Metabolomics is an analysis of small molecules and biochemical intermediates applied on various phenotypes. Although metabolomics may explain only a small proportion of the total phenotypic variability on its own, metabolites have been widely used as biomarkers to identify the onset of many complex diseases. The present work demonstrated a hybrid approach combining genetic algorithm (GA) and Naive Bayesian (NB) method to identify the potential osteoporosis-associated metabolites. We performed a liquid chromatography-mass spectrometry (LC-MS) untargeted metabolomics analysis on 136 serum samples collected from Louisiana Osteoporosis Study. The known metabolites from LC-MS were included in a classical GA which used three main properties of rules ("selection," "crossover," and "mutation") to conduct multiple Random Forests via the evolutionary process to identify the potential osteoporosis-associated metabolites. The top five GA-selected metabolites were Stachydrine, Threonine, Pipecolate/L-Pipecolic Acid, Urate, and Sarcosine/Beta-Alanine. We then applied the NB classifier to the GA-selected metabolites and found that the NB model considering the top 15 GA-selected metabolites had the highest prediction accuracy rate of 73%. It is noteworthy that 4 of the top 5 GA-selected metabolites have previously been reported to have an association with osteoporosis. We conclude that the GA-selected metabolites considered in the NB classifier with highest accuracy rate may potentially be reliable biomarkers for assisting identification of osteoporosis, although further functional validation experiments are needed. Overall, this study shows that GA can efficiently detect osteoporosis-related metabolites with a limited number of subjects.

**Integrating regulatory features for large-scale transcriptome-wide association study from GWAS summary statistics identified novel genes for osteoporosis.** S. Yao, S.S. Dong, Y.J. Zhang, J.B. Chen, Y. Guo, T.L. Yang. Key Laboratory of Biomedical Information Engineering of Ministry of Education, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, China.

Genome-wide association studies (GWASs) have been demonstrated as an effective strategy to identify susceptibility loci for human complex traits. However, the biological mechanisms between genetic variations and traits are not fully understood. Previous studies have demonstrated that many genetic variants could influence complex traits by regulating gene expressions. Here we introduce a strategy to identify novel susceptibility genes for human complex traits based on the interpretation of regulatory features, genotype, gene expression and phenotype. We estimated gene expression effect sizes based on classified single nucleotide polymorphisms (SNPs) with functional features as a prior, and then estimated the associations between predicted expressions and traits with the combination of SNP-trait effect sizes while accounting for linkage disequilibrium among SNPs. We applied our strategy in GWAS summary data of bone mineral density with 185,817 individuals from the Genetic Factors for Osteoporosis (GEFOS) Consortium with expression data from blood across 696 individuals. Finally, we identified 130 bone mineral density-associated genes after multiple test correction ( $P < 5 \times 10^{-6}$ ) after excluding the major histocompatibility complex region. The most significant gene, *FAM3C*, have been reported to be associated with a genome-wide significant increased risk of forearm fracture. Among these identified genes, 104 genes were located near at least one GWAS SNP ( $\pm 500$  kb), and the remaining 26 genes implicated novel targets. Seven of the new identified genes are associated with relevant phenotypes in the Mouse Genome Informatics, which are *FKBP8*, *EPN1*, *PPARG*, *CERS1*, *ATP2B2*, *IDUA*, and *PNPLA1*. Especially, *IDUA* locus was identified to be associated with bone mineral density, and osteoblast cell number in a mouse knockout of *Idua*. Our results revealed the power of integrating regulatory features, genotype, gene expression and phenotype to identify novel genes for human complex traits.

**Integrative analysis of clinical and molecular data on a well-phenotyped lupus cohort identifies distinct molecular subtypes.** I. Paranjpe<sup>1</sup>, C. Lanata<sup>1</sup>, J. Nititham<sup>1</sup>, K. Taylor<sup>1</sup>, M. Gianfrancesco<sup>1</sup>, D. Rychkov<sup>1</sup>, L. Barcellos<sup>2</sup>, P. Katz<sup>1</sup>, M. Dall'Era<sup>1</sup>, J. Yazdany<sup>1</sup>, L. Criswell<sup>1</sup>, M. Sirota<sup>1</sup>. 1) University of California, San Francisco, San Francisco, CA; 2) University of California, Berkeley, Berkeley, CA.

Systemic Lupus Erythematosus (SLE) is a chronic autoimmune disease with heterogeneous manifestations. We aimed to define how molecular differences underlie this clinical heterogeneity through an integrative approach leveraging methylation, genetic, and phenotypic data from a well characterized multi-ethnic cohort of 330 SLE patients. We first stratified patients based on the 18 American College of Rheumatology (ACR) criteria which include hematologic manifestations, serum autoantibody status, cutaneous rash, and neurologic manifestations. Unsupervised K-means clustering on these 18 input features revealed 3 stable clusters, with stability evaluated by a bootstrap resampling method. We found 2 severe clusters, one characterized by serum autoantibodies and lupus nephritis (LN), and the other by serum autoantibodies, LN as well as hematologic manifestations and 1 mild cluster characterized by malar rash, arthritis, photosensitivity, and oral ulcers. Interestingly, these clusters reflect known clinical associations with race, with the mild cluster enriched for White patients and the severe clusters for non-White. We then identified individual CpGs associated with clinical clusters adjusted for age, sex, genetic ancestry, and cell composition. This analysis revealed 241 cluster-associated CpGs (FDR<0.1) with significant enrichment of genes relating to Type 1 Interferon signaling and IFN-gamma. Overall Type 1 interferon genes were hypermethylated in the mild cluster compared to the severe clusters, suggesting a role for epigenetic control of this pathway in SLE outcome. By mapping CpGs to regulatory regions defined by the Epigenome Roadmap 15 chromatin state model, we observed significant enrichment (hypergeometric test  $q < 0.01$ ; odds ratio > 2) of cluster-associated CpGs in enhancers and transcriptional start sites in peripheral T cells, B cells, monocytes, neutrophils, and NK cells, indicating DNA methylation mediated epigenetic remodeling in peripheral blood cells may contribute to the heterogeneity observed in SLE. MeQTL analysis revealed that from the 241 cluster-associated CpGs, 38 were under cis genetic control (FDR<0.01) and 24 under trans control (FDR<0.1), suggesting a functional link between genetic variation and methylation in the Type 1 Interferon pathway. In conclusion, by applying an integrative approach, we reveal several clinically relevant SLE subtypes characterized by multiple phenotypes and supported by a strong epigenetic and genetic signature.

**Development and validation of algorithms using electronic health records to identify azathioprine use and azathioprine-induced leukopenia for pharmacogenetic studies.** A. Dickson, B. Stanley, P. Anandi, V. Kawai, K. Birdwell, A. Hung, C. Stein, Q. Feng, C. Chung. Vanderbilt University Medical Center, Nashville, TN.

**Background:** Use of the immunosuppressant azathioprine (AZA) presents significant challenges: a narrow therapeutic index, marked inter-individual variability, and limited ability to predict frequent side effects. A novel approach to improve prediction of drug response is through the linkage of electronic health records (EHRs) with biobanks in pharmacogenetic studies. Because medical records review may be a limiting factor in these studies' feasibility, we developed and validated algorithms first to identify AZA users and then to determine cases of AZA-induced leukopenia, one of AZA's most serious side effects. **Methods:** Using a database of de-identified EHRs at Vanderbilt University Medical Center, we found potential users of AZA by mining structured (e.g., prescriptions) and unstructured (e.g., clinical notes) data for any mention of AZA or its brand names. Our first algorithm identified periods of current AZA use as 90-day exposure windows following an indicated use of AZA with at least one white blood cell count (WBC) during the exposure window. We estimated the algorithm's ability to predict AZA use through medical records review of a statistically significant random sample of 134 potential AZA users. Our second algorithm defined cases of AZA-induced leukopenia as at least one episode of WBC <4,000/ $\mu$ l within those 90-day exposure windows. We estimated the algorithm's ability to detect leukopenia occurring during AZA exposure in 750 cases and controls (375 each), previously confirmed by medical records review. **Results:** From the 6,625 potential users of AZA we initially found, the first algorithm identified 3,212 as AZA users and excluded 3,413 as non-users or for limited data. Overall accuracy for determining AZA users was 89.55%, with a PPV of 81.54% and a NPV of 97.10% among potential users. Among the 3,212 identified users, the second algorithm categorized 898 as cases of leukopenia during AZA exposure and 2,314 as controls. The agreement between medical records review and the second algorithm's determination of cases and controls was 94.67%, with a Cohen's kappa coefficient of 89.56%. **Conclusion:** Computerized definitions of AZA use and AZA-induced leukopenia, linked with genetic data, can facilitate pharmacogenetic studies of this commonly prescribed immunosuppressant. Its adaptability offers potential for studying multiple side effects of this and other immunosuppressants.

**1368W**

**Computational prediction and molecular validation of novel therapeutic targets for potent splicing modulators.** D. Gao<sup>1,2,3</sup>, E. Morini<sup>1,2</sup>, M. Salani<sup>1,2</sup>, C. Montgomery<sup>1,2</sup>, S. Erdin<sup>1,3</sup>, M.E. Talkowski<sup>1,2,3,4</sup>, S.A. Slaughaupt<sup>1,2</sup>. 1) Center for Genomic Medicine, Massachusetts General Hospital, 185 Cambridge St, Boston, MA 02114, USA; 2) Department of Neurology, Harvard Medical School, 25 Shattuck St, Boston, MA 02115, USA; 3) Program in Medical and Population Genetics and Stanley Center for Psychiatric Research, Broad Institute, Cambridge, MA 02142, USA; 4) Departments of Psychiatry and Pathology, Massachusetts General Hospital, Boston, MA 02114, USA.

While Mendelian genetics has seen remarkable advances in recent years in the discovery of novel genes and pathogenic mechanisms, therapeutic development remains incremental. One strategy for speeding development is to discover novel targets for known compounds. Here we applied a combination of *in silico* and molecular approaches to identify targets of splicing modulator compounds (SMCs), which target splicing in various diseases. We treated six independent human fibroblast cell lines from healthy individuals with BPN-15477, one of the SMC compounds originally designed to target *ELP1* (*IKBKAP*) splicing in familial dysautonomia. We investigated splicing using RNA-seq by assessing all plausible exon 'triplets' (three consecutive exons) transcriptome-wide. Percentage-of-spliced-in ( $\psi$ ) analysis of the middle exon from each triplet revealed 73 exon inclusion (EI) and 130 exon skipping (ES) outcomes in treated vs. untreated cells. We trained gradient boosting machines for EI and ES respectively, to learn sequence features that correlate with treatment consequences and to predict transcriptome-wide splicing influence of the drug. Our EI machine with sixteen features achieved an ROC of 0.89 while our ES machine with four features gave an ROC of 0.68. Applying the two machines across the transcriptome enabled us to predict potential gene targets for the drug. In 11,150 triplets (3.0% of 330,523 total), exon inclusion is predicted after treatment while skipping was predicted in 9,244 triplets (2.8%). Next, we explored the potential applications of the drug under two functional models: 1) That the EI effect of the treatment can ameliorate the impact of exon skipping caused by pathogenic mutations in human disease and 2) That ES might rescue gene expression in diseases where mutations create premature termination codons that result in nonsense-mediated decay. By comparing the overlap of these predicted triplet candidates with causal mutations in ClinVar, we found that 61 triplets were associated with mutations that could be rescued by EI (e.g. cystic fibrosis, Lynch syndrome and phenylketonuria) and 66 triplets associated with mutations rescuable by ES (e.g. Duchenne muscular dystrophy, retinoblastoma and Gorlin syndrome). While confirmation of these predictions using *in vitro* models is ongoing, our method demonstrates the potential impact of coupling machine learning strategies with transcriptional signatures to identify novel targets for known splice modulator drugs.

**1369T****Meta-analysis of gene expression variability in Alzheimer's disease.**

*L.R.K. Brooks<sup>1,3</sup>, G.I. Mias<sup>2,3</sup>.* 1) Microbiology and Molecular Genetics, Michigan State University, East Lansing, MI; 2) Biochemistry and Molecular Biology, Michigan State University, East Lansing, MI; 3) Institute for Quantitative Health Science and Engineering, Michigan State University, East Lansing, MI.

The Centers for Disease Control and Prevention rank Alzheimer's disease (AD) as the 6<sup>th</sup> leading cause of death within the United States (US). AD is a significant health-care burden, given its increased occurrence (particularly in the aging US population), ineffective treatments and a lack of preventive methods. AD and other dementias, will account for an estimated \$277 billion US society costs in 2018. AD targets neuronal function and can cause neuronal loss due to the buildup of amyloid-beta plaques and intracellular neurofibrillary tangles. Increased risk of developing AD has been previously associated with aging. However, it is still unclear how to differentiate between normal- and AD- age-related memory loss (and associated brain degeneration). We will present our investigation of temporal changes within gene expression using a meta-analysis of AD and healthy cohort gene expression, utilizing publicly available microarray expression datasets, that we collected and curated from the Gene Expression Omnibus (GEO) database by National Center for Biotechnology (NCBI). We utilized any datasets that reported donor age and gender, irrespective of platform (8 datasets, 2,089 samples). We preprocessed the microarray raw data, including background correction, normalization across arrays and correction of batch effects. To identify temporal trends in the data across ages, brain region and varying tissue, and disease state we performed a linear model analysis, including age as a linear time series. Statistically significant data ( $p < 0.05$ ) were further analyzed using our MathIOmica framework to identify overrepresented Reactome pathways and gene ontology terms. Our results include gene expression differences (2,309 genes) between disease and healthy individuals, and also with respect to varying age. We identified differences in more than 300 genes associated to the Immune System, as well as 29 genes related to Neuronal System and transmission across Chemical Synapses, and pathways such as Regulation of TP53 Expression. Our approach allowed us to effectively combine multiple microarray datasets and identify gene expression differences between AD and healthy individuals including age considerations. Our findings provide potential gene and pathway associations that can be targeted to improve AD diagnostics and potentially treatment or prevention.

**1370F****VCPA: Genomic variant calling pipeline and data management tool for Alzheimer's disease sequencing project.** *Y. Chou<sup>1</sup>, Y.Y. Leung<sup>1</sup>, O. Valadares<sup>1</sup>, H.-J. Lin<sup>1</sup>, A.B. Kuzma<sup>1</sup>, L. Cantwell<sup>1</sup>, L. Qu<sup>1</sup>, P. Gangadharan<sup>1</sup>, A.D. Sequencing Project (ADSP)<sup>1</sup>, W.J. Salerno<sup>2</sup>, G.D. Schellenberg<sup>1</sup>, L.-S. Wang<sup>1</sup>.*

1) Penn Neurodegeneration Genomics Center, Department of Pathology and Laboratory Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

The Alzheimer's Disease Sequencing Project (ADSP) is an integral component of the National Alzheimer's Project Act (NAPA) towards a cure of Alzheimer's Disease (AD). ADSP will eventually analyze whole-genome sequencing (WGS) and whole-exome sequencing (WES) data from >20,000 late-onset AD patients and cognitively normal elderly to find new genetic variants associated with disease risk. To ensure all sequencing data are processed consistently and efficiently according to best practices, a common workflow called "Variant Calling Pipeline and data management tool" (VCPA) was developed by the Genome Center for Alzheimer's Disease (GCAD) in collaboration with ADSP. VCPA 1) is optimized for large-scale production of WGS/WES data, 2) includes a tracking database with web frontend for users to track production process and review quality metrics; 3) is implemented using the Workflow Description Language for better deployment and maintenance, 4) is designed for the latest human reference genome build (GRCh38/hg38, version GRCh38DH) and follows best practices for WGS analysis with input from TOPMed (Trans-Omics for Precision Medicine) and CCDG (Centers for Common Disease Genomics). VCPA consists of two independent but interoperable components: a tracking database with a web frontend and a SNP/indel calling pipeline. The pipeline (available as an Amazon Machine Images (AMI)) was optimized for automatic processing WGS/WES data in various file formats (either WGS/WES pair-end reads in FASTQ, BAM, or CRAM (compressed BAM) with flow cell information), from mapping sequence reads to the latest human reference genome (GRCh38) and variant calling. The tracking database (available as another AMI) was designed for monitoring the job status and recording quality metrics for each processed sample. With a dynamic web interface of the database, researchers can easily compare, share and visualize all these individual level quality metrics. The workflow is modularized and consists of four stages. Users can configure the workflow to skip individual stages to reduce time and cost. We evaluated our pipeline using the NA12878 sample from the Genome In A Bottle project using the hg38 high confident set. Sensitivity/precision of VCPA calls were 0.999/0.994 for SNPs and 0.985/0.987 for indels respectively. The pipeline source code and step-by-step instructions are available from the National Institute on Aging Genetics of Alzheimer's Disease Data Storage Site (<http://www.niagads.org/VCPA>).

**Statement of Purpose:** NIAGADS is a national genetics data repository for genotypic data concerning the study of late-onset Alzheimer's disease (AD) and related neuropathologies. The Alzheimer's Genomics Database (DB) is a searchable annotation resource provided by NIAGADS that allows researchers to interactively explore, interpret, and analyze public datasets from the NIAGADS repository, including both published GWAS summary statistics and AD-specific variants and annotations compiled by the Alzheimer's Disease Sequencing Project (ADSP). **Methods:** The NIAGADS Alzheimer's Genomics DB (<https://www.niagads.org/genomics>) makes available to the public 43 GWAS summary statistics datasets from 11 NIAGADS accessions for interactive exploration and data-mining. The GWAS results are linked to dbSNP variants, NHGRI GWAS Catalog annotations, and allele frequencies and linkage disequilibrium inferred from 1000 Genomes data, as well as variant annotations compiled by ADSP, including predicted variant effect and effect impacts, transcription factor occupancy (CATO), deleteriousness (CADD), and ExAC allele frequencies. Using the website's graphical search interface, users can perform sophisticated data-mining of the NIAGADS datasets in real time and use analysis tools (e.g., co-location) to perform data transformations or find overlap between variants and genes lists, functional genomics datasets from ENCODE or FANTOM5, or uploaded user data. Search results can be downloaded, or saved and shared with other researchers, both privately and publicly. The NIAGADS Alzheimer's Genomics DB also provides tools for interactively browsing genomic regions of interest and downloading region- or feature-specific subsets of the available datasets or annotations, including detailed variant, gene, and genomic region record pages. **Results:** With a powerful search interface, analysis tools, and comprehensive record pages linking GWAS summary statistics and feature annotations to variants and genes, the NIAGADS Alzheimer's Genomics Database is a rich resource and valuable tool for AD research.

**1372T**

**Integration of deep learning and causal discovery for medical image semantic segmentation and their application to longitudinal neuroimage data for Alzheimer's disease.** Y. Liu<sup>1</sup>, Q. Ge<sup>2</sup>, R. Jiao<sup>1</sup>, N. Lin<sup>1</sup>, Z. Li<sup>3</sup>, M. Xiong<sup>1</sup>. 1) Department of Biostatistics and Data Science, The University of Texas Health Science Center at Houston, Houston, TX; 2) Fudan University, Shanghai, China; 3) Chengdu Jinjiang District Maternity and Child Health Hospital, Chengdu, China.

Sematic segmentation and image feature selection play an important role in prediction, diagnosis, treatment and imaging-genomics data analysis. Convolutional neural networks (CNN) have achieved great success for image classification in medical research, but it is also well known as a 'black box' due to its low interpretability to humans. Understanding and visualizing the image features involved in CNN classification will provide us valuable information about brain regions and disease pathology. Causal inference has been an emerging topic in various domains, with great potentials to speed up biomedical discoveries. We have developed a novel general framework that integrate neural networks and causal inference for semantic segmentation and feature discovery. The new paradigm consists of two stages: (1) use occlusion map to find image regions that are most distinctive for disease status and (2) the state-of-the-art causal inference tools to determine if the selected image regions are causal for AD under the additive noise model framework. This two stage platforms for performing image semantic segmentation and searching image features were applied to the Alzheimer's Disease Neuroimaging Initiative (ADNI) longitudinal dataset. Our CNN models achieved prediction accuracies of 0.9371, 0.9290, 0.9275, and 0.9272 at baseline, 6 months, 12 months and 24 months, respectively. In addition, we were able to predict disease status from baseline to 6 months, from 6 months to 12 months, and from 12 months to 24 months with accuracies of 0.9284, 0.8957, and 0.8137, respectively. We have successfully identified several brain regions including temporal lobe which were important for the progression of Alzheimer's disease as indicated by CNNs and our causal detection tools.

**Background:** NIAGADS is a national genetics data repository that facilitates access of genotypic data to qualified investigators for the study of the genetics of late-onset Alzheimer's disease (AD) and related dementias (ADRD). Collaborations with large consortia and centers such as the Alzheimer's Disease Genetics Consortium (ADGC), Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium, the Alzheimer's Disease Genome Sequencing Project (ADSP), and the Genome Center for Alzheimer's Disease (GCAD) allow NIAGADS to lead the effort in managing large AD datasets that can be easily accessed by the research community and utilized to their fullest extent. In 2018, NIAGADS began hosting and distributing GRCh38 mapped and variant called data from the ADSP and other NIA-funded studies. **Methods:** Since 2012, NIAGADS has been supported by National Institute on Aging (NIA) under a cooperative agreement (U24 AG041689). All data derived from NIA funded AD genetics studies are expected to be deposited in NIAGADS or another NIA approved site. NIAGADS has developed a Data Sharing Service (DSS) that facilitates the deposition and sharing of genomic data and association results with approved users in the ADRD research community. In addition, researchers are able to freely use the NIAGADS Genomics Database to search annotation resources that link published AD studies to AD-relevant sequence features and genome-wide annotations. **Results:** As of June 2018, NIAGADS houses 37 datasets with >37,000 samples and over 24 billion genotypes, of which 11 have summary statistics loaded into the Genomics Database for interactive exploration and data-mining. The first release of data in the DSS will include 3,985 ADSP whole-genomes from the Discovery + Extension phases and 809 ADNI whole-genomes, all mapped to GRCh38 and processed by GCAD. Qualified Investigators can submit an application for the sequencing data through the newly developed DSS Data Access Request Management system and can download the data through the DSS Portal. Raw data on GRCh38 and quality controlled VCF files are available as of summer 2018. **Conclusions:** NIAGADS is a rich resource for AD researchers, with the goal of facilitating advances in AD research. By housing datasets from multiple projects and institutions, NIAGADS enables AD researchers to be more efficient in meeting their research goals. Datasets, guidelines, and new features are available on our website at [www.niagads.org](http://www.niagads.org).

**1374W****Genotyping of variable number tandem repeats with adVNTR.** M. Bakhtiari<sup>1</sup>, S. Shleizer-Burko<sup>2</sup>, M. Gymrek<sup>1,2</sup>, V. Bansal<sup>3</sup>, V. Bafna<sup>1</sup>.

1) Department of Computer Science and Engineering, University of California San Diego, San Diego, CA; 2) Department of Medicine, University of California San Diego, San Diego, CA; 3) Department of Pediatrics, University of California San Diego, San Diego, CA.

**Motivation.** Whole Genome Sequencing is increasingly used to identify Mendelian variants in clinical pipelines. These pipelines focus on single nucleotide variants (SNVs) and also structural variants. Repeat mediated sequence variants are relatively less explored with the exception of Short Tandem Repeats (STRs) which are exact repeats of a pattern 1-6bp. We consider the problem of genotyping Variable Number Tandem Repeats (VNTRs), composed of inexact tandem duplications of short (6-100bp) repeating units. VNTRs span 3% of the human genome, are frequently present in coding regions, and have been implicated in multiple Mendelian disorders (e.g., Medullary cystic kidney disease and Myoclonus epilepsy) as well as complex disorders such as Alzheimer's disease and Bipolar disorder. Despite their importance in resolving the genetic basis of these disorders, VNTR genotyping (requiring identification of variation in the number of tandem repeats as well as mutations in the VNTR sequence) remains a challenging problem. Here, we describe a method, adVNTR, that can be used to reliably genotype VNTRs including determination of Repeat Unit (RU) counts and mutation detection. **Method.** adVNTR uses Hidden Markov Models (HMMs) to model the repeat units allowing for sensitive detection of VNTR containing reads, specialized counter-states for RU counts, and a Bayesian model for genotyping diploid counts. Separate models for each VNTR were generated for short-read (Illumina) and single molecule (PacBio) whole genome and exome sequencing. We evaluated adVNTR using long range PCR experiments and assessed Mendelian inheritance consistency in two trios. **Result.** We found that more than 130,000 of the 160,000 VNTRs in exonic region, introns, and promoters of human genes in human genome could be reliably genotyped using adVNTR with Illumina data. While STR genotyping tools such as ExpansionHunter and HipSTR were unable to make calls on cases with non-identical repeating patterns, adVNTR's estimates were perfect in 90.5% of the cases (97% accuracy for one of the two haplotypes). We also used adVNTR for larger population-scale studies of VNTR genotypes and identified many allelic differences between sub-populations. While repeat frequencies were consistent with HW equilibrium in most sub-populations, their violation in a few cases suggested a functional role for those VNTRs.

**A minimally-supervised case-control classifier based on integrative deep-learning.** *B. Henning*<sup>1,2</sup>, *T. Araújo*<sup>1,2</sup>, *M. Molck*<sup>1,2</sup>, *F. Torres*<sup>1,2</sup>, *M. Viana*<sup>3</sup>, *I. Lopes-Cendes*<sup>1,2</sup>, *F. Cendes*<sup>2,4</sup>, *C. Yasuda*<sup>2,4</sup>, *B. Carvalho*<sup>2,5</sup>. 1) Department of Medical Genetics, University of Campinas, Campinas, São Paulo, Brazil; 2) Brazilian Institute of Neuroscience and Neurotechnology / BRAINN, Campinas, Brazil; 3) IBM Research, São Paulo, Brazil; 4) Department of Neurology, University of Campinas; 5) Department of Statistics, University of Campinas.

Integrative medicine can improve diagnosis and treatment efficiency by fusing data from heterogeneous sources, such as modalities including, molecular data, imaging exams, environmental variables, and personal lifestyle information. Currently the data integration is carried out manually due to the lack of appropriate statistical and bioinformatics tools. Here we aim to start fulfilling this lack giving the first step towards a truly integrative analysis. We developed a deep learning-based framework to classify subjects as case or control using two modalities of data annotated for epilepsy by experts, brain MRI (3T-Philips, T1-weighted images, isotropic voxels 1x1x1mm) and the corresponding genetic data that was obtained with genome-wide human SNP array 6.0 (Affymetrix). We trained a single mode classifier with MRI (106 case and 71 control subjects) and compared its performance with a multimodal classifier that uses both MRI and the genetic data obtained by the CRLMM algorithm. Both classifiers are composed by 2D convolutional layers that are suitable for learning high-level features of input images. The genetic data was encoded as a three-channels image, where each channel represents a genotype (AA, AB, BB). The output of the convolutional layers in both classifiers is used as input for a fully-connected layer that predicts the subject class. Our findings indicate that both classifiers easily overfit the training data and do not generalize well for the testing set. This behavior may be improved by adding extra information on the subjects. In particular, the genetic information we have currently available is comprised of genotypes obtained at SNPs commonly observed in populations worldwide. Common SNPs may not be sufficient to express predisposition for complex phenotypes like epilepsy and events like these may be better explained with more detailed information, like copy number status. Another source of difficulties is the small number of subjects available and the high dimension of the genetic data, that spans many times the number of subjects in our dataset. Additionally, the minimalist case-control annotation of our data does not contain any information about regions of the MRI or the genetic data relevant for the disease diagnosis. To overcome the current challenges we plan to use 3D convolutional layers, reduce the genetic data dimension and incorporate other types of data.

**1376F**

**Methods for genotype-based risk prediction for complex neuropsychiatric disorders.** *Z. Yang*<sup>1</sup>, *A. Bose*<sup>2</sup>, *P. Drineas*<sup>2</sup>, *P. Paschou*<sup>1</sup>. 1) Biological Science, Purdue University, West Lafayette, IN; 2) Computer Science, Purdue University, West Lafayette, IN.

Genome-wide association study (GWAS), as a widely-used approach to investigate the genetic basis for complex neuropsychiatric disorders, detects the association between common single nucleotide polymorphisms (SNPs) and phenotypic traits. However, the results from GWAS are always sensitive to change of sample size or even minor genotyping errors, which makes some of the findings extremely difficult to be replicated. Moreover, due to the lack of robustness, variants returned by GWAS do not necessarily yield a satisfying accuracy when being used for trait prediction. To great extent, this deficiency in robustness is resulted from the presence of noise in dataset. Here, we apply denoising techniques over genotyping datasets in order to increase the reliability of trait-related predictor selection. Subsequently, machine learning approaches are implemented on the denoised dataset, with the expectation of a better performance in disorder trait prediction. This framework has been applied over synthetic genotype data as well as genotype of neuropsychiatric and neurological disorders such as Parkinson disease and schizophrenia. A successful application of this framework will lead to an increased power in predictive disorder-related genetic marker detection and higher accuracy in risk prediction.

**Variation among intact tissue samples reveals the core transcriptional features of human CNS cell classes.** *K.W. Kelley, H. Inoue, A.V. Molofsky, M.C. Oldham.* UCSF, San Francisco, CA.

It is widely assumed that cells must be physically isolated to study their molecular profiles. However, intact tissue samples naturally exhibit variation in cellular composition, which drives covariation of cell-class-specific molecular features. By analyzing transcriptional covariation in 7221 intact CNS samples from 840 individuals representing billions of cells, we reveal the core transcriptional identities of major CNS cell classes in humans. By modeling intact CNS transcriptomes as a function of variation in cellular composition, we identify cell-class-specific transcriptional differences in Alzheimer's disease, among brain regions, and between species. Among these, we show that *PMP2* is expressed by human but not mouse astrocytes and significantly increases mouse astrocyte size upon ectopic expression *in vivo*, causing them to more closely resemble their human counterparts. Our work is available as an online resource (<http://oldhamlab.ctec.ucsf.edu>) and provides a generalizable strategy for determining the core molecular features of cellular identity in intact biological systems.

**Comparative analysis of gene prioritization tools for neuromuscular disorders.** *P.S. Lai, S. Tomar, R. Sethi, P.S. Low, S.K.H. Tay.* National University of Singapore, Singapore, Singapore.

Identifying true causal genes for rare Mendelian disorders from whole genome sequencing (WGS) data remains a challenging and time-consuming effort. Gene prioritization is the process of filtering and ranking annotated variants to facilitate gene-disease associations for clinical diagnostics. In this study, a cohort of 30 patients with neuromuscular disorders (NMDs) carrying previously identified variants in genes such as *LAMA2*, *LMNA*, *CAPN*, *NEB*, *DMD*, *FKRP*, *FHL1*, *MYH7*, *TTN* and *RYR1* were analysed using four popular web-based gene prioritization tools (VarElect, Phenolyzer, OMIMExplorer and Endeavour). The aim was to investigate how well each previously identified gene could be identified as the top candidate or among the top candidates by the four tools upon blinded re-analysis of annotated variants generated from WGS. **METHODOLOGY:** Patient specific HPO terms were used as queries and performance assessed using four well-established measures, namely Median Rank Ratio (MedRR), Normalized Discounted cumulative gain (NDCG), Area under the curve (AUC) and Receiver Operating Characteristic (ROC) curve. **RESULTS:** When candidate genes from the top 5%, 10%, 30% and 50% of the prioritized gene lists were compared, VarElect showed lowest MedRR scores (0.76 – 4.17) and highest NDCG value = 1 across all 30 cases showing that it ranked each real causal gene higher up in the list than the other tools. However, OMIMExplorer was able to correctly identify the causal gene with a 100% true positive rate across all ranked gene lists. The area under the ROC curve gave the probability whether a tool would correctly identify a causal gene in top 1% of gene list across all gene prioritizations and OMIMExplorer showed the highest performance (0.823 AUC; 100% sensitivity) followed by VarElect (0.745 AUC; 84.8% sensitivity), Endeavour (0.736 AUC; 85.3% sensitivity) and Phenolyzer (0.731 AUC; 87.90% sensitivity). Significant correlation was observed between VarElect and Phenolyzer rank ratios. In this NMD cohort, the use of gene prioritization tools was a useful decision-support strategy in identifying causal variants. We recommend incorporating a comprehensive phenotype-based gene prioritization step into the computational pipeline for efficient clinical variant identification and interpretation.

**1379F****Molecular modeling, informatics, and pathway prediction of varying complex biological systems for drug repositioning, repurposing, and rescue.**

K. Nguyen<sup>1,2,4</sup>, L. Tian<sup>1,2</sup>, A. Wenocur<sup>1,2</sup>, X. Wang<sup>1,2</sup>, P. Sleiman<sup>1,2,3</sup>, H. Hakonarson<sup>1,2,3</sup>. 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Center for Dynamic Data Analytics, Rutgers University, Piscataway, NJ.

Precision medicine refers to the tailoring of medical treatment to the individual characteristics of each patient based on harvesting information from multiple methods establishing an information pipeline. In this case, the first and last (for validating purposes) series of steps traditionally consist of a high performance and throughput *in silico* approach using state-of-the-art supercomputers, computer clusters, or graphical processing units (in single workstations). If a gene and its encoded protein are well-characterized and directly linked to the disease in question, then Molecular Docking and Dynamics Simulations through Structure-Activity Relationships, its derivatives, and Structure-Based Virtual Screening can be performed using well-resolved experimental structures. These methods have been successful in elucidating interactions that are not tractable with the most advanced experimental methods. However, there have been instances where this is not the case. For a therapeutic targeting a molecular pathway, Ligand-Based VS and Computational Pharmacological methods can provide valuable information to determine if modifying the structure will provide a better solution. These chemical/molecular informatics methods were created to be delocalized and dynamic with traditional biological informatics and systems/network biology methods. As a result, repurposing therapeutics to target genes and proteins with respect to their disease have been made increasingly transparent. Here, the examples analyzed from this pipeline are associated with amyloidosis and characteristically neurodegenerative. An Artificial Intelligence approach, derived from Deep Machine Learning, has also been in development for benchmarking purposes with respect to each traditional method in the pipeline. In this case, VS using Molecular Descriptors in Computer-Aided Drug Design has been well-established where their property (structure and energetics) and activity (dynamics and function) can be generated using artificial neural networks through layers of nonlinear processing units. Current progress has been validating shallow data sets before increasing to a more proper architecture. Drug Repurposing is already a fraction of the time and cost of traditional *de novo* efforts. Nevertheless, the purpose of exploring this approach is to execute this pipeline with greater speed, effectiveness, and affordability.

**1380W****Automated extraction of multiple sclerosis treatment timelines: Preparing free-text electronic health record data for use in pharmacogenetic analyses.** J.T. Beales<sup>1</sup>, J.C. Denny<sup>2</sup>, M.F. Davis<sup>1</sup>. 1) Department of Microbiology and Molecular Biology, Brigham Young University, Provo, UT; 2) Departments of Biomedical Informatics and Medicine, Vanderbilt University Medical Center, Nashville, TN.

Disease-modifying treatments for multiple sclerosis (MS) are associated with a number of adverse drug reactions (ADRs), including hepatic and cardiac damage. Attempts to use pharmacogenetic analysis to identify genetic factors associated with such ADRs are complicated by the relative rarity of some ADRs. Using large databases of electronic health records (EHRs) represents one potential approach to overcoming this challenge. However, this approach necessitates the ability to reliably extract treatment timelines from these records. We developed a rule-based algorithm able to extract MS treatment timelines for glatiramer acetate, a common MS treatment, to aid in pharmacogenetic studies. Records referencing glatiramer acetate from 846 MS patients were retrieved from the Vanderbilt University Medical Center Synthetic Derivative, a deidentified version of the EHR, and used to develop the algorithm. Regular expressions were developed to match language patterns used by clinicians to indicate a beginning, continuation, or end of a treatment period. The algorithm employs these regular expressions to classify EHR medication references, generating a timeline of treatment events for patients. This timeline can guide ADR extraction in future studies. A training dataset of 100 EHR notes was manually reviewed and classified. For the medication references in the training set, the algorithm reliably identified treatment initiation events (accuracy, sensitivity, specificity, and precision were > 95%) and treatment discontinuance events (accuracy, specificity, and precision were > 95%, sensitivity 88.9%). More rigorous testing of this particular algorithm is necessary to assess its performance on larger datasets. However, this study demonstrates that automated, rule-based extraction of MS patient treatment timelines from free-text EHRs is possible. These timelines will be used in pharmacogenetic studies to investigate variants associated with ADRs to glatiramer acetate. .

