. Cho<sup>1,2</sup>, Y. Kim<sup>1,2</sup>, S. Park<sup>1</sup>, J. Lee<sup>1</sup>, S. Choe<sup>1,2</sup>, J. Huh<sup>1,2</sup>. 1) National Primate Research Center, Korea Research Institute of Bioscience and Biotechnology(KRIBB), 30 Yeongudanji-ro, Ochang-eup, Cheongwon-gu, Cheongju-si, Chungcheongbuk-do, Korea; 2) Department of Functional Genomics, KRIBB School of Bioscience, Korea University of Science & Technology(UST), 217 Gajeong-ro, Yuseong-gu, Daejeon, Korea.

Transposable elements (TEs) moving around the genome are considered as a powerful source in gene transcript diversification by being involved in RNA splicing process. *AluYRa1*, one of TEs, has previously been identified in rhesus macaque genome. In this study, we found that some of *AluYRa1* are forward-oriented and located at the end of several genes by in-silico analysis of crab-eating monkey genome. To investigate this phenomenon, further detailed computational analysis of recently registered mRNA sequences and experimental validation were performed. Computational analysis revealed that 9 genes, *GTPBP4*, *PEX26*, *IRF9*, *BLOC1S6*, *TK2*, *CMBL*, *SLC16A14*, *PDK4* and *UBE2B* are expected to contain forward-oriented *AluYRa1* at their ends. Therefore, we carried out PCR for the target site of these genes to analyze both species specificity and evolutionary insertion time of *AluYRa1* and RT-PCR to check expression pattern of them. Our results show that *AluYRa1* is distributed in rhesus monkey and crab-eating monkey, and forward-oriented *AluYRa1* at 3'UTR tends to provide proper environment for alternative polyadenylation. Additionally, this element shows polymorphic insertion pattern in *TK2* and *PDK4*. In conclusion, *AluYRa1* is one of Old World monkey specific TEs contributing to gene transcript diversity with forward oriented insertion pattern specifically by alternative polyadenylation.

**Tracing changes in gene regulation during human evolution by imputing ancient gene expression.** L.L. Colbran<sup>1</sup>, M.R. Johnson<sup>2</sup>, E.R. Gamazon<sup>1,3</sup>, P. Evans<sup>1</sup>, N.J. Cox<sup>1</sup>, J.A. Capra<sup>1,4</sup>. 1) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 2) Vanderbilt School for Science and Math, Vanderbilt University, Nashville, TN; 3) Clare Hall, University of Cambridge, Cambridge, United Kingdom; 4) Department of Biological Sciences, Vanderbilt University, Nashville, TN.

Despite multiple interbreeding events, the majority of the Neanderthal genome does not persist in modern human genomes, and the demographic and selective pressures that determined the landscape of remaining Neanderthal sequences are unresolved. Given the importance of changes in gene regulation to the evolution of differences between species, we hypothesized that gene regulatory divergence between modern humans and Neanderthals was a driver of loss of introgressed Neanderthal DNA. We tested this by adapting the PrediXcan approach to impute the effects of absent Neanderthal DNA on modern human gene regulation and identified 1,345 genes with significant evidence for differential regulation by non-introgressed Neanderthal DNA. Integrating data from Vanderbilt University's BioVU biobank, we demonstrated that human variation in the regulation of these genes is associated with neurological and immune phenotypes, with significant enrichment for mental disorders. This suggests that effects on regulation, especially in the brain, were likely a barrier to introgression of Neanderthal DNA. We also compared the imputed gene regulation of two Neanderthals and a Denisovan, revealing variation in immune system regulation between archaic populations that likely reflects of differing environmental pressures between them. Since diverging from their last common ancestor with Neanderthals, human gene regulation has continued to evolve in response to environmental and cultural shifts. To identify potentially adaptive gene regulation changes, we expanded our analyses to include the rapidly-increasing number of samples from ancient humans. In our pilot analysis, we imputed expression and analyzed differences in 12 ancient Hungarians spanning from 5,710 calBC to 1,180 calBC that encompass substantial shifts in diet and lifestyle. We identified 196 genes that were differentially regulated between the oldest and youngest samples, including four genes associated with gluconeogenesis and seven involved in mitochondrion organization. These differentially regulated genes suggest that genetic changes influenced metabolism across the timespan and highlight specific genes and pathways. Overall, our results establish substantial differences in gene regulatory architecture between humans and archaic hominins and demonstrate the potential of this method for studying patterns of gene regulation in ancient humans.

**Genomics of ancient Brazilian populations.** *D.I. Cruz Dávalos<sup>1,2</sup>, M. Allentoff<sup>3</sup>, S. Reis<sup>4</sup>, M. Bastos<sup>4</sup>, J. Stenderup<sup>3</sup>, C.S. Reyna Blanco<sup>5</sup>, S. Neuenschwander<sup>1,2</sup>, V. Moreno-Mayar<sup>3</sup>, C. Rodrigues-Carvalho<sup>4</sup>, E. Willerslev<sup>3</sup>, M.C. Ávila Arcos<sup>6</sup>, A.S. Malaspina<sup>1,2</sup>.* 1) Department of Computational Biology, University of Lausanne, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) Centre for GeoGenetics, University of Copenhagen, Copenhagen, Denmark; 4) Setor de Antropologia Biológica, Museu Nacional, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil; 5) Department of Biology, University of Fribourg, Fribourg, Switzerland; 6) International Laboratory for Human Genome Research, National Autonomous University of Mexico, Juriquilla, Mexico.

When the Portuguese settlers arrived in Brazil, they named “Botocudos” the Central-Eastern inhabitants who wore wooden lip and ear plates. The Botocudos actually comprised several cultural groups speaking distinct languages. Most of the Botocudo groups became extinct by the end of the 19<sup>th</sup> century, when the Portuguese Crown declared war to all indigenous tribes that refused to accept the regime. The National Museum of Rio de Janeiro owns a collection of 35 Botocudo skulls. While analyzing the mitochondrial DNA of 14 of these samples, Gonçalves et al. identified two individuals with Polynesian haplogroups. The ancestry of those individuals was further explored at the nuclear level by Malaspina et al., who determined that both samples had a Polynesian ancestry without signs of admixture from Native American or African populations. Several scenarios were put forward to explain those results including that these individuals arrived in the Americas as part of the Polynesian expansion, or as crew or passenger members in European ships. Here, we report preliminary genomic data from 21 individuals from the Botocudo collection. We perform population genetic analyses to characterize and identify the population structure of those samples. Finally, we specifically look into whether any of our samples had a genetic affinity to non-Native American populations.

**2716T**

**Mount Lebanon provides an opportunity to study DNA from the ancient Near East.** *M. Haber<sup>1</sup>, Y. Xue<sup>1</sup>, C. Scheib<sup>2</sup>, C. Doumet-Serha<sup>3</sup>, T. Kivisild<sup>4</sup>, C. Tyler-Smith<sup>1</sup>.* 1) Wellcome Sanger Institute, Cambridge, United Kingdom; 2) Estonian Biocentre, Institute of Genomics, University of Tartu, Estonia; 3) The Sidon excavation, Saida, Lebanon; 4) Department of Archaeology, University of Cambridge, Cambridge, United Kingdom.

The hot climate of the Near East has limited the study of ancient DNA from this region. Here, we sequenced five whole genomes from ~1,600-year-old individuals who lived during the Roman period in a village in Mount Lebanon. We consistently found surviving endogenous DNA in the petrous bones of the ancient individuals and we attribute this success to the mild climate of Mount Lebanon. The ancient individuals derived most of their ancestry from a population modelled by previously-reported Bronze Age individuals who lived on the Lebanese coast or inland in Jordan. In addition, we found steppe-like ancestry in the Roman Period individuals which we have previously detected in present-day Lebanese but not in Bronze Age individuals. This supports our previous proposition that the steppe ancestry penetrated the region more than 2,000 years ago, and genetic continuity in Lebanon is substantial. Our results show that individuals inhabiting the Mount Lebanon range likely shared similar ancestry with contemporaneous people living elsewhere in the region, but have higher chances of endogenous DNA surviving today and thus provide an opportunity to study past events more easily than in lowland Near Eastern samples.

**2717F**

**Ancient DNAs from China and the origin of the Neolithic Chinese super-grandfather Y haplotypes.** S. Huang<sup>1</sup>, Y. Zhang<sup>1</sup>, X. Lei<sup>1</sup>, H. Chen<sup>1</sup>, H. Zhou<sup>2</sup>. 1) Central South University, Changsha, China; 2) Jilin University, Changchun, China.

Previous studies identified 3 Neolithic Han Chinese super-grandfather Y haplotypes, F5, F46, and F11, but their relationships with the fossil and archaeology records remain unexplored. We here report genome wide DNA sequencing data ( ) for 12 ancient human samples from China ranging from 6500 to 3000 years before present. They were found to lie largely within the variation range of present day East Asians and belong to 4 different groups based on autosomal distances among them, Dashanqian (DSQ) of Xiajiadian culture in the Northeast, Banpo (BP) of early Yangshao culture in the Central West, Zhengzhou Xishan (ZX) of Miaodigou culture in the Central Plains, and Others. Present day F5 samples were closer to the ZX and DSQ groups while F11, C, O1, and O2 samples were closer to the BP group. We also sequenced the Y chromosome of one of the DSQ samples, K12, and found him to carry the haplotype O2a2b1a1a1a2a-F2137. Our analyses indicated gene flows from ZX to DSQ and to Southwest Chinese carrying the F5 subtype O2a2b1a1a6. These results linked F5 with the Miaodigou culture in Central China and F11 with the early Yangshao culture, which is remarkably consistent with archaeological and historical records.

**2718W**

**Tracing the evolution of pigmentation-associated variants in Europe.** D. Ju, I. Mathieson. Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Human skin pigmentation is highly differentiated among populations. This variation has been shaped by both demography and selection driven by adaptation to local levels of UV radiation. Ancient DNA studies have provided direct evidence that alleles associated with light pigmentation in present-day Europe were at much lower frequencies in the past 10,000 years. However, to date, these studies have focused on a small number of large-effect loci and have not considered the wide range of variants involved in this polygenic trait. To study the evolutionary history of pigmentation-associated variants in Europe, we first compiled a list of 43 variants associated with skin pigmentation in present-day populations. From this list, we computed pigmentation polygenic risk scores (PRS) for 1,030 ancient humans dating from 45,000-100 years BP as well as 2,814 present-day individuals. The oldest ancient Europeans (45-20,000 years BP) have pigmentation-associated variation within the range of present-day African populations, as shown both by the PRS and PCA of pigmentation-associated variants. Light pigmentation-associated variation increased in frequency over time ( $p=5.36E-33$ ), a trend which persists when controlling for geography and ancestry ( $p=0.00114$ ). All three major populations present in Holocene Europe (Early Farmers, Hunter-Gatherers and Steppe) show similar increases in light pigmentation-associated variation. While the majority of light pigmentation associated alleles rose in frequency over time, others decreased due to drift and gene flow. To better understand the contribution of individual variants, we examined the behavior of each SNP in our PRS. We determined the factors driving each SNP with regression models and found that 17% of SNPs showed strong evidence for selection while 44% and 22% were driven by ancestry and geography respectively, demonstrating that only a subset of pigmentation-associated loci were strongly selected. Furthermore, we found that a majority of SNPs under selection were polymorphic in the earliest Europeans. We therefore demonstrate a robust trend of depigmentation in Europe over the past 45,000 years driven by both selection and demographic transitions. Finally, we investigate similar trends in the evolution of variants associated with hair and eye pigmentation.

**2719T**

**Investigating Sardinian population history with ancient DNA.** *J.H. Marcus<sup>1</sup>, C. Posth<sup>2,8</sup>, H. Ringbauer<sup>1</sup>, L. Lai<sup>11</sup>, C. Sidore<sup>4,5,6</sup>, J. Beckett<sup>13</sup>, H. Al-asa-dī<sup>2,3</sup>, A. Furtwängler<sup>9</sup>, M. Zoledziewska<sup>4</sup>, C. Chiang<sup>12</sup>, K. Dey<sup>3</sup>, M. Gradoli<sup>4</sup>, G. Abecasis<sup>5</sup>, D. Schlessinger<sup>9</sup>, R. Skeates<sup>10</sup>, J. Krause<sup>7,8</sup>, J. Novembre<sup>1,2</sup>, F. Cucca<sup>4,6</sup>.* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Ecology and Evolution, University of Chicago, IL; 3) Department of Statistics, University of Chicago, Chicago, IL; 4) Istituto di Ricerca Genetica e Biomedica, CNR, Cagliari, Italy; 5) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI; 6) Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy; 7) Max Planck Institute for the Science of Human History, Jena, Germany; 8) Institute for Archaeological Sciences, Archaeo- and Palaeogenetics, University of Tübingen, Tübingen, Germany; 9) Laboratory of Genetics, NIA, NIH, Baltimore, MD; 10) Department of Archaeology, Durham University, Durham, England; 11) Department of Anthropology, University of South Florida, Tampa, FL; 12) Center for Genetic Epidemiology, Keck School of Medicine, University of Southern California, Los Angeles, CA; 13) Independent Contractor, Cagliari, Italy; 14) School of Archaeology and Ancient History, University of Leicester, Leicester, United Kingdom.

The sequencing of ancient DNA (aDNA) has provided new understanding into human movement and demography for many regions around the globe. For mainland Europe, ancient DNA studies have revealed a dynamic history, with major inferred population influxes due to Neolithic and Bronze Age expansions. The population of the Mediterranean island of Sardinia has been notable in these studies—typically aDNA samples of the early Neolithic on mainland Europe cluster with modern Sardinian samples. The standing model is that Sardinia had a high influx of Neolithic ancestry followed by relative isolation from the mainland and subsequent Bronze Age expansions. To gain further insight, we analyze genome-wide capture data (~1.2 millions SNPs) of 26 ancient Sardinians spanning the Neolithic, Copper Age, and Bronze Age, including individuals from Sardinia's Nuragic culture. Merging this novel data with 998 previously studied aDNA samples from across Europe and throughout the last ten millennia, we are able to place the ancient Sardinian samples into the broader context of the peopling of Europe. We confirm that ancient Sardinian samples show a strong affinity to early Neolithic samples and a near complete absence of the "Steppe" ancestry associated with Bronze Age expansions on the mainland. Interestingly, we also detect elevated affinities with pre-Neolithic peoples of Europe. Moreover, we studied genetic change through time within Sardinia. To this end, we analyzed whole-genome sequence data from approximately 1,500 modern Sardinian individuals, densely sampled across much of the island. Using our ancient samples enables us to detect significant signs of recent admixture, in particular with a strong influence from the Mediterranean region. We also find that populations from the more isolated mountainous provinces of Sardinia are less admixed and have experienced high levels of genetic drift. Overall, our analysis allows us to shed new light on the intriguing history of the peopling of Sardinia.

**2720F**

**Reversing the bottleneck: Neanderthals as a genetic reservoir for functional alleles lost in the Eurasian migration out of Africa.** *D.C. Rinker<sup>1</sup>, C.N. Simonti<sup>2</sup>, J.A. Capra<sup>1,3</sup>, D. Shaw<sup>2</sup>, E. Hodges<sup>3</sup>.* 1) Dept Biological Sciences, Vanderbilt University, Nashville, TN; 2) Dept Biological Sciences, Georgia Institute of Technology, Atlanta, GA; 3) Vanderbilt Genetics Institute, Vanderbilt School of Medicine, Nashville, TN.

The ancestral populations of Neanderthals and modern Eurasians each experienced genetic bottlenecks during their respective migrations out of Africa (OOA), with each population likely retaining ancestral variants lost in the other. Thus, introgression of Neanderthal DNA into the ancestors of Eurasians had the potential to reintroduce variants lost in the later OOA bottleneck. To evaluate the likelihood of this scenario, we simulated the two OOA bottlenecks followed by introgression under a range of evolutionary parameters. The simulations demonstrate that reintroduction of lost alleles by introgression was likely very common, predicting one reintroduced lost allele (RA) for every two Neanderthal-derived alleles in modern Eurasians. Furthermore, our models show a disparity in the fitness consequences of these alleles depending upon their evolutionary trajectory into modern Eurasians. Ancient variants introgressed into Eurasians exclusively through Neanderthals are predicted to be more deleterious than variants carried OOA with Eurasians, yet less deleterious than alleles of Neanderthal origin. Analyses of introgressed sequences in modern Eurasians identify tens of thousands of candidate RAs and support the results of our simulations. The observed ratio of RAs to Neanderthal-derived alleles (1:1.9) is very close to the ratio observed in simulations. Moreover, variant effect predictions using both functional (RegulomeDB) and machine learning (CADD) approaches confirm that RAs are less deleterious than Neanderthal-derived variants. We also identified 34 RAs that are eQTLs in lymphoblastoid cells from both Europeans and non-introgressed Africans. This indicates that RAs are often functional. These results suggest that introgressed haplotypes harbor variants with mixtures of fitness effects based on their origins. This raises the provocative possibility that the persistence of some Neanderthal variants may be due to genetic hitchhiking with functional RAs. Research into the consequences of Neanderthal introgression in modern Eurasians has focused almost exclusively on alleles of Neanderthal origin. Here we highlight the presence of ancient alleles on introgressed haplotypes. These RAs were African in origin but lost in the Eurasian OOA migration. Neanderthal introgression reintroduced these variants back into Eurasian populations, and their less- deleterious fitness effects may have facilitated the persistence of some Neanderthal variants.

**Ancient DNA reveals signatures of selection on disease-associated variants from GWAS.** C.N. Simonti, J.L. Lachance. Department of Biological Sciences, Georgia Institute of Technology, Atlanta, GA.

Selection during recent human evolution has altered allele frequencies of both adaptive and disease-causing variants in modern populations. Genetic data from ancient humans has provided new evidence in the study of adaptive loci thought to be under historic selection, and thus is a powerful tool for identifying instances of selection that might be missed by methods that use present-day samples alone. Using a curated set of ~2,700 variants from the NHGRI-EBI GWAS Catalog and samples from 20 ancient DNA studies, we provide an analysis to identify disease-associated variants that bear signatures of selection over time. We accounted for the fact that not every ancient individual contributed equally to modern genomes by determining the maximum potential contribution of 145 ancient samples to modern individuals of European descent. We then used a Bayesian inference method to infer allele frequency trajectories over time, and determine which disease-associated loci exhibit signatures of natural selection. Using a demographic model of constant population size over time, we find that 557 of 2,716 variants (20.5%) show signatures of modest selection ( $s > 0.001$ ). Unsurprisingly, variants found in the MHC locus show increased signatures of selection (58 of 148; 39.2%), but do not drive the overall pattern. Additionally, we find that protective alleles are more likely to increase in frequency over time (i.e. they appear to be positively selected) than alleles that increase the risk of complex diseases; however, allele frequencies of many risk alleles have increased over time. While these patterns could arise due to phenomena such as pleiotropy or genetic hitchhiking rather than selection, they are still informative about changes in associated traits over time. Overall, these results demonstrate the potential of ancient DNA to improve our understanding of how variants associated with disease or benign phenotypes have changed in frequency over time and the likelihood that selection has acted on them. Ancient samples allow us an unprecedented look at how our species has changed over time, which can only improve with additional samples and improvements in methods used to infer selection from time series data. Our results represent an important early step in using this new source of data to better understand how disease risk has changed over time.

**Detecting tracts of introgressed Neanderthal ancestry in genomic sequence data of modern humans.** M. Steinruecken<sup>1,2,3</sup>, J.P. Spence<sup>4</sup>, J.A. Kamm<sup>5</sup>, E. Wiecek<sup>6</sup>, Y.S. Song<sup>3,5,7</sup>. 1) Department of Ecology and Evolution, University of Chicago, Chicago, IL, USA; 2) Department of Biostatistics and Epidemiology, University of Massachusetts, Amherst, MA, USA; 3) Department of EECS, University of California, Berkeley, CA, USA; 4) Computational Biology Graduate Group, University of California, Berkeley, CA, USA; 5) Department of Statistics, University of California, Berkeley, CA, USA; 6) Department of Mathematics, University of California, Berkeley, CA, USA; 7) Chan Zuckerberg Biohub, San Francisco, CA, USA.

Genetic evidence revealed that the ancestors of non-African humans and their hominin sister groups, notably the Neanderthals, exchanged genetic material in the past, and traces of this introgression can still be found in sequence data of modern day humans. Uncovering these tracts has received a lot of attention in recent years. Their distribution not only provides insight into the complex population structure and migration history relating these ancient populations, it also enables studying the adaptive processes that lead to the accumulation or depletion of introgressed genetic variants in certain regions of the genome. Recent efforts to detect these introgression tracts reported long regions depleted of Neanderthal ancestry that are enriched in genes, suggesting general negative selection against the Neanderthal variants. Furthermore, some allelic variants associated with genetic diseases are likely to originate from the Neanderthal population. On the other hand, enriched Neanderthal ancestry in hair and skin related genes suggests that the introgressed variants helped modern humans to adapt to non-African environments. Here we present a Hidden Markov Model framework that allows efficient detection of the introgressed tracts, using a reference sequence for the Neanderthal population. We demonstrate through extensive simulations that our method can be used to accurately and efficiently detect introgression. Furthermore, we apply our method to sequence data of modern humans from the 1000 genomes project and a high coverage Neanderthal individual from the Altai mountains. Our results are in general agreement with previously obtained results, and we will discuss similarities, differences, and functional implications.

***LILRB1/ILT2* polymorphisms detected in Brazil reveal a conserved locus with polymorphism frequencies influenced by ancestry.** *E.C. Castelli<sup>1</sup>, M.L.G. Oliveira<sup>2</sup>, M.A. Paz<sup>1</sup>, A.S. Souza<sup>1</sup>, L.C. Veiga-Castelli<sup>2</sup>, L. Marcorin<sup>2</sup>, G. Debortoli<sup>2</sup>, A.L.E. Pereira<sup>2</sup>, N.C.A. Fracasso<sup>2</sup>, G.V. Silva<sup>3</sup>, A.L. Simões<sup>2</sup>, A. Sabbagh<sup>4</sup>, E.A. Donadi<sup>5</sup>, C.T. Mendes-Junior<sup>2</sup>.* 1) São Paulo State University (UNESP), Molecular Genetics and Bioinformatics Laboratory, School of Medicine, Botucatu, State of São Paulo, Brazil; 2) Departamento de Genética, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, 14049-900, Ribeirão Preto-SP, Brazil; 3) Departamento de Química, Laboratório de Pesquisas Forenses e Genômicas, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, 14040-901, Ribeirão Preto-SP, Brazil; 4) UMR 216 IRD MERIT, Faculté de Pharmacie de Paris, Université Paris Descartes, Paris, France; 5) Departamento de Clínica Médica, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, 14049-900, Ribeirão Preto-SP, Brazil.

*LILRB1 (ILT2)* gene is a member of the Leukocyte Immunoglobulin-like Receptor (LIR) family. *ILT2* encodes an important NK and T cell inhibitory receptor, with the highly polymorphic Human Leukocyte Antigen (HLA) class I molecules as its major ligands. Variability at both ligand and receptor might influence this interaction. *ILT2* DNA and protein variability have been poorly explored, with few studies evaluating only well-documented variants. We evaluated *ILT2* variability at exon segments, translating sequences into full-length protein molecules. Variable sites were assessed in 384 samples from the Brazilian Southeast using the Haloplex technology. Due to sequence similarity with other LIR genes, we expected genotyping errors when using second-generation sequencing. Hence, we developed an approach to score each read based on officially recognized LIR and KIR sequences, addressing them to the most likely locus. Ancestry was assessed using the SNPforID 34-plex panel. Ancestry composition of the population sample was 70.7% European, 21% African, and 8.3% Amerindian/Asian. Samples were stratified into three subgroups: EUR90, including 126 samples with a European ancestry higher than 90%; EUR50, including 307 samples with major European ancestry (> 50%); and AFR50, including 45 samples with major African ancestry (> 50%). Altogether, we detected 58 variable sites, arranged into 87 different coding sequences that encode 17 unique full-length proteins. Three of those proteins account for 72% of the sample, ten presented frequencies higher than 1% and a frequent protein (11%) was not predicted by the *1000Genomes* data. Two of the most frequent proteins here predicted were two times more frequent at the EUR groups than at the AFR50. Moreover, many frequent proteins were detected exclusively at either the AFR50 or EUR groups. This observation is in agreement with the *1000Genomes* data, which also indicates variation on frequencies influenced by ancestry. Although conserved at the protein level when compared with its major HLA ligands, *ILT2* protein frequencies are strongly influenced by the sample ancestry background, thus population stratification must be considered when conducting association studies regarding *ILT2*. Nonetheless, further studies are necessary to elucidate whether these polymorphic *ILT2* molecules interact differently with HLA antigens, and if the frequency shifts result from selective pressures or genetic drift.

**Defining trait core genes with networks.** *B.E. Graham<sup>1,2</sup>, K. Chesmore<sup>3</sup>, S.M. Williams<sup>1,2</sup>.* 1) Systems Biology and Bioinformatics, Case Western Reserve University, Cleveland, OH 44106, U.S.A; 2) Department of Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, Ohio, 44106, U.S.A; 3) Department of Molecular and Systems Biology, Geisel School of Medicine, Dartmouth College, Hanover, NH 03755, U.S.A.

The concept that many genes affect a single trait, i.e., the omnigenetic model, has recently gained momentum due to the observation from GWAS that numerous phenotypes each associate with hundreds of variants. Height is one such omnigenetic, complex trait. It is highly heritable with ~700 GWAS associated loci in the GWAS catalog. We propose a network-based analysis to determine which height associated loci are most important to the presumed genetic architecture of the trait, i.e. the "Core" genes as proposed by Boyle, LI and Pritchard, 2017. Using proteomic, pathway and gene interaction-based analyses of the height associated loci, we found that the best networks used confidence of relatedness between genes, edge weight, to determine nodes (genes) most important to the network (i.e., the Core genes). We investigated the pleiotropy of height genes and the relationship between phenotypes linked to those genes using a multiple phenotype-gene mapping method based on the GWAS catalog. Our resulting network revealed the number of Core genes to be approximately one third of the total, with several well-defined gene clusters, some concentrated around several oncogenes, many of which associate with more than one cancer. Phenotype-gene clusters include both height and BMI related traits as well as fetal size and preterm birth related traits. This last observation is supported by these Core genes being expressed with high confidence in placental and fetal tissues. This study shows that networks are a powerful tool for the mathematical identification of Core genes for complex disease.

**The identification of new protein methylation site acquisition in conserved proteins in human lineage.** *D.S Kim, J.K Kim.* Department of Rare Disease Research Center, Korea Research Institute of Bioscience.