**Target gene notebook: Putting genetics to work for drug discovery.** *M.P. Reeve, J. Wierzbowski, A. Kirby, J. Hutz.* Human Biology and Data Science, Eisai, Andover, MA.

Many thousands of associations between genetic variants and disease/phenotype provide clues to the causal mechanisms of nearly all common human diseases. Very few GWAS hits, however, have yielded actionable therapeutic hypotheses due to challenges in connecting variants to genes and function. While many browsers and databases provide access to genome annotations and different types of genetic results, linking and maintaining group curation of all relevant information from these sources and integration with proprietary experimental data remains challenging. We created freely-available software, Target Gene Notebook (TGN), to facilitate the process of therapeutic target evaluation and creation of durable institutional or public knowledgebases. With a gene or locus as the focal point, TGN gathers published associations from sources including GWAS Catalog, UK Biobank, and GTEx eQTLs and allows the user to review and store an assessment of each finding. Published LD patterns derived from reference panels are used to establish a 'credible set' of variants from each association. Interactive visualization of credible sets allows rapid assessment of colocalization across these diverse results and helps highlight variants of known functional consequence. Along with automated access to large public resources, new associations can be added, either as single associations or as additional datasets. Additional public resources of relevance to target evaluation (e.g., variation patterns in ExAC/Gnomad, tissue expression patterns in GTEx) are also presented. TGN also provides a bibliography – initially seeded with publications from the above resources – permitting manual expansion, curation/annotation and capture of key figures and tables made available in expandable thumbnails. TGN exists to support group annotation with multiple users having write access to specific gene databases and all users having immediate access to new annotations and references added by any user. Implementation is such that private instances can be shared across groups or sites as needed - potential users include groups within pharma (for tracking knowledge of targets across biology, computational and chemistry teams) and disease consortia for collating results and interpretations of their conclusive findings.

**Using model predictions as quantitative traits to expand cohort size for heritability estimation and genetic studies.** *P.M. Thangaraj<sup>1,4,6,7</sup>, A.O. Basile<sup>1,4,6,7</sup>, N. Shang<sup>1</sup>, F. Polubriagino<sup>1,4,6,7</sup>, B.R. Kummer<sup>1,3</sup>, R. Vanguri<sup>1,4,6,7</sup>, T. Lorberbaum<sup>1,4,6,7</sup>, J.D. Romano<sup>1,4,6,7</sup>, K. Quinnes<sup>1,4,6,7</sup>, A. Yahji<sup>1,4,6,7</sup>, K. Kiryluk<sup>2</sup>, A. Gharavi<sup>2,6</sup>, C. Weng<sup>1</sup>, M.S. Elkind<sup>2,5</sup>, G.M. Hripacsak<sup>1</sup>, N.P. Tatonetti<sup>1,4,6,7</sup>.* 1) Department of Biomedical Informatics, Columbia University Irving Medical Center, New York, NY; 2) Division of Nephrology, Department of Medicine, Columbia University Irving Medical Center, New York, NY; 3) Department of Neurology, Columbia University Irving Medical Center, New York, NY; 4) Department of Systems Biology, Columbia University Irving Medical Center, New York, NY; 5) Department of Epidemiology, Columbia University Irving Medical Center, New York, NY; 6) Institute for Genomic Medicine, Columbia University Irving Medical Center, New York, NY; 7) Department of Medicine, Columbia University Irving Medical Center, New York, NY.

Large genetic repositories connected to electronic health records (EHR) form the basis of local and national precision medicine initiatives. These linked repositories promise the ability to perform thousands of simultaneous genetic studies using diagnoses, procedures, and treatment responses that are routinely captured by the EHR. Not all patients have genetic data available, however, limiting what actually can be studied. There is an opportunity to use machine learning methods to derive quantitative proxy variables and expand the sample population. For example, genetic studies of stroke, a complex disease and a leading cause of death, can require hundreds of thousands of patients. In the 6.2 million patient records of New York-Presbyterian Hospital from 1986-2018, we have 79,000 coded cases of stroke. We hypothesized that the output of a supervised machine learning classifier can be used as a proxy probability for a previous stroke diagnosis for cohort expansion. This study investigates the feasibility of converting a dichotomous phenotype to a quantitative phenotype. We applied our model to estimate observational heritability of acute ischemic stroke. We identified families from the EHR using RIFTEHR, an algorithm that uses emergency contact information to infer familial relationships between patients. We then trained classifiers on stroke cases and controls using EHR-extracted features and tested every patient in the EHR for a previous stroke diagnosis. This expanded the cohort 20-fold without the requirement of manual phenotyping. The area under the receiver operative characteristic curve was 0.75-0.99 for the random forest (RF) models. Mean RF classifier heritability,  $0.379 \pm 0.052$ , was within margin of error of the literature heritability estimate, showing successful estimation of heritability using a quantitative trait proxy. To demonstrate the utility of using this proxy in a genetics study, we simulated a complex trait under an additive model, varying the effect sizes, penetrance, and allele frequencies. Finally, we validated our approach by running a GWAS in EHR-linked genotypes containing algorithmically phenotyped cases ( $n=289$ ) and controls ( $n=1721$ ) of venous thromboembolism. We found that conversion from a dichotomous to quantitative trait resulted in minimal changes to the GWAS estimates for established causal variants. We demonstrate that our quantitative proxy trait can improve performance by increasing the effective sample size.

**Identifying splice alterations using RNAseq to improve genetic diagnosis for rare Mendelian disorders.** H. Lee<sup>1</sup>, A. Eskin<sup>2</sup>, S.F. Nelson<sup>1,2</sup>, *Undiagnosed Diseases Network Members*. 1) Department of Pathology and Laboratory Medicine, University of California, Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA.

Whole exome and genome sequencing (WES/WGS) are becoming more accessible as sequencing and computational cost decrease. However, >70% of WES/WGS analyses do not reveal a Mendelian mutation and diagnosis given rare disease case, and the vast majority of DNA variants, both *de novo* and inherited, are difficult to interpret including variants within promoters, introns and exons. Here we describe an analytical approach to identify rare splicing abnormalities linked to specific DNA variants from RNAseq data. We demonstrate how these data can be intersected with WES/WGS data to identify which rare genomic variants are pathogenic and improve genetic diagnosis for individuals within the Undiagnosed Diseases Network and exome negative individuals. RNA was extracted from blood, fibroblast or muscle following standard protocols. Illumina TruSeq Globin-Zero gold (blood) or Ribo-zero gold (other tissues) were used for library preparation and sequencing was performed to generate ~50 million 69 base paired-end reads on the HiSeq 4000. FASTQ files were aligned to the genome using STAR-2.5.2b twopassMode, and splice junctions from STAR output were exported to an internal splice junction database. The splice junction database is populated with count data for each detected splice junction across all RNAseq samples available where there was at least one read that overlapped a given junction. Second, for each start or end of the junction, the junctions are flagged to have "alternative splicing" if there are more than one junction at the same start or end of the junction and categorized into one of the 4 types of alterations that we consider here: full exon skipping, inclusion of intronic pseudoexon, exon extension or exon reduction. Third, a Z score of the ratio of the coverage for the alternate junction(s) in an individual relative to the coverage for the canonical junction is calculated. Commonly observed alternate junctions are filtered out if observed in more than 1% in our internal database. Finally, WES/WGS variants are annotated to correlate DNA variant with effect on mRNA. We describe how this analytical tool identifies rare DNA mutations that lead to unanticipated splice alterations and changes to the mature mRNA, which improves the diagnostic rate for WES/WGS negative cases but can also be widely used to rule out genomic variants that are challenging to interpret, making transcriptome analysis an essential tool to augment WES/WGS data interpretation.

**Repeat expansion detection with whole exome sequencing data.** M. Bahlo<sup>1,2</sup>, M.F. Bennett<sup>1,2,3</sup>, R.M. Tankard<sup>1</sup>, P. Degorski<sup>1</sup>, P. Perucca<sup>4,5,6</sup>, T. O'Brien<sup>4,5,6</sup>, S.F. Berkovic<sup>2</sup>, P. Kwan<sup>4,5,6</sup>, I.E. Scheffer<sup>3,10</sup>, M.B. Delatycki<sup>8,9,10</sup>, P.L. Lockhart<sup>6,10</sup>. 1) Population Health and Immunity Division, The Walter and Eliza Hall Institute of Medical Research, 1G Royal Parade, 3052 Parkville, Victoria, Australia; 2) Department of Medical Biology, University of Melbourne, 1G Royal Parade, 3052 Parkville, Victoria, Australia; 3) Epilepsy Research Centre, Department of Medicine, The University of Melbourne, Austin Health, Heidelberg, Victoria, Australia; 4) Department of Neuroscience, Central Clinical School, Monash University, Melbourne, Victoria, Australia; 5) Departments of Medicine and Neurology, The Royal Melbourne Hospital, The University of Melbourne, Parkville, Victoria, Australia; 6) Department of Neurology, Alfred Health, Melbourne, VIC, Australia; 7) Mathematics and Statistics, Murdoch University, Murdoch, WA, Australia; 8) Bruce Lefroy Centre for Genetic Health Research, Murdoch Children's Research Institute, Royal Children's Hospital, Parkville, Victoria, Australia; 9) Victorian Clinical Genetics Services, Parkville, Victoria, Australia; 10) Department of Paediatrics, University of Melbourne, Parkville, Victoria, Australia.

Repeat expansions cause over 20 neurogenetic disorders that can present with overlapping clinical phenotypes, making molecular diagnosis challenging. Single gene or small panel PCR-based methods are often employed to identify the precise genetic cause, but can be slow and costly, and often yield no result. Genomic analysis via whole exome and whole genome sequencing (WES and WGS) is being increasingly performed to diagnose genetic disorders. However, until recently analysis protocols could not identify repeat expansions in these datasets. Several methods have now been developed to specifically identify repeat expansions in short-read sequencing data, focusing on PCR-free whole genome sequencing application, where PCR stutter error is much reduced. We have developed exSTRa (expanded STR algorithm), an outlier detection method for the detection of repeat expansions in cohorts of sequenced individuals. It can be applied to existing WES or WGS data to identify likely repeat expansions. We demonstrate that exSTRa can be effectively utilized as a screening tool to interrogate WES and WGS sequencing data generated with PCR-based library preparations which can then be followed up with specific diagnostic tests. exSTRa produces informative and unique graphical summaries of the STR motif distributions which aid interpretation of the results. The exSTRa package is available from <https://github.com/bahlo-lab/exSTRa>. exSTRa demonstrated very high predictive capabilities, achieving a median area under the curve (AUC) of 0.9 when applied to WES and WGS (PCR-based library protocols) cohorts comprised of both normal and known repeat expansion disorder patients. An extensive simulation study has been conducted over 20 known STR loci, comparing the repeat expansion detection algorithms ExpansionHunter (Dolzhenko et al, *Genom Res*, 2017), exSTRa (Tankard et al, *bioRxiv*, 2017), TREDPARSE (Tang et al, *AJHG*, 2017) and STRetch (Dashnow et al, *bioRxiv*, 2017). The simulation study demonstrated consistent performance by all four algorithms in the context of repeat length, with longer repeats being more significant. Furthermore results were robust, even when only modest cohort sizes (controls) were available. We have applied these four repeat expansion detection methods to a cohort of 40 focal epilepsy patients that had previously undergone clinical whole exome sequencing (Perucca et al, *Epilepsy Research*, 2017). We detected a previously undiscovered SCA8 expansion in this cohort.

**1385F****Tackling heterogeneity using network based stratification in autism spectrum disorders.**

*Y. Kim*<sup>1,2,3,4</sup>, *F. Cliquet*<sup>1,2,3,4</sup>, *T. Rolland*<sup>1,2,3,4</sup>, *R. Delorme*<sup>1,2,3,4,5</sup>, *T. Bourgeron*<sup>1,2,3,4</sup>, *G. Dumas*<sup>1,2,3,4</sup>. 1) Institut Pasteur, Human Genetics and Cognitive Functions Unit, Paris, France; 2) CNRS UMR 3571 Genes, Synapses and Cognition, Institut Pasteur, Paris, France; 3) University Paris Diderot, Sorbonne Paris Cité, Paris, France; 4) C3BI, USR 3756 Institut Pasteur and CNRS, Paris, France; 5) Department of Child and Adolescent Psychiatry, Robert Debré Hospital, APHP, Paris, France.

Autism Spectrum Disorders (ASD) are heterogeneous neurodevelopmental conditions diagnosed in more than 1% of the population. For better prognosis and treatment, genetic stratification is suggested which aims to stratify patients into more homogeneous subgroups. In the field of cancer research, the method of Network Based Stratification (NBS) has been proposed (Hofree et al. 2013). The NBS integrates the mutation profile of each patient mapped on a Protein-Protein Interactions (PPI) network. We validated the reproducibility of the NBS with a part of the original cancer data and STRING PPI network. We also applied the NBS on simulated data which confirmed efficiency of a clustering qualifying score: Proportion of Ambiguously Clustering (PAC). Then the NBS using Agile Protein Interactomes DataSever (APID) PPI network was applied to a large WES cohort of 2753 ASD patients and 2272 unaffected siblings from the Simons Simplex Collection (SSC). Our preliminary results show that the diffusion of the score of the mutated genes across the PPI network is one of the most important factors on stratification. The investigation of parameters such as minor allele frequency or predicted deleteriousness on the stratification is in progress.

**1386W****Detecting inherited deletions in whole genome sequencing data using family structure.** *K.M. Paskov, D.P. Wall.* Biomedical Informatics, Stanford University, Stanford, CA.

Copy number variants (CNVs) have been linked to neurodevelopmental disorders such as autism, schizophrenia, and developmental delay. CNVs occur more frequently in individuals with developmental disabilities than in their neurotypical counterparts with increased CNV burden associated with more severe phenotypes [Cooper 2011]. CNV size and type both influence pathogenicity with deletions shown to be pathogenic at smaller size ranges (30-500kbp) compared to duplications (>500kbp) [Pinto 2010]. Detecting deletions as small as 30kbp in length is challenging. We introduce a novel method for the detection of inherited deletions from whole genome sequencing data using family structure. Inherited deletions result in distinctive inheritance signatures as variants are transmitted from parents to children. Since variant calling algorithms do not consider the presence of deletions, hemizygous sites (0/- and 1/-) are called as either homozygous reference (0/0) or homozygous alternate (1/1). This results in seemingly non-Mendelian transmission for variants spanning the deletion. Hidden Markov models (HMM) have previously been used to identify crossover sites in nuclear families with a median resolution of 2.6kbp [Roach 2010]. We adapt this approach to identify inherited deletions. Our HMM models the crossover sites and parental chromosomes inherited by each child, and then uses this information to identify regions corresponding to deletion-specific inheritance patterns, supporting each deletion with genotype calls in multiple family members. The resulting model can detect deletions as small as 0.1kbp in length and can identify deletion start and endpoints with a median resolution of 0.2kbp. We applied our method to 30x whole genome sequence data for 869 multiplex families with idiopathic autism, composed of 1747 affected children, 389 unaffected siblings and their parents. We discovered thousands of inherited deletions per family, with 82 regions showing a significant association between presence of a deletion and affected status even after Bonferroni correction. Of these regions, 91% are expressed in infant or fetal brain [Jaffe 2014]. Finally, we compared the sensitivity of our method to Lumpy [Layer 2014] and Breakdancer [Chen 2009], two structural variant detection algorithms that use split reads and read depth to identify deletions. These results demonstrate the value of sequencing whole families and suggest that inherited deletions contribute to autism risk.

**Comparison of tools for RNA-Seq differential gene expression analysis of small, heterogeneous effects requiring large sample sizes.** C. Armoskus<sup>1</sup>, O.V. Evgrafov<sup>2</sup>, D. Conti<sup>1</sup>, J.A. Knowles<sup>2</sup>. 1) University of Southern California, Los Angeles, CA; 2) SUNY Downstate Medical Center, Brooklyn, NY.

Transcriptome analysis via short read massively parallel sequencing (RNA-Seq) presents great opportunities for understanding the biology of many diseases. However, the vast majority of evaluations of differential expression tools are done examining situations with large effect sizes and consistent effects in small sample sizes; the results of such evaluations may not be applicable to examining differential expression in other settings. Common complex diseases which feature small, heterogeneous differences in gene expression that require large sample sizes to identify, such as many psychiatric disorders, present a substantially different situation that must be examined to identify optimal methodologies for this application. To examine relevant gene expression differences for this type of condition, we simulated data based on studies such as the CommonMind and CNON projects, which use hundreds of samples to examine schizophrenia. Simulated data was based on a number of statistical distributions, such as the negative binomial, log-normal, and multinomial, all parameterized to match characteristics observed in real data. A simulation approach allows the creation of data matching a wide variety of specifications as well as knowledge of truth; this offers a clearer examination of correct results compared to consistency based approaches that compare results between different tools or subsets of a dataset. A variety of analysis programs (e.g., DESeq2, edgeR, and voom-limma) with different settings were examined, such as the use of different normalization techniques. Batch effects and other sources of technical variance and methods for removing them (e.g., using covariates such as batch and SVA) were tested and model selection techniques were employed. Methodologies were evaluated primarily by ROC and precision-recall curves, and secondly by power and control of the FPR/FDR. Work is ongoing, with early results showing the superiority of newer normalization techniques such as edgeR's TMM and DESeq2's median-of-ratios methods compared to quantile normalization and scaling to the total number of reads. Following this the greatest variance between programs is based on what distribution they expect, with voom-limma performing better on log-normal data and edgeR/DESeq2 performing significantly better on negative binomial data. This highlights the need for a greater examination of the true/most common distribution of RNA-Seq data both in general and in a specific dataset.

**DISTMIX2: Direct imputation of summary statistics from mixed ethnicity cohort in large reference panel.** C. Chatzinakos, V. Vladimirov, T. Webb, B. Riley, K. Kendler, S. Bacanu. Virginia Commonwealth University (VCU), Richmond, VA.

To increase the signal resolution for large-scale meta-analyses of genome-wide association studies, genotypes at unmeasured Single Nucleotide Polymorphisms (SNPs) are commonly imputed using large multi-ethnic reference panels. SNPs imputation is expected to increase the statistical power because it increases the accuracy of genomic predictions. Direct imputation of summary statistics was shown to be practically as accurate as genotype imputation method, while incurring orders of magnitude lower computational burden. However, to be precise, direct imputation methods need accurate estimates of LD between SNPs and larger reference panels. A previous version of our software, DISTMIX, achieved such estimates by using in-cohort allele frequency (AF) estimates. As genome wide association studies (GWAS) stopped providing AFs, we now use a novel method to estimate ethnic composition of the cohort using only the GWAS summary statistics, e.g. Z-scores, and reference panel data. Simulations under the null hypothesis of no association, show that the proposed method adequately controls the Type I error rates, while using the pre-estimated weights fails to control them. DISTMIX and its main direct imputation competitors still use a small reference panel of 1,000 subject coming from the 1000 Genome (1KG) project. Because the success in GWAS studies depends on good phenotypic and genotypic data (reference panel), the new version of the software, DISTMIX2, uses a much larger reference panel. For the larger reference panel, we use the publicly and privately available data to obtain a 33,000 (33K) panel which includes 11K Han Chinese from the CONVERGE study. We apply the method to impute summary statistics from the ethnically diverse (cosmopolitan) Psychiatric Genetic Consortium (PGC) data sets. Results of these analyses clearly show that the method detects new signals that were not available when using the 1KG panel. Among them, the most interesting is the analysis of PGC Schizophrenia Phase 2, which provides several novel signals in chromosome 13 that seem to be specific to East-Asias.

**An interactome perturbation framework prioritizes damaging missense mutations for developmental disorders.** *S. Chen<sup>1,2,3</sup>, R. Fragoza<sup>1,2,3</sup>, L. Klei<sup>4</sup>, Y. Liu<sup>1,2</sup>, J. Wang<sup>5</sup>, K. Roeder<sup>5,6</sup>, B. Devlin<sup>4</sup>, H. Yu<sup>1,2</sup>.* 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY 14853, USA; 2) Weill Institute for Cell and Molecular Biology, Cornell University, Ithaca, New York 14853, USA; 3) Department of Molecular Biology and Genetics, Cornell University, Ithaca, New York 14853, USA; 4) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania 15213, USA; 5) Department of Statistics and Data Science, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213, USA; 6) Computational Biology Department, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213, USA.

Identifying disease-associated missense mutations remains a challenge, especially in large-scale sequencing studies. Here we establish an experimentally and computationally integrated approach to investigate the functional impact of missense mutations in the context of the human interactome network and test our approach by analyzing ~2,000 de novo missense (dnMis) mutations found in autism subjects and their unaffected siblings. Interaction-disrupting dnMis mutations are more common in autism probands, these mutations principally affect hub proteins, and they disrupt a significantly higher fraction of hub interactions than in unaffected siblings. Additionally, they tend to disrupt interactions involving genes previously implicated in autism, providing complementary evidence that strengthens previously identified associations and enhances discovery of new ones. Importantly, by analyzing dnMis data from six disorders, we demonstrate that our interactome perturbation approach offers a generalizable framework for identifying and prioritizing missense mutations that contribute risk to human disease.

**1390T**

**Systems biology approach to evaluate genetic factors of antidepressant treatment outcome in major depressive disorder.** *A.C. Hauschild<sup>1,2</sup>, M. Maciukiewicz<sup>2</sup>, V.S. Marshe<sup>3,4</sup>, D.J. Müller<sup>3,4,5</sup>.* 1) Krembil Research Institute, Toronto, Canada; 2) University Health Network, Toronto, Canada; 3) Pharmacogenetic Research Clinic, Center for Addiction and Mental Health, Toronto, ON, Canada; 4) Institute of Medical Science, Faculty of Medicine, University of Toronto, Toronto, ON, Canada; 5) Department of Psychiatry, University of Toronto, Toronto, ON, Canada.

Major depressive disorder (MDD) is a costly, debilitating and among the most prevalent psychiatric disorders. Affecting over 350 million people worldwide, it is rated the fourth leading factor of disability globally (WHO, 2016). While different classes of antidepressants are available, they frequently result in solely moderate rates of remission. Hitherto, we are missing knowledge about the underlying genetic and molecular mechanisms that influence treatment outcome. In a previous study by Maciukiewicz et al. 2018, we analyzed a data set of 186 MDD patients treated with duloxetine and subsequently categorized as “responders/non-responders” and “remitters/non-remitters” based on the MADRS score. We used a sophisticated nested cross-validation schema including lasso regression, classification-regression trees and support vector machines to classify responders and remitters. The evaluation identified 19 single nucleotide polymorphisms (SNPs) that were most robust among the cross-validation predictors of remission. Following up this research, we will present a systematic approach to validate those findings in two independent samples and uncover the underlying molecular mechanisms leading to different treatment outcomes. At first, we query the SNPs of interest and corresponding genes for their protein-protein-interactions (PPI) and their interacting neighbors. Subsequently, we identify structurally connected components like subnetworks and cliques in the resulting PPI network that can be annotated with functional information such as gene ontology and metabolic pathways using NAViGaTOR, pathDIP, and g:Profiler. Finally, we show how this evaluation can highlight biological functions and mechanisms that are influencing the effectiveness of antidepressants and pave the way for genotype-driven personalized MDD treatment.

**DVINDEL: Towards an accurate de novo indels caller.** A. Lian<sup>1,2,3,4</sup>, D. Antak<sup>2,3,4,5</sup>, P. Tandon<sup>2,3,4</sup>, O. Shanta<sup>2,3,4</sup>, M. Gujral<sup>2,3,4</sup>, J. Sebat<sup>1</sup>. 1) Center for Medical Genetics, School of Life Sciences, Central South University, China; 2) Beyster Center for Genomics of Psychiatric Diseases, University of California San Diego, La Jolla, CA 92093, USA; 3) Department of Psychiatry, University of California San Diego, La Jolla, CA 92093, USA; 4) Department of Cellular and Molecular Medicine and Pediatrics, University of California San Diego, La Jolla, CA 92093, USA; 5) Biomedical Sciences Graduate Program, University of California San Diego, La Jolla, CA 92093, USA.

De novo mutations (DNMs) affect pathogenic risk for autism. Despite continued success in identifying de novo single nucleotide variants that confer risk, de novo indels (insertions/deletions) have been poorly characterized. Current software tools for detecting de novo indels have limited success and carry a high false discovery rate (FDR), affecting the analysis of genetic associations. Here we develop an accurate and convenient software tool that leverages statistical machine learning to predict de novo indels in next generation sequencing (NGS) with high accuracy. We implemented a Random Forest model trained on 11 pairs of monozygotic twins and their parents, with features obtained from GATK such as Variant Quality Score Recalibration (VQSR). To increase the number of positive examples for training, we created synthetic de novo mutations by genotyping private inherited variants in the offspring with unrelated parents. False positives for training were discordant putative de novo indels. We then optimized model parameters through 10-fold cross validation (FDR: 0.0024, F1 score: 0.941). We tested classifier performance on whole genome sequences from 94 offspring in the REACH cohort. Similar to training, we created synthetic de novo mutations by genotyping inherited variants using unrelated parents and defined false positives as any putative de novo call. We obtained an accuracy of 0.88, FDR of 0.005, and F1 score of 0.926. Finally, we tested the performance of our classifier on previously validated de novo indels from the Simons Simplex Collection (SSC) data (22 offspring) (Lossifov I et al., Nature 2014). Since the de novo variants were discovered using whole exome sequencing, we only tested indel calls in exons and defined false positives as variants that were not previously annotated. Our classifier was able to distinguish between true and false positive de novo indels (accuracy: 0.9862, FDR: 0.1363, F1 score: 0.8837). Due to the high genotyping error rates of indels relative to SNPs, researchers may hesitate to analyze indels. We have shown that it's possible to rapidly detect and filter de novo indels from NGS data without compromising sensitivity and accuracy.

**Identifying biomarkers to build a predictive model for PTSD using machine learning approaches.** S. Woo, H. David. Axio Research, Seattle, WA.

Post-trauma stress disorder (PTSD) is one of the mental diseases which can be developed by traumatic events such as deployment in battlefields or natural disasters. Because traumatic events are more likely associated with mental health, building a predictive model with biomarkers based on machine learning approaches was not developed. In this study, we present workflow of building a predictive model using a publically available PTSD data (RNA-seq, GSE63878). For the task, we adapted machine learning approaches and penalized regression models to identify biomarkers for building a predictive model for PTSD and compared their performances for identifying true PTSD patients. They include Random Forest, Support Vector Machine (SVM), Elastic net, LASSO and Deep learning. Their performances are compared by AUC, Sensitivity, and Specificity as accuracy measures and misclassification rate as an error measure. Because of relatively small sample size, we utilized 0.632 bootstrapping method for simulating replicates (n=1000) and for estimating these accuracy measures and an error measure. Also, we show how those identified biomarkers are truly associated with a biological function or biological signal which have known for mental diseases.

**Meta-analysis of Janssen DiseaseLand omics database for disease signatures and treatments.** C. Wu<sup>1</sup>, T. Lovenberg<sup>2</sup>, B. Huang<sup>1</sup>, X. Yao<sup>1</sup>. 1) Computational Sciences, Discovery Sciences, Janssen R&D LLC; 2) Neuroscience Therapeutic Area, Janssen R&D LLC.

**Background:** Transcriptomics technologies such as high-throughput next-generation sequencing and microarray platforms provide exciting opportunities for improving diagnosis and treatment of complex diseases by facilitating the development of pharmacotherapies able to modulate gene expression. Despite their great promise, individual studies may generate results that are not reproducible due to a small number of samples, potential confounding factors, different platforms and bioinformatics pipelines. A clear understanding and unified picture of many complex diseases is still elusive, highlighting an urgent need to effectively integrate multiple transcriptomic studies for disease signatures. In this study, we provide an illustrative example using multiple meta-analysis algorithms to combine a total of 30 genome-wide gene expression studies for insight into bipolar disorder. **Methods:** We have collected comprehensive high-quality transcriptomic datasets from both public domains and internal sources. In the present study, a total of 30 RNA Sequencing (RNA-Seq) or Microarray-based datasets on bipolar disorders were included. Raw FASTQ or CEL files were extracted from Gene Expression Omnibus (GEO) and our internal Janssen DiseaseLand database. We applied the same QC processes and normalization approaches to datasets from multiple platforms. Both p-value and effect size based meta-analysis algorithms were used to identify differentially expressed (DE) genes. We then conducted pathway enrichment analysis and prioritized candidate compounds via anti-genomic similarity between compound profiles within our Janssen L1000 database and the bipolar-associated gene signature. **Results:** We created a shared DE gene list between the r-th ordered p-value (rOP) and random effect model (REM). Among >10,000 genes, 328 were identified as significantly differentially expressed (FDR < 0.05) in any region of the brain (24 studies) and 204 in the prefrontal cortex (PFC, 15 studies). Among these were *BDNF*, *VGF*, *WFS1*, *DUSP6*, *CRHBP*, *MAOA* and *RELN*, which have been implicated in bipolar disorders. Pathway enrichment analysis revealed a role for GPCR, MAPK, immune system and Reelin pathways. **Conclusions:** We established systematic meta-analysis approaches based on the Janssen DiseaseLand Omics Database. This pipeline can be applied in multiple disease areas to create a unified picture of the disease signature and prioritize drug targets, pathways, and compounds.

**Association of addiction and psychiatric phenotypes to predicted transcript levels.** D.M. Bost<sup>1,2</sup>, C. Bizon<sup>1,2</sup>, J. Tilson<sup>2</sup>, X. Yin<sup>2</sup>, K. Wilhelmsen<sup>1,2</sup>. 1) Genetics (Bioinformatics and Computational Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Renaissance Computing Institute, Chapel Hill, NC.

GWAS studies unveil a wide range of variants associated with complex disease traits. Interpretation of these variants, however, is limited as it does not address the functional mechanisms involved. This deficit in identifying biological mechanisms, along with the penalty for multiple testing, hinders our ability for attributing causality from our variants to our traits. PrediXcan, a gene-based association method that prioritizes genes that are likely causal for phenotypes, has been introduced to circumvent the aforementioned hurdles in single marker analysis. PrediXcan utilizes gene regulation as a means to identify gene to trait associations. By quantifying the association between genetically regulated expression and phenotype PrediXcan allows the user to gather more biological inference from their subset of variants. PrediXcan uses reference transcriptome data to train additive models of gene expression levels. Weights were derived from the estimates of the genetically regulated expression. In regression testing which is used by Hae Kyung Im et al. there is an assumption of independence between data. This does not lend itself to studies with family data. To account for identity-by-descent we implement the use of a linear mixed model(LLM) that will produce a relatedness matrix. We implement this LLM with a Genome-wide Efficient Mixed Model Association(GEMMA) algorithm. Using the model weights estimated by PrediXcan, we predict transcript levels in brain tissues that we then perform association test on with GEMMA. Our association is conducted with addiction phenotypes, from the University of San Francisco Family Study, which include, but aren't limited to, alcohol use, marijuana use, and nicotine dependence. We also performed associations on psychiatric phenotypes obtained from the Minnesota Multiphasic Personality Inventory – 2<sup>nd</sup> edition which include, but aren't limited to, schizophrenia, hypomania, paranoia, and depression.

**1395W**

**Psychiatric disorders related gene co-expression modules in brain development.** *Y. Dai<sup>1</sup>, T. O'Brien<sup>1</sup>, G. Pei<sup>1</sup>, Z. Zhao<sup>1,2,3</sup>, P. Jia<sup>1</sup>.* 1) Center for Precision Health, School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX 77030, USA; 2) Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX 77030, USA; 3) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN 37203, USA.

Psychiatric disorders such as schizophrenia (SCZ), bipolar disorder (BIP), major depressive disorder (MDD), attention deficit-hyperactivity disorder (ADHD), and autism spectrum disorder (ASD) are often related to brain development. Both shared and unique biological and neurodevelopmental processes have been reported to be involved in these disorders. In this work, we developed an integrative analysis framework to seek for the sensitive spatiotemporal point during brain development underlying each disorder. Specifically, we overlaid Genome-Wide Association Study (GWAS) summary statistics of five psychiatric disorders to a reference protein-protein interaction (PPI) network, which was dynamically weighted by spatiotemporal co-expression data featuring four brain regions, including frontal cortex (FC), sub-cortical regions (SC), sensory motor regions (SM), and the temporal-parietal cortex (TP), among three developmental stages (embryonic, birth to 11 years old and older than 13 years). We adapted our previous method, EW\_dmGWAS, to identify highly co-expressed modules in each spatiotemporal sites and ranked them by the combined effect of component genes weighted by GWAS summary statistics. As a result, we found that SCZ and BIP were closely clustered in 10 out of the 12 investigated spatiotemporal sites, while ASD appeared to be distantly related to the other four disorders. Surprisingly, we only observed very limited number of modules that were shared in multiple disorders in each sites, implying a much more complicated relationship among these disorders at the pathway/network level. At the gene level, we identified several genes that were shared among the most significant modules. Example genes included *CTNNB1*, a gene from the Wnt signaling pathway and involved in neurogenesis maintenance, which was found in top modules in SC in stage 2. An immune related gene *LNX1* was found to be in all top disease specific modules in TP in stage 3. A further function analysis of the module genes revealed the enrichment in immune and psychiatric disease related pathways. In summary, our study demonstrated the changes of disease related modules in different spatiotemporal point and discovered that disease related genes could contribute to the development of disorders in different spatiotemporal point.

**A simple bioinformatics tool to facilitate implementation of pharmacogenomics in the clinical practice of psychiatry.** *A. Baskys.* Genomic Medicine Clinic, Newport Beach, CA.

Despite the improved side effect profiles of pharmacological agents, patients continue to experience significant side effects, symptom relapse, lack of treatment response or undesirable drug-drug and drug-gene interactions (DDIs and DGIs). Pharmacogenetic testing (PGx) based on identification of mutations in genes encoding cytochrome P450 peroxidase enzymes (CYP) that define Extensive, Intermediate, Poor and Ultra-rapid metabolizer phenotypes (EM, IM, PM and UM respectively) has recently become commercially available for prescribers. However, relatively large PGx data sets produced by genetic testing are nearly impossible for a human mind to meaningfully integrate into a clinical decision during a short patient visit (7 to 15 minutes), which contributes to a prescriber reluctance to implement PGx in clinical practice. Further, tabular PGx reports may be lengthy, static, and typically do not integrate both the DDI and DGI aspects of interactions. To address these problems, we developed MEDpicker, a simple bioinformatics tool that calculates drug metabolic rate deviations from expected values caused by DDIs and DGIs, and presents this information in a visual format. It factors in *CYP1A1*, *1A2*, *2B6*, *2C9*, *2C19*, *2D6*, *3A4* and *CYP3A5* gene variants that result in EM, IM or PM phenotypes as well as *CYP2D6* and *CYP2C19* Ultra-Rapid Metabolizer (UM) phenotypes to identify non-responders. The reference database includes over 1000 prescription drug-CYP enzyme interaction entries derived from published reports and publicly accessible databases. The graphic presentation of DDIs and DGIs makes medication selection fast and easy regardless of the number of interactions. Medication selections may be modified dynamically by a virtual substitution of one medication with another to obtain an optimal CYP enzyme induction or inhibition level and, consequently, the optimization of medication side effects and their effectiveness. This software tool is transferable from one clinical setting to another and can be used by the patient when selecting over the counter drugs or nutraceuticals. An evaluation version of this bioinformatics tool is freely available for prescribers, and educators with the expectation that it will facilitate the successful implementation of PGx technologies into clinical practice.

**1397F**

**ANCO genes: Annotations and comprehensive analysis of candidate genes for alcohol, nicotine, cocaine, and opiate (ANCO) dependence.** R. Hu<sup>1</sup>, Z. Zhao<sup>1,2,3</sup>, P. Jia<sup>1</sup>. 1) Center for Precision Health, School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX 77030, USA; 2) Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX 77030, USA; 3) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN 37203, USA.

Substance dependence has become a major health, socioeconomical, and behavioral issue across the world. Studies have found that genetic factors might account for approximately half of the likelihood of an individual developing substance dependence. So far, there have been thousands of studies reporting various genetic evidence (e.g. genome-wide association studies (GWAS), genome sequencing, gene expression, noncoding RNA expression, methylation, proteomics, metabolomics, iPSCs, and drug studies). These rich, but highly heterogeneous data, provide us an unprecedented opportunity to systematically collect, curate, and assess the genetic evidence from published studies and to perform comprehensive analysis of their features, functional roles, and druggability. This is especially important to compare the features among major substance dependence. In this study, we performed a comprehensive data collection of four related phenotypes: alcohol dependence (AD), nicotine dependence (ND), cocaine dependence (CD), and opiate dependence (OD). These datasets include resources from GWAS and candidate gene-based studies, transcriptomic studies, methylation studies, literature mining, and drug-target data, as well as derived data such as spatial-temporal gene expression, promoters, enhancers, expression QTL (eQTL). For GWAS, we curated a total of 6,337 SNPs with association *p-value* <  $1 \times 10^{-4}$ . There were 28 SNPs common in AD and ND. In addition, 787 SNPs have been identified to be related with DNA methylation in fetal brain, and 609 SNPs are associated with eQTLs significantly in frontal cortex. There were 580,000 enhancers and promoters mapped to these SNPs ( $\pm 5$ kb). Our PubMed literature mining identified ~60,000 studies with genes related to the four phenotypes. Among them, *ALDH2*, *EGFR*, *BDNF*, and *CAMP* were the most frequently studied genes for AD, ND, CD, and OD, respectively. There were 369 genes shared by three or more phenotypes, among which, 161 genes were commonly reported to all four phenotypes. We further studied drug information for these candidate genes using drug-gene information from pharmacological databases. Finally, these genes can be examined by the tissue-specific expression and eQTLs from our website. We also studied the common or specific mechanisms underlying the development of these phenotypes. All the curated data will be publicly accessed, that allows the user to retrieve, and analyze the genes and their features for AD, ND, CD, and OD.

**Clinical impact of cryptic splice mutations.** J. McRae<sup>1</sup>, K. Jaganathan<sup>1</sup>, S. Kyriazopoulou Panagiotopoulou<sup>1</sup>, S. Fazel Darbandi<sup>2</sup>, S. Sanders<sup>2</sup>, K. Farh<sup>1</sup>. 1) Illumina, Inc, San Francisco, CA; 2) University of California, San Francisco.

Many patients with rare diseases who undergo genetic testing do not receive a molecular diagnosis, despite exhaustive searches of variants in protein-coding regions. We investigated whether cryptic splice variants may contribute to this deficit. We created a model that can accurately predict whether genetic variants outside essential splice sites alter splicing. We assessed the impact of cryptic splice variants in *de novo* mutations from two rare disease cohorts. Cases with autism spectrum disorder were 1.38-fold enriched for cryptic splice mutations compared to healthy controls, whereas cases with intellectual disability were 1.54-fold enriched. We estimate that ~5% of patients with rare diseases have a pathogenic cryptic splice mutation. We also identified seven additional genes at FDR < 0.01 when these variants were included in gene enrichment tests. We attempted to validate predicted cryptic splice mutations from 36 patient samples. We performed high-depth sequencing of RNA from blood-derived cell lines and examined splice events around the predicted variant. The predictions had a high rate of validation, as 75% of the predicted variants showed altered splicing. These results demonstrate the clinical utility of cryptic splice mutations in rare disease.

**1399T**

**Dissecting heterogeneity of neurodevelopmental disorders using seed centric genetic modules.** J.C. Chow<sup>1</sup>, M. Jensen<sup>2</sup>, H. Amini<sup>3</sup>, F. Hormozdiari<sup>4</sup>, O. Penn<sup>5</sup>, S. Girirajan<sup>2,6</sup>, F. Hormozdiari<sup>1,7,8</sup>. 1) Genome Center, University of California, Davis, CA; 2) Bioinformatics and Genomics Graduate Program, The Huck Institute of Life Sciences, Pennsylvania State University, University Park, PA; 3) Department of Plant Biology, University of California, Davis, CA; 4) T.H. Chan School of Public Health, Harvard University, Boston, MA; 5) Allen Institute for Brain Science, Seattle, WA; 6) Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA; 7) MIND Institute, University of California, Davis, CA; 8) Biochemistry and Molecular Medicine, University of California, Davis, CA.

Integration of protein-protein interaction and co-expression networks permits the discovery of highly connected genes that form functional subnetworks or modules. We extended our tool MAGI for the discovery of genetic modules based on high connectivity to an input "seed" gene. We constructed modules from 21 seed genes associated with various neurodevelopmental disorders to reveal unique modules for each of these seed genes. We observed that these modules are significantly associated with disease terms corresponding to their respective seed genes. Modules seeded with epilepsy genes (e.g., *SCN1A*, *GABRA1* and *KCNB1*) are associated with long-term potentiation, synaptic vesicle cycle, and calcium signaling pathways, and modules produced by autism seed genes (e.g., *SCN2A*, *CHD8*, and *POGZ*) are associated with axon guidance, synaptic transmission, and vocal learning. We found significant enrichment of *de novo* non-synonymous mutations and overlap with coding copy number variants within these modules from large cohorts of probands with autism, intellectual disability, developmental disability, or epilepsy. Additionally, the existence of differentially acetylated peaks and differentially edited RNA editing sites in the presence or absence of neurodevelopmental disorders suggests coordinated regulation within modules. We further identify phenotypic differences among probands with *de novo* mutations inside modules, finding lower average IQ, sex differences, and macrocephaly.

**1400F**

**Predicting the clinical impact of human mutation with deep learning.** L. Sundaram<sup>1,2</sup>, J. McRae<sup>2</sup>, SR. Padigepati<sup>2</sup>, H. Gao<sup>2</sup>, Y. Li<sup>2</sup>, S. Batzoglou<sup>2</sup>, X. Li<sup>2</sup>, KK. Farh<sup>2</sup>. 1) Department of Computer Science, Stanford University, Stanford, CA; 2) Illumina Inc, San Diego, CA; 3) National Science Foundation Center for Big learning, University of Florida, Gainesville, CA.

Millions of human genomes and exomes have been sequenced, but their clinical interpretation remains challenging due to the difficulty of distinguishing disease-causing mutations from benign genetic variation. We have trained a semi-supervised deep neural network to classify benign versus pathogenic missense mutations, that substantially improves upon existing methods. When presented with a test set of *de novo* missense mutations from patients with neurodevelopmental disorders and healthy controls, our classifier successfully separates *de novo* mutations coming from cases versus controls with 88% accuracy, about half the error rate of other methods. The deep learning network uses only primary amino acid sequence as its input and learns to assign high pathogenicity scores to residues at critical protein functional domains from sequence, without additional human annotation. We show that the network assigns the highest pathogenicity scores to mutations at crucial amino acid positions within domains, such as the DNA-contacting residues of transcription factors and the catalytic residues. Applying our classifier to stratify damaging missense mutations increases the enrichment of *de novo* missense mutations in patients with intellectual disability from 1.5-fold to 2.2-fold, close to protein-truncating mutations (2.46-fold), while relinquishing less than one third of the total number of variants enriched above expectation. This substantially improves statistical power, enabling discovery of 14 additional candidate genes in intellectual disability, which had previously not reached the genome-wide significance threshold.

Mitochondrial DNA mutations are responsible of various phenotypes, causing partial or entirely unexplained phenotypes. Clinical spectrum is huge and concerns one (e.g. internal ear in sensorineural deafness OMIM 580000) or several organs like muscles and brain (e.g. MERRF, myoclonic epilepsy associated with ragged-red fibers OMIM 545000). When suspected, mitochondrial DNA mutations identification requires targeted strategies on affected tissues. In the context of extending use of whole-exome sequencing (WES) in rare Mendelian disorders diagnosis, we developed a bioinformatics pipeline on WES data in order to detect mitochondrial variants in parallel with the routinely used “in-house” nuclear exome pipeline, in particular to detect mitochondrial disorders in patients with no initial clinical suspicion of this group of disease. FastQ data from the mitochondrial genome were extracted from WES data in 931 patients with developmental (90%) and/or neurological (10%) anomalies. After merging, the variants were filtered out based on database presence, cohort frequencies, haplogroups and protein consequences. In parallel, some patients with previously identified mitochondrial mutations were sequenced and tested as positive controls to validate the method. Two mitochondrial causal variants were identified in 2/931 patients: a homoplasmic m.9035T-C variant in a female with ataxia and axonal neuropathy, and a m.11778G-A variant in a male with Leber optic atrophy not suspected because of a complex phenotype. Two variants of unknown significance were discussed in 3 patients: an unreported homoplasmic variant (m.16114C-A) in a child with migraine headache and cyclic vomiting syndrome, very close to other suspected variants already described with the disease; and the homoplasmic m.5567T-C variant in two individuals with cerebellar ataxia. Mitochondrial genome studies based on WES data also highlighted secondary findings in 4 patients without mitochondrial phenotype at time of the test: the m.1494C-T (1 patient) and m.1555A-G (2 patients) variants described in association with aminoglycoside-induced deafness, and a m.14484T-C (1 patient) variant responsible for Leber optic atrophy. This study demonstrates the interest of including specific mtDNA variants detection in exome pipeline that improve diagnosis, in particular in patients with neurological impairments with no clinical orientation.

**1402T****Mitochondrial variant calling in over 15,000 individuals in the genome aggregation database (gnomAD).**

K.M. Laricchia<sup>1,2</sup>, G. Tiao<sup>1,2</sup>, D.G. MacArthur<sup>1,2</sup>, V.K. Mootha<sup>1,2,3</sup>, L. Gauthier<sup>1,2</sup>, M. Shand<sup>1</sup>, J. Soto<sup>1</sup>, J. Emery<sup>1</sup>, M. Lek<sup>1,2</sup>, S. Calvo<sup>1,2</sup>, gnomAD Consortium. 1) Broad Institute of MIT and Harvard, Cambridge, MA, United States; 2) Massachusetts General Hospital, Boston, MA, United States; 3) Howard Hughes Medical Institute, Chevy Chase, MD, United States.

Mitochondria are maternally inherited organelles that each contain many copies of the 16,569bp mitochondrial genome (mtDNA). mtDNA encodes 13 proteins involved in oxidative phosphorylation, which is required for generating ~90% of all cellular ATP. Over 400 mutations in mtDNA have been associated with human disease, and a complete survey of mtDNA variants in tens of thousands of genomes would provide a powerful resource to help researchers assess the frequency and interpretation of mitochondrial variants. We explored mtDNA variant discovery using data from over 15,000 whole genomes from unrelated individuals, aggregated as part of the Genome Aggregation Database (gnomAD; <http://gnomad.broadinstitute.org>). To date, variants in these genomes have currently only been called for the 22 autosomes and chromosome X, omitting variants in the mtDNA. mtDNA is present in thousands of copies per cell, and the gnomAD genomes typically have >3000x mtDNA coverage. A specialized variant calling methodology is therefore required, as mtDNA variants can exist at any level of heteroplasmy (i.e., the percentage of mtDNA molecules with a given variant). We applied the tool mtDNA-Server, which is optimized for identifying mitochondrial variants, detecting contamination, and determining haplogroups (maternal-line ancestry). We identified low heteroplasmic, high heteroplasmic, and homoplasmic variants among gnomAD individuals. For quality control, we assessed variant concordance across duplicate samples, checked maternal transmission rates in mother-child pairs, and calculated quality metrics for variant detection in samples mixed *in silico* at predetermined heteroplasmic levels. All individuals were also classified into haplogroups, which aids in detecting contamination and provides additional information on ancestry to complement ancestry inference based on nuclear genome variation. This research provides data that can be used to benchmark other mitochondrial variant callers. Including mtDNA variants in future releases of the gnomAD database will provide critical population frequency information to help researchers understand the role of mitochondrial variation in health and disease states.

**1403F**

**Mitochondrial variant detection, annotation and segregation from whole-exome sequencing data.** J.C. Tsai<sup>1,2</sup>, A.D Laporte<sup>1</sup>, D. Spiegelman<sup>1</sup>, G. Rouleau<sup>1</sup>, L. Xiong<sup>1,2</sup>. 1) McGill University, Montreal Neurological Institute, Montreal, Quebec, Canada; 2) Centre de recherche, Institut universitaire en santé mentale de Montréal, Université de Montréal, Montreal, Quebec, Canada.

**Introduction:** Reads containing mitochondrial DNA are the most common off-target captures when performing Whole-Exome Sequencing (WES). Even without enriching panels with mitochondrial probes, it is possible to assemble the mitochondrial (MT) genome from off-target reads at relatively high depths; many open-source pipelines and tools have been developed and adapted to this means: MitoSeek, MToolBox, mtDNA-Server, and MitoSuite. **Methods:** Two alignments to the rCRS of the MT genome were generated with Burrows-Wheeler Alignment Tool (BWA) using cleaned fastq files from Illumina paired-end sequencing. Two alignment protocols for 243 WES samples from 15 Pakistani families containing neuropsychiatric disease subjects and controls were used as input into the MToolbox, mtDNA-Server and LoFreq pipelines. Calls made by the three pipelines were combined and positions present in all three pipeline's variant call files for the entire cohort were extracted, and variant annotation was performed using variants from these common positions. The annotation step was performed using Annovar with an Ensembl gene database, a dbSNP database, and custom-created MitoMap and HmtDB databases. Haplogroups were assigned using the MToolbox pipeline. MitoSuite was used for supplementary graph generation and haplogroup confirmation. **Preliminary Results:** Among the three tested variant callers, MToolbox has the highest concordance with the overlapped variants. A total of 718 MT variants were identified, 25 of which were multi-allelic variants, from 242 of the individuals. 97 variants were classified as non-coding control region variants, 286 were non-coding mt-RNA variants, and 360 were protein-coding variants. 8,955 genotypes were observed using mtDNA-server calls at these positions, of which 40% were homoplasmic variants (>95% heteroplasmy), 5% were heteroplasmic between 50-95% and 55% were heteroplasmic between 0-50%. **Conclusions:** Mitochondrial genome assembly from our WES data is possible with reasonable data quality. Variants with varying levels of heteroplasmy and a large number of homoplasmic variants were detected in our data-set, with some variants having potentially interesting biological significance. Variant segregation with disease phenotypes within the pedigrees will be investigated. Incorporation of MT-variant-calling with the selected pipelines and the Annovar annotation step into a larger WES pipeline is underway.

**Methods for detecting the role of ncRNAs in rare mitochondrial diseases.** V.A. Yopez<sup>1</sup>, M. Gusic<sup>2</sup>, C. Mertes<sup>1</sup>, P.F. Goldberg<sup>1</sup>, L.S. Kremer<sup>2</sup>, R. Kopajtich<sup>2</sup>, H. Prokisch<sup>2</sup>, J. Gagneur<sup>1</sup>. 1) Department of Informatics, Technical University Munich, Munich, Bavaria, Germany; 2) Institute of Human Genetics, Helmholtz Zentrum Muenchen, Neuherberg, Bavaria, Germany.

Mitochondrial diseases represent one of the most frequent inborn errors of metabolism. They may result from pathogenic mutations in the nuclear or mtDNA. Causal defects have been identified in 300+ genes and this number continues to grow. DNA sequencing alone allows the diagnosis of ~50% of the cases, and subsequent use of RNA-Seq has improved the success rate by 10% [1]. Yet, so far focus has been on protein-coding genes. It has become increasingly apparent that the non-protein-coding genome is of crucial functional importance for normal development. Here, we present computational approaches we have developed in order to prioritize ncRNAs with a potential role in rare mitochondrial disorders, using our cohort of 230 patients with rare mitochondrial disorders and more than 9,000 transcriptomes from the GTEx Consortium. First, we applied OUTRIDER [2], a novel statistical method to detect aberrantly expressed ncRNAs. Second, we correlated the expression of ncRNAs with the expression of mito related genes. Third, we correlated the expression of ncRNAs with maximal cellular respiration obtained using OCR-Stats [3]. Finally, we developed a supervised learning method to associate ncRNAs with similar behavior as MitoCarta, mito disease causal and respiratory chain complexes genes, using GTEx data. Our preliminary results show that there are indeed some ncRNAs showing similar expression profiles as mito related genes and that correlate positively with maximal respiration. Our final aim is to identify and functionally characterize ncRNAs that are causal of mito diseases, which would be of great interest not only from the clinical and therapeutical aspects, but also to the better understanding of gene expression regulation. 1. **Condition-dependent allele-specific expression in normal and diseased donor eyes reveals potential therapeutic targets for intermediate AMD.** Q. Li<sup>1</sup>, D. Morgan<sup>2</sup>, L. Owen<sup>2</sup>, D. Nix<sup>1</sup>, M. DeAngelis<sup>2</sup>. 1) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT, USA; 2) Moran Eye Center, University of Utah, Salt Lake City, UT, USA.

While allele-specific expression (ASE) has been demonstrated in many human tissues, the ASE architectural landscape of the human eye is poorly understood. For discovery purposes, we have carried out a survey of well characterized fresh donor eye tissue (post mortem time of  $\leq 6$  hours old) of 14 individuals (6 intermediate stage age-related macular degeneration (AMD) patients and 8 healthy age-matched controls) using whole exome, RNASeq and SNP chip. In silico analyses of these data are of special challenge because no existing statistical method is available for non-paired differential ASE analysis eg., between a disease and a non-disease state. Another challenge is the availability of fresh human donor eyes, particularly the human neural retina and retinal pigment epithelium (RPE)-the tissues affected by AMD, for QPCR validation is very limited. Prioritization of the most promising candidate genes not just based on a significant p-value is very much needed as well. With these caveats in mind, we have developed a comprehensive pipeline to call ASE using rigorous quality control measures to minimize false ASE calling, customized DESeq2 design to deal with non-paired differential ASE analysis and an ensemble prioritization score to further prioritize the most promising candidate genes. In fact, this pipeline discovered significant 36 SNPs in 10 genes, specific to AMD RPE vs normal RPE and 79 SNPs in 11 genes to AMD neural retina vs. normal neural retina for differential ASE. No genes had evidence of differential ASE overlap in these tissue comparisons. This demonstrates the unique contributions of each of these tissue types to the pathophysiology of AMD. Additionally, no imprinted genes demonstrated differential ASE between disease state comparisons in either tissue type. The genes demonstrating differential ASE include those that function in the retina include folic acid metabolism (*FMN1*), *TDRP* (AMD GWAS associated gene) and those in the RPE include, *CAT*, *KDR* and *ITGB8*. Finally, we demonstrate the power of our approach by validating our findings from tissues which have developmentally similar origin as the neural retina and RPE from GTEx ASE data. Blinding diseases, including AMD are the leading cause of visual loss worldwide in the aging population for which there is no cure. Identifying disease mechanisms from our study would pinpoint appropriate therapeutic targets, especially that slow or stop disease progression.

## 1406F

**Toward clinical-grade in silico prediction: A disease-specific machine learning model derived from manually curated dataset peaks accuracy of nonsynonymous variant impact prediction in hearing loss genes.** X. Li<sup>1</sup>, F. Bu<sup>2,3</sup>, Y. Wang<sup>1</sup>, J. Cheng<sup>1</sup>, H. Azaiez<sup>2</sup>, Y. Lu<sup>2</sup>, R. Smith<sup>3</sup>, H. Yuan<sup>2</sup>. 1) GeneDock Co. Ltd., Beijing, China; 2) Medical Genetics Center, Southwest Hospital, Chongqing, China; 3) Molecular Otolaryngology and Renal Research Laboratories, University of Iowa, Iowa, US.

Facilitated by high-throughput sequencing techniques, clinical genetic testing is considered to be a routine method for disorders. However, pathogenicity interpretation of novel variants may often be ambiguous due to lack of functional assessment. Many computational prediction tools have been introduced but only considered suggestive by the ACMG/AMP 2015 guideline because of inaccurate and inconsistent results. The discrepancies were likely caused by 1) inadequately curated training data, and 2) over-comprehensive testing scope that usually includes all genes and diseases. To overcome the issues, we developed a disease-specific model named Deafness Variant function Prediction tool (DVPred) focusing on hereditary hearing loss (HL), a well-studied Mendelian condition featured by high prevalence and genetic heterogeneity. We selected 66 genes which were reported as causal in HL and replicated in the China Deafness Genetics Consortium (CDGC) study, then manually curated 2604 pathogenic SNVs in testing genes from literatures, and retrieved 8149 curated benign SNVs from Deafness Variation Database (DVD) to generate the training dataset. Two testing datasets were composited by newly identified pathogenic SNVs from CDGC and MORL, Iowa. Matched benign SNVs were also retrieved from DVD. 35 gene specific features, 14 population frequency features, and 18 preexisting scores from published tools were included. Gradient boosting decision tree outperformed other machine learning algorithms in 5-fold cross validation. As shown in the table, the Area under the curve (AUC) of Receiver operating characteristic (ROC) is 0.9950 for training set, 0.9976 for testing set 1 (CDGC), and 0.9781 for testing set 2 (MORL). Comparing to commonly used tools, DVPred provides highly credible result that can dramatically improve interpretation of nonsynonymous SNVs in HL. This strategy also sheds light on developing in silico prediction tool in other genetic diseases.

			AUC ROC	AUC PRC
All SNVs	DVPred	Training (n = 10735)	0.995	0.9852

**A geometric morphometrics and machine learning tool for facial shape analysis and classification based on non-invasive facial biomarkers: A Down's syndrome case study.** X. Sevillano<sup>1</sup>, A. González<sup>2</sup>, R. González<sup>2</sup>, J. Sharpe<sup>3</sup>, R. De La Torre<sup>3</sup>, M. Dierssen<sup>4</sup>, N. Martínez-Abadías<sup>2</sup>. 1) Grup de Recerca en Tecnologies Mèdia (GTM), La Salle - Universitat Ramon Llull, Barcelona, Spain; 2) European Molecular Biology Laboratory (EMBL), Barcelona, Spain; 3) Integrative Pharmacology and Systems Neuroscience, IMIM-Hospital del Mar Medical Research Institute, Barcelona, Spain; 4) Center for Genomic Regulation (CRG), The Barcelona Institute of Science and Technology, Barcelona, Spain.

Down syndrome (DS) is a genetic disorder caused by trisomy of chromosome 21, typically associated with cognitive impairment, immunodeficiency, congenital heart disease, and facial dysmorphologies. Focusing on this latter aspect, Geometric Morphometrics (GM), a sophisticated body of statistical tools to measure and compare shapes with enhanced precision and efficiency, has been used to find facial biomarkers to discriminate between Euploid (EU) and DS facial shapes. In this work, we combine GM with machine learning (ML) to develop a software application to classify subjects as EU or SD according to the features extracted from the GM-based face shape analysis. In particular, facial shapes are described upon a set of 21 anatomical landmarks which are subsequently represented in spaces in which statistical differences between the EU and SD groups are maximized: the Procrustes space (PS) and the Euclidean Distance Matrix Analysis space (ES). In PS, shapes are described according to spatial landmarks distribution, using Principal Component Analysis to reduce dimensionality and represent shapes as points on a two-dimensional space defined by the two first principal components, which usually explain around 25-35% of the data variance. In ES, interlandmark distances are employed as shape descriptors, identifying which interlandmark distances define the significant differences between groups. Taking into account that both spaces seek maximizing between-class variance, we consider them as suitable feature spaces for training ML models that learn to classify EU and SD subjects from their facial shapes. Thus, we propose training and testing supervised classification algorithms to create a phenotyping/diagnostic tool based on the PS (using a variable number of principal components) and on the ES (using a variable number of the most significantly different interlandmark distances). Using a sample of 177 EU and 43 SD subjects of ages between 0 and 18, we trained models both in PS and ES over different ranges of age (0 to 3, 4 to 12, and 13 to 18), obtaining classification accuracies over 95% (within the same age range) and 85% (when training and testing on different age ranges). To conclude, this tool combining GM and ML is highly valuable for diagnosis and prognosis based on non-invasive facial biomarkers, which can be applied to other disorders characterized by the presence of minor facial dysmorphologies like schizophrenia, bipolar disorder or autism.

**nanotatoR: An annotation tool for next generation mapping.** S. Bhattacharya, H. Barseghyan, E. Vilain, EC. Delot. Center for Genetic Medicine Research, Children's National Medical Center, Washington, DC.

Whole genome sequencing (WGS) has successfully been used to identify single-nucleotide variants (SNV), small insertions and deletions and, more recently, small copy number variants. However, due to utilization of short reads, it is not well suited for identification of structural variants (SV) and the majority of SV calling tools having high false positive and negative rates. Optical next-generation mapping (NGM) utilizes long fluorescently labeled native-state DNA molecules for de novo genome assembly to overcome the limitations of WGS. NGM allows for a significant increase in SV detection capability. However, accuracy of SV annotation is highly important for variant classification and filtration to determine pathogenicity. Here we create a new tool in R, for SV annotation, including population frequency and gene function and expression, using publicly available datasets. We use DGV (Database of Genomic Variants), which contains SVs from 7965 individuals, to calculate the population frequency of the SVs identified by the Bionano SVCaller in the NGM dataset of a cohort of 50 undiagnosed patients with a variety of phenotypes. The new annotation tool, nanotatoR, also calculates the internal frequency of SVs, which could be beneficial in identification of potential false positive or common calls. The software creates a primary gene list (PG) from NCBI databases based on patient phenotype and compares the list to the set of genes overlapping the patient's SVs generated by SVCaller, providing analysts with an easy way to identify variants affecting genes in the PG. The output is given in an Excel file format, which is subdivided into multiple sheets based on SV type. Users then have a choice to filter SVs using the provided annotation for identification of inherited, de novo or rare variants. Visualization options are available for distribution of the different SV types and size ranges. An option is also available to add the read counts from RNASeq dat to the annotated SVs called by Bionano SVCaller, to determine whether the change in structure results in a change in expression. Additionally we provide the user with the median expression in Transcripts per Kilobase Millions (TPM) of the gene across different tissues from the Genotype-Tissue Expression (GTEx) database. nanotatoR provides integrated annotation and the expression patterns to enable users to identify potential pathogenic SVs with greater precision and faster turnaround times.

**Calling trisomic variants from whole genome sequencing data using PEMapper and PEEaller.** *H.R. Johnston, M.E. Zwick, S.L. Sherman, D.J. Cutler.* Department of Human Genetics, Emory University, Atlanta, GA.

The ability to characterize loci on a trisomic chromosome is of great interest to better understand molecular risk factors of nondisjunction and its consequences. Examining loci along the chromosome arms permits in-depth analysis of the location of recombination events, parent of origin effects, and even suggests likely microdeletion regions, when the allele count appears to be 50/50. We have developed an accurate method to differentiate between the two heterozygous states (AAa vs Aaa) using sequencing data, the most challenging aspect of this characterization. Using samples from the Emory University Down Syndrome Center cohort, approximately 200 whole genomes have been sequenced to 30x depth of coverage. These samples were mapped with PEMapper and called with PEEaller<sup>1</sup>. Starting with ~84,000 variants on chromosome 21 with MAF (a) > .01 in gnomAD, the depth of each called allele was calculated for every position for every sample. A basic set of genotype likelihood models was fit to the data, with L(AAA) representing 99% reference alleles, L(AAa) 66% reference alleles, L(Aaa) 33% reference alleles and L(aaa) 1% reference alleles. We then took these likelihoods and calculated a probability that the underlying genotype is correct. From that, we calculate the probability of the minor allele at each site, as well as the uncertainty in the estimate. Using these estimates, combined with array-based genotypes on the parents of the individuals with trisomy 21, we will be able to construct chromosomal maps that can tell us from which parent the extra copy of chromosome 21 was inherited, the type of nondisjunction error (meiosis I or meiosis II) as well as hone in on the likely recombination breakpoint(s) in that parent in which the error occurred. Additionally, variants that appear to violate the model by having 50% reference alleles will be able to be investigated further for evidence of microdeletions in the region. All of these analyses will help us to better understand the roles that dosage and compensation play in trisomy-associated phenotypes, with specific application in this initial project to Down syndrome. 1. Johnston, H.R., Chopra, P., Wingo, T.S., Patel, V., Epstein, M.P., Mülle, J.G., Warren, S.T., Zwick, M.E., and Cutler, D.J. (2017). **Phenotype enrichment and analysis of hundreds of EHR derived phenotypes in > 4,000 genetically reconstructed pedigrees from a large precision medicine cohort of 92,000 individuals.** *J. Staples<sup>1</sup>, C. Gonzaga Jauregui<sup>2</sup>, R. Metpally<sup>2</sup>, C.V. Van Hout<sup>1</sup>, C. O'Dushlaine<sup>1</sup>, S.E. McCarthy<sup>1</sup>, D.J. Carey<sup>2</sup>, A.R. Shuldiner<sup>1</sup>, A. Baras<sup>1</sup>, L. Habegger<sup>1</sup>, J.G. Reid<sup>1</sup>, Geisinger-Regeneron DiscovEHR.* 1) Regeneron Genetics Center, Regeneron Pharmaceuticals Inc, Tarrytown, NY; 2) Geisinger Health System, Danville, PA.

Rare, phenotypically impactful variants are valuable for better understanding human biology, identifying drug targets, and diagnosing patients. Family-based analyses are particularly useful for identifying these variants co-segregating with phenotypes of interest, whereas these variants may not be easily detected with a population-based approach. Unfortunately, many planned and ongoing large-scale sequencing initiatives are designed to ascertain few related individuals, precluding the use of these powerful family-based analyses. However, this is not the case for the 92K individuals sequenced in DiscovEHR. We have reconstructed 4,697 pedigrees of 3 or more individuals directly from exome sequence data, and we found over 300 electronic health record (EHR) derived phenotypes segregating in a Mendelian fashion amongst these pedigrees, providing over 2,000 potentially informative pedigree-phenotype pairings that enable traditional Mendelian analyses at a large scale. For each individual in these pedigrees, ICD10 three-digit codes were used to define affecteds of binary traits, and affecteds with extreme values for quantitative traits were defined as having a trait value more than two standard deviations from the cohort's mean. We used these sets of affected individuals to identify pedigrees amenable to family-based rare variant segregation analysis, and more than half of the segregating traits were segregating in two or more pedigrees. A preliminary rare variant segregation analysis identified likely causal mutations in known disease-causing genes for hereditary hemorrhagic telangiectasia and motor sensory neuropathy. We also found pedigrees segregating known, highly-penetrant, and actionable Mendelian disease-causing variants for diseases such as familial aortic aneurysms, thyroid cancer, pigmentary glaucoma, and familial hypercholesterolemia. Family-based rare variant segregation analyses are ongoing for these pedigrees to identify novel genes for disease-related traits; for example, we have preliminary evidence for a new candidate gene for bipolar disorder. While many precision medicine cohorts are not designed to directly ascertain pedigrees, we have demonstrated the value of obtaining informative pedigrees directly from the genetic data of a large precision medicine cohort to create a large dataset for traditional Mendelian analyses.

**1411T****Scaling rare disease genomics to tens of thousands of samples. B.**

*Weisburd*<sup>1,2</sup>, *H. Snow*<sup>1,2</sup>, *H. Arachchi*<sup>1,2</sup>, *S. Baxter*<sup>1,2</sup>, *A. O'Donnell-Luria*<sup>1,2,3</sup>, *H.L. Rehm*<sup>1,2</sup>, *M.J. Daly*<sup>1,2</sup>, *D.G. MacArthur*<sup>1,2</sup>. 1) Broad Institute, Cambridge, MA; 2) Center for Genomic Medicine, Massachusetts General Hospital, Boston, MA, USA; 3) The Manton Center for Orphan Disease Research, Division of Genetics and Genomics, Boston Children's Hospital, Boston, MA, USA.

Rapid advances in exome and whole-genome sequencing make it possible to identify the full spectrum of genetic variation in rare disease patients and family members. However, to make sense of this data, and discover the causal variants underlying rare diseases, powerful filtering and decision support tools are needed that can handle the very large data sets now being produced. We are addressing this challenge by developing seqr - an open source, interactive web-based tool that allows researchers to work together to search and annotate variant call-sets from exome and whole genome studies involving families of rare disease patients. The seqr platform has already been used by over 500 researchers to study potential causal variants across 10,000 families affected by rare disease, and is the core analysis platform for the Broad Institute's Center for Mendelian Genomics facilitating over 1,000 diagnoses. This presentation will describe the technology stack underlying seqr, including the database, server-side and client side technologies involved, with a focus on the design choices made to facilitate the scaling of the system to tens of thousands of exome and genome samples. The need to allow interactive searching of terabytes of genomic sequencing data requires custom solutions and thoughtful design trade-offs. We will present the technical details of how seqr dealt with these challenges. Additionally we will describe how interactive visualization of read-level data, copy number variation, detailed phenotype data, and other relevant data types were brought together in a single user-friendly interface.

**1412F****Construction of a structural variant detection pipeline for the Undiagnosed Diseases Program. B. Hospelhorn, D. Adams, W. Gahl.**

Undiagnosed Diseases Program, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

**INTRODUCTION:** The Undiagnosed Diseases Program (UDP) is celebrating its 10th year of seeking diagnoses for individuals with illnesses that remain undiagnosed despite extensive medical workup. Structural DNA variations (SVs) can have a significant impact on an organism's phenotype and are an important subset of candidates to consider when searching for causal variants in genetic disease. Genomic SVs that are copy number balanced or lie between the cytogenetic and short-read-sequencing size optima, have proven difficult to detect through computational means, even after the advent of Next Generation Sequencing. Overall, many software packages are available, but the field has not settled on an optimal analytic approach. We describe initial efforts to develop an SV detection pipeline for our cohort of undiagnosed UDP study participants. **METHODS:** In an effort to consider multiple lines of evidence, the current UDP SV pipeline utilizes multiple SV and CNV callers such as LUMPY and DELLY, and integrates CNV calls from SNP array data and indel calls from standard short-read sequence genotyping for cross-referencing. **RESULTS:** Preliminary results indicate progress toward the prioritization of deleterious variants. Genotyping alone can reduce the number of variants by as much as 75%, and forcing a call set consensus can further reduce that number. Additionally, initial efforts at prioritizing deletions, exonic variants, and segregating variants have proven effective at culling variant lists to almost manageable lengths. Encouragingly, the pipeline was able to detect the causal structural variant in a solved UDP case, a variant which was initially detected from SNP data, but was filtered during the quality control process. Even at this prototypical stage, the SV pipeline shows promise in its ability to pick up variants larger than the upper limit of standard NGS genotype calling (under 500bp), and resolve SVs in the 100-100000bp range far more reliably than can be done with SNP data alone. **CONCLUSION:** Exome and genome sequencing fail to provide a definitive diagnosis in a substantial number of individuals with characteristics of inherited disease. As the SV-detection field evolves, generation of new methods will need to be incorporated in the reanalysis of undiagnosed cohorts. The UDP SV detection pipeline is being positioned to fulfill that role for the NIH Undiagnosed Diseases Program.

**1413W**

**Precision etiology for complex disease classification.** *L.M. Schriml, C. Greene, C. Bearer, R. Lichenstein, R. Tauber, J. Munro, M. Giglio.* University of Maryland School of Medicine, Baltimore, MD.