Protein methylation plays an important role in various biological processes, including chromatin structure remodeling, gene transcription, DNA repair, protein synthesis, RNA metabolism, cell cycle progression, apoptosis and signal transduction. The acquisition of a novel methylation site can have a significant effect on protein structure and function, and this can be seen as a phenotype. We analyzed the human methylation site data and multiple alignments of mammalian proteins including those from human, primate, and other placental mammals. In our analysis, we identified 21 novel protein methylation site in 20 protein that arose in the human lineage during primate evolution. Among them, Arg-320 of Proline and serine-rich protein 2 (PROSER2) and Arg-513 of Sodium channel protein type 5 subunit alpha (SCN5A), gained human specific methylation site after the human-chimpanzee divergence. Notably, the Arg-513 in Sodium channel protein type 5 subunit alpha (SCN5A) is expected to modulate the intracellular calcium levels by affecting the sodium calcium channel. The results of molecular evolutionary analysis suggested that these sites were under positive selection during human evolution. We suggest that the novel methylation sites identified in this study may be useful candidate for functional analysis to identify progressive genetic modifications to advantageous phenotypes acquired in the human lineage.

**Genome-wide identification and characterization of non-coding human specific deletions.** *J. Xue<sup>1,2</sup>, S.K. Reilly<sup>1,2</sup>, R. Tewhey<sup>3</sup>, P.C. Sabeti<sup>1,2</sup>.* 1) Harvard University, Cambridge, MA 02138; 2) Broad Institute, Cambridge, MA 02142; 3) The Jackson Laboratory, Bar Harbor, ME 04679.

The identification and characterization of human-specific regulatory elements is crucial towards understanding our unique evolutionary history. Particularly compelling are highly conserved regions of the primate genome that are deleted specifically in humans. Prior work has focused on identifying large and intermediate sized (>20bp) human CONserved DEletions (hCONDELs) which have been shown to reside almost entirely in non-coding regions and are enriched near genes involved in steroid hormone receptor signaling and neural functions. However, smaller deletions, which are in much greater in abundance, have not been rigorously identified or characterized for their function due to various technical challenges. Using multiple sequence alignments generated by our group from the latest available primate reference genomes, we find that the vast majority of putative hCONDELs (>95%) are very small, suggesting that most hCONDELs are yet to be explicitly described. We computationally validated our hCONDELs by ensuring that these putative deletion sites are completely removed from a diverse set of human populations from the Simons Genome Diversity Project. To characterize the functional importance of the deletions, we employed the Massively Parallel Reporter Assay (MPRA) as a non-coding screen to assess the cis-regulatory impact of 17,197 deletions. We utilized MPRA across a diverse range of cell types to test for function across different tissue backgrounds. hCONDELs which were found to be active were enriched to lie in active regulatory regions of specific tissues. Furthermore, several hCONDELs show significant differences in activity via reporter assay between their native human and chimp contexts, and are prime candidates for contributing to possible human-specific phenotypes. We further characterize these hCONDELs to show changes in epigenetic activity at these loci and also transcriptional changes in nearby genes between human and chimpanzee. On a broader scale, we explored genome-wide trends in transcription factor binding, motif usage, and chromatin activity associated with those sites displaying species-specific activity. The characterization of these sites allows us to construct a clearer picture of the functional significance for sequences lost along the human lineage.

**The orangutan has all the variants you need: Monitoring specificity and sensitivity of diagnostic next-generation-sequencing by establishing orangutan DNA as reference standard.** A. Rump, F. Kuhlee, L. Gieldon, K. Hackmann, E. Schrock. Institute for Clinical Genetics, Faculty of Medicine Carl Gustav Carus, TU Dresden, Germany.

Evaluating the performance of diagnostic sequencing requires well-characterized reference samples (RS) with validated genetic variations. Since human RS tend to harbor relatively few variations within their coding regions, there will always be numerous exons from almost any gene in a given panel where a sequence variation will not be available for quality control (QC). So far, the effort to determine an assay's performance is immense, in terms of both money and time. In recent published cases, where NGS sensitivity and specificity has been assessed by sequencing up to 150 clinical specimens in order to provide 200-300 disease-relevant sequence variants. While this effort might be justified for an initial assay set-up, it is certainly not feasible for consistent QC. In order to overcome these problems we tested an orangutan (OrU) as donor for QC reference materials. So far however, OrU NGS reads have only been obtained from whole genome sequencing (WGS). Therefore, information of how OrU/human sequence divergence affects targeted enrichment by human capture probes is limited. Here, we applied capture-based whole exome sequencing (WES) panels from two different suppliers to gDNA from the commercially available male OrU cell line "EB185-JC" (Sigma-Aldrich). As positive control, the well-defined male HapMap sample NA12877 was sequenced in parallel, along with a 1:1 gDNA mixture of EB185-JC and NA12877. The reads from each of these experiments were mapped to the human reference, the OrU reference and to a combined human/OrU "mix" reference. Using this approach, we could show that OrU exons can be enriched, sequenced and mapped with the same efficiency as the competing human DNA. When mapped to the human reference, the OrU exome provides 903.763 "on target" variants (average 4.4 variants/WES target) and many of these variants would be disease causing if present in a human being. Therefore, OrU DNA can be used to measure both analytical and diagnostic sensitivity for almost every human exon and exceeds the variant variety of NA12877 DNA (average 0.3 variants/WES target) by a factor of 13.5 fold. Therefore, OrU DNA is especially valuable for small, disease-focused NGS panels where human reference DNA fails to provide enough variants for a reliable QC. Furthermore, specific OrU variants, which are very unlikely to occur in humans (neither naturally nor as sequencing artefacts), can be used to trace cross-contamination of reads in highly multiplexed NGS experiments.

**Prediction of eye and hair pigmentation phenotypes using the HlrisPlex system in a Brazilian admixed population sample.** C.T. Mendes-Junior<sup>1</sup>, T.M.T. Carratto<sup>1</sup>, F.D.N. Souza<sup>1</sup>, L. Marcorin<sup>2</sup>, G.V. Silva<sup>1</sup>, A.L.E. Pereira<sup>2</sup>, N.C.A. Fracasso<sup>2</sup>, M.L.G. Oliveira<sup>2</sup>, G. Debortoli<sup>3</sup>, E.A. Donadi<sup>3</sup>, A.L. Simões<sup>2</sup>, E.C. Castelli<sup>4</sup>. 1) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, SP, Brazil; 2) Departamento de Genética, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, SP, Brazil; 3) Departamento de Clínica Médica, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, SP, Brazil; 4) Departamento de Patologia, Faculdade de Medicina de Botucatu, Universidade Estadual Paulista, Botucatu, SP, Brazil.

Human pigmentation is a complex trait, probably involving more than 100 genes. Predicting phenotypes using SNPs present in those genes is of large forensic interest. For this, the Hlrisplex tool was developed for simultaneous eye and hair color prediction, achieving high accuracy among Europeans (76% and 82%, respectively). The application of HlrisPlex in admixed populations has not been deeply evaluated. Prediction of intermediate color phenotypes may be impaired in such populations, since completely different gene-gene interactions may give rise to phenotypes in an admixed background. This study aims to analyze this set of 24 markers in 340 individuals from Ribeirão Preto (SP) region, predicting eye and hair color and comparing these predictions with actual individual phenotypic data. DNA was extracted from blood samples through a salting-out procedure. Fragment libraries including the HlrisPlex markers were created using Haloplex (Agilent Technologies, Inc). Sequencing was held in MiSeq (Illumina) platform and reads were trimmed and aligned to the hg19 reference genome using cutadapt and BWA packages. GATK tool kit and VCFx packages were employed for SNP genotyping. Population genetics analysis was performed using Arlequin 3.5 software. The prediction of eye and hair color was accomplished by the HlrisPlex online tool. Using the default prediction settings, HlrisPlex presented an overall accuracy of 64.2% for hair color prediction, ranging from 29.9% for light-brown to 98.8% for black. Regarding eye color, an overall accuracy of 78.5% was achieved. Although higher accuracy levels were obtained for individuals that have blue (86.5%) and brown (97.5%) eyes, HlrisPlex completely failed in predicting intermediate eye color. Combining eye and hair predictions, the hit rate obtained was only 53.0%. Even when a threshold of  $p > 0.8$  is established for eye color determination, although 20.3% of individuals are left aside, blue and brown eyes accuracy increases to 93.3% and 98.5%, respectively, with an eye color accuracy of 83.4% and overall hair/eyes combined accuracy of 58.2%. Although HlrisPlex proved to be an applicable tool for determination of the most extreme pigmentation phenotypes, it fails in determining intermediate phenotypes, decreasing the overall accuracy of combined predictions and its reliability when used in admixed populations. FINANCIAL SUPPORT: FAPESP (Grant 2013/154470) and CNPq/Brazil (Grant 448242/2014-1 and Fellowship 309572/2014-2).

**Inference and visualization of geographic patterns of variation for variant sets.** A. Biddanda<sup>1</sup>, J. Novembre<sup>1,2</sup>. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Ecology and Evolution, University of Chicago, Chicago, IL.

Most summaries of population structure in genetic data convey the relative similarity of individuals in a sample. However, it is also useful to have a variant-centered view of population structure. For instance, one does not fully understand population structure until one knows the proportion of variants that are shared across all populations versus those that are geographically restricted. This information is relevant for understanding evolutionary history, for designing and interpreting GWAS studies, and more broadly, for building precision medicine solutions that are relevant to all populations. Currently, existing tools for summarizing population structure fail to convey such differences in the absolute frequencies of variants between different populations. To represent patterns of variant-level population structure, we have developed an approach with two major features 1) a visualization toolkit to succinctly display the geographic patterns of multiple variants and 2) a probabilistic clustering algorithm for grouping variants by their absolute frequencies across many populations. For our visualization method, we show heatmaps customized to represent variants by their frequency patterns. When clustering, our method infers a set of "modal frequency patterns" that capture the majority of the variation in the geographic distribution of variants, while also inferring the relative abundance of each modal frequency pattern. Following the inference of these consensus frequency patterns, we then assign variants to their most likely underlying frequency and subsequently calculate enrichment and depletion of particular categories within subsets of variants. Applying our method across a number of publicly available human datasets, we see features of human variation that are expected outcomes from the expansion out of Africa and recent explosive population growth. We also applied our method to different variant sets. For example, among variants in the NHGRI GWAS catalog, we observe an enrichment of European common variants, reflecting the predominantly European ancestry composition of many large-scale GWAS studies. Overall we show that our new methods provide a useful tool for the visualization of multi-dimensional population genomic data, allowing for the characterization of population structure from a variant-centric view that we expect will be of broad utility to the population genetic community.

**2730W**

**Gene-level intolerance to copy number variation in UK Biobank reveals a cohort-level survival bias and novel disease associations.** M. Aguirre<sup>1,2,3</sup>, M. Rivas<sup>2</sup>, J. Priest<sup>1,3</sup>. 1) Pediatric Cardiology, Stanford University, Stanford, CA; 2) Biomedical Data Science, Stanford University, Stanford, CA; 3) Cardiovascular Institute, Stanford University, Stanford, CA.

Copy number variations (CNV) constitute a significant proportion of the total genetic differences between individuals, and many CNVs associate causally with a variety of health outcomes. Here, we use genetic and phenotype data from UK Biobank to measure genetic tolerance to rare structural variation using previously developed methods for determining regional selective constraint. We perform separate constraint analyses for partial gene deletion, whole-gene duplication, as well as any overlapping copy number event as the basis of bayesian burden tests between rare genic CNVs and over 800 derived phenotypes. We observe the strongest intolerance to duplication in developmental (*CSH2* [MIM 118820], *GH1* [MIM 139250]), reproductive (*TUBB8* [MIM 616768]), and autoimmune-related genes (*HLA-DRB1* [MIM 142857]), as well as intolerance to any CNVs overlapping canonical cancer susceptibility genes (*BRCA2* [MIM 600185], *BRCA1* [MIM 113705], *APC* [MIM 611731], *ATM* [MIM 607585], *MSH2* [MIM 609309], and *MLH1* [MIM 120436]). For specific disease associations we find a significant CNV burden in *DLEU1* [MIM 605765] and *DLEU7* [MIM 605766] in leukemia ( $p < 10^{-16}$ ), *PMP22* [MIM 601097] in hereditary peripheral neuropathy ( $p < 10^{-16}$ ), and in *PNKD* [MIM 609023] in stroke ( $p = 4.5 \times 10^{-6}$ ). These associations are consistent with known pathogenic consequences of LoF variants in these genes, while offering novel information on potential disease associations. Ranked intolerance scores suggest a cohort-level selection bias against CNVs conferring risk for lethal conditions with onset in childhood or early adulthood. Our preliminary results recapitulate the role of structural variation in the genetic architecture of known disease, offer novel disease-associations, and contextualize the absence of population-wide burden of CNVs associated with early-onset genetic disease in the UK Biobank.

**2731T**

**Structural variation of the human population: Characterizing and sequence-resolving variation to identify common alleles, correct reference errors, and improve short-read analysis.** P. Audano<sup>1</sup>, A. Sulovari<sup>1</sup>, T. Graves-Lindsay<sup>2</sup>, S. Cantsilieris<sup>1</sup>, M. Sorensen<sup>1</sup>, A. Welch<sup>1</sup>, M. Dougherty<sup>1</sup>, B. Nelson<sup>1</sup>, S. Dutcher<sup>2</sup>, W. Warren<sup>2</sup>, R. Wilson<sup>3,4</sup>, E. Eichler<sup>1,5</sup>. 1) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA 98195, USA; 2) McDonnell Genome Institute, Department of Medicine, Department of Genetics, Washington University School of Medicine, St. Louis, MO 63108, USA; 3) Institute for Genomic Medicine, Nationwide Children's Hospital, Columbus, OH 43205; 4) The Ohio State University College of Medicine, Columbus, OH 43210; 5) Howard Hughes Medical Institute, University of Washington, Seattle, WA 98195, USA.

Although the accuracy of the human reference genome is critical for basic and clinical research, structural variants (SVs) have been difficult to assess because data capable of resolving them have been limited. To address potential bias, we sequenced a diversity panel of nine human genomes to high depth using long-read, single-molecule, real-time sequencing data. Systematically identifying and merging SVs  $\geq 50$  bp in length for these nine and one public genome yielded 83,909 sequence-resolved insertions, deletions, and inversions. Among these, 2,839 (2.0 Mbp) are shared among all discovery genomes with an additional 13,349 (6.9 Mbp) present in the majority of humans, indicating minor alleles or errors in the reference, which is partially explained by an enrichment for GC-content and repetitive DNA. Genotyping 83% of these in 290 additional genomes confirms that at least one allele of the most common SVs in unique euchromatin are now sequence-resolved. We observe a 9-fold increase within 5 Mbp of chromosome telomeric ends and correlation with *de novo* single-nucleotide variant mutations showing that such variation is nonrandomly distributed defining potential hotspots of mutation. We identify SVs affecting coding and noncoding regulatory loci improving annotation and interpretation of functional variation. To illustrate the utility of sequence-resolved SVs in resequencing experiments, we mapped 30 diverse high-coverage Illumina-sequenced samples to GRCh38 with and without contigs containing SV insertions as alternate sequences, and we found these additional sequences recover 6.4% of unmapped reads. For reads mapped within the SV insertion, 25.7% have a better mapping quality, and 18.7% improved by 1,000-fold or more. We reveal 72,964 occurrences of 15,814 unique variants that were not discoverable with the reference sequence alone, and we note that 7% of the insertions contain an SV in at least one sample indicating that there are additional alleles in the population that remain to be discovered. These data provide the framework to construct a canonical human reference and a resource for developing advanced representations capable of capturing allelic diversity. We present a summary of our findings and discuss ideas for revealing variation that was once difficult to ascertain.

**2732F**

**A population genetics approach to discover genome-wide saturation of structural variants from 22,600 human genomes.** L.F. Paulin<sup>1</sup>, A. von Haeseler<sup>1,2</sup>, F.J. Sedlazeck<sup>3</sup>. 1) Center for Integrative Bioinformatics Vienna, Max F. Perutz Laboratories, University of Vienna, Medical University of Vienna, Vienna, Austria; 2) Bioinformatics and Computational Biology, Faculty of Computer Science, University of Vienna, Vienna, Austria; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA.

Structural variants (SV) are an important source of human variations and shown to impact evolution, genetic diseases (e.g. Mendelian diseases and cancer) and sometimes cell regulation. SVs are defined as 50bp or larger deletions, duplications, inversion, and translocations. The current state of the art infers locations of SVs by analysing short reads that are reported to lack sensitivity that can be improved with long reads that are often more expensive and thus cannot be applied when studying larger cohorts. A way out of this dilemma is the development of tools that predict if a certain genomic region is already saturated with SVs. Then one would simply not sequence it anymore and would only sequence not saturated regions with less expensive methods like capture approaches. Based on a multi ethnicity, whole genome sequencing collection (30x) of 22,600 human genomes we developed a statistical model to determine hotspots of diversity of SVs taking into account allele frequencies across the ethnicities. We applied the Ewens Sampling Formula (ESF) over 10kbp windows to predict the genomic regions that did not reach saturation of SVs although sequencing 22,600 WGS. ESF is a well known tool in population genetics reapplied to our question. The ESF describes the probability distribution of the frequency of how many distinct alleles were observed a given number of times under the infinite allele model. Once the parameter of the ESF is estimated from a genomic sample, we can predict the probability to find a new SV in any given window. This approach discovered regions such as HLA, a few regions distributed in the telomers and naturally the centromeres as regions unsaturated regions, with respect to SVs. These regions are potentially relevant for personalized medicine as they are often unique to a few samples and demand suggest a closer investigation with capture based sequencing. Our model is applied to large cohorts such as the 1,000 Human-Genome and the 1,001 Arabidopsis genome project and can be applied to other data-sets to estimate a lower and higher bound variation that can be expected with sequencing additional samples. Thus, our tool provides a more cost efficient way to analyze large population based studies. Already small samples provide enough evidence to sequence only potential hotspots in the genomes of interest rather blindly sequencing whole genomes.

## 2733W

**Quantification of selective pressures on human pigmentation between populations and over epochs.** X. Huang<sup>1</sup>, S. Wang<sup>1,2</sup>, Y. He<sup>3</sup>, L. Jin<sup>1,2</sup>. 1) Chinese Academy of Sciences Key Laboratory of Computational Biology, Chinese Academy of Sciences-Max Planck Society Partner Institute for Computational Biology, Shanghai Institute of Nutrition and Health, Shanghai Institutes for Biological Sciences, University of Chinese Academy of Sciences, Chinese; 2) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, Collaborative Innovation Center for Genetics and Development, School of Life Sciences, Fudan University, Shanghai, 200433, China; 3) Institute of Biomedical Sciences, Shanghai Medical College, Fudan University, Shanghai, 200032, China.

The obvious diversity of human pigmentation—skin, hair, and eye colour—has attracted particular attention from both academic and non-academic investigators for thousands of years, as noted by Charles Darwin one century ago and as noticed by ancient Egyptians more than 4000 years ago. Why human pigmentation diverges still remains a central puzzle in human biology. Some researchers have proposed that human pigmentation diversity is adapted for ultraviolet radiation and driven by natural selection. During the last decade, many studies have detected selection signals in individual pigmentation genes; however, few studies have examined how multiple genes contributed to the evolution of human pigmentation. Moreover, none has quantified selective pressures on human pigmentation between populations and over epochs. Here we report the first systematic quantification of the differences and changes in selective pressures between distinct populations and during different periods with our new approaches. We suggest directional selection not only affected the light pigmentation in Eurasians, but also influenced the dark pigmentation in Africans. Thus, directional selection, rather than the relaxation of selection, is the more likely explanation of human pigmentation diversity, a long-standing debate in the evolution of human pigmentation. We also reveal that the selective pressures on human pigmentation changed markedly during the Out-of-Africa event, and the magnitude of the change has diminished more recently. Our results elucidate the quantitative details of human pigmentation diversity as well as its evolution, and may help researchers to facilitate studies for the evolution of other complex traits. .

**Facial masculinity does not appear to be a condition-dependent male ornament and does not reflect MHC heterozygosity in humans.** J.D. White<sup>1</sup>, A.A. Zaidi<sup>1,2</sup>, B.C. Mattern<sup>1,3</sup>, C.R. Liebowitz<sup>1</sup>, D.A. Puts<sup>1</sup>, P. Claes<sup>4,5</sup>, M.D. Shriver<sup>1</sup>. 1) Department of Anthropology, The Pennsylvania State University, University Park, PA; 2) Department of Biology, The Pennsylvania State University, University Park, PA; 3) Department of Biobehavioral Health, The Pennsylvania State University, University Park, PA; 4) Department of Electrical Engineering, ESAT/PSI, KU Leuven, Leuven, Belgium; 5) Medical Imaging Research Center, MIRC, UZ Leuven, Leuven, Belgium.

Facial masculinity is thought to be a condition-dependent male ornament that may have evolved to indicate immunocompetence and other measures of 'quality' to potential mates and rival males. In non-human animals, male ornaments, such as stag antlers and beetle horns, tend to be exaggerated structures that are hypervariable and sensitive to subtle variation in growth among males. We tested whether this applies to facial masculinity by calculating an objective, vector-based measure of facial masculinity/femininity from three-dimensional images in a large sample (N = 1,233) of people of European ancestry. Using single nucleotide polymorphism (SNP) data from 567,787 markers, we calculated genome-wide heterozygosity as well as genomic ancestry principal components (PCs), to correct for population substructure. An additional measure of immunocompetence was calculated via MHC heterozygosity, estimated using 114 human leukocyte antigen (HLA)-tag SNPs previously reported to capture HLA haplotype variation in Europeans. After controlling for sex, age, weight, and genomic ancestry PCs, we show that facial masculinity is positively correlated with adult height in both males and females ( $T$ -statistic = 8.81,  $p$ -value =  $4.17 \times 10^{-18}$ ). This suggests that variation in growth contributes, at least in part, to variation in facial masculinity, which is characteristic of condition-dependent traits. However, facial masculinity scales with growth similarly in males and females ( $b_{\text{Male}} = 0.227$ ,  $b_{\text{Female}} = 0.299$ ,  $Z$ -score<sub>diff</sub> = -1.18,  $p$ -value = 0.120), suggesting that facial masculinity is not specifically a male ornament, as male ornaments tend to be more sensitive to growth variation in males. Additionally, we show that while height is positively correlated with MHC heterozygosity ( $T$ -statistic = 3.18,  $p$ -value =  $1.54 \times 10^{-3}$ ), facial masculinity is not, regardless of whether height is included in the model ( $T$ -statistic = -0.038,  $p$ -value = 0.970) or not ( $T$ -statistic = 0.586,  $p$ -value = 0.558). Thus, facial masculinity does not reflect immunocompetence in humans, as previously thought. Future studies should explore the relationship between facial masculinity and other measures of immunocompetence. Overall, in this well-powered study, we find no support for the idea that facial masculinity is a condition-dependent male ornament that has evolved to indicate immunocompetence in humans.

**A novel, scalable, and powerful IBD-based method to detect archaic hominin sequence in modern humans.** *L. Chen*<sup>1,2</sup>, *W. Fu*<sup>3</sup>, *J.M. Akey*<sup>1,2</sup>.

1) Ecology and evolutionary biology, Princeton University, Princeton, NJ; 2) Lewis Sigler Institute, Princeton University, Princeton, NJ; 3) 1 Microsoft Way, Microsoft, Redmond, WA.

A number of statistical methods exist to identify sequences that were inherited from archaic hominin ancestors, such as Neandertals and Denisovans. These methods typically require haplotype resolved data, make use of a reference population that does not segregate introgressed sequence, and are computationally intensive. Here, we describe a rigorous probabilistic method based on identity by descent (IBD) to detect Neandertal and Denisovan sequences in modern humans and evaluate its operating characteristics through extensive simulations. Importantly, we show that our approach can be used without a reference population, which increases power to find introgressed sequences. We also show that our IBD based method outperforms existing methods, such as  $S^*$ , and is much more computationally tractable as it operates on genotype data directly. Finally, we apply our method to the 1000 Genomes Project and other sequencing data sets from geographically diverse populations to refine the set of Neandertal and Denisovan sequences segregating in modern humans.

**Localizing and classifying adaptive targets with trend filtered regression.**

*M.R. Mughal*<sup>1</sup>, *M. DeGiorgio*<sup>2,3</sup>. 1) Bioinformatics and Genomics at the Huck Institutes of the Life Sciences, Pennsylvania State University, University Park, PA; 2) Departments of Biology and Statistics, Pennsylvania State University, University Park, PA; 3) Institute for CyberScience, Pennsylvania State University, University Park, PA.

Identifying genomic locations of natural selection from sequence data is an ongoing challenge in population genetics. Current methods utilizing information combined from several summary statistics typically assume no correlation of summary statistics regardless of the genomic location from which they are calculated. However, due to linkage disequilibrium, summary statistics calculated at nearby genomic positions are highly correlated. We introduce an approach termed *Trendsetter* that accounts for the similarity of statistics calculated from adjacent genomic regions through trend filtering, while reducing the effects of multicollinearity through regularization. Our penalized regression framework has high power to detect sweeps, is capable of classifying sweep regions as either hard or soft, and can be applied to other selection scenarios as well. We find that *Trendsetter* is more robust to missing data than similar current approaches, has comparable power, and is also robust to strong background selection. Moreover, the model learned by *Trendsetter* is highly interpretable, as it represents a set of curves modeling the spatial distribution of summary statistics in the genome. Application to human genomic data revealed positively-selected regions previously discovered such as *LCT* in Europeans and *EDAR* in East Asians. We also identified a number of novel candidates and show that populations with greater relatedness share more sweep signals.

Parks<sup>8</sup>, M. Phipps<sup>8</sup>, K. Robson<sup>8</sup>, E.E. Kenny<sup>8</sup>, A.V.S. Hill<sup>8</sup>, A.J. Mentzer<sup>8</sup>, C. Bustamante<sup>4</sup>, A. Moreno-Estrada<sup>1</sup>, G.R. Gignoux<sup>10</sup> On behalf of the Oceanian Genome Variation Consortium. 1) National Laboratory of Genomics for Biodiversity, Irapuato, Guanajuato, Mexico; 2) Computational and Mathematical Engineering, Stanford University, Palo Alto, CA; 3) Department of Genetics, Stanford University, Stanford, CA, USA; 4) Department of Biomedical Data Science, Stanford University, Stanford, CA, USA; 5) University of Oxford, United Kingdom; 6) Undergraduate Program on Genomic Sciences, UNAM, Cuernavaca, Morelos, Mexico; 7) University of California, Davis, Davis, CA, USA; 8) Icahn School of Medicine at Mount Sinai, New York, NY, USA; 9) Monash University, Malaysia; 10) Colorado Center for Personalized Medicine and Department of Biostatistics and Informatics, University of Colorado, Aurora, Colorado, USA.

Oceania comprises the region from Southeast Asia throughout the South Pacific and has a rich demographic history, with the first human settlements in Papua New Guinea dating to ~40,000 years ago. Multiple migration and admixture events have occurred throughout the region, like the Lapita expansion that reached Tonga and Samoa and the colonization of Remote Oceania. Despite the richness of different peoples and cultures, this area of the world remains almost entirely left out of the global genetic mapping efforts. Here, we present the Oceanian Genome Variation Project (OGVP), the largest collection of historic genotyped DNA samples collected by the University of Oxford. The main aims of this project are to reconstruct the population genetic history of the major human migrations into the Pacific and to increase resolution on the characterization of understudied regions. We generated genome-wide SNP data for 980 individuals using the MEGA platform and identified genetic clusters of population differentiation with ADMIXTURE. They broadly correspond to Melanesia, Micronesia and Polynesia, recapitulating cultural and linguistic differences among the islands. In particular, there is decreasing continental East Asian ancestry throughout Malaysia and Indonesia, including some of the remote islands as we move east away from the mainland. The ADMIXTURE patterns seen in the westernmost islands (Tonga, Samoa, and Tuvalu) contrast with the remainder of the Polynesian islands as they have both of the components seen in Polynesia and Melanesia. In addition, Remote Polynesia shows patterns of pervasive European admixture, which contact will be dated to reconstruct the recent demographic dynamics of the region triggered by intercontinental travel. We used BEAGLE to find identity-by-descent (IBD) segments between individuals in Oceania and found that the amount of IBD shared between different populations increases in an eastward direction and that Polynesian populations share the highest amount of IBD. Lastly, we identified maternal and paternal lineages in this dataset. The most common mitochondrial haplogroups were B (namely B4a1), Q and M. Most of the Y chromosome lineages found in Oceania were O, C, K, M and R. The OGVP initiative represents an important effort to include a historically underrepresented area of the world in the publicly available genetic databases and to facilitate the genetic research in the Pacific.

**Detecting signatures of adaptive positive selection from high-density genotyping data in the Lithuanian population.** A. Urnikyte<sup>1</sup>, M. Monda<sup>2</sup>, E. Bosch<sup>3</sup>, A. Molyte<sup>1</sup>, V. Kučinskas<sup>1</sup>. 1) Department of Human and Medical Genetics, Biomedical Science Institute, Faculty of Medicine, Vilnius University, Vilnius, Lithuania; 2) Estonian Biocentre, Tartu 51010, Estonia; 3) Institut de Biologia Evolutiva (UPF-CSIC), Departament de Ciències Experimentals i de la Salut, Universitat Pompeu Fabra, Parc de Recerca Biomèdica de Barcelona, Doctor Aiguader 88, 08003 Barcelona, Catalonia, Spain.

**Introduction:** A characterization of the adaptive history of human populations requires knowledge of the genes that have been affected by positive natural selection which is also important for an analysis of the genetic causes behind human disease. The present study aims to analyze signatures of adaptive positive selection from high-density genotyping data in a total of 399 individuals from the Lithuanian population. **Material and methods:** We analyzed Illumina 770 K HumanOmniExpress-12 v1.1 and Infinium OmniExpress-24 array data from Lithuania combined with CEU, FIN and YRI populations from 1000 genome data for estimating genetic differentiation between continents. Three statistics were employed for scanning high-density genotyping data to infer signs of positive natural selection: Tajima's D,  $F_{ST}$  and cross-population extended haplotype homozygosity (XP-EHH) statistical method. Selected SNPs were annotated using ANNOVAR in GRCh37 (hg19), RefSeqGene, dbSNP147 and CADD version 1.3. **Results:** Based on genetic differentiation, when Lithuanian population is compared with Yoruban, CEU and FIN populations, we identified a region with *TYRP1* gene which is implicated in the lightening of skin pigmentation. In addition *SLC25A27* gene was identified, when comparing Lithuanian and reference populations, which may play role in thermoregulatory heat production and metabolism in brain. Among other genes identified, those with the top XP-EHH values include *PLA2G7* gene, located on chromosome 6, containing nonsynonymous SNP (exon7:c.T593C), which is a candidate gene for developing Asthma disease –the most common chronic disease affecting children and young adults. Other nonsynonymous specific variants for Lithuanian population were identified. **Conclusions:** The selection signatures identified in the Lithuanian population demonstrated positive selection pressure on a set of important genes with potential functions that are involved in many biological processes.

**Archaic deserts: Interpreting human genomic regions depleted of archaic hominin ancestry.** A.B. Wolf<sup>1,2</sup>, J.M. Akey<sup>2</sup>. 1) University of Washington, Seattle, WA; 2) Princeton University, Princeton, NJ.

Recent studies have identified archaic sequence in modern human genomes that is inherited from ancient hybridization with Neanderthals and Denisovans. Strikingly, the distribution of surviving archaic sequence throughout the human genome is heterogeneous. Several large regions of the human genome are significantly depleted of archaic ancestry. In particular, four multi-megabase regions are significantly depleted of both Neanderthal and Denisovan sequence for multiple geographically diverse populations with unique population histories. Understanding the formation and characteristics of archaic deserts will help interpret how archaic admixture influenced human evolution and, possibly, what genes play a role in unique human behaviors. For example, archaic deserts may represent loci where archaic sequence was deleterious and rapidly purged from modern human populations. Alternatively, the stochastic loss of archaic sequence due to drift could contribute to these archaic deserts. To better interpret the mechanisms responsible for archaic desert formation, we have performed an exhaustive set of coalescent simulations under a wide range of neutral demographic models. As well, we have used a range of forward-in-time simulations that incorporate selection on introgressed archaic sequence. Our results show that neutral demographic processes alone are unlikely to explain archaic deserts. Models that incorporate selection acting on deleterious archaic sequence provide a significantly better fit to the empirical data.

**Whole genome sequencing reveals admixture history of Singapore Peranakan Chinese.** D. Wu<sup>1</sup>, P. Li<sup>2,3</sup>, B. Pan<sup>2,3</sup>, J. Dou<sup>1</sup>, C. Bellis<sup>2</sup>, J. Liu<sup>2</sup>, R.S.Y. Foo<sup>2,3</sup>, C. Wang<sup>1,4</sup>. 1) Computational and Systems Biology, Genome Institute of Singapore, Agency for Science, Technology and Research (A\*STAR), Singapore; 2) Human Genetics, Genome Institute of Singapore, Agency for Science, Technology and Research (A\*STAR), Singapore; 3) Cardiovascular Research Institute, National University Health System, National University of Singapore, Singapore; 4) Duke-NUS Medical School, National University of Singapore, Singapore.

*Peranakan Chinese*, also known as Straits-born Chinese, are descendants of early Chinese immigrants settling in the Malay Archipelago between the 15th and 17th centuries. Through the years, this community has developed unique Peranakan culture, which preserves most of their Chinese traditions with strong influence from local Malays. Yet, whether genetic admixture co-occurred with the cultural mixture is debatable even among the Peranakan community. To answer this question, we recruited 177 Singapore Peranakans and performed whole genome sequencing at ~15X. We have by now analyzed 79 Peranakan genomes together with additional whole genome data of Chinese, Malays, and Indians in Singapore, as well as Southern Chinese and Northern Chinese from the 1000 Genomes Project. Principal component analysis and supervised ADMIXTURE analysis suggest that Peranakan Chinese inherit a significant level of Malay ancestry. On average, the estimated Malay ancestry proportion is  $\sim 0.114 \pm 0.009$  (mean  $\pm$  s.e.m, standard error of the mean) in Peranakan Chinese,  $\sim 0.032 \pm 0.004$  in Southern Chinese and  $\sim 0.008 \pm 0.003$  in Northern Chinese. GLOBETROTTER analysis dates the admixture event between Chinese and Malays about 6-12 generations ago. In summary, our preliminary results provide strong genetic evidence to support the hypothesis that genetic admixture co-occurred with cultural mixture in the formation of the Peranakan Chinese community.

**2741F****Landscape of multi-nucleotide variants across 123,136 human exomes.**

Q. Wang<sup>1,2,3</sup>, E. Pierce-Hoffman<sup>2,3</sup>, A. Hill<sup>4</sup>, A. O'Donnell-Luria<sup>2,3</sup>, B. Cummings<sup>2,3,5</sup>, K. Karczewski<sup>2,3</sup>, L. Franciolli<sup>2,3</sup>, L. Gauthier<sup>2,3</sup>, D. MacArthur<sup>2,3</sup>. 1) Program in Bioinformatics and Integrative Genomics, Harvard Medical School, Boston, MA; 2) The Broad Institute of MIT and Harvard, Cambridge, MA; 3) The Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 4) Genome Sciences, University of Washington, Seattle, WA; 5) Program in Biomedical and Biological Sciences, Harvard Medical School, Boston, MA.

Multi-nucleotide variants (MNV) are defined as clusters of two or more nearby variants existing on the same haplotype. When multiple variants in an MNV are found within the same codon, the overall impact may differ from the functional consequences of any of the individual variants (e.g. missense + missense resulting in protein truncating variant, PTV). Moreover, the mutational mechanisms underlying MNVs remain poorly characterized. To create the largest collection of MNVs to date, we scanned phased high-quality SNP pairs within 3bp across 123,126 exome-sequenced individuals aggregated as part of the Genome Aggregation Database (gnomAD) v2 callset. Three different phasing methods showed very high (>94%) concordance when tested on 13 exome trios, conforming the quality of read-based phasing. Our analysis resulted in discovery of 106,492 MNVs (72,220 MNVs of adjacent SNVs, 32,816 MNVs of 2bp apart, and 1,456 MNVs of 3 consecutive bases). Of those, 377 were gained PTV (both SNPs are not PTV, but the resulting MNV is), 1,809 were rescued PTV (at least one of individual SNP is a PTV, but the resulting MNV is not), and 15,534 additional variants altered the protein sequence of the affected gene product, emphasizing the importance of haplotype-based annotation for the complete detection of functional variants. We found a skewed distribution of MNV frequency per base pattern. There were 7,896 CA->TG mutations, but only 52 TA->GC mutations, consistent with the >100x higher mutation rate for CpG transitions compared to non-CpG transversions. Also, we found evidence of previously known two-base substitution mechanism such as polymerase slippage in repeat regions and replication error by polymerase-zeta. We show that the major mutational origin of MNVs differs substantially by sequence pattern (>92% are two SNP event in a row for CA->TG mutation we discovered, >60% polymerase slippage for AA<->TT, and >87% polymerase zeta-induced replication error for TC->AA and their reverse complements.). Finally, we present the results of ongoing analyses investigating the contribution of MNVs to rare disease by applying the methods to >3,000 sequenced individuals from rare disease families, and their distribution in non-coding sequence by analyzing >15,000 sequenced whole genomes. This project provides a validated approach for the detection and interpretation of MNVs on very large sequence data sets, and demonstrates their importance for functional and clinical variant interpretation.

**2742W****Population-specificity of eQTL effect sizes across tissues.** S. Kasela<sup>1,2</sup>,

P. Hoffman<sup>1</sup>, S. Castel<sup>1,2</sup>, T. Lappalainen<sup>1,2</sup>, GTEx Consortium. 1) New York Genome Center, New York, NY; 2) Department of Systems Biology, Columbia University, New York, NY.

Genetic variation modulating gene expression is widespread in the human genome. Previous studies have shown a high level of sharing of regulatory genetic effects across populations, based on eQTL analysis in a subset of blood cell types. Here, we conducted systematic approach to characterize population differences in effect sizes of *cis*-eQTLs in 31 tissues with up to 588 individuals of European and up to 86 individuals of African ancestry from the Genotype-Tissue Expression (GTEx) Project v8 release. We measured eQTL effect size using our previously developed metric, allelic fold change (aFC), which is robust to differences in allele frequency and expression level, and allows replication of the eQTL results using allele-specific expression data. While the vast majority of the top *cis*-eQTLs discovered in GTEx showed similar effect size in both of the populations, up to 0.6% of the top *cis*-eQTLs tested had significantly divergent magnitude of aFC per tissue at FDR 5%, with no obvious tissue enrichment for these effects. We observed that eQTLs with significant differences were likely to be shared across tissues, suggesting that population differences appear mostly shared as well. Controlling for differences in LD, we defined a set of high confidence *cis*-eQTLs with population-specific effects. One such eQTL was rs1815739 where there derived T allele creates a premature stop codon in the actinin alpha 3 (*ACTN3*) gene that is expressed only in fast-twitch muscle fibers responsible for causing force at high velocity. This relatively common variant especially in European populations is well known to trigger nonsense-mediated decay and associate to reduced sprint performance. In skeletal muscle of European Americans the SNP reduced *ACTN3* dosage substantially, as expected,  $\log_2 aFC = -5.2$ , 95% CI -5.7..-4.7. However, in African Americans the effect was nearly absent ( $\log_2 aFC = -0.3$ , 95% CI -3.2..1.5) with allele-specific expression data suggesting dosage compensation. This raises interesting questions of molecular mechanisms as well as potential population-specific phenotypic effects of this variant. Taken together, our results have widened the knowledge of population differences across variety of tissues, confirming the high overall similarity of genetic regulation of gene expression between populations but also highlighting interesting exceptions that shed light to molecular drivers of human diversity.

**2743T**

**Ethnic specific reference genome may salvage "unmapped" reads to the global reference of GRCh38.** *J. Kim<sup>1</sup>, I.C. Yang<sup>2</sup>, Y.K. Bae<sup>2</sup>, J. Sung<sup>3</sup>.* 1) Interdisciplinary program in Bioinformatics, Seoul National University, Korea, Republic of, MPH; 2) Korea Research Institute of Standards and Science, Center for Bio-Analysis, Daejeon, Korea, PhD; 3) Complex Disease and Genome Epidemiology Branch, Department of Epidemiology, School of Public Health, Seoul National University, Seoul, Korea, PhD, MD.

"Re-sequencing" methods relying on the Reference Human Genome (GRCh38) have enabled the current deluge of cost-efficient and high-throughput NGS analyses. The use of the GRCh38, the most complete human genome assembly with multi-ethnic mosaic, was sometimes asked whether it is truly representative of all ethnic groups, but few studies empirically showed the utility and implications of having a well-established ethnic-specific reference genome. A reference genome for Asians might be a good example given the current GRCh38 still has low contributions from Asians. The AK1 is a de novo genome assembly based on a Korean man, which has about 45 Mb of scaffold N50. We used fourteen individuals (5 East Asian, 4 European, and 5 African ancestry) whole genome sequencing (WGS) data aligned to the GRCh38 from the 1000 genome database which are Illumina PCR-free and with high coverage. We extracted unmapped reads from the data and aligned these unmapped reads to AK1 assembly as a reference genome. In average 95.6% of the total reads (773 million out of 809 million) NGS reads were mapped to the GRCh38 with alternative sequence leaving 4.4% unmapped. Among the unmapped (by GRCh38) reads, average 0.90% for 3 ethnic group was newly aligned to AK1. Specially, alignment rate for East Asian was 0.95% which was higher than other ethnic groups (European; 0.86% and African; 0.84%). When we divided the 2832 scaffolds of AK1 into three groups: group 1) almost uniquely mapped to single chromosome of GRCh38 (>90% to one chromosome); group 2) mapped to multiple chromosome; group 3) scaffolds not recognized by the chromosomes of GRCh38, unmapped reads were aligned to the group 3 scaffolds of AK1 (8.8% of total unmapped reads), but also to group 1) and 2). When we examined some newly mapped reads with high depth by introducing AK1 as a reference genome, (only scaffolds which are linked to chromosomes of GRCh38), some new blocks were identified, mostly flanking repeated sequences such as AluSx, MIRc, or Tigger1. It is noteworthy that AK1, a high-quality genome assembly of a Korean, revealed new genomic information and sequences for not only Asians but also European and African ancestry genomes.

**2744F**

**L1 retrotransposition machinery is maintained via the live-and-die model of evolution in primate genomes.** *P. Liang, W. Tang, J. Nanayakkara.* Brock University, St. Catharines, Ontario, Canada.

Mobile elements are genetic elements capable of moving or copying/inserting into new locations in the genome, and they make up approximately half of primate genomes. Although mobile elements used to be viewed as genome parasites, they are now known to play important roles in genome evolution and gene function. LINE1 (L1) sequences are mobile elements that are capable of encoding the molecular machinery for retrotransposition, the mobilization of DNA sequences through an RNA intermediate. Most other active transposons in primate genomes rely on L1s to provide functional proteins for their retrotransposition. However, an evolutionary model of intact L1 evolution and retention in the genomes has not been proposed. Using a bioinformatics comparative genomics approach, we performed an analysis to determine 1) the biochemical requirements of intact L1s, 2) the mode of evolution of intact L1s, and 3) *cis*-preference of intact L1s on a genome-wide scale. Intact L1s were found to require a full length ORF1, ORF2, and promoter to maintain retrotransposition activity in the genome. High rates of human-specificity and polymorphism were found among intact L1s compared to non-intact L1s. Case studies of L1 clusters revealed that current intact L1 copies came from L1s which may be currently non-intact. Based on the analysis, we established that intact L1s evolve through a "Live-and-Die" model. Under this model, L1s that are capable of encoding functional proteins may produce many new copies of themselves while "alive" in a *cis*-preference fashion. Over evolutionary time, the original parental L1s acquire random, inactivating mutations to lose transcription and/or coding capacity and "die". Thus, it leaves the new generation of intact L1s to take over the responsibility to produce transposition molecular machinery for the entire genome. Interestingly, the human genome has a much higher number of intact L1s (more than 10 times) than all other primates examined, including its close relative, chimpanzee. This suggests that humans, of all primates, have the greatest potential to further evolve via retrotransposition. Moreover, most intact L1s in humans are human-specific, among which a significant portion also represent polymorphic insertions, further demonstrating the youth and plasticity of the human genome.

**A complete characterization of the HLA-A haplotype structure in a**

**Brazilian population sample.** T.H.A. Lima<sup>1,2</sup>, I.O.P Porto<sup>1,3</sup>, M.A Paz<sup>1,3</sup>, L.C Veiga-Castelli<sup>4</sup>, M.L.G Oliveira<sup>4</sup>, E.A Donadi<sup>5</sup>, D. Meyer<sup>6</sup>, A. Sabbagh<sup>7</sup>, C.T Mendes-Junior<sup>8</sup>, E.C Castelli<sup>1,2,3</sup>. 1) São Paulo State University (UNESP), Molecular Genetics and Bioinformatics Laboratory - Experimental Research Unity, School of Medicine, Botucatu, State of São Paulo, Brazil; 2) São Paulo State University (UNESP), Genetics Program, Institute of Biosciences of Botucatu, Botucatu, State of São Paulo, Brazil; 3) São Paulo State University (UNESP), Pathology Program, School of Medicine, Botucatu, State of São Paulo, Brazil; 4) Department of Genetics, School of Medicine of Ribeirão Preto, University of São Paulo (USP), Ribeirão Preto, State of São Paulo, Brazil; 5) Department of Medicine, School of Medicine of Ribeirão Preto, University of São Paulo (USP), Ribeirão Preto, State of São Paulo, Brazil; 6) University of São Paulo, Department of Genetics and Evolutionary Biology, São Paulo, Brazil; 7) UMR 216 MERIT, IRD, Université Paris Descartes, Faculté de Pharmacie, Sorbonne Paris Cité, Paris, France; 8) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, São Paulo, Brasil.

The Human Leucocyte Antigen (HLA) complex comprises some of the most polymorphic human genes, including *HLA-A*. *HLA-A* is a classical HLA class I gene that encodes a key molecule for antigen presentation and recognition of self and non-self antigens. It is also associated with NK cell modulation through the interaction with NK activating and inhibitory receptors. *HLA-A* variability in exons is frequently explored in many worldwide populations, but minor attention has been given to regulatory segments and introns, as well as to other exons such as the ones encoding the  $\alpha 3$ , transmembrane and cytoplasmic domains. Variability in these neglected segments might influence the *HLA-A* expression profile, signaling, cytotoxicity, anchorage, and stability of the molecule on the plasmatic membrane. Here we present a molecular and computational strategy to evaluate the complete *HLA-A* variability including its regulatory segments (promoter and 3'UTR) by using second-generation sequencing, surveyed on 408 individuals from the Brazilian Southeast. We detected 453 variable sites considering the entire *HLA-A* segment, arranged into 94 different haplotypes. The *HLA-A* locus was highly polymorphic and presented a high Linkage Disequilibrium (LD) pattern along the entire segment, with many polymorphisms in complete LD. The promoter region presented 100 variable sites and 25 haplotypes. This low number of haplotypes could be explained as a consequence of the LD pattern observed and the fact that many of these variable sites were in complete LD. There was a direct correlation among the promoter, coding and 3'UTR haplotypes here observed, thus few variable sites are necessary to capture which promoter/coding/3'UTR haplotype groups are present in a sample. We observed a high nucleotide diversity throughout the gene, exception made for the 3'UTR region. The *HLA-A* promoter segment seems to be as polymorphic as the coding region, but with a conserved 'core promoter'. Positive Tajima's D was detected for all segments demonstrating a balancing selection profile across the entire *HLA-A* gene segment. However, exon 4 presented evidence of purifying selection, and this exon encodes a domain that interacts with the CD8 receptor. It is possible that each promoter here detected (and their associated coding alleles) is related to a distinct expression profile. Functional evaluations are still required to fully understand the biology and expression pattern of this gene.

**Black South African Bantu-speakers<sup>(\*)</sup> show evidence of significant population structure with implications for biomedical research: H3Africa SNP array data.** M. Ramsay<sup>1,2</sup>, D. Sengupta<sup>1</sup>, A. Choudhury<sup>1</sup>, S. Aron<sup>1</sup>, S. Tollman<sup>3</sup>, S. Norris<sup>1</sup>, M. Alberts<sup>5</sup>, S. Hazelhurst<sup>1,6</sup>, members of AWI-Gen and the H3Africa Consortium. 1) Sydney Brenner Institute for Molecular Bioscience, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg; 2) Division of Human Genetics, National Health Laboratory Service and School of Pathology, Faculty of Health Sciences University of the Witwatersrand, Johannesburg, South Africa; 3) MRC/Wits Rural Public Health and Health Transitions Research Unit (Agincourt), School of Public Health, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg 2193, South Africa; 4) MRC/Wits Developmental Pathways for Health Research Unit, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, South Africa; 5) Department of Pathology and Medical Science, School of Health Care Sciences, Faculty of Health Sciences, University of Limpopo, Polokwane, South Africa; 6) School of Electrical & Information Engineering, University of the Witwatersrand, South Africa.

Genetic diversity among extant black South African Bantu-speakers (BS) is the result of multiple waves of migration during the Bantu-expansion over the past ~2000 years and complex gene flow from resident hunter-gatherer and agro-pastoralist populations. To date, disease mapping studies have essentially treated BS as a monolithic group and the impact of population structure on discovering robust genetic associations among the BS has remained largely unexplored. This is the first large-scale study on the genetic diversity of black first language Bantu-speakers in South Africa, including ~4000 participants representing over 9 major ethnolinguistic sub-groups recruited in three provinces (Soweto – urban Gauteng; Dikgale – rural Limpopo; Agincourt – rural Mpumalanga). They were genotyped on the newly designed H3Africa 2.5M array. Principal component analysis (PCA) showed population structure among the BS, with the three more northern groups, Tsonga, Pedi and Tswana showing a clear east to west cline. The Tsonga, Pedi, Zulu and Xhosa also showed a north to south cline. The distribution of these groups on PCA mirrored the most recent geographic settlement defined according to ethnolinguistic clustering and was consistent with the history of Bantu-migration. Admixture analyses detected the level of Khoesan (KS) ancestry to be a major differentiating factor for these groups, varying from minimal in Tsonga (~2%), intermediate in Pedi (11%), to high among Tswana (~22%). The level of maternal KS ancestry (L0 mtDNA haplogroup) demonstrated a similar trend from lowest in Tsonga to highest in Tswana. ALDER and MALDER were used to date the timing of gene flow from the KS populations, providing an estimate of the timeline for the arrival of various BS populations in South Africa. We report a deep relatedness within the two rural South African communities (more than 30% related at a PIHAT cutoff of 0.05) likely reflecting geographic and cultural isolation that would require consideration in GWASs. This study provides new insights into the origins and population structure of black South African Bantu-speakers. <sup>(\*)</sup> Bantu-speakers are a substantive component of the Niger-Congo ethnolinguistic group, one of the four major ethnolinguistic groupings in Africa (Nilo-Saharan; Afro-Asiatic; Niger-Congo; Khoesan).

**Initiatives to increase the diversity of populations represented in genetics research.** A.J. Shastri, M.E. Moreno, N. Litterman, G.D. Poznik, A. Auton, J.L. Mountain, the 23andMe Research Team. 23andMe, Inc., CA.

Studying diverse populations is critical not only for maximizing new discoveries but also for ensuring that the results of research benefit all. Throughout its history, 23andMe has worked to increase the diversity of its genetic data. In 2011 we launched the Roots into the Future initiative, which enrolled over 10,000 African Americans in genetics research through access to 23andMe's service. In 2016, we launched the African Genetics Project, a study of individuals with recent African ancestry, which aimed to improve our ability to provide more detailed ancestry results and to contribute to the global understanding of how people have migrated within Africa and from Africa to the rest of the world. Contributions of over 700 research participants enrolled in the study have helped to provide finer resolution within our Ancestry Composition report for more than half a million customers. With NIH funding, we are sequencing more than 2,000 African American customers who consented to participate in research. Through this project, we will broaden the 23andMe sequencing panel for imputation. Participants have also agreed to make their de-identified data available through an NIH database, dbGAP, to qualified researchers conducting health-related studies. In 2017, we also launched the Global Genetics Project, which provides kits at no cost to participants with all four grandparents born in a country underrepresented in our reference data panel. The project has enrolled over 3,000 participants in just 5 months. **In our newest effort, the Populations Collaborations Program, we partner with researchers working to genotype people in communities across Africa, Asia, the Americas and beyond. We provide financial and scientific support for qualified researchers and use the data to simultaneously expand our Reference Data Panel and support researchers who are working with understudied populations, thereby expanding the breadth of genomic studies. In evaluating projects for this program, we consider scientific merit as well as how the research benefits the community being studied. We give preference to studies that engage local researchers and community members, and we provide support for community investments. Through prior collaborations of this nature, we have generated data on populations from Democratic Republic of Congo, Sierra Leone, Tanzania, and Southern Africa, which have enabled us to provide more detailed African ancestry.**

**HLA-C diversity and natural selection profile surveyed in a Brazilian population sample.** A.S. Souza<sup>1,2</sup>, M.A. Paz<sup>1,3</sup>, L.C. Veiga-Castelli<sup>4</sup>, I.O.P. Porto<sup>1,3</sup>, E.A. Donadi<sup>5</sup>, A. Sabbagh<sup>6</sup>, C.T. Mendes-Junior<sup>7</sup>, E.C. Castelli<sup>1,2,3</sup>. 1) São Paulo State University (UNESP), Molecular Genetics and Bioinformatics Laboratory - Experimental Research Unity, School of Medicine, Botucatu, State of São Paulo, Brazil; 2) São Paulo State University (UNESP), Genetics Program, Institute of Biosciences of Botucatu, Botucatu, State of São Paulo, Brazil; 3) São Paulo State University (UNESP), Pathology Program, School of Medicine, Botucatu, State of São Paulo, Brazil; 4) Department of Genetics, School of Medicine of Ribeirão Preto, University of São Paulo (USP), Ribeirão Preto, State of São Paulo, Brazil; 5) Department of Medicine, School of Medicine of Ribeirão Preto, University of São Paulo (USP), Ribeirão Preto, State of São Paulo, Brazil; 6) UMR 216 MERIT, IRD, Université Paris Descartes, Faculté de Pharmacie, Sorbonne Paris Cité, Paris, France; 7) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, São Paulo, Brasil.