Beyond monogenic diseases, clinical diagnosis is challenged by the complexity of etiologies for many genetic diseases. The complexity of etiologies for differential diagnosis challenges established bioinformatic knowledge capture in biomedical ontologies. Classification of complex disease necessitates an evolution towards precise disease etiology captured through clinically-defined semantic assertions. Here we describe how the Human Disease Ontology (DO) project ([www.disease-ontology.org](http://www.disease-ontology.org)) is addressing the need to rigorously incorporate genetic etiology and environmental drivers through strictly defined semantic logical definitions (with OBO Foundry ontologies), precisely defining that a disease has exactly 1, a minimum (or maximum) of [x number] of (functional or structural) alteration(s); symptom(s); transmission method(s); infectious agent(s); environmental trigger(s); phenotype(s); anatomical location(s); cell type(s) of origin; food-based allergic trigger(s); or genetic susceptibility. As the OBO Foundry's domain ontology for human diseases, the DO represents the breadth of (~ 16,000) common and rare diseases in an etiology-based classification as both an axiomatized OWL and an OBO formatted ontology. The DO semantically integrates (> 46,000) disease and medical vocabulary terms through extensive logically-defined cross mapping (MeSH, ICD, NCI's thesaurus, SNOMED and OMIM). The DO provides standardized descriptions of human disease improves the capture and communication of health-related data across several hundred resources including biomedical databases, bioinformatics tools, genomic and cancer resources. Addressing these challenges the DO project has developed a complex disease model to drive the restructuring of DO knowledge for differential diagnosis. The DO's clinical team has assessed a set of complex and environmental diseases to expand DO's complex disease knowledgebase. Initially, examining the pleiotropy of a dozen diseases including: Prader-Willi syndrome, which can be a chromosomal deletion, a methylation defect or a single gene disorder; alpha 1-antitrypsin deficiency, which has variable expression and critical contributions from environmental factors; and cystic fibrosis, which involves multiple organ systems in a single disorder. The outlined enhancements are enabling precise incorporation of genetic and environmental components of disease etiology for complex diseases and thus the utility of the DO for clinical diagnosis.

**The use of AI technologies in genomic interpretation, a pilot study.** *R. Attali<sup>1</sup>, S. Tzur<sup>1</sup>, O. Farchy<sup>1</sup>, T. Talmy<sup>1</sup>, Y. Yang<sup>2,3</sup>, C. Eng<sup>2,3</sup>, C. Shaw<sup>2</sup>, F. Xia<sup>2,3</sup>, BG WES review group; BG Bioinformatics group.* 1) Emedgene Technologies, Tel Aviv, Israel; 2) Baylor Genetics, Houston, Texas, USA; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA.

**Introduction** Due to the rapid growth in the use of genome sequencing in medicine, the interpretation workload for genome specialists has amplified dramatically. Hence, rises a need for novel solutions aimed at reducing analysis time, by implementing advanced technologies to provide autonomic findings and thereby support rapid clinical decision making. In this pilot study, we assessed the use of artificial intelligence (AI) technologies in diagnostic genomic analysis. **Methods** The pilot was performed by the experienced genomic specialists team of Baylor Genetics (BG) while applying technologies rooted upon machine learning and natural language processing (NLP), developed at Emedgene Technologies. The BG team performed paired analyses of 79 cases. The first analysis was performed using BG's standard operating procedure (SOP), whereas the second implemented the capabilities and additional findings provided by the AI pipeline. The auto-analysis output consisted of several dozen prioritized candidate variants, backed by a literature synopsis displaying relevant publications as part of a comprehensive graphical representation of supporting evidence, to be used for manual inspection. **Results** All notable variants reported for high impact or further investigation using the regular SOP procedure were successfully identified in candidate lists generated by the AI pipeline, barring one unsolved case, where a monoallelic nonsense variant in an AR gene was missed. The number of variants identified for review per case was significantly reduced when incorporating the AI pipeline as compared to regular pipeline (Mean 79%, range 59%-94%). Median analysis time was reduced by more than 47% per case for genomic specialists. Interestingly, the time saving effect looks to be more significant for less experienced genomic specialists. **Conclusions** Using novel AI technologies, genomic analysis was completed in a time efficient and evidence-based manner. Genomic specialists now can work more efficiently as a result of having a "virtual geneticist" at their side, performing a preliminary assessment of sequencing data and identifying suspicious variants. Moreover, the use of AI solutions provided a higher consistency in results between different team members. AI solutions could be an integral part of genomic diagnosis and are expected to enable full automatic interpretation and re-analysis of cases for the future era of precision medicine and mass population sequencing.

**1415F**

**A novel machine learning algorithm for variant prioritization using genotype, phenotype and tissue-specific expression data.** *L. Lange<sup>1,2</sup>, A.T. Pagnamenta<sup>1,2</sup>, D. Sims<sup>3</sup>, J.C. Taylor<sup>1,2</sup>, Health Innovation Challenge Fund 2 (HICF2) Project Team 1, 2.* 1) National Institute for Health Research Biomedical Research Centre; 2) Wellcome Trust Centre for Human Genetics (WTCHG), University of Oxford, Oxford OX3 7BN, UK; 3) MRC Weatherall Institute of Molecular Medicine Centre for Computational Biology, John Radcliffe Hospital, University of Oxford, Oxford OX3 9DS, UK.

**Background:** Variant prioritization algorithms (VPA) are a widely used approach for clinical whole genome sequencing (WGS) analysis from rare disease (RD) patient samples. Existing algorithms combine genomic data and phenotypic terms in the Human Phenotype Ontology (HPO) format to rank variants. We developed a novel machine learning VPA that also leverages expression data for tissues assumed to be affected based on the patient's HPO profile. **Methods:** A dataset (N=50,514), consisting of 30% disease-causing variants from OMIM and 70% likely benign variants from the 1,000 Genomes project was used for training. Variants were annotated with Exomiser's pathogenicity and phenotype scores. HPO terms for each variant were used to create binary labels (BLs) for 25 GTEx tissues, capturing if a tissue was likely affected or unaffected by the phenotype. Cross-tissue and cross-gene scores, indicating relative gene expression across tissues and within tissues, were generated for each gene using GTEx data. To test if BLs improved performance, we trained a logistic regression classifier on the dataset, with and without binary vectors. Further, we trained the classifier on the entire dataset, benchmarking against Exomiser. We compared our algorithm's performance with Exomiser's on four RD patient cases from our WGS cohort. Strong candidate variants in novel genes, identified manually by human disease experts, were used as benchmarks. **Results:** With an accuracy of 0.84, BLs significantly improved the expression-based signal (accuracy = 0.70). Combining BLs, expression data and Exomiser scores, our algorithm outperformed Exomiser (accuracies of 0.96 and 0.91). Both algorithms ranked two out of four RD case benchmark variants in the top 10. Exomiser performed better for candidate genes that were novel for the patients' phenotype, but had previously been annotated with HPO terms. Our algorithm improved performance for candidate genes that had not been associated with disease phenotypes. **Conclusions:** Our results suggest that the HPO implicitly contains valuable information on tissue-specific expression of disease-related genes. Combining BLs with genomic and phenotypic data can improve VPA accuracy. Importantly, our algorithm performs well for novel genes with no known phenotypic annotations, demonstrating a powerful additional use of the HPO. Efforts are underway to apply our algorithm to more RD cases. Our pipeline will be made available on GitHub.

**1416W**

**A statistically-based, heuristic for allele-specific, position-based error modeling of Illumina next-generation sequencing data for rare mosaic variant calling in unmatched samples.** *J.N. Dudley, J.J. Johnston, L.G. Biesecker.* Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD.

Mosaic variant calling for single-gene somatic disorders (e.g., Proteus and PROS) is a fundamentally different problem than in cancer. In these disorders, clinical limitations in sampling and tissue heterogeneity can result in a wide range of variant allele fractions (VAF), from <0.1 to 50%, that are clinically relevant to diagnosis. In cancer, VAF detection of <10% is generally not relevant or useful. Most mosaic callers are designed for the cancer application and are therefore not sensitive or useful for VAF <10%. Next-generation sequencing (NGS) platforms are prone to misincorporations as the main source of error due to sequence context and motifs, including non-random errors. Thus, differentiating low level biological VAF from NGS error is critical. This requires evaluating the non-reference base calls not only within their sequence context, as related to their genomic position, but also the identities of the variant and reference alleles and their presence in a control genome and/or population. In this work, we provide clarity to this problem by using an allele-specific, position-based modeling approach for assessing VAF. To build our model, exome sequencing (ES) data from 1,017 patients in the ClinSeq® cohort was used to obtain total depth and total allele counts at every targeted position in a mosaic overgrowth gene panel. The depth and allele-specific VAF count of candidate test variants were then screened against the modeled position using a Fisher's Exact Test followed by multiple test correction. This approach addresses multiple concerns in regard to NGS analysis of rare somatic mosaic variation. First, low frequency variants are distinguished from background variation from sequencing. Second, variants that are common in the model population are filtered out. And finally, it eliminates the need to run matched normal samples that are required for many somatic variant callers. Using this approach to probe the most common causative variants in PROS with data produced by a MiSeq we identified low level variants with a positive predictive value greater than 60%. We found that at a depth of 1500, which is typical using standard flow cells with v2 chemistry, our limit of detection ranged from 0.5 to 0.7%.

**Short tandem repeat expansions in undiagnosed rare genetic disease cases.** P.A. Richmond<sup>1,2,3</sup>, B.I. Drögemöller<sup>1,3</sup>, I.S. Rajan-Babu<sup>1,3,7</sup>, M. Tarai-lo-Graovac<sup>4,5</sup>, A.B.P. van Kuilenburg<sup>6</sup>, C.J. Ross<sup>1,3</sup>, C.D. van Karnebeek<sup>2,6</sup>, W.W. Wasserman<sup>1,2,3</sup>. 1) BC Children's Hospital Research Institute, Vancouver, BC, Canada; 2) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, BC, Canada; 3) Departments of Pharmaceutical Sciences, Paediatrics, and Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 4) Alberta Children's Hospital Research Institute, University of Calgary, Calgary, AB, Canada; 5) Departments of Biochemistry, Molecular Biology and Medical Genetics, Cumming School of Medicine, University of Calgary, Calgary, AB, Canada; 6) Departments of Clinical Chemistry, Pediatrics and Clinical Genetics; Laboratory Genetic Metabolic Diseases, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands; 7) BC Children's & Women's Hospital, Vancouver, BC, Canada.

Exome sequencing has been used to diagnose rare genetic diseases for the past few years by identifying genomic variants, single nucleotide variants (SNVs) as well as short insertions and deletions (indels), over exonic regions. While it is a powerful tool, current diagnosis rates of 25-45% lead to speculation that variants beyond the exome are responsible for undiagnosed disease cases. An alternative, PCR-free whole genome sequencing (WGS), is now being used in place of exome sequencing in some clinical research endeavours. WGS offers the distinct advantage of being able to identify variation beyond the exome, and can additionally detect other forms of genomic variation including microsatellite repeats, copy number variants, and complex structural variants. Short tandem repeats (STRs) have been implicated in genetic diseases, involving both expansion and contraction of repeat numbers. These repeats, herein defined as having unit lengths of 1-6bp, impact genes via both protein-coding and regulatory mechanisms. Trinucleotide STR loci have been implicated prominently in genetic disease, including coding expansions within *HTT* leading to Huntington's Disease, and 5' untranslated region expansions causing repression of *FMR1* in Fragile X Syndrome. Across the human genome are many potentially functional repeats that may contribute to disease risk. We investigated the potential for STRs to explain undiagnosed rare genetic disease cases. To do so, we first identified and annotated STRs throughout the genome, and tailored a bioinformatic pipeline that uses the ExpansionHunter tool to detect them from patient WGS data. Running this pipeline on 300 WGS samples allowed us to construct an in-house database to better establish the frequency of variation in the repeats for the experimental population. Next, we applied the informatics pipeline to undiagnosed cases of rare genetic disease WGS, including cases with extensive phenotypic data (gene expression and metabolite profiles) and strong candidate genes. This led to diagnosis of two cases with a STR expansion in the 5' UTR of a novel disease gene, which were further confirmed by triplet-primed PCR. As we continue to apply our pipeline to undiagnosed cases, we may identify new candidate STR expansions within genes that explain disease phenotypes. The bioinformatics pipeline is available on GitHub to enable the community to explore how genotyping STRs from WGS data can aid in the diagnosis of rare genetic diseases. .

**Vegetarian diet-modulated epigenetic clock and longevity.** X. Chen<sup>1</sup>, W. Chen<sup>1</sup>, K. Jaceldo-Siegl<sup>2</sup>, V. Filippov<sup>2</sup>, P. Duerksen-Hughes<sup>3</sup>, C. Wang<sup>1</sup>. 1) Center for Genomics, Loma Linda University, Loma Linda, CA; 2) Center for Nutrition, Loma Linda University, Loma Linda, CA; 3) Basic Sciences, Loma Linda University, Loma Linda, CA.

Diet importantly impacts health, disease resistance, and longevity, but the molecular mechanisms mediating the effects of diet are poorly understood. The major reason for this profound knowledge gap is that we don't yet have a comprehensive understanding of how diet influences specific epigenomes. To address this knowledge gap, we exploit a powerful, well-characterized, long-standing cohort that has already made many significant advances: the Adventist Health Study 2 (AHS2), which constitutes a multi-ethnic group of participants whose detailed diets are known. Our CENTRAL MODEL is that long-term dietary patterns cause epigenomic reprogramming in ways that alter disease susceptibility, maintenance of health, and longevity. We performed DNA methylome studies using Illumina 450K BeadChips, TruSeq Epic next-gen sequencing (NGS) technologies and the frozen human white blood cells derived DNA from AHS2 participants consisting of three different groups: vegan, pescetarian and non-vegetarians. Age, gender, race, BMI, exercise, drinking and smoking status were balanced in each group. We determine the impact of dietary factors on both Horvath and Hannum epigenetic clocks, which are algorithms that use DNA methylation patterns to estimate biological age of specific cells and tissues. We also developed a new epigenetic clock, which, unlike Horvath and Hannum epigenetic clocks that only work for the array-based data, can measure the DNA methylation age using both array and NGS data. Our epigenetic clock shows consistent better prediction of biological age and performance metrics than Horvath and Hannum clocks using many benchmark samples. Overall, our results show that a lifetime vegetarian diet can reprogram the epigenomes, which contributes approximately 5 extra years of lifespan compared to non-vegetarians based on our AHS2 cohort. Our pilot DNA methylome study support our HYPOTHESIS that maintaining a specific diet causes epigenomic reprogramming leading to programming of health and longevity in humans.

**Background:** Genomic prediction of disease risk factors might be helpful since genome-wide genotyping costs are lower than many clinical tests. We tested whether machine learning (ML) methods could provide clinically-relevant prediction of a highly-heritable trait, quantitative ultrasound measurement of bone speed of sound (SOS)—a risk factor for osteoporotic fracture. **Methods:** We used 298,768 individuals from UK Biobank with SOS measures at the calcaneus and genome-wide genotypes in lasso-regularized regression models to genomically predict SOS (gSOS), followed by model selection and model testing in 42,682 and 85,362 separate individuals also from UK Biobank, respectively. We then tested if gSOS predicted incident major osteoporotic fractures derived from questionnaire and ICD10 coding and whether genomic pre-screening could complement FRAX, a widely used osteoporotic fracture risk prediction tool. **Results:** Age, sex and body mass index explained 4.2% of variance in SOS. gSOS was correlated with measured SOS ( $r = 0.49$ ,  $P < 10^{-100}$ ) and explained 25% of its variance. gSOS was uncorrelated with clinical risk factors included in FRAX. In the test dataset, after adjusting for FRAX clinical risk factors (other than family history of hip fracture, which was not available), the association between gSOS and incident major osteoporotic fractures (2,030 fracture cases/83,332 controls, odds ratio = 1.33 [1.27-1.39]) was of slightly lower magnitude than for measured SOS (OR = 1.49 [1.41 – 1.57]). Individuals in the bottom 2.5% of gSOS had a 4-fold increase in the odds of fracture compared to the top 2.5%. A model combining gSOS with calculated FRAX score (without bone mineral density), yielded improved outcome discrimination compared with FRAX alone (area under the receiver operator curve = 0.65 [0.64-0.66] vs 0.63 [0.62-0.64] respectively) and improved the sensitivity 1.6-fold. Last, introducing a gSOS pre-screening step into the UK National Osteoporosis Guideline Group screening algorithm resulted in a reduction in the number of people requiring screening by 70% and the number of people requiring BMD testing by 50%, while only reducing the sensitivity of current guidelines to identify individuals eligible for therapy from 99% to 95%. **Summary:** ML-based genomic prediction of SOS resulted in a clinically-relevant prediction of fracture. This information could increase the efficiency of screening programs for osteoporotic fracture prevention.

**Exonic variants in aging-related genes are predictive of biological aging status.** M.E. Breitbart<sup>1,2</sup>, S. Greenspan<sup>3</sup>, N.M. Resnick<sup>3,4</sup>, S. Perera<sup>3,5</sup>, A.U. Gurkar<sup>3</sup>, D. Absher, A.S. Levine<sup>6,7</sup>. 1) HudsonAlpha Institute for Biotechnology; 601 Genome Way, Huntsville, AL 35806; 2) University of Alabama in Huntsville; 301 Sparkman Drive, Huntsville, AL 35899; 3) Division of Geriatric Medicine, Department of Medicine, University of Pittsburgh School of Medicine; ; 3471 Fifth Avenue, Kaufmann Medical Building Suite 500, Pittsburgh, PA 15213; 4) Aging Institute of UPMC; 3600 Forbes Avenue at Meyran Forbes Tower Suite 10065 Pittsburgh, PA 15213; 5) Department of Biostatistics, University of Pittsburgh Graduate School of Public Health; 130 DeSoto Street, Pittsburgh, PA 15213; 6) Department of Microbiology and Molecular Genetics, University of Pittsburgh School of Medicine, 450 Technology Drive, Pittsburgh, PA 15219; 7) UPMC Hillman Cancer Center; 5117 Centre Avenue, Pittsburgh, PA 15213.

Recent studies investigating longevity have revealed very few convincing genetic associations with increased lifespan. This is, in part, due to the complexity of biological aging as well as the limited power of genome-wide association studies, which assay common single nucleotide polymorphisms (SNPs) and require several thousand subjects to achieve statistical significance. To overcome such barriers, we performed comprehensive DNA sequencing of a panel of 20 genes previously associated with aging, in a cohort of 200 individuals, half of whom were clinically defined by accelerated aging phenotypes (“early agers”), and half of whom were defined by reduced aging phenotypes (“late agers”). A validation cohort of 511 “late” agers was used to verify our results. We found early agers were not enriched for more total variants in these 20 genes than late agers. To identify variants or genes predictive of “late” aging, both logistic regression analysis and random forest-based machine learning were performed on the genetic variants identified across the 20 aging-associated genes. A variety of models were tested, and we found the most predictive model incorporated damaging exon variants (CADD > 15). Furthermore, the most heavily weighted variants were within genes involved in repair of DNA damage and maintenance of genomic stability. Overall, this study implemented a framework to apply machine learning to identify sequencing variants associated with aging and improves our understanding of how genetic variation contributes to the aging process.

**Predicting splicing from primary sequence with deep learning.** *K. Jagathan<sup>1</sup>, S. Kyriazopoulou Panagiotopoulou<sup>1</sup>, J.F. McRae<sup>1</sup>, D. Knowles<sup>2</sup>, Y. Li<sup>2</sup>, W. Cui<sup>2</sup>, J. Hakenberg<sup>2</sup>, S. Batzoglu<sup>2</sup>, K. Farh<sup>2</sup>.* 1) Illumina Inc, San Diego, CA; 2) Stanford University, Stanford, CA.

At present, only 25-30% of rare disease patients receive a molecular diagnosis from examination of protein-coding sequence, suggesting that the remaining diagnostic yield may reside in the noncoding regions of the genome. Noncoding mutations that disrupt the normal pattern of pre-mRNA splicing despite lying outside the essential AG or GT splice dinucleotides, also known as cryptic splice variants, are recognized to play an important role in rare genetic diseases, but have been difficult to identify since the genomic space where they may occur is very large. To facilitate the interpretation of these variants, we developed a novel deep learning network that accurately predicts splice junctions from arbitrary pre-mRNA transcript sequence. Examination of the specificity determinants of our model reveals that it recapitulates well-studied mechanisms that confer spliceosome specificity, such as the interplay between motif strength, exon/intron lengths, and nucleosome positioning. Predicted cryptic splice variants validate on RNA-seq at nearly the same rate as essential splice disruptions, demonstrating that most of these predictions are functional. Using data from the ExAC and gnomAD cohorts, we show that synonymous and intronic variants with predicted splice-altering effects are negatively selected at a rate similar to stop-gain and frameshift variants, indicating that they are strongly deleterious. We estimate that each person carries an average of ~6 rare functional cryptic splice variants with less than 0.1% allele frequency, compared to ~9 rare protein-truncating variants, and that cryptic splice variants outnumber essential AG/GT splice disruptions roughly 3:1. These results point to a significant role of cryptic splice variation in human disease and show that our model is a powerful tool towards interpretation of the noncoding genome.

**Bioinformatic analysis of TE-fusion internal exons and nonsense-mediated mRNA decay within human genome.** *KH. Park.* Department of Core Facility Management Center, Korea Research Institute of Bios, Daejeon, South Korea.

To better understand the mechanism of genetic diversity and control of gene expression, we conducted a large scale analysis of reliable exonization of transposable elements (TE) in non-protein coding regions of the human genes. To study the connection between the TE-fusion internal exons and nonsense mediated mRNA decay, we used the publicly available mRNA and EST to genome alignment data from the UCSC genome browser. In this study, we systematically identified TE which can lead NMD from TE-fusion internal exons. With this procedure, we identified NMD putative 519 transcripts that are derived from 321 known genes. The result shows that TEs can make premature termination codon (PTC) to nonsense-mediated decay (NMD) when they are analyzed with human expressed sequence tag and mRNA sequences dataset. In 519 cases (26.8%) of 1931 TE-fusion internal exons that are located within the protein coding region, the insertion of a TE-fusion internal exon results in a shortened protein, through an in frame stop codon within the TE-fusion internal exon itself. The vast majority of the TE-fusion internal exons that appeared within the coding region of mRNA caused a premature termination codon or a frame shift. We believe this discovery can provide biologists insight into a function of TEs as sources of nonsense-mediated decay, which are able to affect phenotypes including diseases. We suggest that TE to NMD process is a mechanism contributing to the evolution of gene regulation in human genome as well as having implications to diseases.

**Conditional generating adversarial networks for synthetic MRI brain images, semantic segmentation and annotation.** Q. Ge<sup>1,2</sup>, W. Lin<sup>1</sup>, M. Xiong<sup>2</sup>, Y. Liu<sup>2</sup>, R. Jiao<sup>2</sup>, W. Pen<sup>2</sup>, Z. Li<sup>2</sup>. 1) School of Mathematical Sciences, Fudan University, Shanghai, CHINA; 2) Department of Biostatistics, The University of Texas School of Public Health, Houston, TX.

Deep learning has been successfully applied to image analysis by using large-scale annotated image datasets. However, obtaining a large number of medical images poses a great challenge. To meet the challenge facing us, we propose to use conditional generative adversarial networks for generating a large number of realistic, synthetic medical images with high quality. The synthesized images can be tuned by adjusting discrete and continuous phenotypes such as sex, blood pressure and cognitive scores. Further analysis for these synthetic brain images has been conducted. Since semantic segmentations of medical images can be considered a kind of image mapping, an image-to-image generative adversarial network is used to create semantic segmentation maps on images. The proposed methods were applied to ADNI dataset with MRI images. The results were very encouraging.

**1424F**

**Challenges in calling CNVs from low read-depth genome sequencing data for products of conception.** J.W. Ahn<sup>1</sup>, B. Wild<sup>1</sup>, C. Donaghue<sup>2</sup>, D.T. Bonthron<sup>2</sup>, C.M. Watson<sup>2</sup>, K. Mann<sup>3</sup>. 1) Genetics Laboratories, Guy's Hospital, London, UK; 2) MRC Medical Bioinformatics Centre, Leeds Institute for Data Analytics, University of Leeds, Leeds, UK; 3) Genetics Laboratories, Viapath, London, UK.

Products of conception (POC) and fetal tissue (FT) samples are routinely tested for CNV to investigate the cause of fetal abnormality and/or demise in order to inform future recurrence risk. Our laboratory currently provides a CNV detection service (1Mb resolution) for POC using cytogenomic microarrays (CMA). However, it is not always possible to reach this resolution due to the poor quality of DNA in these samples. Low read-depth genome sequencing (GS) has been demonstrated to detect CNV and has been proposed as a cost-effective, resilient alternative to CMA. We therefore assessed the performance of this technology in comparison to the current standard of care by sequencing samples with known CNVs. Samples were sequenced to an average read depth of 5X (2 x 100bp) and aligned to genome build hs37d5. The resulting BAM files were then processed with a number of CNV callers to evaluate performance. These included Canvas, Lumpy, Manta, Breakseq2, Breakdancer, Delly, and CNVnator. We also investigated a CNV caller developed by the Leeds MRC Medical Bioinformatics Centre. Overall, low read-depth GS performed similarly to CMA for CNVs >0.5Mb, however, issues surrounding mapping repetitive regions and breakpoint accuracy need to be resolved. We plan to test a refined pipeline on POC/FT samples with known CNVs to further develop this method. Our aim is to demonstrate whether the advantages of low read-depth GS for CNV detection offer an improved, low-cost service in comparison to CMA.

**1425W**

**Rapid and reproducible data processing with CWL, Toil and the Sentieon Tools.** R. Aldana, D.N. Freed, X. Liu, Z. Li, L. Chen. Sentieon Inc., Mountain View, CA.

Rapid whole-genome sequencing is essential in certain clinical contexts such as infectious disease and neonatal care, where rapid WGS has been shown to decrease infant morbidity in certain patient populations. Distributed data processing pipelines have the ability to shorten analysis times, but these can be complex to implement and maintain. Recently, several workflow tools and languages have been developed to improve the reproducibility and portability of scientific data processing pipelines, including the Common Workflow Language (CWL), the Workflow Description Language (WDL), Nextflow and Snakemake. In this work, we implement Sentieon's distributed DNaseq pipeline for rapid analysis of NGS data using Common Workflow Language and demonstrate the performance of our implementation on the Google Cloud Platform with the Toil workflow engine. Our pipeline is capable of processing a standard 30x Illumina WGS sample in 2.5 hours on a single 64-core machine, while distributed processing on ten machines can reduce the turn-around time to under 30 minutes. Our CWL pipelines are open-source and are available from <https://github.com/Sentieon/Sentieon-cwl>.

**1426T**

**Findings from the Critical Assessment of Genome Interpretation, a community experiment to evaluate phenotype prediction.** G. Andreatti<sup>1</sup>, R.A. Hoskins<sup>1</sup>, J. Moulton<sup>2,3</sup>, S.E. Brenner<sup>1</sup>, CAGI Participants. 1) University of California, Berkeley, CA 94720, USA; 2) Institute for Bioscience and Biotechnology Research, University of Maryland, 9600 Gudelsky Drive, Rockville, MD 20850; 3) Department of Cell Biology and Molecular Genetics, University of Maryland, College Park, MD 20742.

Interpretation of genetic variants plays an essential role in the analysis of cancer and monogenic disease, and increasingly also of complex trait disease, with applications ranging from basic research to clinical decisions. The field has lacked a clear consensus on the effectiveness of current methods for these different uses. The Critical Assessment of Genome Interpretation (CAGI, 'kǎ-jē) is a community experiment to objectively assess computational methods for predicting the phenotypic impacts of genomic variation. CAGI participants are provided genetic variants and make blind predictions of resulting phenotype. Independent assessors evaluate the predictions by comparing with experimental and clinical data. CAGI has completed four rounds of challenges with the goals of establishing the state of art in genome interpretation and of encouraging new methodological developments, with the last round having a special issue of *Human Mutation*. Predictions for the fifth round of CAGI, comprised of 14 challenges, have been submitted. Challenges for CAGI5 include nonsynonymous protein variants with activity, growth, stability, and phenotypic assays; cancer protein variants with integrative assays and case-control studies; variants impacting expression and splicing, and their molecular impact; complex disease exomes; clinical panel and genomes with associated diseases. Assessment for CAGI5 is underway and will be completed in July 2018. There have been notable discoveries throughout the CAGI experiments. Independent assessment has found that top missense prediction methods are highly statistically significant, but individual variant accuracy is limited. Missense methods tend to correlate better with each other than with experiment. Bespoke approaches often enhance performance. Interpretation of non-coding variants shows promise but is not at the level of missense. In challenges using clinical data predictors identified causal variants overlooked in the initial clinical pipeline analysis. CAGI results are increasingly used to inform clinical use of computational tools, including the ClinGen working group comments on the ACMG guidelines for appropriately considering evidence from computational approaches. For example, CAGI results suggest that running multiple uncalibrated methods and considering their consensus may result in undue confidence in a pathogenic assignment. Detailed information about CAGI may be found at <https://genomeinterpretation.org>.

**1427F****Not by systems alone: Identifying functional outliers in rare disease**

**pedigrees.** S. Ballouz, M. Doerfel, J. Crain, M. Crow, G.J. Lyon, J. Gillis. Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

Studies of rare disease cohorts are inherently small and low-powered. Thus, for differential expression analyses it is common to take a “systems” approach to identify functional signals in aggregate through gene set or pathway enrichment. However, in some instances, the identified functions are not specific to the disease (e.g., protein binding) or are confounded with a biological signal stronger than the disease (e.g., population variation). What, then, is the true disease signal, and how does one look for it? Our focus is on a rare disease cohort, the *TAF1* syndrome, where we evaluate systems approaches by testing replicability across six pedigrees. The probands each have a unique variant in their *TAF1* transcription factor and share phenotypic attributes including intellectual disability, facial dysmorphism, general hypotonia, an unusual gluteal crease and cardiovascular structural defects. To assess systems-based analysis within small cohorts, we sequenced the blood transcriptomes of all family members of the six pedigrees, then analyzed each pedigree individually. We tested the validity of the family-specific results by looking for recurrence across the cohort. To evaluate the differentially expressed genes we used both standard gene set enrichment methods and a novel meta-analytic co-expression assessment that exploits thousands of publicly available expression datasets to detect outlier events. Using the standard systems approach we find that differentially expressed gene sets are highly disjoint between pedigrees and that enrichment signals are mostly unique, with recurrent enrichment occurring only in large and non-specific gene sets. In contrast, with our outlier analysis we find recurrence of two genes, *CACNA1I* and *IGFBP3*, that are both downregulated in 5 out of the 6 pedigrees. We call these “functional outliers” as they appear to be uniquely dysregulated in the cohort, specifically acting inconsistently with respect to the primary systems-signal within the data, and therefore missed by standard systems analysis. Our outlier analysis revealed otherwise difficult-to-observe signals in the case of the *TAF1* syndrome cohort. We anticipate that future transcriptomic studies of rare disorders would benefit from the application of this approach.

**1428W****Timely detection and bioinformatic mitigation of rapid whole genome**

**sequencing genome-wide biases in a clinical lab setting.** S. Batalov, S. Chowdhury, Y. Ding, S. Kingsmore, N. Veeraraghavan, *RCIGM Investigators*. Rady Children’s Institute for Genomic Medicine (RCIGM), San Diego CA.

The speed, accuracy and lowering costs of whole-genome sequencing (WGS) can change the acute care of infants in the intensive care units (ICU). In a clinical setting, it is imperative to establish a robust and scalable system for quality control (QC) of every patient’s genome through all steps of the high volume rapid sequencing lab and *in silico* workflows, and emphasis on rapid QC metrics that can quickly identify potential processing issues in real-time is essential. We present a fast and sensitive workflow called **CoNvince**, to identify problematic genomic libraries that may contain GC-biases that could impact downstream small and large variant calling. **Methods:** WGS was performed via Illumina SBS chemistry and alignment and variant calling performed via EdicoGenomics DRAGEN. Copy number variation (CNV) calling was performed via a combination of the CNVnator and Manta callers with population frequency filtering. A BAM file is an input to the **CoNvince** software that identifies genome coverage biases in a few hundred representative genomic regions for each nucleotide compositional class. Typical robust PCR-free libraries have a small negative, positive or essentially no GC compositional bias (within +/-25%). However, libraries with larger bias can produce an abundance of false positive CNV calls. This contrast was exploited as a signal for library quality. **Results:** Retrospective analysis revealed that 1.5-2% of the 1400+ sequenced samples were identified as having high GC-content biases. These samples all resulted in a higher number of CNV calls that correlated with the degree of GC bias. Only DNA library re-preparation and sequencing resolved the issue, while re-sequencing the existing libraries did not. We have developed a CNV workflow (**CoNvince**) which resamples the aligned reads to counter the identified compositional biases systemically in conjunction with using such tools as CNVnator/CNVkit and others. This framework serves to inform sequencing quality as well as reduce false positives in CNV calls from affected samples. **Conclusions:** The ability to implement rapid and reliable QC metrics in the rapid WGS process is essential as hours can make the difference in the impact a genetic diagnosis may have in the management of the patient. With the significance that CNVs play in the genetic disease burden in the intensive care unit, this quality control step can help rapidly identify samples that require additional laboratory processing.

**1429T****Re-computing NGS read depth statistics to standardize coverage metrics when using disparate variant call outputs for clinical genomics applications.**

*A. Bhattacharya, A. Gerasimova, Q. Nguyen, C. Elzinga, E. Moler.* 1) Quest Diagnostics Inc, 33608 Ortega Hwy, San Juan Capistrano, CA 92675; 2) Quest Diagnostics Inc, 200 Forest St, Marlborough, MA 01752.

Next-generation sequencing (NGS) produces large quantities of sequencing data of variable quality. One of the requirements of clinically validated NGS pipelines is accuracy of computed coverage depth and variant frequency with specified minimum base quality. Because different tools have different strengths, multiple variant callers can be used to improve accuracy of variant calling. However, the associated read counts for reference and alternative alleles will often differ depending on the approach used. These differences can be dramatic in particular sequence contexts, such as repetitive regions. Here we present a user-friendly Python tool that can use BAM and VCF input files and a user-provided PHRED scaled quality score cutoff to calculate the reference and alternative allele counts for SNPs, INDELS, and structural variants. The tool provides separate per-strand counts to facilitate measuring strand bias, and works in the context of multiallelic sites if present. The tool can also be used at a regional level, performing coverage analysis using BAM sequence and BED region definitions files. In this case, it provides the minimum, maximum, and mean depths for each region, and also provides details of each nucleotide count, and insertion and deletion counts, for every base in each BED region. Re-computing NGS read depth using this tool allowed separation of clinically relevant variants from common variants with a high level of accuracy, including successfully separating myeloid neoplasm-associated mutations from common variants in 47 genes.

**1430F****The newborn screening translational research network: Advancing the understanding of genetic disease in newborns and children using a shared infrastructure of genomic and phenotypic information.** *A.M. Brower, J.A. Adelberg, D.E. Ekoma, M.S. Watson.* American College of Medical Genetics and Genomics, Bethesda, MD.

Since its inception over half a century ago, state-based newborn screening (NBS) programs annually screen 4 million newborns for genetic conditions that require immediate treatment to prevent morbidity and mortality. Research that capitalizes on the NBS system offers an opportunity to improve understanding of genetic disorders in newborns and children, develop novel technologies, and study the effectiveness of new treatments. Researchers have begun to explore the use of genomics in NBS, and state-based NBS programs have begun screening for disorders that have a large amount of genetic heterogeneity, including onset of symptoms in childhood or beyond. Natural history studies that capture longitudinal information on cases resulting from this expanded NBS will establish the clinical validity and clinical utility of identified disorders, and pilots of novel NBS technologies will provide analytical validation. Because the majority of the conditions that are part of, or candidates for, newborn screening in the United States are rare or very rare, a shared informatics system is critical. The ideal system will support the collection, analysis and sharing of genomic and phenotypic data from the basic research designed to advance understanding of the disease process, to translational research to develop technologies to screen and therapies to treat, to public health implementation of a comprehensive newborn screening program to identify newborns at risk. To support these efforts, the National Institute of Health *Eunice Kennedy Shriver* National Institute of Child Health and Human Development (NICHD) Hunter Kelly Newborn Screening Research Program created the Newborn Screening Translational Research Network (NBSTRN). The American College of Medical Genetics and Genomics (ACMG) operates the NBSTRN Coordinating Center (NBSTRN-CC) that is working to develop and implement a suite of tools to efforts to translate basic research discoveries to the state-based newborn screening programs. We report on the use of standardized vocabularies, interactive computer systems, and robust security measures used by over 100 researchers across 8 studies are utilizing genomic and phenotypic data. Data from 1900 participants with over 1 million data points have been collected. The use of the LPDR by researchers will create unique cohorts of individuals with genetic disease and accelerate understanding of these conditions. .