*HLA-C* is a highly polymorphic Human Leukocyte Antigen class I gene associated with antigen presentation and NK cell modulation. *HLA-C* is the only classical *HLA* gene expressed on the maternal-fetal interface, where it plays an important immunomodulatory role. *HLA-C* variability at exons is frequently explored in worldwide populations, but minor attention has been given to regulatory and intron segments, as well as to other exons such as the one encoding the transmembrane and cytoplasmic domains. Variability at these neglected segments might influence the *HLA-C* expression profile and stability of the molecule. Here we present the variability and haplotype structure of the entire *HLA-C* locus, including introns and regulatory segments, surveyed in 400 individuals from the Brazilian Southeast. Variability was assessed using second-generation sequencing and in-house software to map reads taking into account *HLA* genes variability and structure. *HLA-C* presented 363 variable sites with a strong linkage disequilibrium (LD) among them, configuring 92 different extended haplotypes. The promoter segment (1,525bp upstream the first translated ATG) presented 82 variable sites and 29 haplotypes, the coding region (including introns) presented 245 variants and 83 haplotypes, and the 3'UTR segment presented 36 variants and 20 haplotypes. Each coding allele group was associated with the same promoter and/or 3'UTR haplotype groups. Nucleotide diversity was high throughout the gene, but the promoter and the 3'UTR initial segment (region of conserved targets for miRNA) presented the lowest indices detected. *HLA-C* presented signatures of balancing selection throughout the entire locus, exception made for the promoter segment and exon 1. Additionally, exon 1, which encodes the leader peptide, that is not part of the mature protein but an HLA-E ligand, presented evidence of positive selection. Together, these results indicate that *HLA-C* presents evidence of balancing selection along the entire locus, but it also presents conserved segments mainly related to expression regulation. Moreover, because of the high LD detected, few variable sites are necessary to capture the promoter, coding and 3'UTR haplotypes. Functional studies are fundamental to better understand the relationship between the *HLA-C* variability pattern and its function and expression profile, and also whether different promoters are related to a differential expression profile.

**2749T**

**Genetic variants in *ST6GAL1* gene are associated with thyroglobulin plasma level in healthy individuals.** *T. Zemunik<sup>1</sup>, A. Matana<sup>1</sup>, M. Popović<sup>1</sup>, T. Boutin<sup>2</sup>, V. Torlak<sup>2</sup>, D. Brdar<sup>2</sup>, I. Gunjača<sup>1</sup>, I. Kolčić<sup>1</sup>, V. Boraska Perica<sup>1</sup>, A. Punda<sup>3</sup>, O. Polašek<sup>4</sup>, M. Barbalčić<sup>1</sup>, C. Hayward<sup>2</sup>.* 1) Department of Medical Biology, University of Split, School of Medicine, Split, Croatia; 2) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, United Kingdom; 3) Department of Nuclear Medicine, University Hospital Split, Spinčićeva 1, Split, Croatia; 4) Department of Public Health, University of Split, School of Medicine, Šoltanska 2, Split, Croatia.

**Background:** Thyroglobulin (Tg) is the largest and most abundant protein in the thyroid gland that serves as a precursor for thyroid hormone synthesis. A twin study showed that there is a strong genetic component to the variability of serum Tg; however, no genome-wide association study (GWAS) of serum/plasma Tg levels has been reported so far. The aim of this study was to identify genetic variants associated with plasma Tg levels among healthy individuals. **Methods:** We performed GWAS meta-analysis within two Croatian populations, CROATIA\_Split and CROATIA\_Korcula. The analyses included 1094 healthy individuals. The selection of healthy individuals was based on detailed thyroid function assessment (including measurements of Tg, TSH, fT3, fT4, TgAb, and TPOAb) and anamnestic data. A total of 7 597 379 variants, imputed using the 1000 Genomes reference panel, were analysed for the association. GWAS was performed under an additive model, controlling for age, gender, and relatedness within each data set. Meta-analysis was conducted using the inverse-variance fixed-effects method. **Results:** Sixteen polymorphisms located on chromosome 3 within the *ST6GAL1* gene reached genome-wide significance. The most significant SNP was rs4012172 ( $P=1.29 \times 10^{-10}$ ), which explained 3.19% of the variance in Tg levels. *ST6GAL1* belongs to the sialyltransferase proteins family which has a fundamental role in the synthesis of specific sialylated structures on various glycoproteins, including thyroglobulin. *ST6GAL1* could have a role in the regulation of thyroglobulin level through receptor-mediated signalling transduction, helping to recycle immature Tg from thyrocytes into the follicle lumen, subsequently causing the alteration of Tg release in the circulation. **Conclusions:** In this first reported GWA meta-analysis of Tg levels, we identified a highly biologically plausible locus that could have a role in the regulation of plasma Tg levels in healthy individuals.

**Systematic comparative genomic analysis reveals differential DNA transposition as a significant mechanism in primate evolution.** *W. Tang, P. Liang.* Department of Biological Sciences, Brock University, St. Catharines, Ontario, Canada.

Mobile elements generated via DNA transposition represent an abundant type of DNA elements in primate genomes, ranging from ~47% in the green monkey genome to ~52% in the human genome. As a result of past and ongoing activity, DNA transposition is known to be responsible for generating inter-species and intra-species genomic variations, and it plays important roles in shaping genome evolution and in impacting gene function. While limited analysis of mobile elements has been performed in a few primate genomes, a large-scale systematic comparative genomic analysis is still unavailable. Using a bioinformatics comparative genomics approach, we performed an analysis to identify species-specific mobile elements (SS-MEs) in 8 primate genomes, which include human, chimpanzee, gorilla, orangutan, green monkey, crab-eating macaque, rhesus monkey, and baboon. These genomes have good representations for ape and monkey group of the primates for which genome sequences are available. Our analysis identified a total of 230,855 SS-MEs from the 8 primate genomes, which collectively contribute to ~82 Mbp genome sequences. Several new interesting observations were made based on these SS-MEs. First, the DNA transposition activity level was shown to be drastically different across species with the highest (baboon genome) being more than 30 times higher than the lowest (crab-eating macaque genome) by the number of SS-MEs. Second, the compositions of SS-MEs differ also significantly across genomes. By the copy numbers of SS-MEs divided into major ME classes, SINE represents the dominant class in all genomes, but more so in the monkey genomes than the ape genomes with orangutan genome being the outlier of this trend by having LINE as the dominant class. While AluY forms the major SINE classes in the ape genomes, AluYRa1 is the dominant SINE in the monkey genomes. For LINES, each genome seems to have different dominant L1 subfamilies. Third, DNA transposons, despite being considered to be dead in primate genomes, were in fact shown to have a certain level of activity in all genomes examined with a total of ~2,400 entries as SS-MEs. Representing the first systematic comparative analysis of mobile elements in primate genomes, our study has shown that mobile elements evolved quite differently among different groups and species of primates, indicating that differential DNA transposition has served as an important mechanism during primate evolution.

**2751W****Whole-genome based linkage disequilibrium maps in sub-Saharan**

**African population: Functional clustering and relationship to disease.** R. Jabal-Ameli Forooshani, W. J. Tapper, S. Ennis, A. Collins. Genetic epidemiology & Genomic Informatics, University of Southampton, Southampton, United Kingdom.

The extent and strength of linkage disequilibrium (LD) reflect the historical impact of recombination, selection and population history. The LD landscape in human population is known to comprise highly punctate hotspots that divide extended blocks of low haplotype diversity from narrow regions of LD breakdown. LD maps based on whole-genome sequence (WGS) data enables complete resolution of LD structure across human chromosomes. Increased marker density from WGS-derived data provides superior power for delineation of regions of the genome that are differentially recombined. We posited that recombination rate and haplotype diversity can be considered as a proxy for gene essentiality and establish the interesting relationship between gene function and LD strength. The weaker LD in sub-Saharan African population achieves unprecedented resolution for functional analysis LD maps in the context of human disorders. We constructed LD maps from WGS data across six sub-Saharan African populations according to the Malécot-Morton model of allelic association. The LD maps are constructed on the scale of linkage disequilibrium units (LDU) in which the decline of LD to 'background' levels across a variable physical distance corresponds to one LDU. The LDU scale enables direct comparison of the extent of LD in different genomic regions independent of the physical scale. The gene-specific LDU size across 17,927 genes was corrected for gene length and converted to a gene-specific Z-scores. Functional gene clustering analysis across quartiles was carried out in PANTHER (v.13.1) and taxonomic comparison of gene clusters was carried out using HomoloGene database (release 68). Our results demonstrate that the magnitude of LDU size across different populations directly reflects the paleogeographic characteristic of the respective population. We identified that gene clusters with intense LD are enriched with genes involved in developmentally important pathways such as DNA damage response or regulators of cell-cycle checkpoints. We also identified that gene clusters with extensive LD are generally evolved earlier during evolution. In contrast genes with low LD appear to be enriched with gene clusters that evolved more recently. In conclusion, fully saturated LD maps generated from whole-genome data in SSA populations provides a framework for accurate delineation of signatures of selective sweeps in the human genome.

**2752T****A map of constrained coding regions in the human genome.**

A. Quinlan, J. Havrilla, R. Layer, B. Pedersen. Department of Human Genetics, University of Utah, Salt Lake City, UT.

Deep catalogs of genetic variation collected from many thousands of humans enable the detection of intraspecies constraint by revealing coding regions with a scarcity of variation. While existing techniques summarize constraint for entire genes, single metrics cannot capture the fine-scale variability in constraint within each protein-coding gene. To provide greater resolution, we have created a detailed map of constrained coding regions (CCRs) in the human genome by leveraging coding variation observed among 123,136 humans from the Genome Aggregation Database (gnomAD). The most constrained coding regions in our map are enriched for both pathogenic variants in ClinVar and de novo mutations underlying developmental disorders. CCRs also reveal protein domain families under high constraint, suggest unannotated or incomplete protein domains, and facilitate the prioritization of previously unseen rare variation and de novo mutation in studies of disease. Finally, we hypothesize that CCRs with the highest constraint exist within genes that are likely to cause yet unobserved human phenotypes owing to strong purifying selection. As such, they have the promise of revealing new genic regions, that when mutated, lead to severe developmental phenotypes. .

**Bayesian factor analysis for inference of population structure and polygenic selection.** *A. Kousathanas, M. Robinson.* Complex Trait Genetics Group, Department of Computational Biology, University of Lausanne, Switzerland.

Human populations display substantial within and between-population phenotypic variation. It is unknown to what extent between-population phenotypic differences have been driven by adaptive evolution to each population's local environment. Understanding local adaptation is crucial as it may underlie population differences in disease risk, especially when individuals move to new environments during their life that are different from their ancestor's. The highly polygenic architecture of most quantitative traits and common diseases, suggests that adaptive evolution should be driven by the cumulative effect of selection over many loci. Existing methods to detect selection on traits that underlie local adaptation take advantage of this expectation by using the cumulative selection signal across several loci associated with a particular trait. However, these methods typically only use loci that are strongly associated with a particular trait, suffer from ascertainment biases that may be extreme, require defined populations which is particularly difficult in cases of heavy admixture, and provide limited inference as to the genomic regions involved in polygenic adaptation. Here, we address these issues, by developing an approach based on Bayesian factor analysis, that is a generalization of the widely used principal component analysis (PCA). Our method jointly infers population structure, the effect of each locus on population differentiation ( $z$ ), the effect of each locus on one or multiple traits ( $b$ ), and the covariance between locus effects and genetic differentiation ( $cov(z,b)$ ). We present theory and extensive simulation work to demonstrate how the estimation of  $cov(z,b)$  provides unique inference of polygenic selection. The signal detected can be decomposed to reveal the populations that experienced local adaptation, the direction of the phenotypic differentiation, and the genomic regions involved. We analyse a range of human genotype-phenotype datasets, testing for population genetic differentiation of height, body mass index, and common complex disorders of cardiovascular disease and type-2 diabetes. Overall, our method not only unifies population genetic structure and genetic association analyses into a single framework, but provides a comprehensive way to infer the signal of polygenic selection.

**A standardized statistic improves power to detect long-term balancing selection.** *K.M. Siewert<sup>1</sup>, B.F. Voight<sup>2,3,4</sup>.* 1) Genomics and Computational Biology Graduate Group, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Department of Systems Pharmacology and Translational Therapeutics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Institute for Translational Medicine and Therapeutics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Balancing selection is an evolutionary force which can maintain genetic variation in a population over long evolutionary time periods. Detection of genomic targets of this type of selection can reveal selective pressures and phenotypically interesting haplotypes in the genome. Until recently, methods to detect this type of selection suffered from a lack of power or were computationally intensive. We recently reported a method (Beta) to detect balanced haplotypes without the need for genomic data from an outgroup species. This method uses a difference of two estimators of the mutation rate, one which is sensitive to balancing selection and one which corrects for the background mutation rate. Here, we present new work which incorporates between-species substitution data into a novel mutation rate estimator integrated into the Beta statistic framework. We show that this new approach outperforms existing summary statistic methods in simulations under a broad array of parameters. In addition, we derive formulas for the variance of both versions of Beta -with and without substitution data- allowing for the calculation of a z-score. This facilitates appropriate interpretation of the evidence of balancing selection across samples, populations, and allele frequencies, variables that hampered previously described methods. As a result, the Beta statistic is a well-powered approach to detect balancing selection in a wide variety of species.

**2755T****Population pharmacogenomics for precision public health in Colombia.**

*E.T. Norris*<sup>1,2,3</sup>, *M. Robledo-Moreno*<sup>4</sup>, *S.D. Nagar*<sup>1,2,3</sup>, *L. Rishishwar*<sup>2,3</sup>, *K.L. O'Neal*<sup>1</sup>, *S. Vélez*<sup>4</sup>, *I. Torres*<sup>4</sup>, *M.A. Medina-Rivas*<sup>5</sup>, *A. Valderrama-Aguirre*<sup>6</sup>, *I.K. Jordan*<sup>1,2,3</sup>, *J.E. Gallo*<sup>4</sup>. 1) School of Biological Sciences, Georgia Institute of Technology, Atlanta, GA, USA; 2) IHRC-Georgia Tech Applied Bioinformatics Laboratory, Atlanta, GA, USA; 3) PanAmerican Bioinformatics Institute, Cali, Valle del Cauca, Colombia; 4) GenomaCES, Universidad CES, Medellín, Antioquia, Colombia; 5) Centro de Investigación en Biodiversidad y Hábitat, Universidad Tecnológica del Chocó, Quibdó, Chocó, Colombia; 6) Biomedical Research Institute, Faculty of Health, Universidad Libre-Seccional Cali, Cali, Valle del Cauca, Colombia.

While genomic approaches to precision medicine hold great promise, they remain prohibitively expensive for developing countries. The precision public health paradigm, whereby healthcare decisions are made at the level of populations as opposed to individuals, provides one way for the genomics revolution to directly impact health outcomes in the developing world. Genomic approaches to precision public health require a deep understanding of local population genomics, which is still missing for many developing countries. We are investigating the population genomics of pharmacogenetic variants in an effort to inform healthcare decisions in Colombia. Our work focuses on two neighboring populations with distinct ancestry profiles: Antioquia (European) and Chocó (African). We discovered a number of pharmacologically relevant variants that show anomalous effect allele frequencies within and between the two populations and found these differences to be associated with their distinct genetic ancestry. For example, the C allele of the SNP rs4149056, which is associated with an increased risk of toxicity to a commonly prescribed statin, is found at relatively high frequency in Antioquia and associated with European ancestry. In addition to alleles related to increased toxicity risk, we also have evidence that alleles related to dosage and metabolism have anomalous frequencies between the two populations and are associated with specific ancestries. Using these findings, we have developed and validated an inexpensive allele-specific PCR assay to test for the presence of such population-enriched pharmacogenetic SNPs in resource-limited settings like Colombia.

**2756F****A new paradigm for pharmacogenomic discoveries: Capturing drug response during surgery.**

*S. Wenric*<sup>1</sup>, *J.M. Jeff*<sup>1</sup>, *T. Joseph*<sup>2</sup>, *K. Slivinski*<sup>1</sup>, *M-C. Yee*<sup>3</sup>, *G.M. Belbin*<sup>1</sup>, *A.O. Obeng*<sup>1,4,5</sup>, *S.B. Ellis*<sup>1</sup>, *E.P. Bottinger*<sup>1</sup>, *O. Gottesman*<sup>1</sup>, *M.A. Levin*<sup>2,6</sup>, *E.E. Kenny*<sup>1,7,8,9</sup>. 1) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai Hospital, New York, NY; 2) Department of Anesthesiology, Icahn School of Medicine at Mount Sinai Hospital, New York, NY; 3) Carnegie Institution for Science, Dept. of Plant Biology, Stanford, CA; 4) Division of General Internal Medicine, Icahn School of Medicine at Mount Sinai Hospital, New York, NY; 5) Department of Pharmacy, Icahn School of Medicine at Mount Sinai Hospital, New York, NY; 6) Division of Cardiothoracic Anesthesia, Icahn School of Medicine at Mount Sinai Hospital, New York, NY; 7) Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai Hospital, New York, NY; 8) Department of Genetics and Genomics, Icahn School of Medicine at Mount Sinai Hospital, New York, NY; 9) Center for Statistical Genetics, Icahn School of Medicine at Mount Sinai Hospital, New York, NY.

We present a novel pharmacogenomic approach in which we define **real-time drug response to intravenous medication administered during surgery**. We have built a database of surgical procedures that capture drug administration events and succeeding physiological responses, as well as type and length of surgery, anesthetic technique, quantity of fluids administered and other patient information. These data are linked to an internal Biobank of patients from New York, with genotype, sequence, and rich phenotypic data from the electronic medical record. Leveraging this resource, we investigated real-time response to phenylephrine, a selective  $\alpha$ 1-adrenergic receptor agonist that is used to treat hypotension during surgery. We found that administration of a bolus of phenylephrine (50-200 $\mu$ g) increases MAP an average of **17.03 mmHg (SE $\pm$ 0.44), 14.8 mmHg(SE $\pm$ 0.48), and 14.89 mmHg(SE $\pm$ 0.41), in self-reported European-Americans (EA;n=1389), African-Americans (AA;n=1221) and Hispanic/Latino (HL;n=1714), respectively. Overall EAs have a greater response to phenylephrine compared to HLs and AAs (Mann-Whitney-Wilcoxon p-value < 0.0003 and 0.0004 respectively). We performed a GWAS to test whether genetic variation influences  $\Delta$ MAP after phenylephrine drug bolus. We confirmed associations in biologically relevant  $\alpha$ 1-adrenergic receptors, *ADRA1A* (p<2\*10<sup>-2</sup>) and *ADRA1B* (p<4\*10<sup>-3</sup>) and overall association enrichment in *ADRA1A*. Notably, **we discovered a suggestive GWAS signal (p=5.16\*10<sup>-9</sup>) in ERICH1 gene**, which codes for glutamate rich protein 1. This work demonstrates our ability to define real-time drug response, detect population differences in phenylephrine response, large effect alleles and novel genes affecting pharmaceutical response, and identify a subset of phenylephrine 'non-responders' with implications for personalized treatment during surgery.**

**2757W**

**Genetic substructure in the State of Jammu and Kashmir, India: Insights from two populations based on autosomal, Y-chromosomal and mitochondrial DNA analyses.** *M. Singh<sup>1</sup>, A. Sarkar<sup>1</sup>, D. Kumar<sup>2</sup>, M.R. Nandineni<sup>1</sup>.*

1) Centre for DNA Fingerprinting and Diagnostics, Hyderabad, India; 2) Central Forensic Science Laboratory, Kolkata, India.

Indian sub-continent is bestowed with cultural, linguistic and genetic diversity. Jammu and Kashmir (J&K) is the northern most frontier of the country and its strategic location at the crossroads of China and Tibet in the north-east and Afghanistan and Pakistan in the north-west provides a great opportunity for population geneticists. Here we present the analysis of two populations of J&K viz., Gujjars (GJ) and Ladakh populations (LL). GJ are nomadic/semi-nomadic tribes practicing high level of endogamy, whereas LL are from high altitude region (>3,000 m above sea level (masl)), though one of the most difficult places for inhabitation but was once considered as 'Silk-Road' that played crucial roles in trade and exchange of culture. Both GJ and LL were analyzed employing markers on autosomes (single nucleotide polymorphisms (SNPs) and short tandem repeats (STRs)), Y-chromosome (Y-STRs) and mitochondrial DNA sequences (control region). Pairwise  $F_{ST}$  values and cluster analysis based on 275 SNPs shortlisted previously showed that GJ behaved differently than the rest of the populations. Principle co-ordinate and cluster analyses based on 22 autosomal STRs highlighted that GJ and LL were not only genetically distant to each other but they were also shown to be distant to other populations studied. These observations were further substantiated by 23 Y-STRs which also highlighted the unique nature of both the populations. On comparison with other populations of the world, interestingly we observed genetic proximity of GJ with Pashtuns, Pathans and Sindhis. LL populations on other hand showed genetic affiliations with populations from Nepal, Tibet and Uighur-China. GJ were represented by Y-haplogroup; R1a, H and L whereas LL comprised of R1a, L, Q, J1, R1b and I2a1 Y-haplogroups. A total of 19 and 42 unique haplogroups based on mtDNA analysis were assigned to GJ and LL respectively and revealed much lower genetic diversity for GJ than LL, which indicated a greater heterogeneity in LL as compared to GJ. Higher ratio of patrilineal to matrilineal  $F_{ST}$  was observed in both GJ and LL which is indicative of patrilocal practices in these groups. Overall this study provides a comprehensive picture of GJ and LL which would connect the dots to trace the ancient trails of human migration in this part of the globe. .

**2758T**

**Examining highly differentiated genotypes in the Tangier Island genetic study.** *T.M. Brunetti<sup>1</sup>, M. Daya<sup>1</sup>, A. Shetty<sup>1</sup>, N. Rafaels<sup>1</sup>, M. Boorgula<sup>1</sup>, S. Chavan<sup>1</sup>, M. Campbell<sup>1</sup>, C.R. Gignoux<sup>1</sup>, T.H. Beaty<sup>2</sup>, K.C. Barnes<sup>1</sup>, R.A. Mathias<sup>2</sup>.* 1) Department of Medicine, University of Colorado, Aurora, CO, USA; 2) Department of Epidemiology, Bloomberg School of Public Health, JHU, Baltimore, MD, USA.

**RATIONALE:** Population isolate communities continue to exist in the United States. During 1993-2001, we recruited ~60% of the 650 individuals living on Tangier Island, Virginia, into a genetics of asthma and associated traits study. Tangier Islanders have retained Cornish speech attributes, reflecting their British heritage and relative isolation. The island can be reached by 45-minute boat ride or by small aircraft, but limited occupational opportunities minimized immigration to the island in the 20<sup>th</sup> century. We used genealogical data to reconstruct the extended pedigree of 3,512 individuals to the settlement of the community founded in 1722. In this study, we aimed to identify disease relevant alleles that are common in the Tangier Island population, but rare in comparable populations of European Americans. **METHODS:** Samples were genotyped on the Illumina's MEGA. After quality control, 404 samples were available, after which PRIMUS was used to identify a maximal set of 88 independent individuals for further analysis to mitigate inherent bias within a highly related population. HLA genotypes were estimated using HIBAG and its multi-ethnic reference panel, and genotypes with posterior probability > 0.5 were assigned to subjects. HLA allele frequencies of European Americans were downloaded from allelefrequencies.net and compared with the Tangier Island frequencies. Logistic regression (PLINK) was used to identify SNPs across the genome with relatively large frequencies in Tangier Island compared to 90 Thousand Genomes Project (TGP) individuals from Great Britain (GBR). ClinVar annotations were performed using ANNOVAR. **RESULTS:** We identified multiple HLA alleles that are rare in European Americans but quite common on Tangier Island: DBP1\*02:02 (0.7% vs. 10.8%), DBP1\*05:01 (1.8% vs. 8.5%), DRB1\*01:02 (1.3% vs. 20.45%), DRB1\*01:03 (1.2% vs. 10.8%), DRB1\*04:02 (1.1% vs. 8.5%), DQA1\*01:04 (3.2% vs. 18.2%), B\*14:01 (1.0% vs. 22.2%) and A\*02:05 (0.9% vs. 20.5%). Additionally, 23 SNPs were identified in ClinVar as likely pathogenic and one SNP located on chromosome 11 at position 16691634 was found to be more common in Tangier Island compared to TGP GBR with minor allele frequencies of 0.1477 and 0.05, respectively (Bonferroni corrected p-value < 0.05). **CONCLUSION:** Tangier Island is a genetically isolated founder population, and we speculate such alleles rose to higher frequency due to founder effects and subsequent isolation, which we aim to quantify in future work.

**2759F**

**Detecting fine scale population structure, migration and recent population expansion in the Netherlands.** *R.P. Byrne<sup>1</sup>, W. van Rheenen<sup>2</sup>, L.H. van den Berg<sup>2</sup>, J.H. Veldink<sup>2</sup>, R.L. McLaughlin<sup>1</sup>.* 1) Smurfit Institute of Genetics, Trinity College Dublin, Dublin, Leinster, Ireland; 2) Department of Neurology, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, the Netherlands.

We present a detailed genetic study of the population structure and history of the Netherlands, exploiting both genome wide SNP data (N=1626) and geographic information (N=1422), which together allow us to explore the interplay between genetics and local geography. Our study exploits recently developed methods to: i.) Explore fine-scale population structure within the country; ii.) Model local patterns of migration; iii.) Estimate changes in effective population size in recent years. To explore fine scale population structure we applied the ChromoPainter/fineSTRUCTURE pipeline, which defines genetic clusters based on patterns haplotype sharing across samples. We observed that our genetic clusters correlate closely with geography, and demonstrate regional structure at a level not previously seen, revealing subtle differences both between and within the provinces of the Netherlands. These genetic clusters are robust and demonstrate high genetic differentiation (Mean pairwise  $F_{st}$ : 0.000458), with some pairs showing pairwise  $F_{st}$  as high as 0.001. This is comparable to the level of differentiation observed between some European countries. At the coarsest level of clustering we identified a clear north/south split, roughly separated by the Rhine. To investigate whether this split reflects a barrier to gene flow, we estimated regional rates of migration across the country using the recently developed "Estimating Effective Migration Surfaces" (EEMS) method. EEMS models local migration rates based on the relationship between genetic and geographic distance. Our analysis revealed a strong migrational cold spot spanning the center of the Netherlands broadly overlapping the Rhine, supporting evidence that it may act as a barrier to gene flow. Finally we explored recent changes in the effective population size ( $N_e$ ) using the IBDNe method. IBDNe harnesses information from long inferred segments of Identity By Descent (IBD) in a population to estimate  $N_e$  across recent generations. We observed a super-exponential population expansion across the past 50 generations, which rapidly increases in rate from ~1650 CE onwards, roughly corresponding to the Dutch Golden age in the 17th century. This growth may have been triggered by the increased prosperity and immigration during this period. Notably our  $N_e$  estimates from the northern provinces are systematically lower than in the south, consistent with increased IBD sharing and ROH in northern provinces reported previously.

**Detection of shared balancing selection in the absence of trans-species polymorphism.** *X. Cheng<sup>1,2</sup>, M. DeGiorgio<sup>1,3,4</sup>.* 1) Department of Biology, Pennsylvania State University, University Park, PA; 2) Huck Institutes of Life Sciences, Pennsylvania State University, University Park, PA; 3) Department of Statistics, Pennsylvania State University, University Park, PA; 4) Institute for CyberScience, Pennsylvania State University, University Park, PA.

Trans-species polymorphism has been widely used as a key sign of long-term balancing selection across multiple species. However, such sites are often rare in the genome, and could result from mutational processes or technical artifacts. Few methods are yet available to specifically detect footprints of trans-species balancing selection without using trans-species polymorphic sites. In this study, we develop summary- and model-based approaches that are each specifically tailored to uncover regions of long-term balancing selection shared by a set of species by using genomic patterns of intra-specific polymorphisms and inter-specific fixed differences. We demonstrate that our trans-species statistics have substantially higher power than single-species approaches to detect footprints of trans-species balancing selection, and are robust to those that do not affect all tested species. We further apply our model-based methods to human and chimpanzee whole genome sequencing data. In addition to the previously-established MHC and malaria resistance-associated *FREM3/GYPE* regions, we also find outstanding genomic regions involved in barrier integrity and innate immunity, such as the *GRIK1/CLDN17* intergenic region, and the *ABCA13* and *THSD7B* genes. Our findings echo the significance of pathogen defense in establishing balanced polymorphisms across human and chimpanzee lineages. Finally, we show that these trans-species statistics can be applied to and work well for an arbitrary number of species, and integrate them into open-source software packages for ease of use by the scientific community.

**A comprehensive map of genetic variation in the world's largest ethnic group - Han Chinese.** C. Chiang<sup>1</sup>, S. Mangul<sup>2</sup>, C. Robles<sup>2</sup>, S. Sankararam<sup>2</sup>. 1) University of Southern California, Los Angeles, CA; 2) University of California, Los Angeles, Los Angeles, CA.

As are most non-European populations around the globe, the Han Chinese are relatively understudied in population and medical genetics studies. From low-coverage whole-genome sequencing of 11,670 Han Chinese women we present a catalog of 25,057,223 variants, including 548,401 novel variants that are seen at least 10 times in our dataset. Individuals from our study come from 24 out of 33 administrative divisions across China (including 19 provinces, 4 municipalities, and 1 autonomous region), allowing us to study population structure, genetic ancestry, and local adaptation in Han Chinese. We identify previously unrecognized population structure along the East-West axis of China, demonstrate that a general pattern of isolation-by-distance among Han Chinese, and report unique signals of admixture across geographical space, such as European influences among the Northwestern provinces of China. Finally, we identified a number of highly differentiated loci, such as MTHFR, ADH7, and FADS, among others. These putative signals of local adaptation may be driven by immune response, climate, and diet in the Han Chinese. On the other hand, we find that Neandertal ancestry does not vary significantly across the provinces, and contrary to a previous report, Neandertal ancestry does not explain a significant amount of heritability in depression. We have published allele frequency estimates stratified by administrative divisions across China in the Geography of Genetic Variant browser. Our findings provide the largest genetic data set so far made available for Han Chinese and provide insights into the history and population structure of the world's largest ethnic group.

**Transcriptome and chromatin accessibility in diverse African populations enables fine-mapping GWAS.** M.K. DeGorter<sup>1</sup>, E. Karakoc<sup>2,3</sup>, T. Carstensen<sup>2,3</sup>, M.P.S. Moorthy<sup>1,4</sup>, V.R. Dwaracherla<sup>1,4</sup>, K.S. Smith<sup>1</sup>, C. Pomilla<sup>2,3</sup>, J. Fellay<sup>5,6</sup>, P. McLaren<sup>7,8</sup>, D. Gurdasani<sup>2,3</sup>, P. Flicek<sup>9,10</sup>, S.B. Montgomery<sup>1</sup>, M. Sandhu<sup>2,3</sup>. 1) Department of Pathology, Stanford University, Stanford, CA; 2) Human Genetics, Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 3) Department of Medicine, University of Cambridge, Cambridge, UK; 4) School of Engineering, Stanford University, Stanford, CA; 5) School of Life Sciences, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland; 6) Precision Medicine Unit, Lausanne University Hospital, Lausanne, Switzerland; 7) JC Wilt Infectious Diseases Research Centre, Public Health Agency of Canada, Winnipeg, Canada; 8) Department of Medical Microbiology and Infectious Diseases, University of Manitoba, Winnipeg, Canada; 9) European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Genome Campus, Hinxton, Cambridge, UK; 10) Wellcome Sanger Institute, Wellcome Genome Campus, Hinxton, Cambridge, UK.

The increased genetic diversity and lower linkage disequilibrium in African populations provides a powerful opportunity to improve our understanding of genetic variants influencing gene expression, gene regulation and disease. Despite this potential, functional genomics data from African populations have been mainly limited to the Yoruba population sample. To more broadly characterize transcriptome diversity in Africa, we measure gene expression using RNA-Seq in LCLs from 599 individuals from six African populations, including 166 Maasai (MKK), 97 Luhya (LWK), 42 Yoruba (YRI), 112 Gambian (GWD), 99 Esan (ESN) and 83 Mende (MSL). Using whole genomes from the 1000 Genomes Project and 166 deeply-sequenced Maasai, we identify expression and splicing quantitative trait loci (eQTLs/sQTLs) and assess patterns of sharing between populations and with European individuals sampled as part of the GEUVADIS project. We use ATAC-Seq to assess chromatin accessibility in a subset of 100 of these individuals, including from 17 GWD, 16 LWK, 17 ESN, 17 MKK, 16 MSL and 17 YRI individuals. Using these data, we characterize differential gene expression and differential chromatin accessibility across African populations and their relationship to population differentiation. To characterize the whole range of the transcript structure in African populations, we also assemble novel transcripts in these six populations. In addition to identifying 99.4% of all known annotated transcripts, we identify novel transcripts and exons, providing insights into the transcriptomic landscape among African populations. Finally, we use gene expression and chromatin accessibility in African populations to fine-map GWAS signals for a range of complex diseases. This project provides a powerful functional genomics resource for biomedical research to identify causal variants, understand population genetic history and interpret the genomic basis of disease.

**2763W****A statistical model for reference-free inference of archaic local ancestry.**

A. Durvasula<sup>1</sup>, S. Sankararaman<sup>1,2,3</sup>. 1) Human Genetics, UCLA, Los Angeles, CA; 2) Computer Science, UCLA, Los Angeles, CA; 3) Bioinformatics IDP, UCLA, Los Angeles, CA.

Statistical analyses of genomic data from diverse human populations have demonstrated that archaic hominins, such as Neanderthals and Denisovans, interbred with the ancestors of modern humans. Central to these analyses are methods for inferring archaic ancestry along the genomes of present-day individuals. Methods for archaic local ancestry inference rely on the availability of reference genomes from the ancestral archaic populations for accurate inference. However, several instances of archaic admixture lack archaic genomes, making it difficult to characterize these events. We present a statistical method that combines diverse population genetic summary statistics to infer archaic local ancestry inference without access to an archaic reference genome. We pose the problem as a classification problem, where we are interested in the probability of a haplotype being archaic. We simulate data using the coalescent according to a demographic history that approximates human-Neanderthal history. Then, we calculate summary statistics informative of admixture and train a logistic regression model, learning the weights of each summary statistic. We validate the accuracy and robustness of our method in simulations and find that our method is robust to structure as well as misspecification in the demographic model. When applied to genomes of Europeans, our method recovers segments that are substantially enriched for Neanderthal ancestry without having access to any Neanderthal reference genomes. Overall, we find ~1.99% of European genomes have Neanderthal ancestry at a false discovery rate of 20% consistent with previous estimates. We also validate previous signals of high frequency archaic introgression at the *BNC2* gene and *OAS* gene cluster. Finally, we recapitulate the reduction in the frequency of archaic ancestry in selectively constrained regions of the genome. We then applied our method to west African Yoruban genomes and find that on average, ~7.97% of these genomes trace their ancestry to a deeply-diverged ancestral population. We find that these segments of ancestry are not enriched for Neanderthal ancestry suggesting that this ancestry is not a result of Neanderthal introgression. We also find no enrichment for ancestry related to Biaka and Mbuti populations suggesting that this ancestry does not derive from these hunter-gatherer populations. Our results indicate that our method can be useful in characterizing ancient admixture in modern human populations.

**2764T****Population genetics and historical demography of North American immigrant communities.**

D. Garrigan<sup>1</sup>, S. Song<sup>1</sup>, A.J. Stern<sup>1,3</sup>, J.K. Byrnes<sup>1</sup>, E.L. Hong<sup>1</sup>, C.A. Ball<sup>1</sup>, K.G. Chahine<sup>2</sup>. 1) Ancestry.com, San Francisco, CA; 2) Ancestry.com, Lehi, UT; 3) University of California Berkeley, Berkeley, CA.

Contemporary North American populations are a genetic mosaic resulting from admixture between numerous founding groups, each of whom immigrated at different times and in different numbers. A large pairwise identity-by-descent (IBD) network among millions of immigrant North American individuals enables us to identify recent fine-scale population structure. We refer to clusters in these IBD networks as "genetic communities" and the distributions of shared pairwise IBD segment lengths within these communities can be leveraged to estimate the recent trajectory of the community effective population size. Interestingly, many of the genetic communities show a pronounced enrichment for IBD segments with lengths corresponding to coalescence events occurring between 8-13 generations before the present. Our model of historical demography attributes this observed enrichment to transient reductions in the historical effective size of a genetic community. To explore possible alternative demographic models, we examine the distribution of IBD segment lengths in simulated ancestral recombination graphs generated under models that include gene flow and admixture. The simulations suggest that the most likely explanation for this transient reduction in historical effective size is a bottleneck/founder event. Furthermore, the putative bottleneck/founder event pattern is preferentially inferred for older, or more geographically isolated, immigrant communities. Conversely, the founder event pattern is absent from genetic communities who likely immigrated to North America more recently. To complete this characterization of the demographic histories of these genetic communities, we use historical genealogical records to estimate both dispersion rate and generation time from each of the communities. We found that father-child distance is significantly higher than mother-child distance among all genetic communities and generation time differs between sex and genetic communities significantly. Finally, we consider the implications of these recent demographic events by examining how the distributions of allele frequencies of clinically relevant variants and allele ages vary across these genetic communities.

**Fast and accurate identification of diploid IBD segments in large biobank cohorts.** X. Geng<sup>1</sup>, A. Naseri<sup>2</sup>, X. Liu<sup>3</sup>, S. Zhang<sup>2</sup>, D. Zhi<sup>1</sup>. 1) School of Bio-medical Informatics, University of Texas Health Science Center at Houston, Houston, TX; 2) Department of Computer Science, University of Central Florida, Orlando, Florida 32816, USA; 3) Department of Epidemiology, Human Genetics & Environmental Sciences, The University of Texas Health Science Center at Houston, Houston, Texas 77030, USA.

Diploid IBD segments, or IBD2 segments, are IBDs on both copies of chromosomes between two individuals. Obviously, diploid IBDs are enriched among of full-siblings and double-cousins and are useful for tracing relatives. IBD2 is relatively less well-studied compared to haploid IBD (IBD1) but over 30 unexpected IBD2 sharing were found in 1,397 individuals from HapMap III, suggesting the presence of unnoted inbreeding. Effectively, diploid IBDs create "local identical twins", i.e., complete identical pair of chromosomal segments only up to a few mutations. Therefore, studies of diploid IBDs is potentially connected to the twin-study literature. Also, IBD2 is informative for mapping phenotypes with strong local recessive effects. IBD2 matrix can be used as an additional matrix for estimating heritability beyond additive effects. Although diploid IBDs are much-less prevalent than haploid IBDs, they are enriched in populations experienced a recent bottleneck or populations with endogamy. Therefore, they are also informative for inferring recent demographic history. However, diploid IBDs are not well-studied in population settings due to lack of sensitive and efficient detection methods. We developed an efficient method for the detection of diploid IBDs in population setting, RaPID-IBD2. Our methods is an extension of our previous methods for IBD1 segment detection, RaPID. In simulated data sets, we showed that our method scales up linearly with the sample size, and can detect IBD2 segments with high power and accuracy. We apply RaPID-IBD2 in UK Biobank data and reveal interesting patterns.

**Genetic ancestry and population structure of Scotland and its surrounding isles.** E.H. Gilbert<sup>1</sup>, S. O'Reilly<sup>2</sup>, M. Merrigan<sup>2</sup>, D. McGettigan<sup>2</sup>, V. Vitar<sup>2</sup>, P.K. Joshi<sup>4</sup>, D.W. Clark<sup>4</sup>, H. Campbell<sup>4</sup>, C. Hayward<sup>5</sup>, S. Ring<sup>5</sup>, J. Golding<sup>6</sup>, N. Timpson<sup>7</sup>, P. Navarro<sup>3</sup>, S.M. Kerr<sup>3</sup>, C. Amador<sup>3</sup>, A. Campbell<sup>8</sup>, C.S. Haley<sup>3,9</sup>, D.J. Porteous<sup>8</sup>, G.L. Cavalleri<sup>10</sup>, J.F. Wilson<sup>3,4</sup>. 1) Molecular and Cellular Therapeutics, Royal College of Surgeons in Ireland, Dublin, Leinster, Ireland; 2) Genealogical Society of Ireland, Dún Laoghaire, Ireland; 3) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Edinburgh, Scotland; 4) Centre for Global Health Research, Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, Scotland; 5) Bristol Bioresource Laboratories, Population Health Sciences, Bristol Medical School, University of Bristol, Bristol, UK; 6) Centre for Child and Adolescent Health, Bristol Medical School, University of Bristol, Bristol, UK; 7) Avon Longitudinal Study of Parents and Children, MRC Integrative Epidemiology Unit, University of Bristol, Bristol UK; 8) Centre for Genomic and Experimental Medicine, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Edinburgh, Scotland; 9) The Roslin Institute and Royal (Dick) School of Veterinary Sciences, University of Edinburgh, Edinburgh, Scotland; 10) FutureNeuro Research Centre, Royal College of Surgeons in Ireland, Dublin, Ireland.

Scotland and Ireland are separated in places by less than 20 kilometres of sea. They share related Gaelic languages and similar frequencies of particular alleles and phenotypes, hinting at shared ancestry. The population structure within England and Ireland have recently been described. However, the extent of structure within the majority of Scotland, its surrounding islands, and their links to Ireland are less understood and have been described with less resolution. We present an analysis of the British Isles and Ireland using a combined and comprehensive sample (n=2,556) of all major regions – expanding coverage in mainland Scotland (n=567), the Hebrides (n=57), the Isle of Man (n=40), Orkney (n=111) and Shetland (n=172). By analysing individuals with extended ancestry from specific regions with haplotype-based methods, we demonstrate extensive structure in all regions of the British Isles and Ireland, as well as some of the finest scale structure observed worldwide within Orkney. We resolve the shared genetic history between Ireland and Mainland Scotland, confirm the strongest differentiation of Orkney and Shetland from other populations, show the major differentiation in Mainland Scotland is between the south-west and the north-east, and reveal the distinctiveness of the Hebrides and the Isle of Man. Finally we also show a decreasing cline of Norwegian ancestry in the north of Britain and Ireland, across northern Scottish islands to Ireland and the Isle of Man, following the spread of the Norse Vikings. Our work represents a comprehensive description of genetic structure in the British Isles and Ireland and greatly expands the knowledge of genetic stratification within the north of the British Isles. This informs on the study of rare genetic variants and genetic trait associations in these populations, as well as supplementing our knowledge of Scottish history.

**2767T**

**Population structure and demographic history of Ethiopian hunter-gatherers.** S. Gopalan<sup>1</sup>, R.E.W. Berf<sup>2</sup>, G.M. Belbin<sup>3</sup>, C.R. Gignoux<sup>4</sup>, M.W. Feldman<sup>5</sup>, B.S. Hewlett<sup>6</sup>, B.M. Henn<sup>7</sup>. 1) Stony Brook University, Stony Brook, NY; 2) Colorado State University, Fort Collins, CO; 3) Icahn School of Medicine at Mount Sinai, New York, NY; 4) University of Colorado, Anschutz Medical Campus, Aurora, CO; 5) Stanford University, Stanford, CA; 6) Washington State University, Vancouver, WA; 7) University of California, Davis, Davis, CA.

The process by which populations transitioned to agropastoralism remains a major research question in both archaeology and genetics. In particular, the fate of hunting and gathering populations during the agricultural transition, by cultural adoption, extinction, or incorporation into expanding populations, may be heterogeneous within Africa. Here, we investigate the genetic signatures of a transition to agriculture by studying three populations in southwest Ethiopia: the Chabu, who were primarily hunter-gatherers until the 1990s, and their close neighbours, the Majang and the Shekkacho. The genomes of the Chabu indicate that they are a genetically distinct group from all other Ethiopians characterized so far, with strong genetic affinities to Mota, an ancient Ethiopian man who lived 4,500 years ago. They are also more related to the Majang than the Shekkacho, with Chabu individuals sharing a mean of 49,706 kb of their genomes identically by descent with Majang individuals, compared to only 1,780 kb with Shekkacho individuals. We also show that the Chabu have been experiencing a steady decline in population that has accelerated in the past 30 generations, and are currently significantly more endogamous than their neighbours. We compare and contrast the demographic histories of the Chabu with additional populations of the region, including other former hunter-gatherers. These results serve to elucidate the various consequences the spread of agriculture had on hunter-gatherer populations in Ethiopia.

**2768F**

**Identifying and classifying shared selective sweeps from multilocus data.** A.M. Harris<sup>1,2</sup>, M. DeGiorgio<sup>2,3,4</sup>. 1) Molecular, Cellular, and Integrative Biosciences, Pennsylvania State University, University Park, PA; 2) Department of Biology, Pennsylvania State University, University Park, PA; 3) Department of Statistics, Pennsylvania State University, University Park, PA; 4) Institute for CyberScience, Pennsylvania State University, University Park, PA.

Positive selection causes beneficial alleles to rise to high frequency, resulting in a selective sweep of the diversity surrounding the selected sites. Accordingly, the signature of a selective sweep in an ancestral population may still remain in its descendants. Identifying genomic regions under selection in the ancestor is important to contextualize the timing of a sweep, but few methods exist for this purpose. To uncover genomic regions under shared positive selection across populations, we apply the theory of the expected haplotype homozygosity statistic  $H_{12}$ , which detects recent hard and soft sweeps from the presence of high-frequency haplotypes. Our statistic,  $SS-H_{12}$ , is distinct from other statistics that detect shared sweeps because it requires a minimum of only two populations, and properly identifies independent convergent sweeps and true ancestral sweeps, with high power. Furthermore, we can apply  $SS-H_{12}$  in conjunction with the ratio of a different set of expected haplotype homozygosity statistics to further classify identified shared sweeps as hard or soft. Finally, we identified both previously-reported and novel shared sweep candidates from whole-genome sequences of global human populations. Previously-reported candidates include the well-characterized ancestral sweeps at *LCT* and *SLC24A5* in Indo-European populations, as well as *GPHN* worldwide. Novel candidates include an ancestral sweep at *RGS18* in sub-Saharan African populations involved in regulating the platelet response and implicated in sudden cardiac death, and a convergent sweep at *C2CD5* between European and East Asian populations that may explain their different insulin responses.

**2769W**

**Mapping African ancestry among African Americans.** C.C. Jones<sup>1,2</sup>, P.S. Ramos<sup>3,4</sup>, S.J. Chanock<sup>5</sup>, S.A. Tishkoff<sup>6,7</sup>, S.M. Williams<sup>8</sup>, M.C. Aldrich<sup>1,2,9</sup>, *African American Lung Cancer Consortium.* 1) Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Thoracic Surgery, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Medicine, Medical University of South Carolina, Charleston, SC; 4) Department of Public Health Sciences, Medical University of South Carolina, Charleston, SC; 5) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 6) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 7) Department of Biology, University of Pennsylvania, Philadelphia, PA; 8) Department of Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 9) Division of Epidemiology, Vanderbilt University Medical Center, Nashville, TN.

The transatlantic slave trade led to the forced movement of Africans to the US, with distinct ports of embarkation in Africa and debarkation along the coastal Southeast. Subsequent mating between African- and European-descent populations resulted in mixed ancestry in African Americans. We present fine-scale resolution and a geographic assessment of African genetic ancestry among African Americans from across the US, with a focus on the Southeast, where most slave trade ports of entry occurred. Rural communities within the Southeastern US were a focus of our study due to potentially less admixture. We used genome-wide data from 6,998 African Americans from eight populations with distribution across the US, including the Gullah Sea Islands (N=239). About one-third of our population included dense sampling (N=2,133) across 12 Southeastern states. Global ancestry was estimated using ADMIXTURE with European (CEU, N=99) and representative African individuals from 13 countries (N=1,262) as putative ancestral groups. The genomic data were consistent with the presence of six (K=6) ancestral sub-populations among reference individuals: (1) European, (2) Pygmy, (3) San, (4) Fulani, (5) Senegambian/Sierra Leonean, and (6) Bantu ancestry. Nigerian ancestry split between Senegambian/Sierra Leonean and Bantu ancestries. In African Americans, Senegambian/Sierra Leonean/Nigerian ancestry contributed the highest median percentage of African ancestry (36%), followed by Bantu/Nigerian ancestry (30%). Compared to study populations outside the South, samples in the Southeast and the Gullah had substantially more Senegambian/Sierra Leonean/Nigerian ancestry and less European ancestry. Within the Southeast, European ancestry was significantly higher among individuals living in urban areas ( $p=0.002$ ), while Senegambian/Sierra Leonean/Nigerian ancestry was significantly higher in rural areas ( $p=0.01$ ). Ancestry was significantly correlated with geolocation, with Senegambian/Sierra Leonean/Nigerian ancestry increasing from West to East ( $p=1.6 \times 10^{-10}$ ) and from North to South ( $p=2.1 \times 10^{-4}$ ) within the Southeastern US. Our study established multiple sources of West African ancestry among African Americans and provided the first fine-scale characterization of geographic variation in African ancestry across the Southeastern US. These findings shed light on the African ancestries and population structure of African Americans.

**From genome-wide to world-wide: Shared genetic etiology and ancestry among major complex diseases.** T.B. Mersha, Y. Gautam, S. Ghandikosa. Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

While genomic studies have been successful in identifying genetic variants that influence specific disease risk primary in European ancestry, it is important to understand the impact of genetic variants across multiple ancestry. An improved understanding of shared genetic etiologies could provide valuable insights into shared pathophysiological mechanisms and novel therapeutic targets. Our aim is to determine unique and shared genetic risk factors among complex diseases in the context of big data and ancestry variations. Cross-phenotype genetic studies can also provide a better understanding of phenotypic characteristics associated with particular genetic variants. Using genomic resources from the database of Genotypes and Phenotypes (dbGaP) and NHGRI GWAS catalog and our own datasets, we will survey and present geographically relevant risk factors and pathways in human populations around the world. We will present novel research strategies such as cross-database gene set analysis and ancestry variations among genome-wide studies. In cross/database gene set analysis, we will present how we implement over-representative analysis methods to evaluate the relative contributions of the shared gene clusters to individual disease entity by using hypergeometric distributions. Additionally, we will compare and present the SNP variation datasets and large-scale consortium gene expression patterns across multiple disease using GTEx, ENCODE, and NIH Roadmap Epigenomic for functional annotations of non-coding genome with genomic, transcriptomic, and epigenomic data resources. In this presentation, we hope to deliver research strategies to tackle the complex genetic relationships across multiple diseases and ancestry, and outline the importance of expanding current genome wide research in European ancestry to worldwide.

**Building human reference genomes for Africa.** *M.O. Pollard<sup>1,2</sup>, E. Karakoc<sup>1,2</sup>, T. Porter<sup>1,2</sup>, J. Prado Martinez<sup>1</sup>, C. Pomilla<sup>1,2</sup> on behalf of GDAP investigators.* 1) Human Genetics, Wellcome Sanger Institute, Cambridge, United Kingdom; 2) Department of Medicine, University of Cambridge, United Kingdom.

The current version of the human reference GRCh38 is largely a mosaic of European haplotypes with limited contribution from genome sequences from Africa. As such, using the current human reference genome for global population studies may bias inferences, including for population genetics and genomic discovery. Recent attempts to broaden the repertoire of reference haplotypes, and develop population specific references have shown that these enable discovery of novel regions within the genome, and provide a resource for improved mapping and subsequent variant calling. The high levels of genetic diversity in Africa, highlight the need for a high resolution resource of genome assemblies representing genetic diversity across Africa. Here, we present the African reference resource, comprised of 43 individuals with highly contiguous assemblies from 23 populations across Africa. These data have been assembled using a combination of approaches, including 42 genomes on the 10x Chromium platform, and one Zulu genome sequenced at 55x coverage and 30x coverage on the PacBio and 10x Chromium platforms, respectively. We also created BioNano optical maps for this sample to perform assembly scaffolding, quality control and the discovery of structural variation. Our assemblies using different platforms show a high degree of concordance with regard to structural variants. We use the Africa reference genome resource to identify novel population specific sequences and structural variation. Development of a resource of reference genomes across Africa will enable population genetics research, and genomic discovery using sequencing studies from this region and globally.

**2772W**

**High-throughput local ancestry inference reveals fine-scale population history.** *A. Sedghifar<sup>1</sup>, S. Song<sup>1</sup>, Y. Wang<sup>1</sup>, K. Noto<sup>1</sup>, J. Byrnes<sup>1</sup>, E.L. Hong<sup>1</sup>, K.G. Chahine<sup>1</sup>, C.A. Ball<sup>2</sup>.* 1) AncestryDNA, San Francisco, CA; 2) AncestryDNA, Lehi, UT.

An individual's genome can be viewed as a mosaic of haplotype blocks from different ancestral origins, the sizes of which depend on the timing of admixture events. Recovering the length of these local ancestry blocks, together with their ethnic origin, provides information on the admixture and recombination events that shape current day genomes, thus shedding light on personal history as well as population history. As genomic databases rapidly approach sizes on the order of millions of genomes, there is an increased demand for super efficient approaches to identifying local ancestry blocks. Our team has developed Polly, an ultra fast algorithm for estimating genome-wide ancestry proportions in admixed individuals. Here, we present a modification of the Polly algorithm for accurately inferring local ancestry blocks. We evaluated the performance of our algorithm on simulated admixed individuals, and also assessed accuracy of estimated tract length distributions in admixed populations. Finally, we applied our method to estimate tract length distributions in historically admixed African American and Latin American populations.