**1431W**

**A bioinformatics framework for identification of mishandled samples in clinical NGS based tests.** K. Cao<sup>1</sup>, P. Jayaraman<sup>1</sup>, M. Gonzalez<sup>1</sup>, F. Lin<sup>1</sup>, Z. Yu<sup>1</sup>, S. Baker<sup>2</sup>, C. W<sup>1</sup>, M. Li<sup>1,2</sup>, M. Sarmady<sup>1,2</sup>. 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Philadelphia, PA.

Next-generation sequencing (NGS) workflow in the clinical laboratory is very complex and involves multiple manual steps. It is therefore, susceptible to contamination and human errors including sample mislabeling, swapping or DNA/RNA mix-ups. Misdiagnosis as a result of such incidents can lead to serious medical consequences. We have developed a bioinformatics framework to detect the above incidents. Each one method in the framework can be applied independently to either target panel or whole-exome based tests. Given the high sensitivity of NGS assays, DNA of the sample mixed with others could result in false mosaicism and/or somatic changes and ultimately false positive calls and potentially missing true positive calls. We applied the tool *VerifyBamID* on whole-exome bam files with predetermined DNA mixture levels ranging from 0.5-5%. We assessed the correlation of contamination level between computational prediction and *in-silico* mixture. We then identified the acceptable contamination level that has least impact on variant genotyping as the QC threshold in our NGS bioinformatics pipeline. Prediction on gender not only helps define hemizyosity of variants found in sex chromosome but also can quickly identify whether the sample is mislabeled or swapped when it shows opposite gender to the patient's chart. We developed an algorithm to predict the gender using selected variants presented in non-pseudoautosomal regions of *ChrX* using whole-exome data. We determined the Het/(Hom+Het) ratio in females and males using a cohort of samples with known gender. We then predicted the sample's gender by comparing the het ratio in the sample to predetermined thresholds for male and female. Sample identity confirmation is urged for all NGS tests in clinical laboratories. We determined the sample identity by cross-matching the calculated genotypes of sixteen preselected fingerprint SNPs to the results generated by TaqMan assay using second DNA extraction on the same sample. Specifically, for cancer genetic tests using both targeted panel and fusion panel, we cross-matched genotypes of a set of comparable fingerprint snps in DNA and RNA NGS data to confirm the sample identity. In summary, we proposed a framework that enables early detection of mishandled samples in NGS-based diagnostic tests in clinical laboratories before they enter downstream interpretation, and therefore minimizes the possibility of misdiagnoses due to sample miss-processing.

**HLA-Helper: HLA sequence conversion and association analysis toolkit.** W. Choi<sup>1</sup>, Y. Luo<sup>2</sup>, S. Raychaudhuri<sup>2</sup>, B. Han<sup>1</sup>. 1) Department of Medicine, Seoul National University College of Medicine, Korea, Seoul, South Korea; 2) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, USA.

Human Leukocyte Antigen (HLA) genes encode the Major Histocompatibility Complex (MHC) protein, which controls human immune responses and affects susceptibility of various diseases. In an association analysis to fine-map which allele or amino acid position is driving the disease, researchers use HLA typing technologies to genotype HLA or computational approaches to impute HLA from intergenic SNPs. Each high-resolution HLA allele represents a specific DNA or amino acid sequence. Thus, given typed or imputed alleles, the alleles must be converted to sequence information to be used in association analysis of the exonic SNPs and amino acids. Here we introduce a new software package HLA-Helper that helps to process HLA sequence information from typed or imputed HLA information. The package accepts HLA input information in a wide spectrum of formats ranging from imputation technologies (SNP2HLA, HIBAG, HLA\*IMP) and typing technologies (Serological low-resolution typing, 2-field high-resolution typing, and 3- or 4- field sequence-based typing), and undertakes the converting job to generate output in binary markers which can be used in various statistical tests. Researchers can choose either the latest version or a specific previous version of IMGT/HLA database for the sequence information. The package also includes the basic association analysis tools for the univariate, multivariate, and conditional association tests and the plot generation tools for the Manhattan plot, amino acid plot, and association heatmap plot.

**Hi-Lite, generalized linear model based similarity measurement for Hi-C samples.** C. Crowley<sup>1</sup>, Y. Yang<sup>2</sup>, M. Hu<sup>3</sup>, Y. Li<sup>2,2</sup>. 1) Biostatistics, University of North Carolina Chapel Hill, Chapel Hill, NC; 2) Genetics, University of North Carolina Chapel Hill, Chapel Hill, NC; 3) Quantitative Health Sciences, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH.

Genome-wide three-dimensional (3D) organization of DNA chromatin can directly influence their genomic function. Chromatin conformation capture (3C) and derived technologies, such as Hi-C, provide a genome-wide view of chromosome spatial organization (i.e., interactome). Hi-C data, in the raw form, is usually presented in the form of a contact frequency matrix where the read counts (constituting the matrix elements) contain various sources of uncertainties, biases, and noises. It is therefore challenging to quantify the similarity of the interactome between two different Hi-C experiments, which can be two replicates of the same sample, samples from two different time points, or two different tissues or cell lines. To address this challenge, we present a generalized linear model (GLM) based approach, named as Hi-Lite, to measure the interactomic similarity between different Hi-C samples. We have re-analyzed our most recent published compendium of interactome datasets. Our results suggest that Hi-Lite provides more biologically relevant clustering results compared to other similarity (or dissimilarity) metrics, including Euclidian (i.e., L2) distance, L1 distance, Pearson correlation, and Spearman correlation.

**Accessing and extracting informations from binary sequence alignment/map (bam file) in a non-unix environment with python 3.6+.** J.G. Damasceno<sup>1</sup>, F.F. Gouveia Filho<sup>2</sup>, G.M. Novo Filho<sup>1</sup>, A.T. Dias<sup>1</sup>, A.M. Nascimento<sup>1</sup>, E.A. Zanardo<sup>1</sup>, F.A.R. Madia<sup>1</sup>, O.S. Akl<sup>1</sup>, M.M. Montenegro<sup>1</sup>, Y.G. Oliveira<sup>1</sup>, L.D. Kulikowski<sup>1</sup>. 1) Laboratório de Citogenômica LIM 03, Departamento de Patologia, Faculdade de Medicina da Universidade de São Paulo, São Paulo, SP, Brazil; 2) Núcleo de Tecnologias Estratégicas em Saúde, Universidade Estadual da Paraíba, Campina Grande, PB, Brazil.

The Sequence Alignment/Map (SAM) file is the most suitable way to store sequence alignments information provenient from massive parallel sequencing methodologies. In its binary form (a BAM file), it is a compressed gzip file used to store the same information in less computational space, while still providing quick access to the data. SAMTools is used to access, read and extract information from both file formats in a quick and reliable way, while other tools like Pysam (for Python 3+) and Rsamtools (for R) utilize other languages to achieve the same results. Both SAMTools and Pysam are UNIX only, while Rsamtools is available in many different platforms. John Longinoto developed the non-UNIX Pybam algorithm (Python 2) that decodifies the binary file back to a text (read-friendly), although Pybam became outdated by current standards and Python upgrades. Inspired by this approach, we developed an adapted algorithm that works with Python 3.6+ in a Windows distribution, allowing the user to transform and handle the sequence data stored inside the file. The algorithm takes less than a second to write the file into memory, has O(N) complexity and an average of 1\*10<sup>6</sup> loops/minute while reading the data with no memory overuse. Working in an UNIX environment is common to bioinformaticians, but is not to the average researcher that will be held back by a lack of working tools. The development of bioinformatics tools that work on Windows environments are crucial in that aspect, as less than 12% (April, 2018) of the world utilizes UNIX machines.

**1435T**

**Storage and use of dbGaP data in the cloud.** *M.L. Feolo<sup>1</sup>, A. Stine<sup>1</sup>, C. O'Sullivan<sup>1</sup>, S. Kravitz<sup>2</sup>, J.B. Holmes<sup>1</sup>, B.L. Kattman<sup>1</sup>, S.T. Sherry<sup>1</sup>.* 1) National Center for Biotechnology Information, Bethesda, MD; 2) MITRE Corp., McLean, VA, USA.

The National Center for Biotechnology Information (NCBI) database of Genotypes and Phenotypes (dbGaP) is an NIH-sponsored archive charged to store and provide access to information produced by genome-scale studies that investigate the interaction of phenotype and molecular data. The next-generation sequence data deposited to dbGaP are processed and distributed by NCBI's Sequence Read Archive (SRA) or by various NIH "trusted partners". The dbGaP has progressed from a central archive to one with federated storage solutions. This progression was done initially by incorporating NIH contracted trusted partners that provision data on servers external to NCBI, and now to cloud-hosted data driven by the increasing scale of sequencing projects. Some studies in dbGaP now contain raw sequence data (e.g. BAM or CRAM) of the size that are time-consuming to download, and may best be analyzed using scalable, cloud computing. Fortunately, both NIH policy and commercial cloud capabilities have evolved to provide solutions to this problem. The Sequence Data Delivery Pilot (SDDP) is an NIH funded project to develop cloud-hosted data solutions in support of the NIH Genomic Data Sharing policy. In coordination with the SDDP, NCBI's SRA has extended accessions to allow reference to cloud locations for BAM, CRAM, and VCF files. The SRA accession space, and search methods on the NCBI sites are otherwise unchanged. In addition, a partnership with MITRE has resulted in a SDDP released software package (Fusera) implementing FUSE in the user's cloud computing account that allows read access for dbGaP/SRA data from cloud accounts without the need to move files from the original location. Approved researchers that require a local copy of the files can use "sracp" utility to copy the files to the their own cloud storage/compute account. Changes to dbGaP/SRA in collaboration with SDDP provides a new paradigm in data sharing by providing direct access to large cloud based datasets via dbGaP approvals, eliminating the need for download. The dbGaP still supports studies that are not using cloud storage, and a single dbGaP study accession may contain phenotypes and genotypes (i.e., .VCF or PLINK files) stored at NCBI, and raw sequence data available in the cloud. This presentation will describe how dbGaP/SRA has been successfully extended to provision storage and direct access of data on Google (GCP) and Amazon (AWS) in support of the SDDP and the NIH GDS policy.

**High accuracy somatic variant detection with TNscope.** *D.N. Freed, R. Aldana, R. Pan, H. Chen, H. Feng, L. Chen.* Sentieon Inc., Mountain View, CA.

Accurate identification of somatic variation is critically important in Oncology where somatic variation guides treatment decisions. However, accurate identification of somatic variation remains difficult due to its low allele frequency and sequence noise. We developed TNscope, a haplotype-based somatic variant caller, to provide highly accurate identification of somatic variation. Sentieon TNscope provides significant improvements over existing tools. New algorithms for local *de novo* assembly enable full evaluation of all possible haplotype candidates, resulting in increased sensitivity for low allele frequency variant candidates. All variant candidates are evaluated by rigorous PairHMM-based analysis without any down-sampling. These variant candidates are further annotated with novel features for improved variant filtering. Structural variants are identified through a combination of split-read and paired-read methods. Filtering of SNVs and Indels is performed with a pre-trained machine-learning model for increased accuracy. The engineering version of this method was used in the most recent ICGC-TCGA DREAM Mutation Calling challenge, and ranked first on the leaderboard for all three categories: SNV, Indel, and SV. To evaluate the performance of TNscope, we compared Sentieon TNhaplotyper -- a tool that matches the results of MuTect2, with Sentieon TNscope with a post-processing model trained on an *in-silico* mixture of HG002 and HG001. We then evaluated the performance of both tools on a tumor-normal pair of GIAB samples with an *in-silico* mixture of HG005 and HG004 as tumor and HG004 as normal, with tumor fractions of 0.1, 0.15, and 0.20, and both tumor and normal samples at 100x depth. TNscope significantly outperforms TNhaplotyper. On the three tumor fractions, TNhaplotyper achieves F1-scores of (59.8, 73.0, 77.0) for SNPs and (39.7, 48.6, 52.3) for Indels, while TNscope achieved F1-scores of (91.7, 97.4, 98.7) for SNPs and (86.9, 93.2, 95.2) for Indels.

**1437W**

**Phenotype-based variant triaging for use in clinical whole genome sequencing (cWGS).** *V.G. Gainullin<sup>1</sup>, B.R. Lajoie<sup>1</sup>, A.L. Halpern<sup>1</sup>, A. Scocchia<sup>1</sup>, A. Chawla<sup>1</sup>, M. Rajan<sup>1</sup>, S.S. Ajay<sup>1</sup>, A. Warren<sup>1</sup>, J. Avecilla<sup>1</sup>, F. Mullen<sup>1</sup>, V. Rajan<sup>1</sup>, R.T. Hagelstrom<sup>1</sup>, M.L. Cremona<sup>1</sup>, D.L. Perry<sup>1</sup>, J.J. Belmont<sup>1</sup>, D.R. Bentley<sup>2</sup>, R.J. Taft<sup>1</sup>. 1) Illumina Inc., 5200 Illumina Way, San Diego, CA, USA; 2) Illumina Cambridge Ltd., Chesterford Research Park, Little Chesterford, UK.*

Clinical whole genome sequencing (cWGS) detects a greater range of genetic variation than either targeted or whole exome sequencing, and as the time required for sequencing and secondary analysis continues to shorten, interpretation is becoming the limiting factor for scalable deployment. We have found that a typical rare, undiagnosed and genetic disease (RUGD) cWGS analysis test detects approximately 4,000,000 variants per sample, with >10,000 variants passing preliminary filtering based on allele frequency and quality filters. Subsequent filtering steps result in ~700 variants that meet stringent genotype, inheritance, consequence and pathogenicity prediction filters, of which an average of 75.6 variants map to a gene linked to at least one of the patient's phenotypic features. Although multiple gene disease relationship (GDR) resources exist, no single resource captures recently described GDRs or the complete phenotypic spectrum associated with a locus. To address this problem we developed an approach to compute similarity indices reflecting the phenotypic overlap between the patient and established GDRs derived from OMIM GeneMap, HPO and PubMed Central abstracts. Patient phenotypes are populated using a catalog of synonyms, and novel phenotypic terms are discovered through word embedding models. Additionally, HGNC loci symbols are mapped between any current or prior names, or other aliases. Gene-phenotype pairs are weighted by the strength of the support in the primary literature. Genes without GDRs inherit the phenotypes linked to their interaction partners and/or orthologous mouse genes to aid in the identification of novel research candidates. Preliminary evaluation in 14 resolved cases (5 proband-only and 9 trios) showed that this approach results in greater sensitivity than using any individual GDR resource. Across 14 cases, the causal variant had an average rank of 2.7 of 75.6 strong candidate variants per case (top 3.5%). Taken together, our results demonstrate that computational phenotype-based interpretation is likely to be an effective method to significantly reduce the curation burden of cWGS RUGD cases.

**Comparison of phenotype-driven variant prioritization tools for diagnostic exome sequencing.** *Y. Guo, M. Harr, D. Watson, X. Wang, B. Almoguera, K. Stumm, C. Chung, L. Tian, F. Mafra, R. Pellegrino, H. Hakonarson, A. Santani.* The Center for Applied Genomics at the Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA.

Exome sequencing has been widely used in clinical testing for identifying genetic variants that cause Mendelian disorders. The amount of genomic data collected in some clinical labs has increased to a tipping point where semi-automatic or automatic bioinformatics pipelines are required to assist manual variant prioritization by human analysts. Multiple tools are designed to implement such tasks and our current work aims at evaluating and comparing those tools using real cases. We selected 74 Mendelian disease cases of different inheritance models as a test dataset, each with positive genetic testing result, detailed clinical phenotype in the format of Human Phenotype Ontology (HPO) terms, and whole exome sequencing data generated from Illumina HiSeq machines. Four different variant prioritization/clinical correlation tools (Phenolyzer, Phenomizer, Exomiser, and Moon) were assessed and the results were compared to the genetic diagnosis. The tools differentiate in 4 aspects, a) final ranking of the diagnosis in the resulting variant/gene list, b) availability to be incorporated into a bioinformatics pipeline, c) whether it is publicly accessible or a commercial product, and d) customizability and scalability. Moon achieve the best ranking of the known diagnosis. All four tools allow HPO terms as input, and Phenolyzer, Phenomizer and Moon can take both HPO terms and free text of phenotypes as input. Exomiser and Phenolyzer provide gene/variant lists as outputs and can be run in batch mode, enabling easy integration into script-based pipelines. Phenomizer requires manual input while in Moon users can either input manually or import data with API. Exomiser and Moon have the ability to assess disease associations not just for genes, but also at the variant level, taking into account pathogenicity estimates of the variants. Moon is a commercial software while the others are open to the public. And Phenolyzer showed flexibility in customization and scalability with the option to include additional databases. We assessed 4 variant prioritization tools for the identification of causal variants of Mendelian disorder cases with whole exome sequencing data. Comparison with the known diagnosis showed strengths and areas for improvement for each tool. A comprehensive, open-to-the-public method is needed to achieve optimal ranking of diagnosis in the test dataset, capability to be integrated into bioinformatics workflow, and flexibility in customization and scalability.

**1439F****Are we close to constructing a fully diploid view of the human genome?**

*B.T. Hannigan, C. Fungtammasan, N. Hill. DNAnexus, Mountain View, CA.*

The publication of the draft human genome sequence in 2001 ushered in the era of large-scale comparative human genomics. Over the following decade and a half, researchers have continued to refine the initial draft to create the series of human reference genomes used today to diagnose rare genetic disorders, examine a patient's cancer risk profile, or even to monitor the health of a developing fetus. While this resource has proved to me invaluable, there are still a number of improvements that researchers have proposed. One such improvement is to move from a haploid view of the genome to a diploid view. The latest version of the human reference genome, GRCh38, moves in that direction with its inclusion of alternative alleles at certain genomic loci, but some researchers, such as those involved in the Vertebrate Genome Project, have proposed a more radical approach to the creation of reference genomes: a fully phased diploid genome. Here, we build on previous work by other groups to build a phased genome assembly for the Ashkenazi son of the Personal Genome Project by applying recent algorithm and technology improvements such as trio-binning and 10X linked-reads. We examine the quality of the assembled genome as well as the structural variants identified, with a particular focus on challenging but biologically important genomic regions such as those containing the HLA genes.

**1440W****Tissue transcriptomics: Potential for postmortem interval predictions.**

*N. Herrick<sup>1</sup>, R. Srivastava<sup>2</sup>, G. Sandusky<sup>2</sup>, S.C. Janga<sup>2</sup>, S. Walsh<sup>1</sup>.* 1) Department of Biology, School of Science, Indiana University - Purdue University Indianapolis, Indianapolis, IN; 2) Department of BioHealth Informatics, School of Informatics and Computing, Indiana University - Purdue University Indianapolis, Indianapolis, IN; 3) Pathology and Laboratory of Medicine, Indiana University School of Medicine, Indianapolis, IN.

Accurate prediction of the postmortem interval (PMI) is one of the most important and complex tasks forensic coroners perform. Investigators have attempted to determine PMI, the elapsed time between death and discovery of a body, with numerous biological, chemical, biochemical, and/or physical indicators for civil and criminal investigations (Hunter, M.C. et al., 2017). Maintaining and developing ample methods to determine PMI is advantageous as death is entirely circumstantial and different approaches are necessary due to evidence type availability. Transcriptomics offers a better alternative for the condition of death as differential expression of transcripts within various tissues can ultimately provide more precise PMI indicators, as shown by Ferreira, P. G. et al., 2018, and can ultimately be used to produce trained prediction models regarding the tissue type, accuracy, and/or context. The Genotype-Tissue Expression (GTEx) Project provides RNA-seq data (dbGaP accession number phs000424.v7.p2) across 9,777 sample tissues from 550 subjects utilized for the development of PMI prediction models. Here we have mined this data to further refine potential key predictors associated with PMI using blood and salivary gland tissues. This short list of candidate markers has been elucidated from the dataset and prediction models generated using advanced machine learning techniques. Validation of these systems (biological assays and prediction models) was applied on an additional cohort to measure prediction performances. This cohort includes newly obtained postmortem cell types that possess time of death metadata. Tissue transcriptomics derived and analyzed from postmortem samples that utilize this novel tool will immensely aid forensic investigators in PMI prediction and contribute to a broader understanding of postmortem biological processes.

**1441T**

**A model based association test considering multiple causal variants.** *J.J. Joo<sup>1</sup>, F.H Hormozdiari<sup>2</sup>, E.E Eskin<sup>3,4</sup>.* 1) Department of Computer Science and Engineering, Dongguk University-Seoul, 04620 Seoul, South Korea; 2) T.H. Chan School of Public Health, Harvard University, 665 Huntington Avenue, Boston, MA 02115; 3) Department of Computer Science, University of California, Los Angeles, Los Angeles, CA 90095, USA; 4) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA 90095, USA.

The standard genome-wide association studies (GWAS) search for an association between a single variant and a phenotype of interest. Recently, several studies reported that at many risk loci, there are more than single causal variant. For the loci with multiple causal variants with small effect sizes, the standard GWAS approach may be inappropriate as it is underpowered to detect small effects. Alternatively, an approach considering effects of multiple variants may increase statistical power by incorporating effects of multiple causal variants. In this work, we propose a new statistical method, MARS(-Model-based Association test Reflecting causal Status), that tries to find an association between variants in risk loci and a phenotype considering the causal status of the variants. Applied our method to several simulated datasets, our method successfully controlled type I error as well as improved statistical power compared to standard univariate GWAS. Applied to GTEx data, we identified more eGenes than the one reported by GTEx.

**Med2RDF: A semantic knowledge base for genomic medicine.** *T. Kawayama<sup>1</sup>, M. Kamada<sup>2</sup>, S. Kawashima<sup>1</sup>, R. Kojima<sup>2</sup>, M. Nakatsu<sup>2</sup>, Y. Okuno<sup>2</sup>.* 1) Database Center for Life Science, Joint Support-Center for Data Science Research, Chiba, Japan; 2) Kyoto University, Kyoto, Japan.

We have compiled a collection of Japanese genomic variations and annotated the variants as two newly developed databases toward a realization of the genomic medicine. The TogoVar database, developed by National Bioscience Database Center (NBDC) and Database Center for Life Science (DBCLS), provides a comprehensive archive of the Japanese variants. While, the Medical genomics Japan Variant Database (MGeND), developed by Kyoto University, accumulates variants which have been curated by the experts of each disease domain. For conducting curation of variants of uncertain significance (VUSs), it is required to integrate interpretation of expertise related to mutation, treatment results, and clinical information of the patients. Because this procedure takes a lot of labor, we plan to make it computer aided especially with the support of artificial intelligence (AI) and machine learning (ML) technologies. In order to realize this, we first need to integrate existing knowledge which biomedical experts apply for curation, based on medical guidelines. In which, relations among mutations, genes, functions, diseases and drug compounds, and frequency of mutations, approval status of trials are used as the judging criteria. These are stored in the distributed biomedical databases, however, it is hard to integrate and use them for effective knowledge extraction because each database has its own data format and structure. To resolve this issue, we introduced the Semantic Web in which heterogeneous data can be unified by the Resource Description Framework (RDF). RDF data uses globally unique Uniform Resource Identifiers (URIs) to identify concepts and objects in the datasets, ontologies to describe semantic types, and links to relate information across multiple databases seamlessly. We transformed major biomedical databases into RDF by developing ontologies to describe variations. Resulting RDF datasets, which includes data on clinical relevance, mutation frequency, protein interactions, and gene-drug relations, are distributed at the Med2RDF project website (<http://med2rdf.org>) developed by DBCLS and Kyoto University in collaboration. In the poster, we will report the results of (1) integration of these datasets in the TogoVar database, and (2) applications on predicting pathogenicity of variants and relations of variation-drug based on our in-house developed AI/ML methods. Those are expected to help experts and curated results will be incorporated into the MGeND database.

**Empirical evaluation of variant calling accuracy using ultra-deep whole-genome sequencing data.** *T. Kishikawa*<sup>1,2</sup>, *Y. Kamatani*<sup>3,4</sup>, *M. Kubo*<sup>5</sup>, *Y. Okada*<sup>1,4,6</sup>. 1) Department of Statistical Genetics, Osaka University Graduate School of Medicine, Suita, Japan; 2) Department of Otorhinolaryngology - Head and Neck Surgery, Osaka University Graduate School of Medicine, Osaka, Japan; 3) Kyoto-McGill International Collaborative School in Genomic Medicine, Kyoto University Graduate School of Medicine, Sakyo-ku, Kyoto, Japan; 4) Laboratory for Statistical Analysis, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 5) RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 6) Laboratory of Statistical Immunology, Immunology Frontier Research Center (WPI-IFReC), Osaka University, Suita, Japan.

In the study design of whole-genome sequence (WGS), a sequencing depth is a crucial parameter to define variant calling accuracy and study cost, while standard recommendations has not been established. We empirically evaluated variant calling accuracy of the WGS pipeline using ultra-deep WGS data (approximately 410×). By randomly sampling sequence reads, we created a series of simulation WGS datasets with a gradual variety of depths ( $n = 54$ ; from 0.05× to 410×). We evaluated genotype concordances of the WGS data with those in the SNP microarray data or the WGS data using all the sequence reads. The WGS data with higher depths showed higher concordance rates, and > 13.7× depth achieved as high as > 99% of concordance. Comparisons with the WGS data using all the sequence reads showed that SNVs achieved > 95% of concordance at 17.6× depth, while indels showed only 60% of concordance. These results recommended the medium degree of the WGS depth setting (around 15×) for an achievement of both accurate SNV calling and cost-effectiveness, while relatively higher depths are required for accurate indel calling..

**1444T**

**Mendelian inheritance errors in whole genome sequenced trios are enriched in repeats and cluster within copy number losses.** *P. Kothiyal*, *W.S. Wong*, *D.L. Bodian*, *J.E. Niederhuber*. Inova Translational Medicine Institute, Inova Health System, Fairfax, VA.

**Background:** Next-generation sequencing (NGS) enables advances in the clinical application of genomics by providing high-throughput detection of variants in the genome. However, NGS technologies, especially whole genome sequencing (WGS), are often associated with a high false positive rate. Trio-based WGS data can contribute significantly towards the development of improved quality control methods that can also be applied to non-family WGS. Mendelian Inheritance Errors (MIEs) in parent-offspring trios are commonly attributed to erroneous sequencing calls, as the rate of true de novo mutations is extremely low compared to MIE incidence. Here, we analyzed WGS data from 1,314 mother, father, and offspring trios across ethnically diverse human populations with the goal of studying the characteristics of MIEs. **Results:** We filtered MIEs on read depth, genotype quality, and allelic balance and observed that quality based filtering has a greater impact on frequent MIEs compared to MIEs unique to a trio. Our results indicate that MIEs are enriched in regions with repeat elements and that MIE density correlates with the density of Short Interspersed Nuclear Elements (SINEs). We also observed clustered MIEs in regions overlapping large deletions. We created population-specific MIE profiles and discovered genomic regions that represent different MIE distributions across populations of differing ethnicity. Finally, we have summarized these MIE distributions to produce population-specific MIE tracks that can be loaded in UCSC Genome Browser. **Conclusions:** While MIEs are frequently used for benchmarking error rate, and have been explored for detection of deletions, we aimed to understand the properties of MIEs before discarding them as errors or including them in alternative applications. With the implication of de novo mutations in various disorders, they are being studied more routinely in clinical practice. We aim to provide a reference that can be used for annotating MIEs with frequencies in a larger population to aid in the filtering of candidate de novo mutations. Finally, the MIE tracks can be used for flagging calls in proximity to clustered MIEs before allele frequency and admixture calculations, annotating candidate de novo mutations, discovering population-specific putative deletions, and for distinguishing between regions that have errors due to sequence quality vs. chromosomal anomalies.

**INTERSPIA: A web application for exploring the dynamics of protein-protein interactions among multiple species.** *D. Kwon, D. Lee, J. Kim, J. Lee, M. Sim, J. Kim.* Konkuk University, Seoul, Korea, Republic of.

Proteins perform biological functions through cascading interactions with each other by forming protein complexes. As a result, interactions among proteins, called protein-protein interactions (PPIs) are not completely free from selection constraint during evolution. Therefore, the identification and analysis of PPI changes during evolution can give us new insight into the evolution of functions. Although many algorithms, databases and websites have been developed to help the study of PPIs, most of them are limited to visualize the structure and features of PPIs in a chosen single species with limited functions in the visualization perspective. This leads to difficulties in the identification of different patterns of PPIs in different species and their functional consequences. To resolve these issues, we developed a web application, called INTER-Species Protein Interaction Analysis (INTERSPIA). Given a set of proteins of user's interest, INTERSPIA first discovers additional proteins that are functionally associated with the input proteins and searches for different patterns of PPIs in multiple species through a server-side pipeline, and second visualizes the dynamics of PPIs in multiple species using an easy-to-use web interface. INTERSPIA is freely available at <http://bioinfo.konkuk.ac.kr/INTERSPIA/>.

**SAMPLLOT: Rapid structural variant visualization for short, long, linked, and phased reads.** *R.M. Layer<sup>1,2</sup>, J.R. Belyeu<sup>3,4</sup>, A.R. Quinlan<sup>3,4,5</sup>.* 1) Department of Computer Science, University of Colorado, Boulder, CO; 2) BioFrontiers Institute, University of Colorado, Boulder, CO; 3) Department of Human Genetics, University of Utah, Salt Lake City, UT; 4) USTAR Center for Genetic Discovery, University of Utah, Salt Lake City, UT; 5) Department of Biomedical Informatics, University of Utah, Salt Lake City, UT.

Structural variant (SV) detection remains a challenging problem. Biological and technical artifacts complicate our ability to differentiate signal from noise causing the accuracy of SV detection to remain worse than that for smaller variants. As a result, visualization has become a standard step in the SV validation process. Inspecting the raw alignment data, genome annotations, and the region surrounding a candidate SV can help remove false positives and confirm breakpoints and genotypes. We created SAMPLOT to support rapid, focused visualization of SVs, that highlights the alignment signals that are hallmarks of SVs including sequence coverage, discordant paired-end reads, split reads, and alignment gaps. For each SV, SAMPLOT creates a subplot for each sample that includes a sample-specific coverage profile and alignments organized along the y-axis by "event size" (insert size for paired-end reads, gap size for split-reads). This organization creates distinct clusters of normal and discordant alignments. Discordant alignments are color-coded by the type of SV they support. SAMPLOT also supports the simultaneous visualization of: - short Illumina paired-end reads, long reads from PACBIO and Oxford Nanopore, and linked reads from 10X - phased BAMs with any number of haplotype assignments - genome annotations such as transcripts, repetitive regions, and mapping quality tracks With SAMPLOT, users can quickly and easily inspect SVs across many samples and technologies to determine if any sample contains discordant alignments that support the candidate SV, which can be especially helpful when evaluating de novo variants in families and somatic SVs tumor/normal samples. Source code and documentation at <https://github.com/ryanlayer/samplot>.

**Hybrid scaffolding of optical maps provides high contiguity and corrects errors in sequence assemblies.** *J. Lee, A. Pang, A. Hastie, J. Wang, T. Anantharaman, H. Cao.* Bionano Genomics, San Diego, CA.

High quality genome assembly of novel genomes has exploded in recent years as a result of novel and maturing technologies. To disambiguate homologous regions of these novel genomes, long reads and linked reads are used to assemble contigs and generate scaffolds with up to 10 Mbp N50 values. Assembling these sequences into chromosome arm or chromosome length can only be accomplished using Bionano Genomics long read mapping or one of the Hi-C based methods. Bionano chromosome assemblies can often be achieved by utilization of the new DLS chemistry and/or by combining with NLRs chemistry. Bionano Genomics, with its long molecules N50 in the range of hundreds of kilobases with the DLS chemistry, is unique in that it can generate megabases long contiguous assemblies with the well understood overlap layout consensus algorithms. These assemblies are then used to scaffold sequences into chromosome or chromosome arm length assemblies by the Hybrid Scaffold pipeline. Alternatively, Hi-C based methods leverage crosslinking of DNA that is in close proximity in vivo through chromatin folding, which is then sequenced using short read sequencing. Since the long range interaction in Hi-C is based on biological connections and encoded by short reads, significant inference is required to reconstruct the interaction information. In comparing Hi-C scaffolds with Bionano DLE Maps, many discrepancies were found. Inverted and rearranged segments of various sizes were identified when aligning the Hi-C scaffolds to the Bionano DLE Maps. Aligning the pre Hi-C scaffolded sequences with BNG DLE maps, we see that most of these divergent breakpoints were at ends of the pre Hi-C scaffolded contigs, suggesting that orientation and arrangement discrepancies were introduced during Hi-C scaffolding. Since the Bionano method leveraged native intact molecules, spanning breakpoints of these segments by Bionano molecules suggests mis-orientations in the Hi-C scaffolds. In another case, a third long read sequencing technology agrees with BNG structure at the regions of discrepancies, further supporting the accuracy of the Bionano assembly.

**QC software for analysis of sequence data in family-based studies.** *Q. Li, J. Bailey-Wilson.* Computational and Statistical Genomics Branch NHGRI/NIH, Baltimore, MD.

In recent years, with the increased popularity of DNA sequence data, the research community has paid more attention to family based studies of complex traits. Pedigree data pose new challenges in the quality control steps for sequence variants. Not only do we need to screen data based on various genotyping calling metrics, we also need to use the pedigree structure to detect any markers with inconsistent inheritance patterns. In this work, we present our QC pipeline software, written in R, for sequence data analysis. It includes functions to extract various genotyping calling measurements, to detect Mendelian inconsistency, and to detect any excessive allele sharing due to remote inbreeding. Our software uses the SQLite database for easy access and short processing time for VCF files. Variant level data is stored in a different table from variant-and-sample level data. Sample level data (related to QC metrics) are broken into multiple tables, each table corresponding to only one specific data quality metric. We used our software to conduct quality control on whole exome sequence data on odd numbered chromosomes in extended pedigrees from the Genetic Analysis Workshop 18 (GAW18). We also simulated Mendelian errors and genotyping errors in the sequence data to evaluate our QC functions. Our simulations showed the functions can detect those errors with high accuracy and within a reasonable time frame. We compared our data extraction functions with what are available in other similar software, such as Golden Helix SVS. Our functions perform equally well in term of accuracy and are much more flexible to use. These software are freely available and will assist researchers in large family studies using whole exome and whole genome sequence data.

**MedGen: A powerful tool for clinical genetics.** A.J. Malheiro, D.R. Maglott, M. Benson, C. Chen, S. Chitipiralla, D. Hoffman, M.J. Landrum, B. Holmes, V. Gorelenkov, W. Shi, B.L. Kattman. National Center for Biotechnology Information (NCBI), NLM, NIH, Bethesda, MD.