**2773T**

**The effect of consanguinity on between-individual identity-by-descent sharing.** A. Severson<sup>1</sup>, N. Rosenberg<sup>2</sup>, S. Carmi<sup>3</sup>. 1) Genetics, Stanford University, Stanford, CA; 2) Biology, Stanford University, Stanford, CA; 3) Braun School of Public Health, the Hebrew University of Jerusalem, Jerusalem.

Consanguineous unions, in which mating pairs share a recent common ancestor, produce offspring whose two genomic copies possess increased sharing of long segments inherited identical-by-descent (IBD). In a population, consanguinity increases the rate at which IBD segments pair within individuals to produce runs of homozygosity (ROH). The extent to which such unions affect IBD sharing *between* rather than within individuals, however, is not immediately evident from within-individual levels. Using the fact that the time to the most recent common ancestor (TMRCA) for a pair of genomes at a specific locus is inversely related to IBD sharing between the genomes in the neighborhood of the locus, we study IBD sharing for a pair of genomes sampled either within an individual or in different individuals. We develop a coalescent model for a set of mating pairs in a diploid population, treating the fraction of consanguineous unions as a parameter. Considering a variety of types of consanguinity, we determine the effect of the consanguinity rate on TMRCA for lineage pairs sampled either within an individual or in different individuals. We find that consanguinity not only increases within-individual IBD sharing, it also increases between-individual IBD sharing, with the magnitude of the effect increasing with the kinship coefficient of the type of consanguineous union. Considering ROH and IBD computations in Jewish populations with consanguinity rates reported from demographic data, the model provides an explanation for an observation that increases in consanguinity and ROH levels inflate between-individual IBD sharing in a population.

**2774F**

**Population diversity of Austro-Asiatic speakers: Complex substructure and intricate layered network of dispersals.** D. Tagore<sup>1</sup>, F. Aghakhanian<sup>2</sup>, R. Naidu<sup>2</sup>, P.P. Majumder<sup>1</sup>, M.E. Phipps<sup>2</sup>, A. Basu<sup>1</sup>. 1) National Institute of Biomedical Genomics, Kalyani, West Bengal, India; 2) Jeffrey Cheah School of Medicine and Health Sciences, Monash University (Malaysia), Selangor, Malaysia.

India and Southeast Asia (SEA) are home to diverse ethno-linguistic groups; the Austroasiatic (AA) language speakers being one of them. Early genetic studies postulated that the ancestors of extant AAs arrived with the first wave of modern human migration out-of-Africa ~60,000 years before present (YBP). The AAs are sparsely distributed in North-East, East and Central India and in many countries of SEA, often as isolated small population groups. Aphorism among linguists and archeologists link the presence of the AAs with the spread of rice cultivation ~10,000 YBP, yet many AAs across the entire Indian peninsula and SEA remain predominantly hunter-gatherers. Events leading to the scattered distribution of AAs over this vast geographical space and the disparity in the times of arrival of the AA ancestors and AA language spread are both poorly understood. To address these issues we analyzed genome-wide polymorphism data on 189 individuals from 11 AA populations of India and SEA (Malaysia) along with comparable genetic data on 322 individuals neighboring the AAs but belonging to different ethno-linguistic background. We also used appropriate subsets of individuals from the 940 individuals in HGDP (Human Genome Diversity Project). AAs of Malaysia, AAs of India and the Tibeto Burman speakers (TB) share multiple distinct long Identical-by-Descent segments suggesting evolution from a distant common ancestor. ADMIXTURE analysis inferred that the genetic ancestry attributed to the Malaysian AAs, is significantly higher amongst TB than in Indian AAs ( $P < 2.117e-10$ ) providing evidence of gene flow between geographically close but linguistically distant TB and Malaysian AAs. This is further corroborated by Treemix analysis. Indian AAs, who also are geographically close to TB form a separate cluster in Principal Components and fineSTRUCTURE analyses while TB and Malaysian AAs closely cluster indicating that neither geography nor language is the sole determinant of genetic distance and population diversity. Also, significantly higher values of D statistics ( $|Z| > 3$ ) indicate that unlike the Indian AAs, both TB and Malaysian AAs have experienced extensive gene flow from the "East Asians of HGDP". This could increase the apparent genetic affinity between Malaysian AAs and TB of India. Apart from revealing directional migration in SEA, our study indicates that this gene flow may help to understand the linguistic history of this region better.

**Differences in polygenic architecture between multiple ethnic human populations revealed by pathway and epistasis analysis.** *M.C. Turchin*<sup>1,2</sup>, *L. Crawford*<sup>1,3,4</sup>, *S. Ramachandran*<sup>1,2</sup>. 1) Center for Computational Molecular Biology, Brown University, Providence, RI; 2) Department of Ecology and Evolutionary Biology, Brown University, Providence, RI; 3) Department of Biostatistics, Brown University, Providence, RI; 4) Center for Statistical Sciences, Brown University, Providence, RI.

Genome-wide association (GWA) studies have identified thousands of significant genetic associations in humans across a number of complex traits, including height, body mass index (BMI), and type 2 diabetes. However, the vast majority of these studies have been conducted in datasets of predominantly European ancestry (Popejoy & Fullerton 2016). It has generally been thought that complex trait genetic architecture should be transferable across populations of different ancestries; but recent work has shown a number of differences between ethnic groups, including heterogeneity in both the causal variants being discovered and in the effect size estimates for many overlapping variants (Martin et al. 2017, Wojcik et al. 2017). Here we compare and reveal further evidence that the genetic architecture of complex traits is fundamentally different between human ethnic groups. To reveal these differences, we jointly leverage the benefits of pathway and epistasis analysis. Under the assumption that a given trait may have differential polygenic architectures across human ancestries, we hypothesize that differences in epistatic effects among human populations may be particularly enriched. However since polygenic traits also tend to have smaller GWA effect sizes, combining variants via pathway analysis may allow us to better reveal these signals. To accomplish this, we build on a recently published method that identifies marginal epistasis (Crawford et al. 2017), moving from testing single variants to testing groups of variants. We apply our method to multiple ancestries present in the UKBio-Bank dataset (Sudlow et al. 2015). Using the C2 gene set from the Broad Institute's MSigDB (Liberzon et al. 2011) and by analyzing height, BMI, and other morphometric traits, we find evidence for differential architecture in these phenotypes among African, Indian, Chinese, and British individuals. We also find evidence that these associations are further differentiated by heterogeneous signals for epistatic effects. This work further reveals that complex trait architecture is heterogeneous among human populations and that assumptions regarding transferability of primarily European-based results may be fundamentally flawed.

**$F_{ST}$  never satisfies the triangle inequality for biallelic markers with distinct allele frequencies.** *I. Arbisser*, *N. Rosenberg*. Stanford University, Stanford, California, CA.

$F_{ST}$ , the widely used population-genetic statistic proposed by Sewall Wright in 1951, describes the apportionment of genetic variation within and between populations. Pairwise  $F_{ST}$  is often treated as a measure of genetic distance between populations between two populations. However,  $F_{ST}$  is not a true distance metric. A distance metric in the mathematical sense must satisfy the triangle inequality: for any three points, the sum of the two shorter distances is always greater than the third, longest, distance. Sewall Wright knew that  $F_{ST}$  did not always satisfy the triangle inequality and provided a counterexample. Here, we prove the stronger result, that for biallelic markers whose allele frequencies differ across three populations,  $F_{ST}$  never satisfies the triangle inequality. We study the deviation from the triangle inequality as a function of the allele frequencies of three populations and show analytically that the maximal deviation occurs, in fact, at the specific counterexample suggested by Sewall Wright. We also examine the extent to which  $F_{ST}$  fails to satisfy the triangle inequality in genome-wide data from human populations. In data on CEU, CHB, and YRI from the HapMap Project, we find that some loci have frequencies that produce deviations from the triangle inequality near the maximum. We examine the consequences of the theoretical results for various types of data analysis that take distance matrices as input, including multidimensional scaling analysis and inference of neighbor-joining trees.

**Cryptic Native American ancestry recapitulates population-specific migration and settlement of the continental United States.** A.B. Conley<sup>1,2,3</sup>, L. Rishishwar<sup>1,2,3</sup>, I.K. Jordan<sup>1,2,3</sup>. 1) School of Biological Sciences, Georgia Institute of Technology, Atlanta, Georgia USA; 2) IHRC-Georgia Tech Applied Bioinformatics Laboratory, Atlanta, Georgia, USA; 3) PanAmerican Bioinformatics Institute, Cali, Valle del Cauca, Colombia.

European and African descendants settled the continental US during the 17<sup>th</sup>-19<sup>th</sup> centuries, coming into contact with established Native American populations. The resulting admixture among these groups yielded a significant reservoir of cryptic Native American ancestry in the modern US population. We analyzed the patterns of Native American admixture seen for the three largest genetic ancestry groups in the US population: African American, European American, and Hispanic/Latino. The three groups show distinct Native American ancestry profiles, which are indicative of their historical patterns of migration and settlement across the country. Native American ancestry in the modern African American population does not coincide with local geography, instead forming a monophyletic group with origins in the southeastern US, consistent with the Great Migration of the early 20<sup>th</sup> century. European Americans show Native American ancestry that tracks their geographic origins across the US, indicative of ongoing contact during westward expansion, and Native American ancestry can resolve Hispanic/Latino individuals into distinct local groups formed by more recent migration from Mexico and Puerto Rico. We found an anomalous pattern of Native American ancestry from the US southwest, which most likely corresponds to the *Nuevomexicano* descendants of early Spanish settlers to the region. We addressed a number of controversies surrounding this population, including the extent of Sephardic Jewish ancestry. *Nuevomexicanos* are less admixed than nearby Mexican-American individuals, with more European and less Native American and African ancestry, and while they do show demonstrable Sephardic Jewish ancestry, the fraction is no greater than seen for other Hispanic/Latino populations.

**2778W**

**The spatial patterns of genetic diversity in the United States.** C.L. Dai<sup>1</sup>, M.M. Vazifteh<sup>2,3</sup>, C.H. Yeang<sup>1</sup>, R. Tachet<sup>2,3</sup>, M.G. Vilar<sup>4</sup>, C. Ratt<sup>2,3</sup>. 1) Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, MA; 2) Senseable City Lab, Massachusetts Institute of Technology, Cambridge, MA; 3) Department of Urban Studies and Planning, Massachusetts Institute of Technology, Cambridge, MA; 4) Institute of Statistical Science, Academia Sinica, Nankang, Taipei, Taiwan; 5) Genographic Project, National Geographic Society, Washington, DC.

Historical migration of individuals into and throughout the United States has contributed to significant mixing of distant ancestries and a heterogeneous genetic landscape. Here, we present a comprehensive view of the genetic ancestry, haplotype relatedness, and population history of 32,589 genotyped individuals from the United States participating in the National Geographic Society's Genographic Project. Varying the geographical scale of analysis, we find that diversity in ancestry origin and admixture reflects the size of present-day metropolitan areas. Haplotype sharing reveals geographically proximate decay of relatedness but also long-range relatedness, especially in populations of non-European ancestry. We further explore migration rates to understand the varying patterns across populations of different ancestries, comparing them with historical demographic events. Dating the admixture histories from ancestral haplotype tracts, we also assess the relationship between admixture patterns and geography.

**2779T****Inference of population structure from ancient DNA.** T.A. Joseph<sup>1</sup>, I.

Pe'er<sup>1,2,3</sup>. 1) Department of Computer Science, Columbia University, New York, NY; 2) Department of Systems Biology, Columbia University, New York, NY; 3) Data Science Institute, Columbia University, New York, NY.

One of the great successes of modern genomics is the ability to reconstruct human history from genetic data alone. Over the past decade, studies to this end have increasingly relied on ancient DNA. Yet, traditional methods to infer population history from ancient DNA either implicitly assume all samples are contemporary, or presuppose population assignment for ancient samples. To overcome this limitation, we developed Dystruct (Dynamic Structure), a time-series model of population history and stochastic variational inference algorithm to discover shared ancestry among sampled individuals (Joseph and Pe'er, In Proc. RECOMB 2018, 90-104). Individuals are modeled as mixtures of populations whose allele frequencies drift over time. Dystruct assumes multiple populations with independent histories, but correctly models later (modern) samples as mixtures of earlier (ancient) ones. We now extend Dystruct to handle more complex population histories. Using simulations, we demonstrate that the accuracy of current methods is substantially impacted by genetic drift – the random fluctuation of allele frequencies over time – when individuals are sampled over time, as is common in ancient DNA datasets. We show that Dystruct offers a correction for the effects of drift, leading to more accurate ancestry estimates. To further demonstrate the utility of our model, we applied Dystruct to a dataset of 92 ancient and 1941 modern samples genotyped at 222755 loci. Ancient samples included early hunter-gatherers groups, Neolithic farmers, and steppe herders from the Pontic-Caspian steppe. Modern samples are from global populations in the Human Origins dataset. We further compared Dystruct to ADMIXTURE, a model ubiquitous for inferring shared ancestry among modern samples, and often applied to ancient DNA datasets. We show that when later samples are mixtures of earlier ones, they appear as such in Dystruct. Conversely, ADMIXTURE tends to present such ancient samples as mixtures of their later counterparts. Most notably, Dystruct is able to capture a migration and admixture event of the steppe herders throughout Eurasia approximately 5000 years ago (Joseph and Pe'er, In Proc. RECOMB 2018, 90-104), a signal supported by the literature but missing from ADMIXTURE. We explore the extent to which modeling more complex population histories improves these results. Our model is a promising first step towards modeling the true complexity in the history of our species.

**2780F****Whole-exome sequencing of 1,050 Turkish individuals reveals population structure and genetic variation.** X. Song<sup>1,9</sup>, Z. Coban-Akdemir<sup>1,9</sup>, D. Pehlivan<sup>1</sup>, E. Karaca<sup>1</sup>, Y. Bayram<sup>1,2</sup>, H. Du<sup>1</sup>, T. Gambin<sup>3</sup>, S.N. Jhangiani<sup>4</sup>, D.M. Muzny<sup>4</sup>, C.A. Shaw<sup>1,5</sup>, E. Boerwinkle<sup>4,6</sup>, R.A. Gibbs<sup>1,4</sup>, J.E. Posey<sup>1</sup>, J.R. Lupski<sup>1,4,7,8</sup>.

1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA; 2) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA; 3) Institute of Computer Science, Warsaw University of Technology, Warsaw 00-665, Poland; 4) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX 77030, USA; 5) Baylor Genetics, Houston, TX 77021, USA; 6) Human Genetics Center, University of Texas Health Science Center at Houston, TX 77030, USA; 7) Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030, USA; 8) Texas Children's Hospital, Houston, TX 77030, USA; 9) These two authors contributed equally.

Turkey, often described as a bridge between Asia and Europe, is a hub of ancient and contemporary population migration. Previous studies on healthy unrelated individuals from the Greater Middle East have demonstrated the occurrence of population diversity and admixture – but also suggested extensive consanguinity. Here, we performed whole-exome sequencing (WES) on 1,050 Turkish individuals, including 695 affected patients representing of a multitude of disease phenotypes and 355 unaffected relatives, in order to study the population structure and disease etiology of a large, but representative, Turkish cohort. We performed principal component analysis (PCA) on the Turkish samples and the African, Asian and European population samples from the 1000 Genome Project. The Turkish samples were isolated from the other three but fell closer to the Asian population. We show that 38.7% of the heterozygous and 25% of the homozygous distinct variants in the Turkish individuals were not present in ExAC, suggesting a necessity of using a population-matched control database in analyzing variant pathogenicity. We then compared the Human Phenotype Ontology (HPO) similarity for each pair of probands with their clinical features recorded in the PhenoDB database. Our analysis revealed that phenotypic heterogeneity accompanied by multi-locus variation in the Turkish population (17/30 cases) results from biallelic variation at 2 loci for an AR + AR trait combination of blended phenotypes. This increased burden of homozygous variants and a larger median span of absence of heterozygosity (AOH) of 90.4 Mb determined by BafCalculator from WES data and consistent with identity-by-descent, in the Turkish samples compared to 25.8 Mb in 5,735 non-Turkish samples locally sequenced through Baylor-Hopkins Center for Mendelian Genomics ( $P = 4.98 \times 10^{-169}$ ). We next analyzed 167 trios in this cohort and curated a list of 606 *de novo* variants. Eleven (11/606, 1.8%) were found to be shared among 2 affected siblings in 17 families and will be investigated further for parental mosaicism. In summary, we generated a database of variants derived from 1,050 exomes for assessing rare potentially pathogenic variants of interest to disease trait biology in the Turkish population. These results show consanguinity within this cohort and emphasize the utility of AOH analysis from WES data revealing identity by descent and deleterious variant burden when evaluating the contribution of *de novo* variants to disease.

**2781W****The role of recent demography in shaping patterns of genetic variation in US Hispanic/Latino populations.** *M.L. Spear<sup>1,2</sup>, D.G. Torgerson<sup>3</sup>, R.D. Hernandez<sup>2,4,5,6</sup>*

1) Biomedical Sciences Graduate Program, UCSF, San Francisco, CA; 2) Department of Bioengineering and Therapeutic Sciences, UCSF, San Francisco, CA; 3) Department of Pediatrics, UCSF, San Francisco, CA; 4) Institute for Human Genetics, UCSF, San Francisco, CA; 5) Institute for Quantitative Biosciences, UCSF, San Francisco, CA; 6) Institute for Computational Health Sciences, UCSF, San Francisco, CA.

Understanding the genetic basis of complex phenotypes is a critical problem in medical and evolutionary genetics. The evolutionary forces of natural selection and demographic history, including migration, have shaped patterns of worldwide genetic variation, which in turn have shaped the genetic architecture of human phenotypic variation. The population of the United States has changed immensely over the 20<sup>th</sup> century as a result of immigration, and this will continue to be one of the primary modes of population growth as the US approaches a "minority-majority" country. Hispanics/Latinos, the largest and fastest growing group, are a genetically heterogeneous population as result of admixture between African, European, and Native American populations. The effect of these large-scale migrations in contributing to shaping genetic variation and subsequently phenotypic variation is unknown. For 9,646 Hispanics/Latinos from the Hispanic Community Health Study/Study of Latinos (HCHS/SOL) we tested the hypothesis that the admixture process in the US has been dynamic over the 20<sup>th</sup> century. Using ADMIXTURE and RFMix we estimated global and local ancestry and investigated how ancestry has changed over time as a function of birth year for Mexican Americans, Puerto Ricans, Dominican Republicans, Cubans, Central Americans, and South Americans. Our results have shown a significant ( $p=3.3 \times 10^{-21}$ ) increase in Native American ancestry in both US born and foreign born Mexican Americans over time. These shifting ancestry proportions could be due to an increase in longer Native American ancestral tracts, variation in the origin of subcontinental Native American ancestry or assortative mating. Our results suggest that the admixture process in the US has been dynamic in the last century, which could have further implications on the genetic architecture of complex traits. This demonstrates a crucial need to improve our understanding of the role of demographic history in shaping the genetic architecture of phenotypic variation in Hispanic/Latino populations.

**2782T****The ChileGenomico Project creates a public resource to test association between socioeconomic and epidemiologic variation among communes of Chile and ancestry.** *R.A. **Introduction and objectives.** The Chilean population is the result of a process of admixture between Europeans, Africans and Amerindians since the XXVI century. The genetic variation between them allows estimating the proportion of ancestors of each of these origins in current individuals. Estimates of ancestry show significant differences between subpopulations of Chile, related to latitude and social stratum. However, a systematic study of the differences in the ancestry components of Chileans has not been carried out. **Material and methods** The ChileGenomico project carried out the largest sampling to date of mixed Chilean population ( $n = 3200$ ), recruiting healthy individuals in nine urban centers from Arica to Puerto Montt. The genome of 48 individuals with Amerindian ancestry was typed by complete genomic sequencing (3.6x) or microarrays. Using a genetic algorithm to maximize genomic coverage and ancestry normativity, we selected 147 autosomal SNPs, then genotyped by KASP in 2,843 individuals. **Results.** The average ancestry was 51% European, 5% African and 44% Amerindian (20% Aymara and 25% Mapuche). The Amerindian ancestry is lower in the central zone, the Aymara decreases with latitude and the Mapuche increases. The Amerindian component rises 5-10% per level of decline in socioeconomic stratification. Average ancestry estimates for 39 communes of Chile were estimated and made available through an online that allows identifying association to socio-economic and epidemiological data (<http://genoma.med.uchile.cl/ancestry>). **Conclusions.** We have created a public resources that will be allow controlling for ancestry heterogeneity of the Chilean population in public health studies and scientific research.

**Interpreting variants of uncertain significance using common variation in non-human primates.** H. Gao, L. Sundaram, S. Reddy, J. McRae, S. Batzoglou, K. Farh. Illumina Artificial Intelligence Laboratory, Illumina Inc., Foster City, CA.

Chimpanzees share 99.4% amino acid sequence identity with human, suggesting that purifying selection operating on naturally occurring chimpanzee variation might also model the consequences on fitness of human mutations that are identical-by-state. Using population sequencing data from human and six species of non-human primates, we show that the presence of an identical-by-state variant at common allele frequencies in a non-human primate species is strongly indicative that the variant is clinically benign in human. We show that, on average, each non-human primate species contributes more likely benign missense variants than the whole of the ClinVar database. Because common variation in each primate species has evolved independently, we estimate that cataloging common variation from each of the 504 extant primate species would be sufficient to saturate most of the possible benign positions in the human genome, substantially improving interpretation for millions of variants of uncertain significance.

Williams<sup>9</sup>, M.W. Wright<sup>1</sup>, J. Zou<sup>1</sup>, C.D. Bustamante<sup>1</sup>, *The Clinical Genome Resource (ClinGen) Ancestry and Diversity Working Group (ADWG)*. 1) Stanford University, Palo Alto, CA; 2) Baylor College of Medicine; 3) University of North Carolina Chapel Hill; 4) National Human Genome Research Institute; 5) University of Washington; 6) University of Colorado, Anschutz Medical Campus; 7) Icahn School of Medicine at Mount Sinai; 8) University of California at San Francisco; 9) Harvard University; 10) Massachusetts General Hospital.

The question of how best to use ancestry information in clinical genomics remains unanswered, leaving patients from groups that are under-represented in clinical genomic databases less likely to benefit from advances in genomic medicine. For example, variant curation guidelines recommend review of allele frequency data from publicly available population databases, but these resources lack robust representation from individuals of non-European ancestry. Lack of population diversity could significantly impact the reliability and comprehensiveness of variant interpretations. The Clinical Genome Resource (ClinGen, [clinicalgenome.org](http://clinicalgenome.org)), a National Institutes of Health (NIH)-funded effort, is dedicated to defining the clinical relevance of genes and variants, and its mission requires the resulting clinical knowledgebase reflects the diversity of human genomic variation. ClinGen's Ancestry and Diversity Working Group (ADWG) was established to ensure clinical genomics professionals have the necessary tools such as robust databases, variant classifications and guidelines for the accurate application of genomics to individuals from traditionally under-represented ancestral populations, many of which already bear a disproportionate burden of illness. The ADWG has begun this work by conducting three primary analyses: 1) characterizing the current questions about patient race, ethnicity, and ancestry (REA) on requisition forms from clinical genetic testing laboratories that frequently submit annotations to ClinVar; 2) quantifying information about different ancestral populations in public databases used for variant interpretation and curation, e.g. gnomAD and ClinVar; and 3) surveying clinical genomics professionals about perceptions and general use practices of REA data in clinical settings. Preliminary results of our analyses show that different clinical labs use highly variable questions to collect REA data, and the amount and quality of information available for clinically relevant variants is highest in European ancestry populations. Clinical genomics professionals may vary in their perceptions about patient REA information and the appropriateness of its use in a clinical setting, which is among the hypotheses we are testing with our survey of clinicians. The ADWG is using these data in the development of recommendations for the use of REA information in clinical genomics.

**2785T****Available protein 3D structures do not reflect human genetic and functional diversity.**

*G. Sliwoski<sup>1,2</sup>, N. Pate<sup>3</sup>, R.M. Sivley<sup>1</sup>, C.R. Sanders<sup>2,4,5</sup>, J. Meiler<sup>2,6</sup>, W.S. Bush<sup>3</sup>, J.A. Capra<sup>1,7,8</sup>.* 1) Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Center for Structural Biology, Vanderbilt University, Nashville, TN; 3) Inst for Computational Biology, Dept of Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 4) Biochemistry, Vanderbilt University, Nashville, TN; 5) Dept of Medicine, Vanderbilt University Medical Center, Nashville, TN; 6) Chemistry, Vanderbilt University, Nashville TN; 7) Biological Sciences, Vanderbilt University, Nashville, TN; 8) Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville, TN.

Genomic databases and clinical trials are substantially biased towards European ancestry populations, and this bias significantly contributes to health disparities. Structural biology has an essential role in investigating protein function and clinical variant interpretation, providing powerful tools for investigating the impact of genetic variants on protein structure and function. However, studies that analyze the 3D structure of proteins typically consider a single "canonical" amino acid sequence as representative of the protein. Here, we evaluate the potential for this simplification to bias results toward different populations by evaluating how well all 66,971 experimentally characterized human protein 3D structures represent the sequence diversity of the proteins they model. Thousands of protein structures have unrepresented alternative sequences commonly found in human populations, and African ancestry individuals' sequences are the least likely to be represented by available structures. Because sequence variability is often limited to a few positions within a protein, we evaluate the likelihood of these small changes to influence protein function. Combining existing annotations and computational modeling, we identify thousands of proteins for which use of a single structure as representative of "wild type" may bias results against certain populations or individuals. Variants segregating in human populations, but unrepresented in structures, are observed across functional sites involved in stability (134 disulfide bond cysteines), regulation (94 phosphorylation sites), DNA binding (322 residues), small molecule binding (1,463 residues with 362 within drug binding sites), and protein-protein interfaces (6,144 residues). We computationally model a subset of unrepresented variants' effects on protein stability and protein-protein interaction. Changes in predicted protein stability are found for 28% (156) of the 556 variants, with stabilizing (41) and destabilizing (115) effects predicted. Of 161 protein-interface variants modeled, 25% (41) are predicted to impact protein-protein binding. These variants in human populations have potential to impact the study of their protein's structure and function. With the widespread use of protein structures in basic science and clinical variant interpretation, human protein sequence and structural diversity must be considered to enable accurate and reproducible conclusions from structural analyses.

**2786F****Mining patterns of singleton and loss-of-function variants in deeply sequenced genomes.**

*D. Taliun<sup>1</sup>, S. Gogarten<sup>2</sup>, S. Zöllner<sup>1</sup>, R. Hernandez<sup>2</sup>, M. Boehnke<sup>1</sup>, G. Abecasis<sup>1</sup>, The NHLBI Trans-Omics for Precision Medicine (TOPMed) Program.* 1) Department of Biostatistics, University of Michigan, Ann Arbor; 2) Department of Biostatistics, University of Washington, Seattle; 3) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco.