MedGen is a free and easily accessible database of information about diseases and phenotypes with a genetic component, housed at NIH's National Center for Biotechnology Information (NCBI). MedGen facilitates the clinical process by providing unrestricted access to related data from multiple sources such as ClinVar and the NIH Genetic Testing Registry (GTR). MedGen has records for Mendelian disorders, pharmacological response phenotypes, complex disorders, and clinical features or findings. The data in MedGen are updated daily; updates are processed as data becomes available from the source. The data are available for bulk download on the ftp site (<ftp://ftp.ncbi.nlm.nih.gov/pub/medgen/>) and can be easily integrated in electronic medical records. Individual records may be viewed on the web (<https://www.ncbi.nlm.nih.gov/medgen/>). A clinician can use MedGen to find information about a genetic phenotype: 1. by name (autocomplete dictionary available); 2. by causative gene (use gene symbol followed by [gene] to get a list of diseases caused by or with some association to that gene); 3. by clinical feature (enter the name of the feature followed by [clinical features] to retrieve a list of diseases with that feature); and 4. by identifier from another database (e.g. OMIM, HPO, OrphaNet). An advanced search feature is available to support complex queries. On a search result page, there are filters to tailor the view of the data to the current needs of the user. Each disease record has a list of all features of a disorder based on data from HPO and OMIM. One can find all disorders with particular feature(s) using the clinical feature field in the Advanced Search (e.g. syndactyl). This presentation will demonstrate how to leverage information in MedGen throughout the clinical process. To research a case: access disease and phenotype information from multiple resources including *GeneReviews*, Genetics Home Reference, Medical Genetics Summaries, OMIM and pre-calculated PubMed queries. To care for a patient: access actionable information such as practice guidelines, recommendations, position statements and evidence-based reviews from authoritative sources as well as a list of relevant orderable clinical and research tests from the NIH GTR and a list of variants for the relevant genes from ClinVar. To find more details from dedicated sites: follow content-specific links to ClinicalTrials.gov, GARD, Orphanet, MedlinePlus, Malacards, PharmGKB, and patient-oriented resources.

**Improving next-generation sequencing determination of antigens in the MNS blood group system through the use of a graph-based reference assembly.** S. McGee<sup>1</sup>, J.D. Smith<sup>1</sup>, K.W. Lannert<sup>2</sup>, J.M. Johnsen<sup>2,3</sup>, M.M. Wheeler<sup>1</sup>, D.A. Nickerson<sup>1</sup>. 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Bloodworks NW Research Institute, Seattle, WA; 3) Department of Medicine, University of Washington, Seattle, WA.

Graph-based reference assemblies aim to improve short read mapping and the subsequent detection of genetic variants. Specifically, graph-based assemblies have been shown to improve variant detection by accounting for known variation in highly polymorphic and homologous regions of the genome. In this study, we hypothesized a graph-based approach would improve variant detection in the segmentally duplicated glycoprotein genes (*GYP A*, *GYP B* and *GYP E*). These genes are located in tandem on chromosome 4 and share approximately 97% sequence identity. Mapping quality and genotyping difficulties have previously been reported for a cluster of single nucleotide variants (SNVs) in exon 2 of *GYP A*. These variants encode clinically-relevant antigens in the MNS blood group system (the M and N antigens); however, genotype analyses of *GYP A* exon 2 variants are currently confounded by high homology to exon 2 of *GYP E*. To address this, we constructed a graph-based reference sequence utilizing SNVs and indels detected in NGS data from approximately 1100 samples for which M and N antigens were previously serologically typed. Using the software package VG, we re-mapped a subset of the 1100 samples (N=100) to this *GYP* graph-based reference assembly. Our results show significant improvement in depth and mapping quality of the reads over *GYP A* exon 2. In addition, there was striking improvement in correlation to M and N phenotype data derived from serology. In previous work, variant calls were determined using GATK HaplotypeCaller and showed concordance with serology of 40% for M+N- (homozygous alternate calls) and 14% for M+N+ (heterozygous calls). With the graph-based approach, the concordance of antigen determination increased to 93% for M+N- and 89% for M+N+, improvements of 2.3 fold and 6.4 fold, respectively. These results illustrate how a graph-based approach can improve mapping quality and variant detection for genetically complex and clinically-relevant genomic loci. We are currently extending these analyses to additional blood group loci and predict further application of this approach will detect novel variation and improve blood group antigen determination from NGS data.

**Scientific benefits resulting from standardizing electronic health records to facilitate multi-site collaboration**. F.D. Mentch<sup>1</sup>, H. Qiu<sup>1</sup>, L.M. Vazquez<sup>1</sup>, D.J. Abrams<sup>1</sup>, J.J. Connolly<sup>1</sup>, P.M.A. Sleiman<sup>1,2</sup>, H. Hakonarson<sup>1,2</sup>. 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

National and international projects to research human health, many including genomic components, are proliferating. Multi-institution collaborations are enhanced if contributing sites can more efficiently and accurately share phenotype data. One way to facilitate data sharing is for each site to migrate electronic health records (EHRs) to common vocabularies and data storage formats. As it takes substantial effort to standardize EHR data, the implementation costs can be perceived as prohibitive. We report on the scientific benefits we found after migrating to standardized vocabularies and a common data model which offset some of the concerns about implementation cost. For example, as a large biobank site (n>500,000) with extensive EHR data (n>110,000), we found a benefit in the global calculation of drug and health condition trajectories, which we would otherwise do piecemeal, and in the consolidation of concepts across the domains of medications, procedures and diagnoses. We found an uneven loss of information in the transformation particularly in diagnosis translations that is greatest where the ICD coding system is weakest. The migration to a common vocabulary for procedures and lab values was found to be particularly advantageous for our site. Perhaps the greatest value in the migration process was tapping into the codes underlying the clinical EHR data capture system of the hospital, giving a closer connection to the clinical descriptions chosen at the time of patient care and mapping these more accurately to a global standard vocabulary.

**Astrolabe: Automated pharmacogenetic allele calling of CYP2D6, CYP2C9 and CYP2C19 from NGS data.** N. Miller<sup>1,2</sup>, G. Twist<sup>1</sup>, N. Gonzaludo<sup>3</sup>, R. Lata<sup>4</sup>, E. Boone<sup>4</sup>, R. Gaedigk<sup>2,4</sup>, E. Farrow<sup>1,2</sup>, A. Gaedigk<sup>2,4</sup>. 1) Center for Pediatric Genomic Medicine, Children's Mercy, Kansas City, Kansas City, MO; 2) School of Medicine, University of Missouri-Kansas City, Kansas City, MO; 3) Illumina, Inc., Foster City, CA; 4) Division of Clinical Pharmacology, Toxicology & Therapeutic Innovation, Children's Mercy, Kansas City, Kansas City, MO.

CYP2D6, CYP2C9 and CYP2C19 contribute to the metabolism of over 30% of drugs in clinical use including antidepressants, antipsychotics, opioids, antiemetics, anti-arrhythmics,  $\beta$ -blockers, cancer chemotherapeutics, the anti-coagulant warfarin and the antiplatelet agent clopidogrel. The activity of these enzymes varies widely among individuals and there is strong evidence that genetic variation significantly contributes to drug efficacy and risk of adverse events. Expert guidelines have been published to improve the use of substrates metabolized by these three genes. The Pharmacogene Variation Consortium (PharmVar) has defined over 100 allelic variants for CYP2D6, 60 alleles for CYP2C9 and 35 for CYP2C19. CYP2D6 allele calling is complicated by copy number variation, gene rearrangements and conversions and the presence of non-functional homologs and pseudogenes. Given these complexities, routine determination of pharmacogenetic alleles by genome sequencing is non-trivial. Previously, we developed a probabilistic scoring tool for pharmacogene haplotype calling from WGS (Constellation, now renamed Astrolabe) and evaluated its performance for CYP2D6. Here, we describe a series of improvements for CYP2D6 and the addition of support for CYP2C9 and CYP2C19. Enhancements include the incorporation of machine learning classifiers for CYP2D6 structural variant detection, configurable weighting of key haplotype variants, improvements in overall software quality and performance, expansion to GRCh38 and the incorporation of versioned haplotype definitions from PharmVar. Compared to a set of 89 samples genotyped with orthogonal methods, Astrolabe calling of CYP2C9 and CYP2C19 had 100% and 96% accuracy, respectively. Results from two different simulations of all possible diplotypes showed calling accuracy of 100% for CYP2C9, 99.8% for CYP2C19 and 95.7% for CYP2D6. Astrolabe performance was also evaluated against 96 Coriell Cell Repository cell-lines previously genotyped by the Centers for Disease Control and Prevention-based Genetic Testing Reference Material Coordination Program (GeT-RM) (Pratt VM et al., J Mol Diag 2016, 18:109-123). Whole genome sequences were released by Illumina and data for selected consented samples are available on ENA (Study PRJEB19931, <https://www.ebi.ac.uk/ena/data/view/PRJEB19931>). Astrolabe software is freely available for research use from the Children's Mercy Genome Software Portal (<https://www.childrensmercy.org/genomesoftwareportal/>).

**Fast model-based detection of identity-by-descent.** *J. Nait Saada, P. Palamara.* Department of Statistics, University of Oxford, Oxford, UK.

Identical-By-Descent (IBD) segments are a fundamental measure of genetic relatedness, and IBD detection is of great interest in many applications, including demographic inference and haplotype-based association. Algorithms that scale to large datasets, such as GERMLINE [Gusev et al., *Genome Res.*, 2009] and RaPID [Naseri et al., *Biorxiv*, 2017] sacrifice modeling accuracy in favor of computational speed. On the other hand, efficient model-based algorithms for IBD detection such as RefinedIBD [Browning and Browning, *Genetics*, 2013] enable detecting shorter IBD segments but do not scale as well. We have developed a new algorithm, called Preprocessed Ascertained Sequentially Markovian Coalescent (PASM), that enables accurate IBD detection while retaining computational efficiency. PASM utilizes string matching to detect candidate IBD segments using the PBWT algorithm [Durbin et al. 2014, *Bioinformatics*] and applies the ASMC algorithm [Palamara et al., *Nature Genetics*, in press] to filter out candidate segments using coalescent modeling. We compared the performance of several methods using coalescent simulation, including PASM, GERMLINE, RefinedIBD, RaPID and ASMC. We simulated 10 independent datasets for a 30Mb chromosome and 300 haplotypes, based on a model of European demographic history and recombination rates from a human chromosome 2. We mimicked SNP ascertainment by subsampling variants to match UK Biobank allele frequencies. We used a grid-search over possible parameter values to optimize the accuracy of all methods, measured using area under the precision-recall curve. We defined a region to be IBD if the most recent common ancestor for a pair of individuals is less than 100 generations. PASM's performance (within the recall range [0.01, 0.50] shared by all methods) was 40.51% (SE=3.61) higher than RaPID, 8.85% (1.51) higher than RefinedIBD, 8.94% (1.01) higher than GERMLINE, and 4.95% (0.62) less than ASMC. Comparing accuracy at a deeper time scale (IBD=250 generations), PASM still outperformed other methods (shared recall range = [0.00, 0.26]); PASM's accuracy was 56.37% (4.96) higher than RaPID, 16.07% (0.96) higher than GERMLINE, 2.76% (0.36) higher than RefinedIBD, and only 1.73% (0.18) lower than ASMC. In addition, PASM's computational time scaled well in a larger dataset of 5000 haplotypes, requiring around 21 min, compared to 32s for GERMLINE, 20min for RaPID, 1h and 25min for RefinedIBD and 13h for ASMC.

**The road to atomistic pathology.** *M.-S Park, A. Chamberlin, I.D Petrik, D. Shinde, R. Lassiter, F. Hernandez, T. Pesaran, C.-L Gau, H.-M Lu, R.B Fenwick.* Ambry Genetics, Aliso Viejo, CA.

Variant classification of missense alterations remains a significant challenge. The predictive capacities of methods that focus on the sequence (e.g. in-silico predictors) are limited and are typically combined with additional lines of evidence (e.g. population frequency, family studies, and functional studies) to obtain robust classification. However the utilization of alternative evidence categories is limited by availability and cost. Biophysical principles provide a promising complementary source for additional lines of evidence, because protein structures provide a rich set of features that elucidate protein function and dysfunction. We present the analysis of a series of missense variants using biophysical methods, such as model building (Kim, Chivian, & Baker, 2004), and stability calculations (Schymkowitz et al., 2005), combined with structural-biological insight. This integrated biophysical approach offers additional predictive power as well as mechanistic insight into the mode of disruption. We find that analyzing variants in the context of the protein structure yields an atomistic view that explains why variants at similar locations in the sequence have different clinical outcomes. We have successfully applied this approach in the past to explain challenging variants in a variety of genes (Martin et al., 2017; Peng et al., 2018; Powis et al., 2018). We illustrate for several cases how active sites can be affected while leaving stability unchanged and how variants can have significant impacts on protein folding and stability. **Keywords:** Protein structure, Bioinformatics, Genetic testing, Molecular pathophysiology, Mutation detection.

**Interrogation of biases from different platforms and different types of library preparations in transcriptome sequencing study.** G. Park, M. Roh, R. Kim, D. Seo. MacroGen Clinical Lab, Rockville, MD.

Nowadays, a gene expression profiling is being conducted with a variety of sequencing platforms and library preparation methods. The sequencing databases like GEO, SRA, and EMBL-EBI have been providing a publicly available transcriptome sequencing data, which enables users to accelerate data sharing and reusability. However, users should still carefully consider using both new sequencing data and public data together due to data discrepancies and biases, which might possibly come from different types of sequencing platform, library preparation methods, sequencing method either paired-end and single end, and length of reads. In this study, we looked into the gene expression profiling from sequencing data produced from the platforms, Illumina HiSeq2500 and NovaSeq, and different library preparation methods such as stranded mRNA, non-stranded mRNA, and globin-zero total RNA kits. Based on our observations, platform biases did not make a huge difference in gene expression profiling; however, different library preparation methods did. The presence of globin significantly affected the gene expression profiling because of the expression of globin related genes. Even though method with strand information kit showed different gene expression profiling, the result had similar overall expression pattern because of the 20% overlap of genes between the top and bottom reference sequences. In conclusion, biases from different platforms of transcriptome sequencing can be insignificant as this can be corrected after removing the batch effects, but different library preparation methods will affect significantly the gene expression profiling. Therefore, the library preparation methods need to be carefully evaluated and selected before conducting meta-analysis of transcriptome sequencing study with publicly available sequencing data.

**Integrated Bayesian analysis outperforms existing methods for variant classification.** D. Qian, Y. Tian, S. Li, J. Clifford, B.A.J. Sarver, A. Chamberlin, R.B. Fenwick, T. Pesaran, C. Gau, H.M. Lu, M.H. Black. Ambry Genetics, Aliso Viejo, CA.

**Introduction:** Common practice for variant classification follows the scheme-based ACMG guidelines (Richards et al. 2015) or utilizes a naïve Bayesian classifier (NBC; Tavtigian et al. 2018) with 7-category evidence data. However, methods to make a definitive variant classification remain a challenge for clinical testing largely due to the lack of effective ways to incorporate patterns of pathogenic information in classified variants in concert with available evidence data. **Methods:** We report a novel integrated Bayesian learning and aggregation analysis using multifactorial variant prediction (MVP) to capture the uncertainty of *in silico* effects and aggregate both qualitative and quantitative evidence in a data-driven probabilistic process. To evaluate classification performance, we assembled a dataset of 1,670 missense variants in 67 genes unambiguously classified by ClinVar consensus as benign (B, n=126), likely benign (LB, n=673), likely pathogenic (LP, n=343) or pathogenic (P, n=528). We also collected 1,056 missense variants of uncertain significance (VUS) supported by 2 or more ClinVar submitters and no conflicting submissions. Each classified variant or VUS in the evaluation datasets had at least 1 type of evidence collected from public resources and a cohort of 176,280 patients who underwent genetic testing at a single diagnostic lab. **Results:** The prediction performance of scheme-based ACMG and NBC methods were roughly equivalent in both classified variants and VUS. While the accuracy of MVP and NBC were comparable for predicting variants with known classifications (99.9% and 99.8%, respectively), the yield of MVP was higher (90.8% vs. 74.2%, respectively). When predicting VUS in the combined set of classified variants and VUS, the accuracy was higher for MVP than NBC (83.4% vs. 62.7%) although both yields were moderate (33.5% vs. 33.1%). Notably, MVP had better performance in predicting pathogenicity; for the 871 LP/P variants, the true positive rates were 90.9% and 53.7% for MVP and NBC, respectively, highlighting a substantial number (n=324, 37.2%) of LP/P variants unclassifiable by NBC that were correctly classified as pathogenic by MVP. **Conclusions:** Taken together, our powerful Bayesian MVP analysis had greater accuracy and considerably higher yield of pathogenic variant classification than other existing approaches, and as such may serve as an automated, data-driven tool to objectively classify missense variants and reduce VUS rates.

**Statistical considerations for the analysis of massively parallel reporter assays data.** *D. Qiao<sup>1</sup>, M.H. Cho<sup>1,2</sup>, E.K. Silverman<sup>1,2</sup>, X. Zhou<sup>1</sup>, N.H. Laird<sup>3</sup>, P. Castaldi<sup>1</sup>.* 1) Channing Division of Network Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 2) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 3) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA, USA.

**Background:** Non-coding DNA is now known to contain a multitude of functional gene regulatory elements that alter gene expression. To identify and functionally characterize these regulatory elements, massively parallel reporter assays (MPRA) utilizing chip-based technologies and next-generation sequencing were developed. Using MPRA, hundreds of thousands of oligonucleotide sequences (oligos) can be examined quantitatively in a single experiment, but the statistical methods to analyze MPRA data, specifically in relation to the regulatory effects of different SNP alleles, have not been fully studied. The methods used to identify allele-specific gene regulatory effects in MPRA include the Mann-Whitney test and t-test on RNA/DNA ratios, Fisher's exact test and QUASAR-MPRA using total oligo counts, and the mpralm method. **Methods:** In this work, we explore fundamental issues with ratio-based representations of gene regulatory effects, and we demonstrate how the baseline allelic imbalance present in most if not all MPRA libraries produces biased results using existing methods. We propose a novel, adaptive testing approach, and we examine the performance of this approach versus all commonly used MPRA methods using simulations. **Results:** We show that, unlike existing methods, the adaptive approach is robust to allelic imbalance and therefore more reliable. We also examine the power of all methods across various realistic scenarios, and we demonstrate that while the mpralm method is biased in certain situations, it also is more powerful across many scenarios. **Conclusions:** We conclude that our recommended approach to MPRA analysis of allelic effects is to use both the adaptive approach and mpralm to maximize power while identifying likely false positive results. We have implemented these tests along with routines for simulating MPRA data in the Analysis Tools for MPRA (atMPRA), which is an R package for the design and analysis of MPRA experiments, available at <http://github.com/redaq/atMPRA>.

**Whole genome sequencing data analysis based on GRCh38 and difficulty on haplotyping for pharmacogenes.** *N. Qu, M. Jian, J. Guo, Q. Shi, A. Ou, X. Liu.* BGI-Shenzhen, Shenzhen, Guangdong, China.

GenBank released GRCh38 (Genome Reference Consortium Human Reference 38) in 2013, whose context ID in UCSC Genome Browser is hg38, which is the most recent genome version and is a more accurate representation of the human genome. The GRCh37 is a single representation of multiple genomes, while the GRCh38 provides alternate contigs ("alt\_sequences") for some genomic regions for whose variability prevents adequate representation by one single reference. We analysed NA12878's WGS data using GRCh37 and GRCh38 at the same time, and compared the SNPs and Indels to GIAB golden standard and sanger verification result. We found that the result using GRCh38 presented a high false negative rate. After removing GRCh38's alternate contigs from reference genome, it results in lower false-negative and lower false-positive than GRCh37. All our databases were transferred into GRCh38 version by liftover software. Such as ExAC, dbNSFP, etc. In addition, we developed an annotation software named bcfanno by C language, which can annotate a WGS sample in 2 hours on a stand-alone system. CPIC (The Clinical Pharmacogenetics Implementation Consortium) has stated that if the subject has two haplotypes which are CYP2C9\*2 (rs1799853) and CYP2C9\*3 (rs1057910), the subject then has a phenotype as poor metabolizer towards warfarin. Or intermediate metabolizer when the two SNPs are on the same haplotype while the other haplotype is CYP2C9\*1, which means no related variations. However, due to the limitation of NGS, it is difficult to distinguish whether they are on the same DNA strand. Normally, it is assumed that all the tested variations are on either the same or separated strand. But neither of these assumptions is accurate enough. Else more, sequencing depth of all locus related to conclusions are need to check. For example, NGS result shows that there was only a heterozygous mutation on the CYP2C9 gene: rs1799853. Then we thought the subject has a phenotype of intermediate metabolizer. However, we next found that the sequencing depth of another loci rs1057910 was actually 0X. And the sanger sequencing result of rs1057910 was homozygous variation but not real negative. So the subject should be poor metabolizer. For those uncovered locus, another sequencing method is required. Or at least we should inform the subject that such locus is not successfully called.

**STAASIS: A web based server for identifying Illumina genotype arrays and initial strand orientation.** *N.W. Rayner<sup>1,2,3</sup>, N.R. Robertson<sup>1,2</sup>, M.I. McCarthy<sup>1,2,4</sup>.* 1) Wellcome Centre for Human Genetics, Nuffield Department of Medicine, University of Oxford Oxford, OX3 7BN, UK; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, Radcliffe Department of Medicine, University of Oxford, Churchill Hospital, Oxford, OX3 7LJ, UK; 3) Department of Human Genetics, Wellcome Sanger Institute, Hinxton, Cambridgeshire, CB10 1SA, UK; 4) Oxford NIHR Biomedical Research Centre, Oxford University Hospitals Trust, Oxford, OX3 7LJ, UK.

Array genotyping remains a popular, cost effective option for large cohorts and along with imputation and meta-analysis has proved extremely successful in identifying novel disease associated loci. A key requirement for both imputation and meta-analysis is that all data are aligned to the same genomic build and strand, an issue we have previously addressed by developing strand files for Illumina and Affymetrix genotyping arrays across all recent genome builds and making them freely available to download. However these strand files assumed that all Illumina data are by default created using the TOP genomic alleles; this is not always the case. Illumina have a number of other possible allele alignments and from the many requests for assistance received to date these alternate alignments appear to be used in a sizeable minority of cases. Another complication is that the array used for genotyping may not be known, or partially known e.g. an OmniExpress array, of which there are 13 versions. This along with the allele alignment issue can make it difficult to select the right strand file to use. To address the requests for help with these issues we had developed programs to automatically identify the array and allele alignment. These though had to be manually configured and run, and with the increase in the number of arrays became increasingly slow to run. We have now redeveloped these programs into a single web server, STAASIS, written in Perl, Java and JavaScript that utilises a client server model with in-memory hashes to reduce the run time from several hours previously to a minute or less. The program accepts a list of variants or a plink format bim file, and whilst both allow for array identification only the latter enables the allele alignment check to be performed. Once submitted the list of variants is checked against the content of all current and previous Illumina arrays, currently numbering more than 160, to identify the most likely array. The alleles from the bim file, if supplied, are compared to all possible allele combinations to determine their orientation. Using 110 bim files we successfully identified the array and orientation in all but one, where the number of variants left after quality control was too low for a definite match. In future we plan to add new features such as Affymetrix chips, position based checks and by extension genome build identification, as well as including the forward genomic strand amongst the possible strand options.

**Machine learning approaches for comparative genome structure analysis.** *C. Rojas<sup>1</sup>, M. N. Tran<sup>1</sup>, L. Huynh<sup>1</sup>, F. Hormozdizadeh<sup>1,2,3</sup>.* 1) University of California, Davis, Davis, CA; 2) MIND Institute, University of California, Davis, USA; 3) Biochemistry and Molecular Medicine, University of California, Davis, USA.

The development of high-throughput chromosome conformation capture techniques (Hi-C) has provided a wealth of data on the three-dimensional architecture of genomes. We can use this data to analyze the topological structure of genome and understand genomic interactions. However, the accurate approach to find conserved or specific genomic interactions in two or more Hi-C contact matrices is an open question. We introduce a convolutional autoencoder an unsupervised machine learning technique to produce a similarity function to compare areas between pairs of Hi-C matrices. Our model is trained on sub-blocks of the Hi-C matrix that are treated as high-dimensional vectors and that are transformed into lower dimensional vectors. We show that our autoencoder outperforms statistical methods such as principal components analysis (PCA) and root-mean-square error (RMSE) for finding genomic interactions which are specific to one of the matrices. This method is useful and accurate in finding genomic interactions specific to one genome which potentially result in changes in gene expression by comparing Hi-C matrices from two or more tissues or species.

**OligoPVP: Phenotype-driven analysis of individual genomic information to prioritize oligogenic disease variants.** *P.N. Schofield<sup>1</sup>, I. Boudellioua<sup>2</sup>, M. Kulmanov<sup>3</sup>, G. Gkoutos<sup>3</sup>, R. Hoehndorf<sup>3</sup>.* 1) Physiology Development and Neuroscience, University of Cambridge, Cambridge, United Kingdom; 2) Computational Bioscience Research Center, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 3) College of Medical and Dental Sciences, Institute of Cancer and Genomic Sciences, Centre for Computational Biology, University of Birmingham, B15 2TT, Birmingham, United Kingdom Institute of Translational Medicine, University Hospitals Birmingham, NHS Foundation Trust, B15 2TT, Birmingham, United Kingdom.

Identification of variants associated with genetic diseases is a major challenge; in particular in the analysis of clinical sequence data from individual patients. An increasing number of disorders have been identified for which two or more variants in one or more genes are required to cause the disease or significantly modify its severity or phenotype. It is difficult to discover such interactions using existing approaches. We have previously developed a pipeline, DeepPVP, that combines automated inference with deep neural networks to identify the likely causative variants in whole exome or whole genome sequence data. This exploits phenotypic similarity between patient phenotypes and the large body of genotype-phenotype data available for both humans and model organisms. Here, we present OligoPVP, which builds on Deep PVP to highlight potential causative variants in multiple genes for which there is evidence of direct protein-protein, network or regulatory interaction, predicated on the observation that variants in genes within the same pathway or network show similar or related disease phenotypes. Using synthetic genomes constructed from information in the Digenic Disease Database ([DIDA: http://dida.ibsquare.be/](http://dida.ibsquare.be/)) and disease annotations to the human phenotype ontology, we are able to recover established digenic and trigenic variants in the same genomes. Out of 164 whole genome sequences where two variants were inserted, we find both causative variants (i.e., the two variants we inserted) as the highest ranked variants in 88 cases (53.66%) and within the top ten ranks in 107 cases (65.24%). For the 25 cases of triallelic diseases, we find all three causative variants within the first three ranks in 10 cases (40.00%) and we find all three causative variants within the top ten variants in 14 cases. Our results show that OligoPVP can efficiently detect digenic and higher order interactions between variants in different genes using a phenotype-driven approach, and identify combinations of potentially etiologically important variants in whole genomes.

**Automated disease-specific variant classification for rare autosomal recessive disorders.** *M.C. Schu, S.W. Erickson, N. Whitehead.* Center for Genomics in Public Health and Medicine, RTI International, Research Triangle Park, NC.

Compiling accurate prevalence estimates and comprehensive inventories of disease-causing variants is an inherent challenge in characterizing rare Mendelian disorders. Because of the low incidence (e.g. 1 case in every 10,000 births or smaller), even large genetic screening studies that actively recruit for cases are likely to miss the full range of genomic aberrations that lead to the disorder. If, however, the causal gene is known for a disease of interest, population genetic databases can be leveraged to help fill in the gaps from large screening efforts and infer the population frequency of predicted disease-causing variants. Nevertheless, even with sophisticated functional classification tools, it is difficult to determine which predicted deleterious variants will alter the protein fitness to a degree that is sufficient for inducing the disease state in carriers. Manual curation of predicted deleterious variant might be used to improve the specificity of functional predictions; however, drawbacks to this approach include scalability limitations and concerns regarding reproducibility. As an alternative method for expanding the inventory of disease-causing markers, we present an automated method for predicting novel variants that are causal for autosomal recessive disorders. Our approach begins by compiling a training set of variants whose pathogenic status with respect to the autosomal recessive disease of interest has been well established in either ClinVar or other comparably rigorous literature sources. This list of confirmed causal and benign variants is then run through a battery of variant functional prediction tools, including PROVEAN, SIFT, and CONDEL. From the scores of these algorithms, a composite model is constructed that predicts the disease state of a hypothetical homozygous carrier for a given variant. The key innovation of our approach is directly predicting the disease state induced by the variant rather than the intermediate impact of the mutation on protein function. The resulting disease-specific classifier can be applied to the user's population database of interest to predict novel variants that are likely to be causal for the disorder in question. We have applied this approach to multiple rare genetic disorders and demonstrate the utility of the method for improving disease prevalence estimates and identifying new targets for genetic screening panels.

**BayesDel and REVEL outperform other *in silico* meta-predictors for variant classification.** Y. Tian, A. Chamberlin, R.B. Fenwick, T. Pesaran, C. Gau, S. Li, H.M. Lu, M.H. Black, D. Qian. Ambry Genetics, Aliso Viejo, CA.

**Introduction:** Many *in silico* predictors have been developed for assessing the pathogenicity of missense variants. However, evidence-based thresholds for assessing *in silico* scores are largely unavailable, and diagnostic laboratories utilize different scores and criteria for variant interpretation. **Methods:** We compiled a dataset of 4,094 missense variants in 66 genes with unambiguous ClinVar classifications, and evaluated 5 commonly used *in silico* meta-predictors: CADD, REVEL, Eigen, MetaSVM and BayesDel, and the combination of 2 individual predictors: SIFT/Polyphen2. We used logistic regression to compute gene-specific and global thresholds for assigning benign and pathogenic evidence based on the estimated probabilities of pathogenicity (0.2 and 0.8 for gene-specific, and 0.1 and 0.9 for global thresholds). We then assessed prediction performance using leave-one out cross-validation.

**Results:** Gene-specific thresholds for benign and pathogenic evidence varied widely among genes. For example, gene-specific REVEL and BayesDel thresholds for benign evidence ranged 0.027 to 0.710 and -0.517 to 0.252, respectively; gene-specific REVEL and BayesDel thresholds for pathogenic evidence ranged 0.501 to 0.969 and 0.002 to 0.550. REVEL and BayesDel had the highest positive and negative predictive values and overall prediction performance (PPV=97%, NPV=97%, and OPP=0.90 for each, respectively) and nearly equivalent yield (76.1% and 75.4%, respectively). Notably, BayesDel had slightly less variation in performance statistics than REVEL across all genes analyzed (OPP SD=0.04 vs. 0.06, respectively). MetaSVM had only slightly lower PPV, NPV and yield (96%, 96%, 74.1%), but greater variation in performance across all genes (OPP SD=0.09). Eigen and CADD had similarly high PPV and NPV (range: 91-97%), but substantially lower yield (53.1% and 52.7%, respectively). The combination of SIFT and PolyPhen2 also had similar NPV (95%), but substantially lower PPV (79%), OPP (0.80), and yield (62%).

**Conclusions:** REVEL and BayesDel outperform other commonly used *in silico* predictors, and their corresponding gene-specific or global thresholds for predicting pathogenicity can be used to provide accurate evidence for variant assessment in accordance with ACMG/AMP guidelines.

**Quality control for 141,456 human exomes and genomes in the Genome Aggregation Database: An open-source, high-throughput computational workflow.** G. Tiao<sup>1</sup>, L. Francioli<sup>1,2</sup>, K.J. Karczewski<sup>1,2</sup>, K. Laricchia<sup>1</sup>, J. Alfoldi<sup>1</sup>, L. Gauthier<sup>1</sup>, T. Poterba<sup>1</sup>, D. King<sup>1</sup>, A. Wang<sup>1</sup>, C. Seed<sup>1</sup>, M. Daly<sup>1,2</sup>, B. Neale<sup>1,2</sup>, D. MacArthur<sup>1,2</sup>, The Genome Aggregation Database (gnomAD) Consortium. 1) Broad Institute of MIT and Harvard, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA.

The Genome Aggregation Database (gnomAD) is the largest public collection of sequenced humans, currently spanning 141,456 unrelated individuals of diverse ancestry. The database is accessible online ([gnomad.broadinstitute.org](http://gnomad.broadinstitute.org)) and is widely used as an aid in clinical variant interpretation and as a general resource for human genetics research. With 125,748 exome and 15,708 whole-genome samples, the size of the gnomAD 2.1 dataset has made it impractical to analyze using standard software programs. In addition, current quality control (QC) analysis of sequencing data typically requires multiple pieces of software that are poorly integrated with each other. Leveraging Hail (<https://hail.is/>), an open-source framework for distributed genetics data analysis, we have built a fast, efficient, and comprehensive computational pipeline that automates sequencing data quality control and scales to hundred of thousands of samples. The pipeline can be parallelized locally or on a cloud platform; generates results that are highly reproducible; and requires little manual intervention to run. Our workflow is written entirely in python using the Hail library and requires no other software. Our workflow is divided into a sample QC component and a variant QC component. The sample QC component automatically infers sex, duplicate samples, familial relationships, and ancestry and then uses this information to compute relevant quality control metrics and generate plots to exclude low-quality samples. The variant QC portion of the pipeline computes allele-level metrics directly from genotype quality metrics and performs allele-level filtering using a random forest model. Variant quality metrics plots are generated. We show that this approach outperforms standard methods such as the Genome Analysis Toolkit (GATK) Variant Quality Score Recalibration (VQSR). Given its advantageous features and the modularity of its components, we believe the workflow will prove useful as a template to other groups working to analyze large genomic datasets and have released the code at [https://github.com/macarthur-lab/gnomad\\_qc](https://github.com/macarthur-lab/gnomad_qc).

**Descriptive analysis of identification and characterization in-silico of genomic susceptibility focus associated with rare diseases, a bioinformatic approach.** *F. Tobar-Tosse, C. López-Burbano, P. Hurtado-Villa.* Department of Basic Science for Health, Pontificia Universidad Javeriana Cali. Cali - Colombia.

**Introduction:** Rare Diseases (RDs) are a group of several diseases with low prevalence, and depending on the country their definition varies ranging from 1 in 500.000 to 1 in 2.000<sup>1</sup>, but all together affects a significant number of people. The World Health Organization (WHO) established that 8% of the world's population are affected by RDs<sup>2</sup>making a cumulative impact importance for public health. The 80% of RDs have genetic etiology, most of them related to single gene disorders<sup>3</sup> and the rest with unknown mechanisms; this diversity makes it important to perform a detailed genetic and molecular approach in each disease that may come from areas such as bioinformatics, which facilitate the understanding of the physiopathology of these entities. **Objective:** to describe patterns among focus of genomic susceptibility associated with RDs, in order to characterize sensible regions to structural variations on the human genome through a bioinformatic analysis of the information available in public databases about RDs. **Methods:** a descriptive repository of phenotypic, clinical, molecular and epidemiological characteristics of RDs was created with information from public databases (*Office of Rare Diseases Research* and *OMIM*). Also, exploring specific databases (*Genebank*, *Genome Browser*, *Kegg*), a molecular repository was created, where genes, proteins, metabolic processes and gene expression (if there was a registry) for each disease were identified. Finally, a descriptive statistical analysis was made. **Results:** We found 145 RDs of importance due to its localization on region sensible to structural variation. The patterns identified were 14 and the genes within these patterns were 25. The genes involved in most biologic processes were *PIK3CA*(68,02%), *COL2A1*(9,72%) and *STAT3*(3,85%). Autosomal Dominant was the most recurrent inheritance pattern, while oncogenic diseases had the major number of biologic processes affected. **Discussion:** structural genomic studies have been established as effective methods for study RDs, since they allow to classify and describe more precisely the genes involved in each of these disorders<sup>3</sup> as well as to establish possible associations between genomic elements and RDs. **Conclusions:** Here we present the first approach to established specific focus of genomic susceptibility for RDs. Further investigation in phenotypic correlation is needed in order to fully understand their genetics and epigenetic factors that enhance an aberrant phenotype.<sup>4</sup>.

**1466F**

**Bioinformatic software pipelines strategies for analysis of amplicon-based assays for clinical applications.** *F. Vezzi.* Devyser AB, Stockholm, Sweden.