The Trans-Omics for Precision Medicine Program (TOPMed) aims to discover mechanisms underlying heart, lung, blood, and sleep disorders by generating whole genome high depth sequencing data in large numbers of well-phenotyped individuals of different ancestries. The current TOPMed release of 463 million high quality genetic variants from >62,000 genomes is already available through both dbSNP and the BRAVO variant browser. The large number of deeply sequenced (38X) individuals makes TOPMed the best source to date for identifying biologically important regulatory and protein-coding regions through patterns of singletons and very rare loss-of-function (LoF) variants. In this analysis, we focused on a subset of >53,000 genomes with permission for broad sharing through dbGaP and where quality control had been completed. These genomes include 410 million variants (46% singletons), including 4,959,646 protein coding variants (47% singletons) and 242,713 predicted protein truncating (or loss-of-function, LoF) variants (58% singletons). The average individual carried 249 LoF variants. Only 997 (5.1%) out of 19,479 protein coding genes had no LoF variants across all individuals. We searched for gene sets with lower numbers of LoF variants per coding base-pair and lower proportions of common variants than expected. These gene sets are less tolerant to protein loss of function. Gene sets depleted in loss of function variants and in common variants included genes encoding for DNA and RNA binding proteins, spliceosomal complexes, translation initiation, and RNA splicing and processing proteins. As expected, genes involved in olfactory receptor activity had higher numbers of loss of function variants and large proportions of common variants. Genes associated with human disease in the OMIM, GWAS Catalog, ClinVar, and COSMIC (cancer) databases showed evidence of fewer LoF variants per base-pair than expected by chance. Among regulatory regions, only promoters and transcription factor binding sites were depleted in common variation after adjustment for mutability. Nonsense mediated decay and immunoglobulin genes had an elevated proportion of singletons in 3' UTR regions, which was not observed among other protein coding genes. In summary, we demonstrate the value of a large collection of high-quality genomes to identify biologically important regions through singleton and LoF variants.

**1341W**

**Synthetic RNA-seq data for intervention and drug discovery by conditional generative adversarial networks.** *M. Xiong<sup>1</sup>, Y. Liu<sup>1</sup>, Q. Ge<sup>2,1</sup>*. 1) University of Texas School of Public Health, Houston, TX., US; 2) School of Mathematical Science, Fudan University, China.

RNA-seq data provide a powerful tool to investigate complex traits and common disorders' pathogenesis. Therefore, whole-transcriptome analysis is increasingly acquiring a key role in unravelling mechanisms underlying complex diseases. However, RNA-seq data are scarce, expensive, and concerned with privacy of individuals. The majority of RNA-seq data is inaccessible for general public research. There are increasingly interests in inexpensively simulating the RNA-seq data under various conditions, filling up the missing data, and creating a public and synthetic RNA-seq dataset to uncover the mechanism of complex diseases, explore artificial interventional operations and open a novel avenue for designing drug targets. To achieve these goals, we propose a novel, generative pipe line that consists of (1) generating ultra-realistic original RNA-seq data by conditional generative adversarial networks via primal-dual subgradient training methods which is the simplified mathematical models of the human brain and one of the most promising advances in artificial intelligence in the past decade, (2) learning functional causal models from observational RNA-seq data to identify causal paths from genes to diseases via gene expressions and phenotypes with deep causal generative neural networks and (3) learning causal implicit generative models from true observational and interventional distribution of RNA-seq with dual adversarial training which can perform interventions and drug tests on the resulting causal implicit generative models. The Generative adversarial networks can integrate diverse RNA-seq data sets, generate RNA-seq datasets under normal and disease status, infer gene regulatory networks, and predict effect of external perturbations on gene expressions. The proposed generative pipe line was applied to a RNA-seq dataset of type 2 diabetes and Alzheimer's disease (AD) with 448 individuals, 19 phenotypes and environments, six type of diseases and 299 pathways with RNA-Seq. We have identified 20 causal gene expressions and 5 causal pathways including FoxO, MAPK and PI3K-AKT pathways shared by type 2 diabetes and AD. The generative adversarial networks are emerging as a powerful tool for understanding the underlying complex structure of the genomic, epigenomic and molecular world which we measure and explore. We are entering a new machine learning era for integrated genomic, epigenomic and imaging data analysis, and biomedical and public health research.

**Discovery of obesity-associated noncoding causal variants based on convolutional neural networks.** *J. Oh, K. Jang, S. Lee, T. Lee, J. Kwon, M. Bae, J.K. Choi*. Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Daejeon, Korea, Republic of.

Obesity is a metabolic disorder resulting from behavioral and heritable causes. A number of genome-wide association studies (GWASs) have been conducted on obesity, but in most cases, the underlying mechanisms by which the variants contribute to obesity remain unresolved. GWASs can only report large clusters of single nucleotide polymorphisms (SNPs), or linkage disequilibrium blocks, including not only causal variants but also many linked neutral SNPs. Moreover, a majority of the obesity-associated GWAS SNPs are found in non-coding regions. Our incomplete knowledge of noncoding regions limits the functional interpretation of underlying DNA variants. To overcome these limitations, we constructed a convolutional neural networks framework for combinatorial, nonlinear modeling of complex patterns shared by risk variants scattered among associated multiple loci. We applied the model to the GWAS data for the body mass index adjusted by the waist-hip ration provided by The Genetic Investigation of ANthropometric Traits (GIANT) consortium. We evaluated the performance of the model and discovered several putative causal noncoding SNPs. Our results will provide insight into the mechanisms by which noncoding variants contribute to the obese phenotypes.

**An Omics Analysis, Search and Information System (OASIS) for enabling discovery in the TOPMed diabetes working group.** *J.A. Perry, J.R. O'Connell on behalf of the TOPMed Diabetes Working Group.* Program for Personalized and Genomic Medicine and Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD, 21201, USA.

**Introduction:** Members of the TOPMed Diabetes Working Group have computed over 200 million single-variant associations between TOPMed whole genomes and harmonized phenotypes for T2D, Fasting Glucose, Fasting Insulin and HbA1c. This massive quantity of results is typical of TOPMed research and transforming this “raw information” into “biological discovery” can be challenging. Scientist-friendly tools are needed to provide an integrated approach that includes data visualization, broad annotation, and fine-mapping techniques. **Methods:** An Omics Analysis, Search and Information System (OASIS) was constructed for the TOPMed Diabetes Working Group by making major enhancements to an existing web-based application developed at the University of Maryland. The enhancements, which support the large TOPMed datasets, required redesign of the underlying database architecture and use of highly efficient data compression and data handling made available with the MMAP software (<https://mmap.github.io/>). The OASIS webserver is an approved “TOPMed Cloud Computing Platform” and thus allows Working Group analysts to directly upload association results for sharing and comparing alternative analyses. Multiple datasets can be created and access control features allow datasets to be selectively shared with other registered TOPMed OASIS users. **Results:** OASIS datasets of up to 70 million associations from TOPMed freeze4 (219 million variants) and freeze5b (470 million) have been created for diabetes phenotypes. Boxplots split by genotype, study and ancestry are used to track populations for rare variants. Significant signals driven by a single study cohort have been identified. Variants are annotated by OASIS as they are reported during a user-initiated query and those lying in regulatory regions are easily spotted. Known-loci lists can be applied to query reports to identify variants in windows around known loci. Conditional and multi-covariate analysis is available for user-selected variants and integrated LocusZoom and Haploview plots provide linkage visualizations. Queries can be filtered by p-value, effect size, gene, variant type and/or function, rsid lists, genomic positions, and allele frequency. **Conclusion:** Transforming massive volumes of TOPMed association results into “biological discovery” has been made dramatically easier. As a web-based tool, OASIS allows both analyst and non-analyst easy access to a wealth of annotation, visualization and fine-mapping techniques.

**AMP-T2D: Federated analysis and discovery of genetic variants with association to type-2 diabetes.** *J.D. Spalding, C.Y. González, J.I. Ciges, S. Kamatchinathan, D. Bennett, T. Keane.* European Molecular Biology Laboratory, European Bioinformatics Institute (EMBL-EBI), Wellcome Trust Genome Campus, Hinxton, Cambridge, CB10 1SD, United Kingdom.

Novel therapeutic targets and functional pathways can be uncovered by discovering genetic variants which have an association to type-2 diabetes (T2D). The Accelerating Medicines Partnership in T2D (AMP-T2D) is a multi-sector, pre-competitive partnership among government, industry, and nonprofit organizations. AMP-T2D will produce and aggregate data, build infrastructure for data storage and presentation (knowledge base), and develop the tools and analytical methods to run on this infrastructure. The resulting open-access resource is the AMP-T2D Knowledge Portal (<http://www.type2diabetesgenetics.org>). This resource provides a wide variety of interactive tools, including custom online association analysis with dynamic sample filtering, covariate specification, and conditional analysis, while enabling sophisticated analytics of sensitive genetic data and ensuring patient privacy. Data are stored in a Data Coordinating Center at the Broad Institute and also at the European Bioinformatics Institute (EBI), in the first of several planned federated nodes. Federation allows integrated analysis across data sets, while ensuring that individual level data can remain at the site of origin where required to comply with ethical, legal, and society issues (ELSI). As the rate at which genetic data is generated increases, federation increases the capacity to store and analyse these data and reduces the requirement to distribute the whole dataset (analysis-to-data instead of data-to-analysis). As of June 2018 the EBI knowledge base (KB) was hosting 18031 samples in 4 datasets, with an additional 3404 samples, which include longitudinal and metabolite data, undergoing analysis and quality control. Federated data storage and subsequent analysis creates challenges in data harmonization, duplication, and management. All data at both knowledge bases must undergo the same analysis, imputation and quality control processes, which require that the same or equivalent pipeline is run at all KBs. To facilitate data harmonization, a registry and accessioning service have been developed. The registry defines the phenotypes (both attributes and terminologies), while the accessioning service either assigns new accessions or returns current accessions for existing object helping to prevent data duplication across a federated network. Where possible we are developing these federated processes to be compatible with standards developed by the Global Alliance for Genomics and Health (GA4GH).

**1345T****Retrospective electronic medical record analysis identifies patients at risk of hypophosphatasia and illustrates paucity of family history information.**

C. Peroutka<sup>1</sup>, M. Marzinke<sup>4</sup>, N. Parikh<sup>2</sup>, A. Alade<sup>1,2</sup>, J. McGready<sup>2</sup>, K. Schulze<sup>2,3</sup>, J. Hoover-Fong<sup>1,2</sup>. 1) McKusick Nathans Institute of Genetic Medicine, Johns Hopkins Hospital, Baltimore, MD; 2) Greenberg Center for Skeletal Dysplasias, Johns Hopkins Hospital, Baltimore, MD; 3) Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 4) Clinical Pharmacology Analytical Laboratory, Johns Hopkins Hospital, Baltimore, MD.

**Introduction:** Hypophosphatasia (HPP) is a pleiotropic condition caused by variants in tissue-nonspecific alkaline phosphatase (*TNSALP/ALPL*), manifesting as perinatal lethal through adulthood with skeletal fragility, respiratory compromise, neurologic and constitutional symptoms. Often unrecognized as pathologic, low serum alkaline phosphatase (AP) is a key indicator of HPP. Thus, HPP is underdiagnosed. Misdiagnosis as osteoporosis may involve bisphosphonate treatment, which counteracts available enzyme replacement for HPP. We conducted a risk prevalence study for HPP, including family history data, by query of a large hospital electronic medical record (EMR), demonstrating this methodology can identify individuals at-risk of rare disease.

**Methods:** The Johns Hopkins (JH) IRB approved this study with waiver of consent. JH patients with  $\geq 1$  AP level from Jan 2013-Dec 2015 were compiled by medical record number (MRN). Site and ICD-9 codes were merged to MRNs with  $\geq 1$  low AP using age- and sex-specific norms. MRNs with hematologic, oncologic, drug and transplant codes associated with low AP, or liver (direct bilirubin  $\geq 5$ ) or renal (creatinine  $\geq 2.6$ ) disease were excluded. Patients with 5-20 AP levels,  $\geq 80\%$  abnormal, were prioritized for chart review. EMR data extracted included medical and family history, and physical features suggestive of HPP. A REDCap database and STATA stored and generated results. **Results:** 45,233 (49% in patients  $\leq 19$ yo) low AP levels from 11,730 patients yielded 7,129 patients for review after exclusion by ICD-9/site codes. 351 had 5-20 AP levels,  $\geq 80\%$  abnormal. Data from 200 charts is presented. Medical history suggests HPP in 31%. Signs/symptoms include: 3% premature tooth loss, 9% excessive caries, 8% nephrolithiasis, 9% muscle pain, and 33% chronic pain. 8% have osteoporosis; 3% received bisphosphonates and 1 subject received a PTH analog. Multiple specialists provide care: 14% endocrinology, 19% orthopedics, 9% genetics, 9% rheumatology, 4% pain management, and 5% nephrology. FH suggests HPP in 2%, but only 48% have FH recorded for  $\geq 3$  relatives. HPP was not on the differential for any patient, though 15% had other molecular testing. **Conclusions:** EMR query of a large diverse population can identify individuals at-risk of rare, treatable conditions like HPP. With IRB approval, we are now contacting at-risk subjects to obtain histories in-person, and offer genetic counseling, molecular testing, and referral for treatment to those affected.

**1346F****A comparison of classical integration methods applied on multi-omics data.**

Y. Zhang<sup>1</sup>, J. Choi<sup>2</sup>, Q.L. Duan<sup>1,2</sup>. 1) School of Computing, Queen's University, Kingston, Ontario, Canada; 2) Department of Biomedical and Molecular Sciences, Queen's University, Kingston, Ontario, Canada.

Recent technological advancements have made it feasible to ascertain multiple types of genome-scale data. In order to gain a more comprehensive assessment of these datasets and infer knowledge about the dynamics of molecular systems, various methods have been developed for integrating multiple levels of biological datasets. However, these are limited by a priori knowledge of biological systems, algorithmic limits, and the variability of information captured at a genome-scale. Previously described methods for integrating biological datasets address three aims: 1) to cluster samples/subjects; 2) to understand molecular mechanisms; 3) to predict clinical outcomes. In this study, we applied two existing methods to integrate transcriptomics and epigenomics data from a childhood asthma cohort (GSE40732 and GSE40576) to identify genomic factors underlying asthma. These methods include: Similarity Network Fusion (SNF) tool, which is designed to cluster subjects and predict clinical outcomes by constructing a fused similarity network based on the different types of omics data; Data Integration Analysis for Biomarker discovery using a Latent component method for Comics studies (DIABLO), which identifies molecular mechanisms and clusters subjects using sparse generalized canonical correlation analysis. DIABLO shows that 35 genes from the transcriptomics data and 46 methylated sites were significantly correlated with asthma. Integration of these two levels of data discovered that a methylation probe correlated with the expression of the *GZMB* (Granzyme B) gene may underlie asthma in this cohort. Ongoing work in our lab aims to address some of the limitations of DIABLO to develop a novel integrative method that combines the network structures efficiency and allow for detection of molecular mechanisms.

**1347W**

**Integration and visualization of phenotype-genotype data and drug response in diabetes mellitus patients using the Diabetome™ Knowledgebase.** *H. GH<sup>1</sup>, R.M. Anjana<sup>3</sup>, R. Praveen<sup>2</sup>, J. Somasekar<sup>2</sup>, S. Jebarani<sup>3</sup>, V. Radha<sup>3</sup>, B. Muthu Narayanan<sup>2</sup>, R. Pradeepa<sup>3</sup>, R. Unnikrishnan<sup>3</sup>, R. Gupta<sup>2</sup>, S. Santhosh<sup>1</sup>, V. Srinivasan<sup>2</sup>, V. Mohan<sup>3</sup>.* 1) MedGenome Inc, Foster City, CA; 2) MedGenome Labs, Bangalore, India; 3) Dr. Mohan's Diabetes Specialities Centre, Chennai India.

Diabetes research today suffers from a number of challenges due to the fragmentation and complexity of the data. The lack of access to cohorts large enough to provide sufficient statistical power hinders the study of disease complications. To alleviate these challenges, MedGenome Inc. had developed Diabetome™ Knowledgebase, a database of >300,000 diabetes phenotypes with longitudinal clinical, biochemical, therapeutic & familial data. In addition to the curated datasets, the solution has integrated analytic and visualization tools that can enable researchers to select specific diabetic cohorts, understand the biology, predict risk of diabetes and stratify patients into responders and non-responders for drugs of interest. It can also help to understand the molecular basis for the differences in response by utilizing the biochemical data captured in the database and facilitate studying the underlying mechanisms of disease via correlation to other phenotypic information present in the database. To demonstrate stratification of cohorts based on response to oral hypoglycemic agents, we considered HbA1c levels up to 6 months before drug treatment and levels till 18 months after drug treatment, and recorded reduction of HbA1c levels by 1 % at any point, compared to pre-drug treatment HbA1c levels as responsive to the drug. We then compared all clinical variables between respondent and non-respondent groups to find out the statistical significance among different variables between the groups. To then demonstrate the utility of integration of genotype-phenotype information of patients in finding association of genetic markers for a particular phenotype, we used whole exome data of 700 subjects from selected phenotype cohorts, identified variants and annotated them using Ensembl VEP (variant effect prediction) tool based on GRCh38 human genome build and further processed into relational database tables. We then performed association analysis on the data to determine association of SNPs with phenotypes using PLINK association test a whole genome association analysis toolset, and considered the variants for association analysis that were retained after cleaning the genotype data with assigned thresholds (MAF of 0.01, HWE of 0.0001), and a Chi-square test with a p-value threshold of 0.01. We will present the new features & studies utilizing the Diabetome™ that can enable early stage pharma discovery, clinical decision making and research towards precision medicine. .

**Multi-resolution association analysis for exome-wide sequencing.** *E. Katsevich, S. Mantravadi, M. Sesia, C. Sabatti.* Department of Statistics, Stanford University, Stanford, CA., USA.

In genetic association studies, the goal is to find a set of variants associated with a given phenotype. Candidate variants discovered by association studies are often interpreted through their membership in various biologically relevant units, like genes or genetic loci. In this sense, a set of genetic variants is associated with sets of scientific hypotheses defined at multiple resolutions. It is thus desirable to provide statistical guarantees on the Type I error not only for single genetic variants, but for all resolutions at which these variants are interpreted. The Multilayer Knockoff Filter (2018) was proposed to address this problem by controlling the false discovery rate (FDR) with respect to an arbitrary set of resolutions. For example, one could find a set of variants whose FDR is controlled at both the single-variant and gene levels. In this work, we (1) make the MKF methodology more flexible by allowing a gene to be discovered even if no "responsible" variant can be pinpointed and (2) apply this extended MKF methodology to an exome-wide sequencing data set. The extension (1) is particularly important in the case of sequencing studies since most variants are rare, and thus their effect can often be detected only when aggregating multiple variants (e.g. via a burden test).

**Adaptive combination of Bayes factors method as a powerful polygenic test for gene-environment interactions when external information is unavailable.** W. Lin<sup>1,2</sup>, C. Huang<sup>1</sup>, Y. Liu<sup>3</sup>, S. Tsai<sup>4,5</sup>, P. Kuo<sup>1,2</sup>. 1) Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 2) Department of Public Health, College of Public Health, National Taiwan University, Taipei, Taiwan; 3) Center for Neuropsychiatric Research, National Health Research Institutes, Miaoli County, Taiwan; 4) Department of Psychiatry, Taipei Veterans General Hospital, Taipei, Taiwan; 5) Division of Psychiatry, National Yang-Ming University, Taipei, Taiwan.

The exploration of “gene-environment interactions” (G x E) is important for disease prediction and prevention. However, G x E have been difficult to identify and replicate. Single marker analysis, a commonly used approach, suffers from low statistical power due to a harsh penalty from multiple testing. To address this difficulty, the scientific community usually uses external information to construct a genetic risk score (GRS), and then tests the interaction between this GRS and an environmental factor (E). However, external genome-wide association studies (GWAS) are not always available, especially for non-Caucasian ethnicity. Although GRS is a popular polygenic approach for detecting G x E in GWAS, its performance remains unclear when there is no external information. We here develop an “adaptive combination of Bayes factors method” (ADABF) as a powerful polygenic approach for G x E when external information is unavailable, and compare it with the GRS based on marginal effects of SNPs (GRS-M) and GRS based on SNP x E interactions (GRS-I). With comprehensive simulations, we find that ADABF is generally much more powerful than GRS-M and GRS-I. ADABF is not only a powerful polygenic test for detecting G x E, but it also can pinpoint individual SNPs that interact with E. A user-friendly R code to perform the ADABF method can be downloaded from: <http://homepage.ntu.edu.tw/~linwy/ADABFGEPoly.html>. We further apply these polygenic methods to Taiwan Biobank data containing 16,555 unrelated subjects. ADABF and GRS-M identified gene x alcohol and gene x smoking interactions on blood pressure (BP). BP-increasing alleles elevate more BP in drinkers (smokers) than in nondrinkers (nonsmokers). Moreover, we identified rs79990035 x smoking interaction on BP (FDR = 1.1%) through the resampling procedure in ADABF. SNP rs79990035 is located in the *acylphosphatase 2 (ACYP2)* gene. Our result replicates the finding that *ACYP2* interacts with smoking, previously reported to be related to blood pressure in the Han Chinese population. In summary, this is the first study about polygenic methods to identify G x E in GWAS when external information is unavailable. Identification of G x E in the context of GWAS has been very difficult to date. Insufficient statistical power of existing methods may be the most important factor behind the limited successes in G x E findings. With the ADABF approach, many hidden G x E are expected to be identified in the near future.

**1350W**

**Prioritizing environment-environment interactions using clarite.** N. Palmiero<sup>1</sup>, A. Lucas<sup>2</sup>, M.D. Ritchie<sup>2</sup>, I. Vazquez-Vidal<sup>3</sup>, P.J.H. Jones<sup>3</sup>, M.A. Hall<sup>1</sup>. 1) Department of Veterinary and Biomedical Sciences, The Pennsylvania State University, University Park, PA; 2) Department of Genetics, Institute for Biomedical Informatics, University of Pennsylvania, Philadelphia, PA; 3) Richardson Centre for Functional Foods and Nutraceuticals, University of Manitoba, Winnipeg, MB, Canada.

While genome-wide association studies are an established method of identifying genetic variants associated with disease, environment-wide association studies (EWAS) highlight the role of non-genetic components in complex phenotypes. However, a lack of high-throughput quality control (QC) pipelines for EWAS data lends itself to analysis plans where the data are cleaned after a first-pass analysis, which can lead to bias, or are cleaned manually, which is arduous and susceptible to user error. We offer a novel R package, CLearning to Analysis: Reproducibility-based Interface for Traits and Exposures (CLARITE), as a way to efficiently clean non-genetic data, perform regression analysis, and visualize results on a single platform through user-guided automation. Despite a focus on EWAS, CLARITE is intended to also improve the QC process for phenotypes and clinical lab measures for a variety of downstream analyses, including phenome-wide association studies and gene-environment interaction studies. Using CLARITE, we performed and sought replication for 4 separate EWAS in the National Health and Nutrition Examination Survey (N overall discovery=8583, N overall replication=9320) for: high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), triglycerides (TG), and total cholesterol (TC) and ~350 environment variables, adjusting for sex, age, body mass index, race, socioeconomic status, statin use, and survey year. Fifty-one HDL-C, 4 LDL-C, 17 TG, and 22 TC results replicated at a Bonferroni  $p < 0.05$ . We further interrogated these results for complex environment-environment interactions (ExE) by prioritizing an interaction search between replicating EWAS results and all other non-correlated variables in the analysis, adjusted for covariates. We identified 11, 20, 58, and 78 ExE models that replicated at a Bonferroni likelihood ratio test (LRT)  $p < 0.05$  in HDL-C, LDL-C, TG, and TC, respectively. Among the top results was an interaction between Folate (ng/mL) and Vitamin A (ug/dL) associated with HDL-C (discovery Bonferroni LRT  $p$ : 1.08e-09, replication Bonferroni LRT  $p$ : 3.08e-12), both of which have demonstrated associations with HDL-C in studies of dietary intake; however, this is the first example of an ExE interaction between these features relating to HDL-C. These findings show the potential impact of ExE in complex phenotypes as well as the utility of CLARITE in the QC pipeline and as a method of prioritizing these interactions.

**1351T**

**Mining publicly available gene expression data in hunt for novel biomarkers for rheumatoid arthritis.** *D. Rychkov<sup>1</sup>, C. Lin<sup>2</sup>, M. Sirota<sup>1</sup>*. 1) Institute for Computational Health Sciences, UCSF, San Francisco, CA; 2) Stanford University, Stanford, CA.

Rheumatoid arthritis (RA) is a chronic inflammatory disease in which the body's immune system targets synovial tissues of the joints. Diagnosis and monitoring the disease progression is challenging and there is currently no biochemical test for detection of the early-stage disease. In this study, we aimed to define a Rheumatoid Arthritis meta-profile and identify biomarkers by leveraging publicly available gene expression data and machine learning approaches. We carried out a comprehensive search for publicly available microarray data in the NCBI Gene Expression Omnibus database for whole blood and synovial tissue in RA and healthy controls. For the synovium, we were able to collect 13 datasets with 312 biopsy samples (276 RA and 36 controls). For whole blood, we were able to collect 11 datasets with 2,153 samples (1,394 RA and 759 controls). Using the Significance Analysis of Microarrays (SAM) approach with the cutoff of  $FDR < 0.05$  and  $abs(FC) > 1.2$  we were able to identify 882 genes (502 up- and 380 down-regulated) that were significantly differentially expressed in the synovium. In blood we identified 339 (166 up- and 173 down-regulated) significantly differentially expressed genes. Leveraging the gene list enrichment analysis tool ToppGene we performed pathway analysis that confirmed the gene regulation of the immune system process and response, type I interferon signaling, and cell activation and aggregation in both innate and adaptive immune system in RA. Then we filtered out genes that cumulatively contribute to the biological variance less than 5% and applied a Variable Selection Using Random Forests (VSURF) approach and found 5 significant genes ( $p$ -value = 0.001) in both tissues in the same direction with 3 up-regulated (*TAP1*, *MMP9*, *DRAM1*) and 2 down-regulated (*DDX3Y*, *MYC*) genes. Finally, we built a Random Forest classification model trained on the synovium data. We obtained Cohen's kappa equaled to 0.61 with sensitivity 0.86 and specificity 0.91. In the final step, we validated the prediction model on the blood data, resulting kappa of 0.57 with sensitivity 0.54 and specificity 0.98. The computational analysis allowed us to perform a comprehensive in-silico search for biomarkers for RA. We found three protein coding genes with the strongest association with RA. Identification of extensive proteins secretion in blood could help in disease detection on an early-stage and make a positive impact on monitoring disease progression and patient treatment.