**Introduction:** Next Generation Sequencing (NGS) is the new black when it comes to finding the genetic cause of inherited diseases as well as oncology. To effectively use NGS in everyday diagnostics a combination of easy laboratory workflow and easy to interpret data analysis are needed. To meet the first requirement, Devyser AB developed four single tube library preparation assays for both oncology (BRCA) and hereditary (Thalassemia THAL, Familial Hypercholesterolemia FH, and Cystic Fibrosis CFTR) conditions. To meet the second parameter, a combination of technical solutions and multiple supported analysis software allow to easily identify both Single Nucleotide Variants (SNV) and Copy Number Variants (CNV) in a stable and reliable way. A study on five different software tools has been conducted to evaluate the ability of the tools to correctly call SNV and CNV. **Method:** Four out of five tools are third party proprietary tools, while the last one is an internally developed tool used for QC and benchmarking. For each assay, we prepared and sequenced samples with previously characterized variants and analyzed each sample with all the tools supporting the kit. 158 samples have been analyzed with five tools for BRCA germline variants, 88 FFPE samples have been analyzed with four tools for somatic variants, 188 samples have been analyzed with five tools for CFTR variants, 24 samples have been analyzed with four tools for FH related variants, and 279 samples have been analyzed with three tools for THAL variants. **Preliminary Results:** All the tools show a clinical sensitivity >99.9% for SNVs, thus showing their ability to correctly identify SNV variants. Analyzing samples for germline variants, the number of False Positive (FP) calls is negligible. When analyzing samples for somatic variants and searching for low frequency variants we noticed the presence of tool-specific variants that can be discarded via a frequency database approach. Reliable calling of CNV in amplicon based panels is a difficult task. In order to improve CNV calling, all Devyser kits are designed to have a low amplicon run variability. In addition to this, special amplicons, dubbed Direct Detection amplicons (DD), are designed to span over important CNVs with known breakpoints. Tools able to combine standard CNV analysis to DD are not only able to correctly identify all possible clinically relevant CNVs, but can also facilitate the reporting of complex variants, for example in Thalassemia.

**A suite of automated sequence analyses reveals a difference in the genetic burden of probands versus unaffected siblings.** A. Wu, F. Gu, M. Gordon, L. Vlahos, S. Macnamara, A. Kim, E. Burke, M. Malicdan, C. Lau, D. Adams, C. Tiff, C. Toro, T. Markello, W. Gahl. National Human Genome Research Institute, Bethesda, MD.

Continuing problems in genome-wide analyses for disease discovery prevent complete analysis of sequence data in small, informative regions of the genome. Most of these regions are typically excluded by the use of a global quality score threshold, potentially excluding true positive deleterious variants. The intramural NIH Undiagnosed Diseases Program (UDP) has developed a phenotype-blind, automated, agnostic pipeline that allows high-confidence genotyping in regions of low coverage and/or low variant quality score, and permits analysis in coding and noncoding regions for variant Mendelian models, including homozygous recessive, de novo dominant, compound heterozygous recessive, X-linked, hemizygous, and, in very well-sequenced positions, novel exon deletions. The recovery of true positive genotype calls involves combined strategies, including re-genotype calling with ethnically matched population prior probabilities and pedigree-aware conditional probabilities in nuclear families. Algorithms were developed that interrogate local BAM file regions to include true positive and reject false positive variant calls without using global quality scoring; instead the algorithms use pedigree inheritance, random base error density, and ethnically matched population frequency prior probabilities obtained from 1300 exomes of the UDP cohort. The pipeline also detects larger deletions on the exon-level for individuals with no coverage in regions well covered in other family members and in 1300 samples using identical chemistry. To evaluate the pipeline's effectiveness in capturing truly deleterious candidate variants as part of a person's genetic burden, two symmetrical analyses were performed using the pipeline. First, the proband was the subject of analysis ( $n=97$ ) and, second, the proband's unaffected sibling(s) was the subject. This test resulted in short lists of deleterious candidate variants that numbered 6.6 per proband versus 5.8 per sib ( $p<0.05$ ). This indicates that, for most of these cases, the true causal change for each proband is likely present in their respective output from our pipeline. These additional potential solutions, if validated, would nearly double the current 30% success rate for the UDP in quartet pedigree cases. We offer this pipeline to the community for new disease discovery.

**Enhanced knowledge generation of rate-changes in transcriptional regulation using ontology rules, sentence structure and deep neural networks.** Y. Zhang, W. Liu. Hubei University of Medicine, shiyan, China.

Considering the complexity of biosystems, it's very challenging to automatically and accurately generate biological knowledge from bio-literatures. The existing biological databases do not record temporal information of gene regulations, which are very important to understand the underlying mechanism of many diseases and biological processes. We previously constructed a corpus of time-delays related to the transcriptional regulation (bio-events) of yeast from the PubMed abstracts, summarized the knowledge rules of the bio-events as rate-changes in transcriptional regulation ontology, and obtained 86% accuracy by using the decision tree classifier with the ontology rule features. Deep neural networks (DNN) achieve great success in many machine learning applications including knowledge generation. The word2vec model learned the word embedding features from documents can achieve 50-70% accuracy on many text classification tasks. However, the sentence structure and domain knowledge are rarely considered in DNNs of document classification. We proposed to combine word2vec features, sentence structure, and our ontology rule features to improve DNNs for knowledge generation of rate-change in transcriptional regulation. Experimental results show that on predicting transcriptional regulation, the word2vec in DNN model achieves 73% accuracy, while our combined features in DNN with same parameters achieves 96% accuracy; on predicting the rate-changes in transcription regulation events, word2vec in DNN achieves only 59% accuracy, and our combined features in DNN achieves 90% accuracy. This shows the power of ontology rules and sentence structure features with DNN in knowledge generation.

**MUNIn (Multiple tissue UNifying long-range chromatin Interaction detector): A statistical framework for identifying long-range chromatin interactions from multiple tissues.** Y. Yang<sup>1</sup>, M. Hu<sup>2</sup>, Y. Li<sup>1,3,4</sup>. 1) Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Quantitative Health Sciences, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH; 3) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 4) Department of Computer Science, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Chromatin spatial organization (interactome) plays a critical role in genome function. Deep understanding of interactome can shed insights into transcriptional regulation mechanisms and human disease ontology. One essential task of interactomic data analysis is to identify long-range chromatin interactions (i.e., peaks). Existing approaches, such as HiCCUPS, Fit-Hi-C and FastHiC, are all designed for single tissue analysis. None of them is able to account for unbalanced sequencing depths and heterogeneity among multiple tissues in a unified statistical framework. To address these challenges, we have developed a novel statistical framework MUNIn (Multiple tissue UNifying long-range chromatin Interaction detector) for identifying long-range chromatin interactions from multiple tissues. MUNIn adopts a hierarchical hidden Markov random field (H-HMRF) model, in which the status of each pair of interacting chromatin loci (peak or non-peak) depends not only on the status of loci pairs in its neighborhood region, but also on the status of the same loci pair in other tissues. To benchmark the performance of MUNIn, we performed comprehensive simulation studies and real data analysis. Compared to tissue-by-tissue analysis, MUNIn can achieve much lower false positive rates for detecting tissue-specific peaks (2.6 ~ 35.4%), and much enhanced statistical power for detecting tissue-constitutive peaks. Our data have demonstrated that MUNIn is a powerful tool for the integrative analysis of multi-tissue interactomic data.

**1470W**

**ChIA-PoP: An integrated tool for ChIA-PET data analysis.** W. Huang<sup>1</sup>, L. Niu<sup>2</sup>. 1) National Exposure Research Laboratory, US EPA, RTP, NC; 2) Department of Environmental Health, College of Medicine, University of Cincinnati, Cincinnati, OH.

Chromatin Interaction Analysis by Paired-End Tag Sequencing, or ChIA-PET, is a popular assay method for studying genome-wide chromatin interactions mediated by a protein of interest. The main goal of ChIA-PET data analysis is to detect interactions between DNA regions. Here we propose a new method and the associated data analysis pipeline, ChIA-PoP, to detect chromatin interactions from ChIA-PET data. We compared ChIA-PoP with other popular methods, including hypergeometric model (used in ChIA-PET tool), MICC (used in ChIA-PET2), ChiaSig and mango. The results show that ChIA-PoP outperforms those methods by detecting chromatin interactions more accurately. ChIA-PoP software tool is freely available to the public as an R package.

**1471T**

**The NIH Genetic Testing Registry (GTR): A 2018 genetic test submission trends report.** *M.A. Hoepfner, A.J. Malheiro, M. Benson, S. Chitipiralla, B. Gu, V. Hem, C. Liu, Z. Maddipatla, D. Maglott, G. Zhou, J.B. Holmes, B.L. Kattman.* Medical Genetics and Human Variation, National Center for Biotechnology Information, Bethesda, MD.

The Genetic Testing Registry (GTR, <https://www.ncbi.nlm.nih.gov/gtr/>) is a free, searchable, online repository of clinical and research genetic tests voluntarily submitted by US and international laboratories. Tests can be molecular, cytogenetic or biochemical and evaluate somatic phenotypes, Mendelian disorders, and pharmacogenetic responses. Housed at NCBI, GTR standardizes test data, promotes transparency, and fills gaps in information about genetic tests. Atomized into orderable test units and indexed by key fields, GTR enables clinicians to find the most appropriate test for the patient. As of May 2018, GTR includes 54,612 genetic tests submitted by 507 laboratories from 40 countries, covering 16,426 genes and 11,208 conditions. We compared test submissions by field entries for June 2014 and May 2018. Entry rates for minimal fields such as 'Analytical Validity' remain consistent as they are required for test registration, and top values for 'Purpose of the Test' showed only minor changes from the earlier year. Primary methodology presents the most striking change: the top 5 methods in 2014 are Bi-directional Sanger Sequencing (B-Sanger; 52.2%), Multiplex Ligation-dependent Probe Amplification (MLPA; 10.2%), Uni-directional Sanger sequencing (U-Sanger; 7.8%), Comparative Genomic Hybridization (CGH; 7.1%), and Next-Generation (NGS)/Massively parallel sequencing (MPS) (6.2%); in 2018 NGS (53.2%) leads followed by B-Sanger (28.3%), MLPA (5.1%), CGH (3%), and U-Sanger (2.2%). This dichotomy is expected, as the clinical community remains dedicated to providing diagnostic services, though the methods to analyze samples have quickly changed. Test counts showing completion of recommended fields such as Target Population, evaluation methods for Variants of Uncertain Significance (VUS), Proficiency Testing Method, Clinical Utility, and Clinical Validity are all increased in 2018 compared to 2014 data, although there is a decrease in completion for these fields as a percentage of total tests (between 30-37%). GTR has massively expanded during recent years with enhanced efficiency in submission for more complex tests. There is a trend towards submission of tests employing high-throughput NGS. Recommended fields such as VUS evaluation and Clinical Utility are being submitted at a lower rate; however, with expansion in the number of tests available, this information is becoming increasingly important to the ordering clinician.

**1472F**

**Variant Ranking Toolkit (VaRTK): An ensemble approach for rapid variant interpretation in clinical diagnosis.** *M. Manoharan, L. Iyer, GP. Singh, R. Gupta, R. Gupta.* Bioinformatics, Medgenome, Bangalore, India.

**Background:** The growing availability of NGS platform for diagnosis of Mendelian disorders calls for robust methods to facilitate scalable variant prioritization. Distinguishing disease-causing genetic variants from a large number of candidate variants is a complex task. While there are several tools available to identify putative causal variants, their performance vary widely. Therefore new improved methods that can rank the rare coding variants based on their pathogenicity would help in narrowing down the search space and aid prompt diagnosis. **Methods** We developed an ensemble method (VaRTK) based on a logistic regression model trained using rare (MAF  $\leq 0.01$ ) putative benign variants from 1000G (8,993 variants) and disease causing missense variations (DM) from HGMD added after Jan 1, 2015 (11,016 variants). We used 18 different rank scores from 14 prediction tools as features. The model was tested using 55,208 DM mutations added in HGMD before 2015 and 108,968 benign variants from 1000G. An independent evaluation of VaRTK was also performed using data from ~1200 clinical samples which was manually interpreted for clinically actionable variants using standard filtering approaches.

**Results:** The Area Under the Curve (AUC) for VaRTK was 0.88 for the training data and 0.90 for the testing data. For ~1200 clinical samples, VaRTK was able to rank the reported variants among the top5 ranked variants in ~40% of the samples. For the remaining clinical samples, VaRTK prioritized the reported pathogenic variants in the top 100 and likely pathogenic variants in the top 500, thereby reducing the otherwise large search space of ~1000-1500 variants. On the contrary, other popular tools such as SIFT and Polyphen2 predict many variants to be deleterious, therefore decreasing their efficiency to be used as a ranking method. **Conclusions:** The observed results opens up the possibility of using ensemble methods such as VaRTK, MetaLR, MetaSVM in ranking variants for efficient clinical interpretation. This will largely expedite variant identification and enable scalability in a clinical setting reducing the interpretation time by 5-10 fold. Our analysis also highlights the issues with SIFT and Polyphen2 scores due to lack of specificity and recommends the use of ensemble approaches. We are further evaluating the use of other gene-based prioritization scores to enhance the utility our method.

**1473W**

**The genesis of good visualizations - AVADIS Platform.** *H.K. Adil, S. Malhan, S. Ramachandrala, A.K. Pabbathi.* Strand Life Sciences Pvt. Ltd., Bangalore, Karnataka, India.

**Access, Visualize, Analyze, Discover (AVADIS)** is the philosophy that lies at the heart of StrandNGS, our one-stop software for all sequencing data analysis. With the motto of deskilled decision analytics for biologists, we have created an architecture that allows researchers to dive into analysis, visualization, and modeling while the software takes care of the statistical, mathematical, and computational principles. Each visualization option in AVADIS is created by following engineering and design principles to ensure accurate depiction of large-scale data and facilitation of intricate interpretations. Additionally, all plots are configurable, interactive, and ease the exploration across plot types. In addition to the already existing metadata framework, elastic Genome Browser, data-specific gene views, and covariate analyses options, we have added a new functionality called the smooth scatter plot. Here, illustrating this plot we discuss the thought process that goes into the design of a good publication-quality visualization. When scatter plot has several points stacking up at a given (x,y), it is hard to visualize the distribution of points in the plot. Very often, multi-colored heat-scatters are used to indicate the density in unit squares. However, they are discrete and hard to read; leading to quick and false interpretation of the data patterns. To overcome this problem, a smoothed version of scatter plot can be used by applying image-blur techniques that are well known in image processing world. Once the scatter plot data is transformed into image by binning into some predetermined grid size, Gaussian blurring technique is used to get a smoothed image. The density of points at each location is then depicted by a monochromatic hue color scheme designed based on Ostwald color cones to give the most accurate visualization of the scatter density. Given that the AVADIS framework supports lassoing across views, the genes that are of interest could be highlighted in the smoothed scatter by selecting them in this plot itself or any other plot type that is using the same dataset. Therefore, this visualization plot derived from smoothing of closely stacked data points is of immense help in exploratory transcriptomics studies that aim biomarker identification. Using a large-scale single-cell RNA-Seq study with multiple cell types and developmental stages, we illustrate the purpose, perceptions, and aesthetics involved in the design of these visualizations.

**Deep linear mixed models for structured, high-dimensional trait GWAS.** *F.P. Casale<sup>1</sup>, A.V. Dalca<sup>2,3</sup>, N. Fusi<sup>1</sup>, J. Listgarten<sup>4</sup>.* 1) Microsoft Research New England, Cambridge, MA, USA; 2) Computer Science and Artificial Intelligence Lab, MIT, Cambridge, MA, USA; 3) A.A. Martinos Center for Biomedical Imaging, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA; 4) Department of Electrical Engineering and Computer Sciences, University of California, Berkeley, CA, USA.

Genome-wide association studies (GWAS) have revealed thousands of associations between human diseases and genetic variants, but remain largely limited to simple phenotypes, which limits our understanding of the underlying functional mechanisms. For many diseases, genetic analyses of human anatomy as seen through medical images can help gain functional insights by revealing spatial, tissue and organ-level intermediate effects. However, the methodology for such analyses has not kept pace with the availability of data, owing in part to the challenges in properly modelling the structured, high-dimensional phenotype matrices and to the relatively low sample sizes. In this work, we propose a new statistical method for the genetic analysis of structured, high-dimensional phenotypes. Our approach combines the best of several paradigms: (i) linear mixed models for the proven capabilities in genetic association studies; and (ii) rich-capacity neural networks to extract latent (low-dimensional) phenotypes from high-dimensional data. The resulting deep linear mixed model generalizes mixed models for multiple traits [1] and for transformed phenotypes [2], and extends standard approaches in imaging genetics, which often decouple the phenotype extraction step from the genetic modelling. After benchmarking our method using rigorous simulations, we demonstrate it on ~5,000 brain MRI scans of patients from the Alzheimer's Disease Neuroimaging Initiative, revealing known and novel effects of risk loci for neurological and psychiatric disorders on brain structure. Importantly, our method can predict both localized and broad-scale structural changes associated with these variants. Finally, we analyze multiple mental-health-related measures from individuals in UK Biobank, where we extract and characterize a heritable and high-dimensional generalization of the neuroticism phenotype. Overall, our results demonstrate the general utility and broad applicability of our method and provide new functional insights in the genetics of degenerative and psychiatric disorders. [1] Casale FP, Rakitsch B, Lippert C, Stegle O. Efficient set tests for the genetic analysis of correlated traits. *Nature methods*. 2015 Aug;12(8):755. [2] Fusi N, Lippert C, Lawrence ND, Stegle O. Warped linear mixed models for the genetic analysis of transformed phenotypes. *Nature communications*. 2014 Sep 19;5:4890.

**A fast hierarchical model that leverages multi-mapping reads for the quantitation of gene expression from droplet single-cell RNA sequencing data.** K. Choi, M.J. Vincent, G.A. Churchill. The Jackson Laboratory, Bar Harbor, ME.

Single-cell RNA sequencing (scRNA-Seq) opens a new perspective on the dynamics of gene expression that can be obscured in whole tissue samples. However, quantifying gene expression from scRNA-Seq data poses multiple analytical challenges caused by amplification of the cellular RNA and the limited size of the RNA pool in individual cells. The current trend in droplet-based scRNA-Seq toward exceedingly larger numbers of cells -- with very low per-cell depth of coverage -- increases the sampling bias and technical variability. For example, high proportion of zero counts has been one of the major issues in quantitation of gene expression. We found the current practice of discarding multi-mapping reads (multi-reads) aggravates the challenge of data sparsity and inflated proportion of zeros. Since the read mappability is different from gene to gene, ignoring multi-reads also distorts the rankings of expression level, critical information for many nonparametric approaches in the downstream analyses of single-cell transcriptome profiling. We developed an expectation-maximization algorithm that leverages all the aligned reads including multi-reads and quantifies expressions in each cell at the isoform and gene level. Our hierarchical algorithm then combines information across cells for each gene and updates expression abundance in each cell by referring to how the gene behaves in other cells. In this model, zeros are not all same zeros as we can interpret them in the context of cell population dynamics. We show our partial pooling approach controls issues due to data sparsity in individual cells while maintaining cell-to-cell heterogeneity in the final counts we provide. We demonstrate that our approach improves the performance on downstream analyses such as identifying subpopulation of cells or detecting differentially expressed genes. We also provide a scoring test to determine whether the count data requires zero-inflated models and show that simple hierarchical models are flexible enough to manage inflated proportion of sampling zeros. Probabilistic allocation of multi-reads effectively controls the number of zeros to a degree that zero-inflated models are not a requirement. We implemented our algorithm as an open-source Python package, scBASE, that is available at <https://github.com/churchill-lab/scbase>.

**RUFUS: Reference free variant detection improves accuracy and sensitivity.** A. Farrell, D. Lee, W. Richards, G. Marth. University of Utah, Salt Lake City, UT.

We developed a novel k-mer based variant detection tool, RUFUS, that vastly improves specificity and sensitivity for germline and somatic/tumor *de novo* mutations, and may reveal some of the missing heritability in many genetic diseases. RUFUS is based on direct k-mer comparison, removing the reference from variant detection, and any associated reference bias. This vastly improves the detection of medium sized (20-500bp) insertions/deletions (INDELs) that current methods are unable to reliably detect: small variant detectors (e.g. GATK, FreeBayes) are effective at finding 1-20bp events in read alignments; and structural variant callers (LUMPY, WHAM, etc.) are effective at >500bp events where insert size variations and read coverage anomalies can be confidently detected. As a result, medium length, INDELs have been missed by most sequencing studies. We are currently applying RUFUS to 519 family quartets (mother, father, autistic child, unaffected sibling), a total of 2,076 samples sequenced by the Simon's Foundation Autism Research Initiative to 30x whole genome coverage. This will be the largest *de novo* variation study to date, and combined with RUFUS's sensitivity for all variant types and sizes will provide the most complete picture of *de novo* variation ever constructed. Our preliminary data on a 40 family pilot study has shown that the rate of medium length *de novo* events is twice that of structural events (12 medium-length vs 6 SV events), suggesting that these events may be more common than previously thought. In addition to increased sensitivity for variants of all sizes, RUFUS also shows far higher specificity over mapping based approaches. Previous research has suggested that the human per-nucleotide *de novo* SNV mutation rate is  $\sim 1.25 \times 10^{-8}$ , or roughly 75 mutations per generation. In our analysis of numerous disease family trio data sets at the University of Utah, RUFUS finds between 77 and 116 *de novo* mutations per child genome, including 74-101 SNV mutations; 98% also seen in mapping-based variant calls. Conversely, traditional mapping based methods call on average 150,000 *de novo* calls per child, dominated by mapping and reference errors, drowning out true variation, and post-processing and genome masking is necessary to improve these, still leaving thousands of *de novo* calls. RUFUS requires no filtering or masking of the genome, enabling true genome wide variant detection of all mutation types, at uniquely high specificity.

**Preparing short read sequencing data for variant filtration and calling with deep learning.** S. Friedman, L. Gauthier, Y. Farjoun, E. Banks. Broad Institute of MIT and Harvard, Cambridge, MA.

Initially developed for image processing, Convolutional Neural Networks (CNNs) have recently been applied to genomics, where they have advanced the state-of-the-art in a number of important applications. Several CNN-based algorithms for both variant calling and filtration have shown impressive results. To be processed by a neural network, a site of genetic variation must be encoded as a numeric tensor. The 'one-hot' encoding represents each genomic site as a 4-vector, one row for each DNA base, with a 1 in the row corresponding to the observed base and 0s everywhere else. This is a natural and unbiased encoding for raw DNA sequences, but when the input is short read sequencing data, as output by an Illumina sequencing machine for example, the tensor encoding involves many subtle and consequential choices. Here, we show several of these choices have profound impacts on the performance of CNNs. Specifically, we explore three ways to improve CNN performance, as measured by F1-score, AUC-ROC and AUPRC, via tensor encoding alone. All encoding methods are available in the GATK's new CNNVariant toolset. First, we quantify the importance of local re-alignment of the reads with a de Bruijn graph to resolve long insertions and deletions. Then, we show how read sorting by reference start position, as is often practiced in the literature, is inferior to sorting based on alternate allele support or pileup entropy. If a heterozygous site of variation exist in the region covered by the tensor, then sorting by the base read at this site clearly reveals the support for each of the haplotypes. This is especially important for CNNs that include convolution in the pileup direction, because the weight sharing in those convolutions assumes structure along the pileups. For variant calling applications, at the time of tensor creation, it is unknown if there are any heterozygous sites within the region covered by the tensor; nonetheless, sorting the reads by the pileup column with maximum entropy produces a similar effect. Lastly, we demonstrate a natural and efficient encoding for base qualities. Finally, varying CNN architectures by depth, width, connection-type and capacity we explore the relative importance of tensor encoding versus hyper-parameter optimization. Experiments across many CNNs with vastly different hyper-parameter settings establish the curious fact that in many cases the choice of tensor encoding is more consequential than the CNN architecture itself.

**Medical ontologies for precision medicine and translational research.** M.A. Haendel<sup>1,2</sup>, J.A. McMurry<sup>2</sup>, N.L. Harris<sup>3</sup>, R. Relevo<sup>2</sup>, C.J. Mungall<sup>4</sup>, P.N. Robinson<sup>2</sup>, C.G. Chute<sup>5</sup>. 1) Dept of Environmental and Molecular Toxicology, Oregon State University, Corvallis, OR., USA; 2) Department of Medical Informatics and Clinical Epidemiology, Oregon Health and Science University, Portland, OR 97239, USA; 3) Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA; 4) The Jackson Laboratory, Farmington, CT 06032, USA; 5) School of Medicine, School of Public Health, and School of Nursing, Johns Hopkins University, Baltimore, MD 21205, USA.

The quantity and variety of medical information is exploding, both in research labs and in the clinic. To realize the promise of precision medicine, informatics tools are needed to unify and leverage this data for medical decision making. For this, we need systematic ways to represent knowledge across multiple disciplines such that it can be reasoned over--in other words, we need ontologies. Ontologies go beyond most standard clinical taxonomies or controlled vocabularies by defining relationships between concepts to enable computational logical reasoning. However, ontologies and their corresponding machine learning implications are a young field; many of those who could benefit do not yet know what ontologies are or how to use them. We therefore recently developed an introductory review of medical ontologies including the literature from 2008 - 2017. There are many disease and phenotype ontologies, with varying approaches to data representation and a wide range of applications in biomedicine. The one used most often for rare disease diagnosis is the Human Phenotype Ontology (HPO), which encodes phenotypic abnormalities encountered in human disease. The HPO currently includes over 13,400 terms, most of which have layperson synonyms associated with them. By representing specific phenotypes in a structured, hierarchical form, disease ontologies allow patient phenotype profiles to be computationally compared with the typical presentation of known diseases to aid in diagnosis. Resources such as the HPO also enable patients to record their own phenotypic data (using tools such as Phenotypr.com) to facilitate discussions with their physicians and help improve diagnosis and treatment. The creation and application of models of disease, phenotypes, and the environment using interoperable ontologies will be a game changer, with profound impact on patients, diagnostic practices, and healthcare. Clinical judgment will always remain central to medical decision making, but by unburdening physicians from routine information retrieval tasks and by providing a computational foundation for the interpretation of medical data, ontologies are accelerating our progress towards true precision medicine.

**Updating an efficient pipeline for local ancestry inference.** *E.M. Jewett, G.D. Poznik, K.F. McManus, K. Bryc, J.L. Mountain, A. Auton, 23andMe Research Team.* 23andMe, Mountain View, CA.

The goal of local ancestry inference is to identify the population of origin at each base in the genome of an individual. At 23andMe, inference is performed by an efficient pipeline known as Ancestry Composition. Ancestry Composition employs support vector machines (SVM) to assign local ancestries to windows along the genome, as well as a hidden Markov model to combine information across window-level SVM calls. The Ancestry Composition pipeline is computationally efficient and has demonstrated low error rates on both simulated and real data. Here, we explore methods for improving the window-level classification component of the pipeline by introducing a method based on the positional Burrows-Wheeler transform (PBWT). This adaptation of Ancestry Composition improves precision and recall, enables window-free local ancestry estimation, and improves computational efficiency.

**Exploring the consistency of the quality scores with machine learning for next-generation sequencing experiments.** *M. Oh<sup>1</sup>, E. Cosgun<sup>2</sup>.* 1) Virginia Tech, Blacksburg, VA 24061; 2) Microsoft AI & Research, Redmond, WA 98052.

Next-Generation Sequencing (NGS) enables massively parallel processing, allowing lower cost than the other sequencing technologies. In the subsequent analysis with the NGS data, one of the major concern is the reliability of variant calls. Although researchers can utilize raw quality scores of variant calling, they are forced to start the further analysis without any pre-evaluation of the quality scores. Here, we present a machine learning approach for estimating quality scores of variant calls derived from GATK best practice powered by Microsoft Genomics service. Based on three machine learning algorithms, including Multivariate Linear Regression (MLR), Random Forest Regression (RFR), and Neural Network Regression (NNR), data-driven predictive models were trained on variant call format (VCF) files, which contain technical values of GATK annotation module for each variant call. We analyzed correlations between the quality score and these annotations, specifying informative annotations which were used as features to predict variant quality scores. Some annotations that are simple statistics or scaled values originated from another annotation were excluded from the features. To test the predictive models, we simulated twenty-four paired-end Illumina sequencing reads with 30x coverage based on twenty-four artificial human genomes generated by perturbing a human reference genome with an injection of a wide range of variants, including SNPs, small indels, and large structural variants. Also, twenty-four human genome sequencing reads resulted from Illumina paired-end sequencing with at least 30x coverage were secured from Sequence Read Archive (SRA). Using Microsoft Genomics service, VCFs were derived from simulated and real sequencing reads. We trained the regression models on training data obtained by splitting each VCF data into training and test data, evaluating the prediction performance on the test data. We observed that the prediction models learned by RFR outperformed other algorithms in both simulated and real data. The quality scores of variant calls were highly predictable from informative features of GATK Annotation Modules in the simulated human genome VCF data (R<sup>2</sup>: 96.7%, 94.4%, and 89.8% for RFR, MLR, and NNR, respectively). Interestingly, the robustness of the proposed data-driven models was consistently maintained in the real human genome VCF data (R<sup>2</sup>: 97.8% and 96.5% for RFR and MLR, respectively).

**Exploring disease-associated regions across genes and gene families at *mbv.broadinstitute.org*.** E. Pérez-Palma<sup>1</sup>, P. May<sup>2</sup>, S. Iqbal<sup>3</sup>, H. Heyne<sup>3,4</sup>, P. Nürnberg<sup>1</sup>, A. Palotie<sup>3,4,5</sup>, M. Daly<sup>3,4,5</sup>, D. Lal<sup>1,3,4,6,7</sup>. 1) Cologne Center for Genomics, University of Cologne, Cologne, Northern-Rhine Westphalia, Germany; 2) Luxembourg Centre for Systems Biomedicine, University Luxembourg, Esch-sur-Alzette, Luxembourg; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 4) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA; 5) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 6) Epilepsy Center, Neurological Institute, Cleveland Clinic, Cleveland, OH; 7) Genomic Medicine Institute, Lerner Research Institute Cleveland Clinic, OH.

Protein key functional regions are more frequently subject to pathogenic variants in patients than to neutral variants in controls. However, patient/control gene level comparisons of missense variant distribution is still underpowered to identify disease-associated regions. Yet, key functional regions are conserved among gene family members. We hypothesize that gene family members display a similar missense variant distribution pattern. Our aim was to leverage gene-family information to increase the statistical power in patient-vs.-control variant burden analyses to identify disease-associated regions and guide pathogenic interpretation. Gene family information was retrieved from the Biomart platform of Ensembl v92 and only the canonical transcript was considered. Protein alignments were performed using the MUSCLE software. "Neutral-control" and "Pathogenic-patient" missense variants were extracted from gnomAD v0.2 and ClinVar/HGMD databases (Feb, 2018), respectively. We implemented a binary approach to map the variants in each gene and gene-alignment. Further, a Fisher's exact test was performed to identify "missense pathogenic regions" (MPRs) defined as amino acids (aa) regions that are at the same time depleted from variation in the general population and enriched with pathogenic variants. We mapped 2,219,811 gnomAD and 97,391 ClinVar missense variants into 9,991 protein sequences belonging to 2,871 gene families. We identified 398 MPRs spanning 4,827 aa in 1,090 genes. In addition, single-gene analysis was able to identify 225 additional significant MPRs involving less than half of the aa (n = 2,344) detected with family alignment. For 46.7% (2,254/4,827) of the aa in MPRs no patient variants have been reported yet. To evaluate the utility of MPRs, we tested MPR enrichment in a set of 84 disease-associated genes vs. all other genes for *de novo* missense variants from 11,000 trios with neurodevelopmental disorders. We observed enrichment for variants within MPRs in known disease-associated genes compared to other genes (p=1.09x10<sup>-37</sup>). Our method can evaluate pathogenicity of positions across the linear protein sequence alignment and highlight disease-associated regions that would not have been identified through single-gene approaches. All results were deployed online into a user-friendly platform available at <http://mbv.broadinstitute.org> where MPRs as well as the raw gnomAD/ClinVar missense burden data can be explored at a gene- or gene-family level.

**AVX2 based hardware acceleration in StrandNGS.** A. Pal, S. Ramachandru, S.C. Cherukuri. Strand Life Sciences Pvt. Ltd., Bangalore, Karnataka, India.

Algorithms that identify similarity between two nucleotide sequences lie at the heart of aligning Next Generation Sequencing (NGS) data. The standard methods identify the substrings of maximal similarity, as defined by similarity matrix, for a pair of two nucleotide sequences. The problem could be solved by exact dynamic programming (DP) method using Smith-Waterman algorithm which is applied to determine if the read matches around the area anchored by the seed. Given the prominence of this step, coupled with its inherent complexity, many commercial and open-source software solve this problem in varied ways. Additionally, there are recommendations from these and other vendors to couple these software with expensive, specialized hardware. Here, we propose how a now commonplace hardware feature could be used to the optimum and also save time. StrandNGS, our flagship NGS analysis software could accelerate Smith-Waterman algorithm on Intel and AMD heterogeneous architectures. StrandNGS takes advantage of Single Instruction Multiple Data (SIMD) computing through the use of Advanced Vector Extensions 2 (AVX2) extensions on the processor. On a heterogeneous platform, using AVX2 instructions, Smith-Waterman dynamic programming takes 30 mins for execution, whereas, on a normal hardware (without SIMD) it takes 3-4 hours. AVX2 can execute sixteen 16 bit instructions simultaneously, that means 16 different seed alignments can be performed in parallel in a thread. So, if a machine has 16 threads, 256 (16x16) DPs can be performed simultaneously. Here the most advantageous part is that we are making parallel processing using AVX2 which comes as an in-built processor in all new systems including commodity hardwares like Intel(R) Core(TM) i5-4300U, AMD Zen processor etc. StrandNGS integrates SSE2 and AVX2 seamlessly so that if an old machine doesn't support AVX2, it will automatically switch to SSE2. There is no need of either any high configurable machines nor any external plug-ins. Hence, this is more cost effective for the users. We intend to showcase how StrandNGS continues to make best use of cutting-edge technological advancements for a continuous improvement of NGS analyses efficiency and thereby enhancing user experience.

**Predicting pathogenicity of missense variants using deep learning.** Y. Shen<sup>1,5,6</sup>, H. Zhang<sup>1</sup>, H. Qi<sup>1,2</sup>, C. Chen<sup>1,3</sup>, W.K. Chung<sup>4</sup>. 1) Department of Systems Biology, Columbia University, New York, NY; 2) Department of Applied Mathematics and Applied Physics, Columbia University, New York, NY; 3) Department of Biological Sciences, Columbia University, New York, NY; 4) Departments of Pediatrics and Medicine, Columbia University, New York, NY; 5) Department of Biomedical Informatics, Columbia University, New York, NY; 6) JP Sulzberger Columbia Genome Center, Columbia University, New York, NY.

Accurate predictions of genetic effects of missense variants is critical to the interpretation of genome sequence. Previously published prediction methods have been used to improve power in genetic studies and identify pathogenic variants in clinical genetic testing. However, the performance of these methods is suboptimal, due to several issues, including the complexity of the mechanisms of pathogenic variants, false positives in the training data, and suboptimal usage of large training data sets. Here we report on a new prediction method MVP. MVP uses a deep learning approach to learn protein-context-specific pathogenicity of amino acid changes from large number of curated pathogenic variants. We define the protein context as a window centered on the missense variant. For each residue in the context, we collect information about structural and biophysical properties, evolutionary conservation, and depletion of variation in general population. MVP uses convolutional networks to learn salient features without prior knowledge. Using cancer hotspot mutations as a benchmark, MVP achieved an area under the receiver operating characteristic curve of 0.9, substantially better than other published methods. Applied in genetic analyses of autism and congenital heart disease, MVP had better performance in prioritizing pathogenic *de novo* missense variants than other published methods. To further assess the utility in clinical genetic diagnostic testing, we obtained functional data of ~1800 missense variants (441 deleterious) in *BRCA1* and ~1800 missense variants (258 deleterious) in *PTEN* benchmarks. The area under the precision-recall curve of MVP is 0.76 and 0.81 in *BRCA1* and *PTEN*, respectively, substantially better than previously published methods (0.72 and 0.67, respectively). Setting a threshold to achieve a positive predictive value (PPV) of 0.9, previous methods only correctly classify 20-25% of pathogenic variants, categorizing most of the true pathogenic variants as variants of uncertain significance (VUS). MVP is able to identify 40% of true pathogenic variants with the same PPV threshold, substantially reducing the number of VUS. In summary, we show that MVP significantly improves predictions of pathogenic missense variants by capturing protein context-dependent information using deep learning, and it has the potential to significantly increase the power in genetic studies and enhance the utility of clinical genetic testing.