**1352F**

**Typing highly divergent genes (HLA/KIR) from large-scale next-generation sequencing projects.** *S. Tian<sup>1</sup>, H. Yan<sup>1</sup>, S. McDonnell<sup>1</sup>, W. Ding<sup>2</sup>, N. Ihrke<sup>3</sup>, M. Kalmbach<sup>3</sup>, E. Klee<sup>3</sup>, S. Baheti<sup>4</sup>, S. Johnson<sup>1</sup>, J. Olson<sup>4</sup>, J. Cerhan<sup>4</sup>, L. Bergsage<sup>5</sup>, S. Slager<sup>1</sup>*. 1) Division of Biomedical Statistics and Informatics, Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55905, USA; 2) Division of Hematology/Medical Oncology, Department of Internal Medicine, Mayo Clinic, Rochester, MN 55905, USA; 3) Division of Research and Education Support Systems, Department of Information Technology, Mayo Clinic, Rochester, MN 55905, USA; 4) Division of Epidemiology, Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55905, USA; 5) Division of Hematology/Oncology, Department of Internal Medicine, Mayo Clinic, Phoenix, AZ 85054, USA.

Whole-genome (WGS) and whole-exome sequencing (WES) have been widely used to identify variants implicated in human disease. However, current variant discovery approaches often start with reads mapping, whose performance deteriorates in hyperpolymorphic regions, such as human leukocyte antigen (HLA) and killer immunoglobulin-like receptors (KIR) that play pivotal roles in the immune system. To date, many large-scale sequencing projects, including the 1000 Genomes, have created deep catalogues of human genetic variation, representing valuable resources for identifying genetic basis of diseases. However, limited by the bioinformatics challenges, the genetic variation of highly divergent regions, such as HLA/KIR, are not well characterized. Furthermore, the existing HLA typing algorithms only type a few HLA class I (A/B/C) and/or class II genes (*DRB1/DQA1/DQB1*), missing over 50 highly divergent genes that may also have important roles in immune diseases. To maximize the use of information from large-scale sequencing projects, we developed a bioinformatics workflow for accurate typing of HLA/KIR genes in the IPD at four-digit resolution (accuracy: 92.3%, success rate: 94.7 for class I genes with WGS). Specifically, this pipeline selects informative reads for haplotype-based assembly, optimizes the inference of allele status, and uses well-performing HLA typing algorithm to minimize typing ambiguity. We typed 39 HLA and 17 KIR genes across 981 (53,988 alleles) and 956 (21,362 alleles) Mayo Clinic Bobank samples (*EUR*/WGS), respectively, and 2,328 (82,492 alleles) and 2,494 (43,862 alleles) samples from 5 populations (WES) in the 1000G Project. For the majority of the HLA genes, the levels of heterozygosity are largely comparable among populations. However, marked differences exist in several genes including *TAP1* (e.g., 62.5% heterozygosity in *SAS* vs. 28.6% in *EUR* ( $p < 0.000001$ ,  $OR = 4.08$ ), suggesting obvious ethnic diversity. Given that several HLA/KIR alleles are known to be associated with multiple myeloma (MM) risk, we demonstrated the potential application of these large collections of HLA/KIR alleles from multiple ethnic groups by typing nearly 600 MM patients (WES, CoMMpass Study in MMRF). All samples were typed for HLA/KIR, generating 32,228 and 10,480 alleles, respectively. Our bioinformatics workflow for accurate typing of HLA/KIR genes expands our ability to interrogate complex genomic regions through sequencing studies for discovery of disease genes.

**CRISPResso2: Characterization of repair outcomes and allele specific analysis from CRISPR nuclease and base editor genome editing.** *K. Clement<sup>1,2,3</sup>, H. Rees<sup>1,4,8</sup>, M.C. Canver<sup>1,2,3</sup>, J.M. Gehrke<sup>2,3</sup>, R. Farouni<sup>1,2,3</sup>, J.Y. Hsu<sup>1,2,3</sup>, M. Cole<sup>5,6,7</sup>, D.R. Liu<sup>1,4,8</sup>, J.K. Joung<sup>2,3</sup>, D.E. Bauer<sup>5,6,7</sup>, L. Pinello<sup>1,2,3</sup>.* 1) Broad Institute of MIT and Harvard, Cambridge, MA; 2) Molecular Pathology Unit, Center for Cancer Research, and Center for Computational and Integrative Biology, Massachusetts General Hospital, Charlestown, MA; 3) Department of Pathology, Harvard Medical School, Boston, MA; 4) Department of Chemistry and Chemical Biology, Harvard University, Cambridge, MA; 5) Division of Hematology/Oncology, Boston Children's Hospital; Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA; 6) Department of Pediatrics, Harvard Medical School, Boston, MA; 7) Harvard Stem Cell Institute, Cambridge, MA; 8) Howard Hughes Medical Institute, Harvard University, Cambridge, MA.

The field of genome editing is rapidly advancing, and technologies to modify the genome are becoming increasingly more accurate, efficient and versatile. These technologies are accelerating discovery and interpretation of functional genetic variants from GWA and eQTL studies by enabling targeted perturbations, even of a single base pair. Amplicon sequencing is the gold standard for studying editing outcomes, but the technical expertise required to analyze amplicon sequencing data is a critical barrier to correct interpretation of editing outcomes. In addition, current software toolkits are not designed for modern genome editing tools such as base editors which are capable of inducing single-nucleotide changes. Here, we introduce CRISPResso2, a comprehensive analysis toolkit that introduces five key innovations for the analysis of genome editing data: (1) Comprehensive analysis of sequencing data from base editors; (2) Allele specific quantification of heterozygous reference sequences; (3) A novel biologically-informed alignment algorithm; (4) Ultra-fast processing time; and (5) Batch mode for analyzing and comparing multiple editing experiments. We generated experimental data for six modern genome editing agents: Cas9, four C→T base editor variants, and one A→G base editor using guides targeting five well-studied genomic loci. To demonstrate the utility of CRISPResso2, we analyzed this dataset and provide an in-depth characterization of the editing properties of these agents. Using the intuitive graphics produced by analyzing multiple samples simultaneously, the editing characteristics of each agent can be distinguished and compared. When comparing the four C→T base editor variants, our plots specifically designed for base editors highlight shifted activity windows and increased editing purity resulting from modification to the deaminase enzyme. We also used CRISPResso2 to recover alleles important for fetal hemoglobin induction by analyzing targeted perturbation of key enhancer elements harboring trait-associated variants. Together, these results emphasize the utility of CRISPResso2 in analyzing amplicon sequencing data from genome editing experiments, particularly in comparing mutational profiles and properties of different editing agents including base editors and enabling accurate and intuitive analysis of coding and non-coding elements in perturbation studies. CRISPResso2 is available online at: [crispresso2.pinellolab.org](http://crispresso2.pinellolab.org).

**1354T**

**Machine learning classifiers for chronic fatigue syndrome using immune cell specific RNA-seq.** *P. Comella, ND. Beckmann, GE. Hoffman, EE. Schadt.* Genetic and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Chronic Fatigue Syndrome (CFS) is a disease resulting in extreme fatigue without any known underlying medical condition. CFS often presents in patients following a viral infection and patients may appear to have slightly impaired immune systems. With no positive diagnostic, CFS is often misunderstood and misdiagnosed. A pilot clinical study was established to give further insight into the immunological role of CFS. This pilot study included 15 CFS patients and 15 age and sex matched controls undergoing cardiopulmonary exercise testing (CPET). Blood was extracted at four time points - immediately before, 1 day after, 2 days after and 3 days after. Five immune cell types were sorted from whole blood collected from each participant, and RNA was extracted and sequenced for each cell type, as well as whole blood, at each time point. Additionally, each participant underwent extensive clinical surveys and questionnaires. Our team has employed state of the art machine learning approaches to construct classifiers that can accurately distinguish CFS from non-disease states in immune cells using RNA-Seq data. This technique has generated non-linear gene associations that can be used to understand distinct gene expression differences between disease and non-disease states. We were able to identify B cell and Monocyte classifiers as being the highest performing classifiers in the immune cell populations, suggesting these cell types contain more interesting disease-state biology. Our classifier pipeline further illustrates the stability of the features/genes of the classifier, resulting in specific genes that are consistently chosen as important features to classify disease with. These classifier algorithms can also be used to predict unseen observations as a future diagnostic tool.

**1355F****A computational approach to identify novel disease-causing genes**

**from exome sequencing.** S. Rana<sup>1</sup>, U. Sunderam<sup>1</sup>, K. Kundu<sup>1</sup>, Y. Zou<sup>2</sup>, A.N. Adhikari<sup>2</sup>, A.G. Sharo<sup>2</sup>, J.M. Puck<sup>3</sup>, S.E. Srinivasan<sup>1</sup>. 1) Innovation Labs, Tata Consultancy Services, Hyderabad, India; 2) University of California, Berkeley, CA 94720, USA; 3) Department of Pediatrics, University of California San Francisco, San Francisco, Box 3118, CA, USA; 4) Institute for Bioscience and Biotechnology Research, University of Maryland, Rockville, MD, USA; 5) School of Life Sciences, Fudan University, Shanghai, China.

Whole exome sequencing has advanced discovery of causal variants underlying rare genetic disorders. Many rare Mendelian diseases, such as severe combined immunodeficiency (SCID) are life threatening without treatment, yet can be effectively treated if diagnosed early. Whole exome sequencing can facilitate diagnosis by identifying the disease-causing variants. However, detecting the causative genomic variants is challenging, due to a number of difficulties, including variant prioritization, pathogenicity prediction, and limited knowledge of gene function and pathways involved in disease. To address this challenge, we have developed a variant prioritization protocol that is optimized for trio-exome sequencing of primary immunodeficiency cases. To yield high quality sets of possible causative variants, we used multi-sample calling and integrated variant annotation, variant filtering, and gene prioritization. We first focus on candidate variants from genes previously known to be associated with the disease. If there are no compelling findings in these genes, we expand the disease gene list by integrating information from patient phenotypes and gene pathways. This expanded list includes genes extracted from Human Phenotype Ontology (HPO), Mouse Phenotype Ontology (MPO) and various protein interaction databases. To prioritize important genes, we score each gene based on its associated phenotypes. We categorize patient phenotypes into 1) primary phenotypes, relevant to patient diagnosis and indicative of a functional defect, and 2) secondary phenotypes, derivative consequences of the primary functional defects. The genes associated with a patient's primary phenotype are given a higher score than the genes associated with the patient's secondary phenotype or generic HPO and MPO ontology terms. Our protocol has revealed causative variants in SCID and other immunodeficiencies including early diagnosis of Ataxia Telangiectasia, Nijmegen Breakage Syndrome, as well as several novel syndromes. These cases highlight unique features of the analysis framework that facilitate discovery of genetic variants leading to disease. These findings provide crucial information for avoidance of a diagnostic odyssey, to inform prompt and appropriate treatment and to guide family genetic counseling. .

**An application of *ChARMDiff* to discover epigenetic difference between CD4 memory and naive primary cells.** S. Park, S. Kim. Soongsil University, Seoul, South Korea.

Various chromatin modifications, identified in large-scale epigenomic analyses, are associated with distinct phenotypes of different cells and disease phases. To improve our understanding of these variations, we have developed *ChARMDiff*, a new computational approach based on association rule mining, which is pattern discovery of *de novo* differential chromatin modifications and characterize biological significance of globally occurred patterns for combinatorial chromatin state difference between multiple cell types and conditions. We report an application of *ChARMDiff* to two pairs of epigenomes in CD4 memory and naive primary cells from roadmap epigenomics project. *ChARMDiff* provides a scalable framework that can easily be applied to find various levels of combination patterns, which should reflect a range of globally common to locally rare chromatin modifications. Our approach provides new insights into the resolution of the histone code hypothesis to characterize epigenetic variations in distinct phenotypes of different cells, disease phase and experimental conditions.

**The NIAID clinical genomics data repository, Genomic Research Integration System (GRIS): Streamlined data capture, standardization, integration, and analysis to enable identification of immune-related genetic variants for clinical reporting and genomics research.** S. Xirasagar<sup>1</sup>, A.J. Oler<sup>1</sup>, Z. Li<sup>1</sup>, X. Cheng<sup>1</sup>, K. Huang<sup>1</sup>, D. Veltri<sup>1</sup>, M. Similuk<sup>2</sup>, Y. Zhang<sup>2</sup>, C. Hong<sup>2</sup>, M. Walkiewicz<sup>2</sup>, J. Johnson<sup>2</sup>, J. Barnett<sup>1</sup>, L. Zhang<sup>1</sup>, Y. Fan<sup>1</sup>, O. Juarez-Espinoza<sup>1</sup>, M. Lenardo<sup>2</sup>, J.D. Milner<sup>2</sup>. 1) Office of Cyber Infrastructure and Computational Biology (OCICB), NIAID, National Institutes of Health, Rockville, MD; 2) NIAID Clinical Genomics Program, Division of Intramural Research, NIAID, National Institutes of Health, Bethesda, MD.

The NIAID Genomic Research Integration System (GRIS), a web-based collaboration-engendering web application facilitates identification of causal genetic variants of rare and or novel immunological disorders. Users can access integrated and standardized phenotypic and genomic data that is analyzable via powerful genetic analysis tools. Systematic and automated capturing and linking of patient clinical and genomic data from disconnected systems and paper-based records accompanied by standardized annotations allow cross comparisons across data from different clinical studies. Multiple levels of access coupled with secure data storage and transfer facilitates quick access to relevant data for all aspects of the clinical study lifecycle. Data access and sharing workflows are optimized to promote maximum data usage while protecting patient privacy and confidentiality. The use of standardized vocabularies allows researchers to efficiently query and retrieve data from all the studies in GRIS, thus increasing the analysis power and making discoveries otherwise not possible from individual study datasets. The system leverages existing open source tools, ontologies, and genomic annotation databases. A customized version of PhenoTips<sup>®</sup>, with a user-friendly interface has been implemented to enable capture, searching, and display of patient annotations standardized with controlled vocabularies including the Human Phenotype Ontology (HPO) and Online Mendelian Inheritance in Man<sup>®</sup> (OMIM). An intuitive pedigree editor allows documentation, display and reporting of pedigrees for publication or in machine-readable formats for use within genetic analysis tools. The genetic variant analysis tool, seqr, has been integrated in conjunction with standardized analysis pipelines based on open source tools (BWA, PICARD, GATK/Queue, BCFtools, VEP) for sequence alignment, variant data processing, quality control, and annotation. seqr enables Mendelian and custom inheritance variant analysis at individual, family, or family group levels. Advanced filtering capabilities and high-quality genomic annotation databases including HGMD, ClinVar and OMIM facilitate meaningful biological interpretation. Importantly, GRIS enables both standardized variant analyses for clinical reporting and flexible analyses for research analyses. GRIS is thus a scalable platform to accelerate the pace of molecular diagnosis and treatment of diseases.

**BREATH: An open-access database of normal lung development generated by the molecular atlas of lung development program (LungMAP).** R.F. Clark<sup>1</sup>, N.C. Gaddis<sup>1</sup>, J.L. Levy<sup>1</sup>, M. Duparc<sup>1</sup>, M.C. Krzyzanowski<sup>1</sup>, C. Ball<sup>1</sup>, S.M. Palmer<sup>2</sup>, the LungMAP Data Coordinating Center. 1) RTI International, Research Triangle Park, NC; 2) Duke Clinical Research Institute, Duke University School of Medicine, Durham, NC.

The lung is a complex organ with high cellular heterogeneity, and research is needed to define the interactive gene networks and dynamic crosstalk among multiple cell types that coordinate normal lung development. Significant knowledge gaps exist in the understanding of lung development from late fetal to perinatal stages and through early childhood, a critical period when the diverse lung cells go through terminal differentiation and maturation and when alveoli form. Coordination of information from disparate assays and experimental approaches is critically needed to help the pulmonary research community uncover the molecular determinants of lung development. The goal of LungMAP is to build an open-access resource providing a comprehensive molecular atlas of late-stage lung development in humans and mice, making otherwise dispersed data, reagents, and protocols freely available to the research community. We have created the Bioinformatics REsource ATlas for the Healthy lung (BREATH) database, applying novel data management and bioinformatics approaches to manage high-throughput multidimensional experimental data. BREATH is built on a triplestore database backbone, integrated with anatomical ontologies for lung development, and provides access to novel web-based tools for the analysis and visualization of data generated by the four Research Centers and Human Tissue Core of the LungMAP Consortium. The current version of BREATH contains confocal immunofluorescence images, *in situ* hybridization images, histological images, nano-DESI, and 3D Vibra-SSIM confocal and uCT images of developing mouse and human lungs at several time points, as well as single-cell RNAseq, multi-cell RNAseq, microRNA, MeDIP-seq, proteomic, lipidomic, and metabolomic data from mouse and human lung cells. The LungMAP website ([www.lungmap.net](http://www.lungmap.net)) provides an entry portal to the BREATH database and tools for exploring and interacting with the lung images and omics data. A better understanding of the basic molecular pathways that regulate normal lung development will enable development of innovative therapies that advance treatment of lung injury repair and regeneration.

**Deep recurrent neural networks for accurate variant calling in 21-hydroxylase-deficient congenital adrenal hyperplasia.** A. Ganesh<sup>1,2</sup>, S. Hong<sup>1</sup>, D. Muzzey<sup>1</sup>, K.R. Haas<sup>1</sup>, D. Peticolas<sup>1</sup>, K.A. Beauchamp<sup>1</sup>. 1) Counsyl, South San Francisco, CA; 2) Stanford, CA.

Introduction Congenital adrenal hyperplasia (CAH) is an autosomal recessive disease that impairs steroidogenesis. CAH affects approximately 1 in 10,000 persons but is often excluded from expanded carrier screening (ECS) due to variant-calling challenges posed by high homology and frequent gene rearrangements between the *CYP21A2* gene and its pseudogene *CYP21A1P*. We previously described—and have used extensively in a clinical setting—a molecular and computational strategy that identifies 11 common CAH-causing variants but requires nuanced manual review. Here we show that a deep learning model trained on human-annotated samples calls CAH variants with high sensitivity and specificity, critically lessening the burden of human review. Methods An anonymized cohort of 118,476 ECS patients was split into training and validation sets of 94,781 and 23,695 patients, respectively. For each patient, we aggregated two classes of next generation sequencing features. First, we collected allele-balance measurements summarizing the fraction and count of genic and pseudogenic alleles of interest. Second, we obtained copy-number measurements consisting of normalized sequencing depths at important loci on *CYP21A2* and *CYP21A1P*. The observations for training were the human-reviewed (and possibly human-re-labeled) output of our classical variant-calling algorithm, stored as 11 binary genotypes per patient. These data were used as input to a five-layer recurrent neural network comprised of long short-term memory (LSTM) cells and a weighted cross entropy loss function. The model was implemented in TensorFlow and trained using the Adam optimizer. Results Considering the human-reviewed calls as ground truth, the LSTM showed a validation error rate of approximately 1 in 1000. For example, the 30kb deletion variant was called with 99.58% sensitivity (1,406 true positives / 1,412 total positives), and 99.97% specificity (22,276 true negatives / 22,283 total negatives). We also evaluated performance on a held-out subset of 243 difficult calls for which human relabeling had been necessary. Model accuracy was 95% on this challenging set, suggesting that the LSTM model is capturing domain knowledge of expert human reviewers. Conclusions Deep recurrent neural networks achieved high accuracy for a technically challenging CAH variant calling task. When large training datasets are available, deep learning can streamline complex, human-aided processes in clinical sequencing workflows.

**Predicting the time-to-event outcome of cystic fibrosis related diabetes using genotype data.** Y. Lin<sup>1</sup>, L.J. Strug<sup>1,2</sup>. 1) Department of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 2) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada.

Cystic Fibrosis (CF) is a life-limiting genetic disease caused by mutations in the Cystic Fibrosis Transmembrane Conductance Regulator (*CFTR*). CF affects multiple organs including the exocrine pancreas which contributes to Cystic Fibrosis Related Diabetes (CFRD), seen in over 40% of patients by age 40 with an estimated incidence of 3.4% per year. Untreated CFRD is associated with increased CF-related mortality whereas early detection can improve outcomes. Given the variation in age-of-onset of CFRD, we aim to develop a predictive model to identify individuals at risk of CFRD at different ages based on genetic and clinical measures early in life. Early-age clinical measurements that are robust CFRD biomarkers but prone to missingness further complicate model generation. Using 2,347 individuals participating in the Canadian CF Gene Modifier Study, we separate 1,600 and 747 participants into training and test sets, respectively. Regression models are used to estimate early-age biomarkers including Immunoreactive Trypsinogen (IRT) at birth in individuals for whom these measures are not available. Initial model generation has used penalized Cox Proportional Hazard models with 3,984 SNPs annotated to previously associated gene sets and early clinical variables including gender, estimated IRT and Meconium Ileus (MI). Component-wise gradient boosting and LASSO were employed for model-fitting, and a 10-fold cross validation procedure was used to select the parameters. Area Under the Curve (AUC) for time-dependent ROC curves were computed between ages 8 and 40, with emphasis on improved CFRD prediction at younger ages. The final predictive model included MI, IRT and 22 SNPs including 4 *CFTR* variants. Adequate predictive accuracies are achieved when assessing risks at older ages (AUC=0.708, Age=40); however, improved performance is required for predictive risk at younger ages (AUC=0.608, Age=12). Ongoing work involves the inclusion of genome-wide genotype data and longitudinal BMI measurements to improve predictive accuracy among younger CF patients. Moreover, significant variability in the final model when conducting variable selection on high-dimensional data highlights the limitation of AUC and other discrimination measures alone for validation. Future work will incorporate calibration and methods with optimized statistical properties into model generation.

**Development of the BiomedScrape data-mining suite for deep semantic structure-based drug repurposing for DMD: A pilot feasibility study.** *J.W. Ulm, S.F. Nelson.* UCLA Medical Center, Department of Genetics, Los Angeles, CA., Select a Country.

A text-mining-based pilot feasibility study was initiated to focus on identification and quantification of deep semantic structures (DSS's) so as to determine and amplify a telltale "information scent" linking DSS's of disease-related literature (for e.g. CF or DMD) with those of literature pertinent to potential drug repurposing candidates, derived from published abstracts or comprehensive pharmaceutical databases such as Drugbank. To accomplish this, it was necessary to first create a large-scale "informatic infrastructure" to provide the tens of millions of documents in the form of lists of strings or nested lists—within the biomedical field but unrelated to the specific topic of interest—to train the AI-like text-mining models. This was accomplished through development of the comprehensive BiomedScrape tool, written chiefly in the Python programming language, which has provided these document corpora (semantic spaces) for the first time, in the form of carefully delimited abstracts scraped from 1911 that can be randomly recombined into training corpora, alongside dozens of modular code blocks facilitating rapid and highly versatile text-mining studies. Subsequent application of the tool has provided indications of a DSS-based information scent that has partially recapitulated previous serendipitous drug repurposing findings, with the scent amplified by a number of data-mining parameters such as a specific focus on drug and disease molecular mechanism reports, chronological narrowing, and word bigram or trigram comparisons versus traditional bag-of-words. These studies have in turn produced preliminary hints of potential drug repurposing candidates for DMD, though as yet no test statistic or index that can be used to firmly predict a single high-probability candidate. As the BiomedScrape tool is still early in development, future efforts will focus on elucidating indices and summary statistics that can more robustly identify a "smoking gun" that decisively suggests a repurposing candidate indicated by previous findings but otherwise overlooked.

**A 29-gene signature predicts progression to active tuberculosis in exposed household contacts.** *Y. Zhao<sup>1,2</sup>, S. Leong<sup>3</sup>, W.E. Johnson<sup>1,2</sup>, P. Salgame<sup>3</sup>.* 1) Section of Computational Biomedicine, Boston University School of Medicine, Boston, MA; 2) Bioinformatics Program, Boston University, Boston, MA; 3) Rutgers New Jersey Medical School, Newark, NJ.

**Background:** One-third of the world's population is latently infected with *Mycobacterium tuberculosis* (Mtb). Clinical management of latent tuberculosis (TB) infection (LTBI) remains a challenge due to lack of diagnostic biomarkers that can predict which individuals will progress to active TB disease. **Methods:** RNA-sequencing was performed on peripheral blood mononuclear cell samples from a prospective Brazilian household contact (HHC) cohort consisting of individuals with LTBI that either progressed to TB disease (progressors) or not during long-term follow-up (nonprogressors). We used the RNA-Seq data from GSE79362 dataset to train a baseline biomarker, using an ensemble feature selection pipeline, and then validated this biomarker on the RNA-seq data from our Brazilian cohort. **Results:** The published 16-gene correlate of risk signature derived from an adolescent cohort (ACS-COR) performed poorly in predicting progressors from non-progressors in the Brazilian dataset. Since the performance of the ACS-COR signature improved closer to the time of TB diagnosis, we used the earliest time-point samples from progressors and non-progressors from the African dataset to derive a novel 29-gene signature that was significantly better at predicting progressors from non-progressors in the Brazilian dataset with a sensitivity of 74.2% and a specificity of 84.8%. **Conclusions:** PREDICT29 signature offers strong predictive performance in distinguishing nonprogressors from progressors at early time-points, several years prior to TB diagnosis, and across geographical regions and despite ethnically distinct host and bacterial genetics. Therefore, this signature is a potential tool for risk stratification of infected individuals for targeted anti-TB preventive therapy.

**From GWAS to the cross-phenotype neighborhood of diseases in the interactome: Network-based pathway prioritization identifies concordant and discordant pathways between COPD and IPF.** A. Halu<sup>1,2</sup>, S. Liu<sup>1,3</sup>, S.H. Baek<sup>1</sup>, B.D. Hobbs<sup>1,4</sup>, M.H. Cho<sup>1,4</sup>, E.K. Silverman<sup>1,4</sup>, A. Sharma<sup>1</sup>. 1) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Center for Interdisciplinary Cardiovascular Sciences, Cardiovascular Division, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 3) Department of Computer Science and Engineering, University of Notre Dame, Notre Dame, IN; 4) Division of Pulmonary and Critical Care, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Chronic obstructive pulmonary disease (COPD) and idiopathic pulmonary fibrosis (IPF) are two pathologically distinct diseases that result from similar exposures, show common symptoms, and have high comorbidity. Genome-wide association studies (GWAS) have identified shared loci for COPD and IPF, including ones with opposite directions of effect. The existence of further such loci, as well as shared mechanisms between the two diseases at the molecular level remains to be explored. Taking a network-based approach, we studied the shared molecular neighborhood of COPD and IPF in the interactome, with the aim of discovering genes and pathways involved in both diseases. We used GWAS- and literature-derived genes as seeds to prioritize disease-associated candidates by a random walk-based method that corrects for degree bias. We built disease modules using an approach that maximizes connectivity significance. We validated the biological relevance of the resulting COPD and IPF disease modules using gene expression data from lung tissue, where the module genes displayed strong disease signals at the transcriptional level. The two disease modules showed statistically significant overlap and network proximity, sharing 19 genes. To uncover pathways at the intersection of COPD and IPF, we developed a metric, NetPathScore, which prioritizes the pathways of a disease by their shared interactome neighborhood with another disease. Applying NetPathScore to the pathways enriched in the up- and down-regulated portions of diseases modules enabled the determination of concordant and discordant pathways between the COPD and IPF. These concordant and discordant pathways offer important clues about the pathobiology of the two diseases.