**MOPower: An R-Shiny application for the simulation and power calculation of multi-omics studies.** H. Syed, G. Otto, D. Kelberman, C. Bacchelli, P. Beales. GOSgene, Genetics and Genomic Medicine, UCL GOS Institute of Child Health, University College London, London, United Kingdom.

In recent years there has been an emergence of multi-omics studies, which seeks to integrate information from the genome, transcriptome, epigenome, metabolome and proteome to better understand clinical phenotypes. Power calculators are currently available for the design of genomic and RNA-seq experiments individually for a variety of outcomes (binary, quantitative and survival traits). However, software is not available which encompasses all this information together with data from other high-throughput omics technologies. Doing this is of particular relevance and benefit in rare disease studies where the sample size is small. With the rapid emergence of multi-omics studies and the complexity of information they consider, there is a need for software to perform power calculations over a range of design scenarios and analytical methodologies. We have developed the interactive R-shiny web application MOPower to perform statistical data simulation and power calculations for multi-omics studies with binary and longitudinal outcomes. The application allows simulation of SNP, rare variant, gene expression and methylation data over a range of rare disease study designs (acute and chronic). MOPower offers many different integration and analytical approaches such as joint regression modelling, multi-factor analysis and multivariate projection-based methodology. The tool calculates the power to detect an association with the phenotype of interest over a specified number of replicates. Sample pilot study data can be uploaded to the application to determine the realistic calculation of study design parameters such as fold change, average MAF and mean gene expression, thereby increasing the accuracy of the simulated data. In conclusion, MOPower will aid in the design of multi-omics studies, providing investigators with essential information on optimal sample size and choice of analytical model. With the increasing wealth of omics data from multiple sources, arises a multitude of issues regarding data integration and analysis. Consequently, this application will help with the development of future multi-omics data integration methods through the comparison of existing methodology.

**CNV analysis of whole exome sequencing data in a clinical diagnostic setting.** D. Becker<sup>1</sup>, M. Ziegler<sup>1</sup>, Y. Dincer<sup>1,2</sup>, R. Brumm<sup>1</sup>, K. Pindl<sup>1</sup>, J. Schulz<sup>1</sup>, K. Mayer<sup>1</sup>, S.H. Eck<sup>1</sup>, H.G. Klein<sup>1</sup>. 1) Center for Human Genetics and Laboratory Diagnostics (AHC), Martinsried, Bavaria, Germany; 2) Chair of Social Pediatrics, Technical University of Munich, Munich, Germany.

The implementation of Next Generation Sequencing (NGS) in a clinical diagnostic setting opens vast opportunities through the ability to sequence all genes contributing to a certain indication simultaneously at a cost and speed that is superior to traditional sequencing approaches. Furthermore, these data allow the identification of small to medium sized copy number variations (CNVs). While the detection of single nucleotide polymorphisms (SNVs) and small insertions and deletions (InDels) is very straight forward, the reliable detection of CNVs from NGS data still poses several problems during data analysis. Here we present an approach for CNV calling based on whole exome NGS data in a clinical diagnostic setting as part of our multicentric Multiple Integration and Data Annotation Study (MIDAS). The application of more than one CNV calling algorithm provides significant improvements in sensitivity and robustness against sample variability in the normalization process. The current pipeline incorporates ExomeDepth, CoNVaDING and XHMM as primary CNV detection algorithms as well as VisCap for the visualization of complex events. Results are verified by qPCR to rule out false positive calls. While it became apparent that calling for targeted panel enrichment NGS data lead to acceptable verification effort through a small number of called events, whole exome (WE) data contains more events and therefore poses a much greater challenge. WE Trios are generally filtered for SNV analysis based on quality of the variants, the effect for the protein sequence and inheritance patterns. In contrast, CNVs neither come with an abundance of quality parameters, information about zygosity or annotations, nor are they easily comparable. Various filtering steps, calculation of frequencies and comparison of events in index and parent samples enable us to prioritize certain results, but not to permanently filter out calls. To gain the ability to reduce the noise and identify false positives, it is paramount to build a database and review the mapping of putatively true positive events. Our solution is based on a combination of our in house MIDAS software in combination with a graphical analysis in the integrated genome viewer (IGV). The IGV browser enables the analyst to compare calls from different samples and databases like Decipher, DGV and ExAC CNVs while MIDAS can calculate frequencies and annotates CNVs with further information like occurrences in an indexes parent.

**1486T**

**LinkedSV: Detection of mosaic structural variants from linked-read sequencing.** L. Fang<sup>1</sup>, C. Kao<sup>2</sup>, M.V. Gonzalez<sup>2</sup>, F.A. Mafra<sup>2</sup>, R. Pellegrino da Silva<sup>2</sup>, M. Li<sup>3</sup>, H. Hakonarson<sup>2</sup>, K. Wang<sup>1</sup>. 1) Raymond G. Perelman Center for Cellular and Molecular Therapeutics, Children's Hospital of Philadelphia, Philadelphia, PA19104; 2) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA19104; 3) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA19104.

Reliable detection of structural variants (SVs) from short-reads remains challenging, because the breakpoints are often located in repetitive regions. Linked-read sequencing developed by 10X Genomics provides long-range information by adding barcode tags to short-reads that belong to the same "fragment", and thus has the potential to improve SV detection. However, SV detection from linked-read sequencing data is still in the early stage. Currently available methods cannot reliably detect SVs from capture sequencing (e.g. whole-exome sequencing, WES), somatic mosaic SVs that have low variant allele frequencies (that is, only a small fraction of cells contain the SVs), and SVs for which the breakpoints have no coverage or located in repeat regions. To address these challenges, we introduce LinkedSV, a novel open source SV caller for linked-read sequencing. LinkedSV detects SV breakpoints by incorporating two types of evidence. First, fragments with shared barcodes between two genomic locations and the enriched fragment endpoints near breakpoints provide clues that a SV may be present nearby. Second, reads on two sides of a genomic position with different barcodes are likely derived from DNA molecules with a SV breakpoint. While existing methods utilize the first type of evidence, to the best of our knowledge, LinkedSV is the only SV caller that uses the second type of evidence to detect SV breakpoints. Integrating both types of evidence, we designed a statistical model in LinkedSV to detect SVs from whole-genome sequencing (WGS) and WES data. We assessed the performance of LinkedSV on three simulated data sets and one real data set, and compared its performance with all existing linked-read SV callers including Longranger, GROCSV and NAIBR. When the variant allele frequency (VAF) was 10%, LinkedSV had a recall of 0.761, which was 72% higher than the second best SV caller NAIBR. On the simulated linked-read WES data, LinkedSV also had the highest recall (0.79) and highest F1 score (0.86). In addition, LinkedSV is the only SV caller that successfully detected an inversion in the *F8* gene from a clinical WES data set, where the breakpoints were located in intronic and intergenic regions. In summary, LinkedSV greatly improved the detection of mosaic SVs from linked-reads genome or exome sequencing data.

**1487F**

**Development of structural variation calling in clinical whole genome sequencing: A progress report.** *A.M. Gross, A. Chawla, S.S. Ajay, N. Nariai, X. Chen, C.T. Saunders, D.R. Bentley, R.J. Taft.* Illumina, San Diego, CA.

Here we report progress on the incorporation of structural variants (SVs, insertions, deletions, inversions, and non-homologous chromosomal breakends) into a clinical whole genome sequencing (cWGS) test for the diagnosis of rare and undiagnosed genetic disease (RUGD). We assess the utility of incorporating paired and split read evidence across a pedigree to generate and genotype SV calls using the Manta variant caller. These SVs are used to supplement and extend SNV/INDEL/CNV calling pipelines, and can be combined with depth-based CNVs to provide breakpoint resolution of CNV boundaries, classify copy number gains (as tandem, inverted or dispersed duplications), and link multiple distinct CNVs to resolve complex rearrangements such as unbalanced translocations and DUP-INV-DUP structures. In addition, SV calls are incorporated as priors in a targeted depth-based CNV calling pipeline, expanding CNV detection limits from 10kb (our depth based caller's cutoff) to 1kb. Finally, SV calls are used to increase the upper bound of standard small INDEL calling to the 50bp-500bp range, which includes single exon deletions. To limit interpretation burden, we implement a number of variant filtering and prioritization steps. To improve specificity, we apply a black-list of variable or low complexity regions, which filters 66% of false positive insertions and deletions, with marginal loss of clinical sensitivity (2% of exons are masked). Rare variation is prioritized via practical heuristics for population frequency assessment using a background population of 2,400 samples. Within a test development setting, we used this pipeline to identify a 276bp single exon X-linked recessive deletion on L1CAM and a 4kb inherited NOTCH3 deletion. In addition we used SV calls to characterize over 25 pathogenic CNVs including resolution of unbalanced translocations and dispersed duplications. While the generation of short-read based SV callsets with clinical specificity remains an ongoing challenge, here we show encouraging progress towards their incorporation into a cWGS test for RUGD.

**1488W**

**Cobalt: Improved detection of germline copy number variants from hybrid-capture NGS data.** *B.D. O'Fallon, J. Durtschi, T. Lewis, D. Close, H. Best.* Biocomputing, ARUP Labs, 500 Chipeta Way, Salt Lake City, UT 84108.

**Purpose** Accurate detection of germline copy number variants (CNVs) from hybrid-capture next generation sequencing (NGS) data remains a significant computational challenge. While many CNV detection methods have been described, several recent reviews have found relatively low sensitivity and reproducibility among these tools, especially for CNVs spanning a small number of capture targets. **Methods** We introduce an improved method for detecting germline CNVs from read depth data and describe two algorithmic advances that increase sensitivity and reduce the number of false positive variants detected. First, we propose a method for estimating target-specific parameters for the emission distributions used to construct the Hidden Markov Model (HMM) for computing CNV probabilities. Secondly, we show that an alternative method of HMM decoding known as "pointwise maximum a posteriori" yields increased sensitivity compared to the more commonly used Viterbi method. Using both simulated and real, orthogonally confirmed CNVs we compared our new method to six other recently developed CNV detection tools. Evaluation samples included 100 human exomes captured with IDT xGen Exome Research Panel v1.0 and sequenced on 4 independent runs of an Illumina HiSeq 4000 instrument, 37 of which contained a previously detected CNV. Reads were aligned with BWA MEM (v0.7.12) and duplicate marked using Picard Tools (v2.9). All callers were individually tuned to maximize overall accuracy as measured by the  $F_1$  statistic. For the simulation study, CNVs 1, 2, 3 and 10 exons in size were introduced into alignment (BAM) files by removing or duplicating reads, and sensitivity and positive predictive value (PPV) were computed for each CNV size class. For real, previously detected CNVs a 50% reciprocal overlap threshold was used to determine correctly called variants. **Results** In the simulation analysis, our method achieved the highest mean sensitivity and PPV of the callers evaluated in each CNV size class. Sensitivity increased from 87% for single-exon deletions to 94% for deletions spanning 10 exons, while PPV ranged from 94%-95%. On exomes containing previously detected CNVs, our method yielded sensitivity indistinguishable from other top-performing callers, but with significantly fewer CNVs called per exome. Our method identified a median of 32 CNVs per sample, while similarly sensitive callers typically identified 300-500 CNVs per sample.

**GATK-SV: Integrating Structural Variation calling in GATK.** V. Ruano-Rubio<sup>1</sup>, S. Huang<sup>1</sup>, T. Sharpe<sup>1</sup>, T. Brookings<sup>1</sup>, M. Walker<sup>1</sup>, C. Whelan<sup>1</sup>, X. Zhao<sup>1,2</sup>, R. Collins<sup>1,2</sup>, H. Brand<sup>1,2</sup>, M. Stone<sup>1,2</sup>, E. Banks<sup>1,2</sup>, C. Nusbaum<sup>1,2</sup>, M. Talkowski<sup>1,2</sup>.

1) Data Science Platform at the Broad Institute of MIT and Harvard, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA.

The Genome Analysis Toolkit (GATK) software is well known and widely used for calling single-nucleotide polymorphism (SNP) and short insertion-deletion (sINDEL) variants in germline DNA-seq data. The latest major release (GATK4+) includes tools to call additional types of variation including small variants in somatic sequencing data and also read-depth based copy number variation (CNV) calls in either somatic and germline datasets. GATK-SV, the latest addition to GATK, provides a structural variation (SV) detection pipeline that integrates multiple SV evidence sources to GATK's variation calling tool set. GATK-SV's algorithmic pipeline includes several stages starting with (i) an initial phase for coverage-bias detection and normalization (ii) sample QC and batching, as these two factors can greatly affect analyses based on read-depth (RD) evidence. Then we progress to (iii) multi-typed evidence collection, plausible break-point detection and filtering. We gather RD, paired-end (PE), and split-reads (SR) evidence and identify likely regions of variation using machine learning with a boosted tree classifier. In order to determine accurate break points we perform (iv) local de-novo assemblies using reads that map to the candidate regions, their mates and other reads that share the same k-mers. Then (v) we compare the reconstructed haplotypes to the reference to classify variation into different types including insertions, deletions, inversions, tandem or dispersed duplications, and arbitrary translocations. Finally we (vi) genotype each variant using the input reads and provide likelihoods of possible genotype in the input sample. A distinctive feature of GATK-SV with respect to other methods is that it uses the Apache Spark distributed computing engine to process large data sets across parallel compute nodes with low latency hosted on the cloud. We provide tools to run the pipeline in Google cloud Dataproc and will make it available in the Broad Institute Fire-Cloud methods repository. In this presentation we will provide details on our algorithm and the benchmarking results including variation calling accuracy and cost per sample. We tested the GATK-SV prototype on the CHM1/CHM13 lines and found the performance was encouraging. In addition to the required processing speed for a scalable tool, the combination of local assembly, PE/SR, and RD signatures appears to be relatively sensitive and comparable with the most sensitive algorithms available.

**1490F**

**CCGT: A database for sharing Chinese children's genetic testing results.**

X. Dong, Y. Lu, Q. Ni, H. Wang, B. Wu, L. Yang, B. Liu, W. Zhou. Children's Hospital of Fudan University, Shanghai Key Laboratory of Birth Defects, The Translational Medicine Center of Children Development and Disease of Fudan University, Shanghai 201102, P.R. China.

**Background** Genetic rare diseases are one of the essential causes of children deaths, often lead to adverse consequences. Rapid and accurate diagnosis could assist therapeutic strategies, reduce adverse consequences and families could be benefit in further fertility plans. Children's Hospital of Fudan University has successfully carried out the Children's Genetic Testing Project, using WES (whole exome-sequencing) and CES (clinical exome-sequencing) to perform genetic testing for children with rare diseases. So far, the project has benefited about 20,000 patients with NGS testing, and nearly 10,000 patients have been diagnosed. Considering the population background, the testing results make a powerful database for rare disease diagnosis in China, offering complementary to existed variant annotation databases such as ClinVar or HGMD. Therefore, we build a server to share the result of these genetic testing with physicians, rare disease researchers and genetic counselors. **Methods & Results** We reviewed 8,742 testing cases with diagnostic report from the last two years, including a total of 14,000 samples (including parents). Variants called from NGS data were first filtered with public population allele frequency and sequencing target region, and then enrolled in the database. The first feature of our database is to calculate and provide local allele frequency separately for WES and CES. Second, for each variant the database would provide summarized clinical phenotype for patients who carried it. Phenotypes were presented in major systems and divided into three groups depending on the diagnostic conclusion of the variant. Variants were labeled with Positive/Likely positive, Related/Uncertain and Additional Findings. The diagnostic conclusion was based on variant's pathogenic level, inheritance model and the match of patient's phenotype. For each system, percentage of patients with related phenotypes among all patients with the same conclusion level would be presented. In this way the patients' privacy was well protected. Finally, if you are interested in further research, you could fill in the online forms for follow-up communication. The current URL is <http://101.230.2.57:8090/>, and users need to register for acquiring information. **Conclusion** This server will be maintained by the translational medicine center of our hospital. We hope that by sharing the above information we can help the diagnosis of genetic rare disease and the interpretation of genetic variant.

**1491W****Variant allele frequency discrepancies in population databases. E.**

Kaseniit, C. Cropper, D. Previte, D. Muzzey. Counsyl, South San Francisco, CA.

**Introduction**The allele frequency (AF) of a variant in different populations is often used as evidence when classifying the clinical significance of the variant. For instance, arguments against a variant being classified as pathogenic include it being too common in controls or not significantly more frequent in cases compared to controls. Two common sources for these control AFs are gnomAD and ExAC. We compared the AFs between these two datasets for variants in 176 genes associated with serious Mendelian conditions to assess whether AF discrepancies due to sequence context may influence variant interpretation. **Methods**Hard-to-sequence regions were defined from Global Alliance for Genomics and Health resources. The two-tailed Fisher's exact test or the chi-squared test (if all contingency table values >5) was used to calculate p-values of pairwise AF comparisons, and a Bonferroni correction was applied. Only entries with the PASS filter were included from ExAC and gnomAD; gnomAD entries with the lcr or segdup flags were ignored. **Results**The AFs of 932 out of 148,269 variants analyzed were found to be significantly different between ExAC and gnomAD in at least one of six considered subpopulations. These "discrepant variants" were enriched in hard-to-sequence regions, which included 15.1% of discrepant variants but only 4.5% of total variants analyzed ( $p < 1e-10$ ). Most discrepant variant AF comparisons (51.6%) had gnomAD AF >5%. Typically, an AF cut-off of 5% is used to classify a variant as too common to be pathogenic; for 123 (7.7%) discrepant variant AF comparisons, the AF was >5% in one dataset but <5% in the other, with a median absolute difference of 3.6% points. Most discrepant variants differed in their AF in one ethnicity, but 30.3% (282) had different AFs in two or more populations. Out of 2,138 variants that were evaluated in each of the six populations, 40 were discrepant variants with significantly different AF in all evaluated populations, and 14 (35%) were in hard-to-sequence regions. In general, ExAC tended to have the higher AF for discrepant variants compared to gnomAD, with a median fold-difference of 1.6. **Conclusions**Our results demonstrate that AF data must be carefully considered during variant classification—even for high-frequency variants—because AF values can differ greatly in common population databases. These differences are enriched in hard-to-sequence areas and may only be revealed via comparison among subpopulations.

**1492T****Increasing phenotypic and functional evidence in ClinVar. M.J. Landrum,**

S. Chitipiralla, M. Benson, G. Brown, C. Chen, B. Gu, J. Hart, D. Hoffman, W. Jang, C. Liu, Z. Maddipatla, R. Maiti, G. Riley, G. Zhou, D.R. Maglott, A. Glodek, J.B. Holmes, B.L. Kattman. National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, Bethesda, USA.

ClinVar is a public archive for submitted reports of human genetic variants and their significance for human health and disease. The database currently holds more than 675,000 submitted interpretations representing 417,000 unique variants. The data in ClinVar have been submitted by clinical testing laboratories, research laboratories, curation groups, OMIM, *GeneReviews*, and expert panels. Most data in ClinVar was submitted by clinical testing laboratories. However, these labs often lack access to certain types of evidence that would aid their ability to interpret variants, such as phenotypic information for patients and functional evidence. ClinVar provides opportunities to submit both of these types of evidence. ClinVar welcomes submissions from clinical providers and patient registries, which are rich sources of phenotypic data for patients who have had genetic testing. Clinical providers may submit their own interpretation of the variant, if they have re-evaluated a variant reported by a testing lab. Both clinical providers and patient registries can submit detailed information about the phenotype of a patient with a variant, along with the date the phenotype was evaluated, the name of the testing laboratory, and the interpretation from the testing laboratory. ClinVar currently holds a small number of interpretations from clinical providers, and more than 500 submitted records that focus on phenotyping only, mostly from GenomeConnect, the ClinGen patient registry. Researchers who have developed functional assays, animal models, or cell culture models are also invited to submit their data to ClinVar. Submissions that focus on functional evidence do not include an interpretation of the clinical significance of the variant. Instead they include a statement about the functional significance of the variant. As evidence for the functional significance, these submissions may include details about the experimental method, including any type of scoring system used, and the results of the experiment for each variant. ClinVar currently has 1,168 variants with functional significance of the variant; 459 variants include details of the experimental methods and results. This presentation emphasizes how clinical providers, patient registries, and researchers can share their phenotype and functional data, and how clinical testing laboratories and others can have integrated access to the data that is critical for classification of variants.

**1493F**

**MGeND: A new Integrated database of clinical and genomic information.**  
*M. Nakatsui, M. Kamada, E. Uchino, R. Kojima, Y. Okuno.* Graduate School of Medicine, Kyoto University, Kyoto, Kyoto, Japan.

Recent advances in powerful technologies such as next-generation sequencing have provided an abundance of genomic information. Even in the clinical practice, genomic information of patients are generated and accumulated continuously. Genetic information, such as genotypes or genetic mutations, has a deep connection with disease onset and progress. For instance, cancer is a disease caused by a genetic mutation. Depending on what kind of mutation is occurring in cancer cells, it is possible to discriminate the type of cancer, and select an appropriate anticancer drug. One of the most important projects in clinical field is accumulating relation of genomic information and clinical patient information, that is clinical significance, in an organized form in various disease area from many medical institutions. Some databases that store genetic information with clinical significance, such as Clinvar developed by NIH in United States, have already been released. Also in Japan, disease area specialized database such as Database of Pathogenic Variants (DPV) specialized for intractable diseases are being developed. However, there are no database that reflect the characteristics of the Japanese and do not specialize in the disease area. In this study, we developed a disease-related genomic information database, Medical Genomics Japan Database (MGeND), reflecting the characteristics of the Japanese population by collecting genomic and clinical information from 11 of clinical groups located in Japan. Initially we collect data from 5 disease area, namely "cancer", "rare disease", "infectious disease", "dementia", and "hearing-loss". The development of MGeND realizes data-sharing of genomic and clinical information among clinical groups crossing disease area. The accumulation and share of genetic information with clinical significance will realize a more sophisticated precision medicine.

**1494W**

**Open access 2030: Economics of data sharing in the genomic age.** *N. Stockham, D. Wall.* Stanford University, Stanford, CA.

**Introduction** The prospect of universal clinical adoption of whole genome sequencing (WGS) is moving swiftly into the realm of probable, sweeping society and science into a new genomic age. However, certain implementation details of this project have not been considered in depth. In particular, three essential problems face the scientific community. First, what are the requisite cost and medical utility conditions necessary to incentivize the universal adoption of WGS in the fields of oncology and newborn screening (NBS), and when will those conditions be met? Second, if widespread WGS is implemented, will the current architectures of data sharing between scientific and medical communities be economically sustainable? Finally, what data sharing architectures will scale economically? These questions are fundamental to the future of human genetics and definite answers are prerequisite for truly population scale genomic science. **Methods** We performed a cost effectiveness analysis (CEA) to establish the minimum additional medical utility of WGS necessary to justify use in oncology and NBS in the United States as a function of WGS price, parameterized by the likelihood of actionable findings from recent studies of NGS at Memorial Sloan Kettering for oncology and twin-studies for NBS. Furthermore, we constructed economic models for ad-hoc, centralized database, and novel compute-in-place (CIP) data sharing architectures, parameterized by number of scientific entities and total data shared. **Results** At \$100 for a whole genome at 30x depth WGS is cost effective for oncology if the expected increase in life exceeds one month, or if it increases probability of remission by more than 1%. For NBS WGS is cost effective if the expected increase in life exceeds two weeks. However, current approaches for data sharing are entirely infeasible. For adhoc and centralized database architectures it would cost on the order of 100 million dollars each year for 10 entities to share %1 of the total United States NBS and oncology data. But, with a CIP architecture, data sharing is free as computation is moved to the data. **Discussion** The \$100 WGS is a stated near-term goal of Illumina, implying WGS will be adopted widely in NBS and oncology before 2025. However, with current architectures this invaluable data will be too expensive to share. The scientific community must implement CIP architecture now, or leave the fruit of human heritage fallow in the field.

**Characterizing individuals with pathogenic variants: An application of the phenotype risk score method.** L. Bastarache, J. Bastarache, J. Moseley, J. Hughey, D. Roden, J. Denny. Vanderbilt University Medical Center, Department of Medicine, Nashville, TN.

**Background** Many patients who have both the genetics and symptoms consistent with a Mendelian disease remain undiagnosed. We test an automated approach to identifying these individuals using the electronic health record (EHR) and extant genetic data (Exome BeadChip). **Methods** We annotated pathogenic & benign alleles in ClinVar with OMIM disease identifiers. We generated star ratings for each variant-disease pair using ClinVar's submission rating algorithm. We restricted our analysis to recessive diseases. In a cohort of 35,842 genotyped de-identified individuals, we identified 1651 pathogenic and 751 benign variants. We calculated Phenotype Risk Scores (PheRS) for target diseases. PheRS is an automated method to score a individual based on their similarity to a disease's clinical profile using the EHR. We generated normalized z-scores (PheRS-z) to compare across diseases & calculated the average PheRS-z for different star ratings. We reviewed charts of individuals who had pathogenic variants with 2+ stars (n=292) to assess if they were diagnosed with or symptomatic for the disease suggested by their genotype. **Results** The average PheRS-z was elevated in homozygotes for pathogenic but not benign alleles (0.38 & 0.03, respectively) & was higher for alleles with more stars (i.e. stronger evidence of pathogenicity). Chart review revealed 50 of 292 homozygotes for recessive pathogenic alleles were clinically diagnosed (mean PheRS-z=2.0). The PheRS-z was elevated among the remaining 142 undiagnosed (mean PheRS-z=0.12). Eight undiagnosed individuals had outlying scores (PheRS-z > 2), with genetics and clinical features consistent with hemochromatosis (*HFE* p.C282Y), Bardet-Biedl syndrome (*BBS1* p.M390R), & Glycogen storage disease IV (*GBE1* c.691+2T>C), among others. Chart review of the undiagnosed individuals confirmed the feature overlap reflected in the elevated PheRS-z, and revealed further features suggestive of undiagnosed Mendelian disease. **Conclusion** PheRS effectively measured the presence of Mendelian disease features in conjunction with genetic data. Many homozygotes for pathogenic alleles did not have elevated PheRS or signs of disease on chart review, which may be due to low or age-related penetrance, genotyping error, or limited phenotypic data. Our work supports the notion that some Mendelian diseases may be under-diagnosed.

Pathogenic variants			
ClinVar rating (stars)	#Variants	#Homozygotes	avg PheRS-z
4	2	2	1.7
3	1	1	1.5
2	37	289	0.6
1	34	147	0.4
0	85	1212	0.3

**1496F**

**Leveraging electronic health records to map the genetic and phenotypic complexity of preterm birth.** A. Abraham<sup>1</sup>, C. Bejan<sup>3,4</sup>, J. Capra<sup>1,2</sup>. 1) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN, USA; 2) Department of Biological Sciences, Vanderbilt University, Nashville TN, USA; 3) Department of Biomedical Informatics, Vanderbilt University, Nashville TN, USA; 4) Vanderbilt Center for Precision Medicine, Vanderbilt University, Nashville TN, USA.

**Background:** Despite advances in neonatal medicine, preterm birth (PTB) causes significant morbidity and mortality across the world. In the United States, ~10% of births each year are preterm and up to 34% of infant deaths are attributable to prematurity. Premature babies are at high risk for both immediate and long-term complications. PTB heritability has been estimated to be as high as 40%. However, our understanding of the genetic underpinnings of PTB remains limited. A variety of different phenotypic factors – infection, placental pathologies, maternal comorbidities, etc. – can increase the risk of PTB. The extent to which these factors influence the genetic basis for PTB remains unknown. We hypothesize that failure to account for this phenotypic complexity has hampered previous genetic studies of PTB and that characterizing it will yield insights into PTB's genetic architecture. **Objective:** This project aims to classify pregnancies into preterm, term, and postterm through a phenotyping algorithm and investigate the shared genetic liability of PTB and comorbid diseases. **Methods:** Using counts of ICD and CPT codes, we identify preterm, term, and postterm deliveries within the electronic health record (EHR). Next, machine learning tools will extract features from the EHR to distinguish spontaneous from medically induced PTB and associated comorbidities. These algorithms will be trained and validated on non-overlapping samples that have been manually phenotyped. Leveraging Vanderbilt's biobank of genotype data linked with EHRs, we will construct genetic risk score models for subtypes of PTB and compare to a control cohort of term birth. **Results:** Delivery classified using one or more relevant ICD code resulted in 11,266, 7,140, and 10,037 individuals with at least one preterm, term, or postterm delivery respectively. A small fraction of individuals (2,314, 8.8%) had more than one type of delivery. The majority of individual (93.0%) within the preterm cohort has only one preterm delivery. To gain clinical insight into comorbidities, ICD codes were grouped into disease categories (PheCodes v1.2). Preterm deliveries showed substantial enrichment/depletion across 12 out of 17 categories. The top three were 'pregnancy complications' (OR = 1.35, p-value = 5.76x10<sup>-100</sup>), 'genitourinary' (0.78, 2.18x10<sup>-39</sup>), and traits with no disease grouping, (0.79, 4.59x10<sup>-31</sup>). We are now exploring the shared genetic architecture of these comorbidities with PTB.

**1497W**

**Data fingerprints: Fast and simple comparison of semi-structured data, with emphasis on electronic health records.** G. Glusman<sup>1,2</sup>, M. Robinson<sup>1</sup>, J. Hadlock<sup>1</sup>, J. Yu<sup>2</sup>, A. Khatamian<sup>3</sup>, J. Matelsky<sup>4</sup>, A.Y. Aravkin<sup>2</sup>, E.W. Deutsch<sup>1</sup>, N.D. Price<sup>1</sup>, S. Huang<sup>1</sup>. 1) Institute for Systems Biology, Seattle, WA; 2) The University of Washington eScience Institute, Seattle, WA; 3) Department of Computational Biology, St. Jude Children's Research Hospital, Memphis, TN; 4) Johns Hopkins University Applied Physics Laboratory, Laurel, MD.

Fast comparison of a large number of semi-structured data records can be valuable for analysis of any knowledge domain. Electronic health records (EHRs) present an important real-world test case because many healthcare questions rely upon finding the similarity between different records. Examples include finding candidates for clinical trials, evaluating treatment response, and investigating cost variation among patients with similar health situations. Currently, approaches to identifying similar records include (1) designing semantically-informed comparisons on structured elements of interest, such as demographics, conditions, or medications, and (2) using semantically and structurally agnostic file comparison. The first requires explicit mapping of domain knowledge to data structure, and the second becomes resource-intensive when scaled to millions of patient records. We present a fast, semantically and structurally agnostic method for analyzing semi-structured data (e.g., JSON or XML formats). Our locality-sensitive hashing strategy summarizes semi-structured data into 'data fingerprints': highly compressed representations which cannot recreate details in the data, yet simplify and greatly accelerate the comparison and clustering of semi-structured data by preserving similarity relationships. Computation on data fingerprints is fast: in one example involving complex simulated medical records (SyntheticMass, in FHIR format), the average time to encode one record was 0.53 seconds, and the average pairwise comparison time was 3.75 microseconds. Both processes are trivially parallelizable. Applications include detection of duplicates, clustering and classification of semi-structured data, which support larger goals including summarizing large and complex data sets, analyzing cohort structure, quality assessment, evaluating methods for generating simulated patient data, and data mining. Beyond EHRs, our approach is applicable to any domain in which semi-structured data are commonly used. While our novel methodology is currently designed for semi-structured data, it can be used to simplify and accelerate analyses of fully structured data, and (based on initial experiments) can be extended to work with fully unstructured data. Project page: [http://db.systemsbiology.net/gestalt/data\\_fingerprints](http://db.systemsbiology.net/gestalt/data_fingerprints) This work is supported by NIH 1U54EB020406 and NCATS award OT3TR002026.

**1498T**

**Evaluating the potential of screening exome sequencing for newborn screening.** A.N. Adhikari<sup>1</sup>, Y.Q. Wang<sup>1</sup>, R.J. Currier<sup>2</sup>, R.C. Gallagher<sup>2</sup>, R.L. Nussbaum<sup>3</sup>, Y. Zou<sup>1</sup>, U. Sunderam<sup>4</sup>, J.T. Shieh<sup>2</sup>, F. Chen<sup>2</sup>, M. Kvale<sup>2</sup>, S.D. Mooney<sup>5</sup>, R. Srinivasan<sup>4</sup>, B.A. Koenig<sup>2</sup>, P.-Y. Kwok<sup>2</sup>, J.M. Puck<sup>2</sup>, S.E. Brenner<sup>1</sup>, *The NBSseq Project*. 1) University of California, Berkeley, CA, USA; 2) University of California, San Francisco, CA, USA; 3) Invitae, San Francisco, CA, USA; 4) Tata Consultancy Services, Hyderabad, TS, India; 5) University of Washington, Seattle, WA, USA.

Exome screening shows Genetics aids public health But just sequence fails The NBSseq project sequenced and analyzed exomes of most newborns affected with any of the 48 inborn errors of metabolism (IEMs) screened by tandem mass spectrometry (MS/MS) amongst the 4.4 million newborns born in California from mid-2005 to 2013. The sequences were obtained under an IRB-approved protocol from 1216 de-identified dried blood spots archived by the California Dept. of Public Health. Using a 180 exome validation set, we developed an interpretation pipeline sensitive for all screened IEMs, yielding few false positives. Final analysis was restricted to 78 genes causing these IEMs, and incorporated curated pathogenic and benign variants, and variant predictions. The pipeline was then run once on the 1016 exome test set for evaluation. Sensitivity for predicting disease from variants varied across IEMs (eg, PKU:93%,3-MCC:71%,citrullinemia type1:77%) with an overall weighted sensitivity of 88% and specificity of 95%. Current newborn screening by MS/MS is 99.3% sensitive and 99.7% specific; therefore, exome sequencing alone cannot currently replace MS/MS screening for these disorders. A pipeline using only curated variants achieved 99.6% specificity and 58% sensitivity. For other disorders with no available screen, a curated variant pipeline could potentially identify a portion of the affected individuals, with few false positives. Of 103 affected individuals not predicted to have disease by our pipeline, 52 had no rare missense variants and 51 contained one heterozygous deleterious variant in a pertinent gene. In two isovaleric acidemia (IVA) patients, whole genome sequencing confidently revealed multi-exon deletions in the causative *IVD* gene, whereas exomes did not. Review of the cases prompted revision of the diagnosed disorder in 63 cases. An individual clinically diagnosed with IVA carried rare homozygous, missense variants (M389V) in *ACADSB*, known to cause 2-MBCD deficiency. Clinical review and demographic data supported this alternative diagnosis. Another individual had positive MCAD/VLCAD MS/MS screens and was clinically diagnosed as an unaffected carrier upon follow-up. The child carried a pair of missense variants (A84T/R175H) in *ETFDH*, suggesting an additional possible diagnosis of late-onset multiple acyl-CoA dehydrogenase deficiency. These results indicate that following a positive MS/MS screen, reflex DNA sequencing could aid precise and timely clinical resolution.

**ExomeLoupe: A secure genetic variant viewer tool.** C. Egas<sup>1,2</sup>, B. Diéguez<sup>1</sup>, F. Santos<sup>1</sup>, M.J. Simões<sup>1</sup>, H.J.C. Froufe<sup>1</sup>. 1) Biocant - Biotechnology Innovation Center, Cantanhede, Portugal; 2) Center for Neuroscience and Cell Biology, Coimbra, Portugal.

One of the applications of NGS technologies is to sequence whole exomes and genomes to identify causal genetic variants in Mendelian diseases and provide useful information for clinical diagnosis. These technologies generate massive amounts of data that have to be processed into meaningful genetic information to be interpreted by clinicians and researchers. Compliance with the new European General Data Protection Regulation (GDPR), which considers human genetic information as personal and sensitive data, requires implementation of security measures to process, store and share genetic data. According to this regulation, measures such as pseudonymization and encryption should be implemented to manage security and mitigate risks for undesirable access to the information. There is a lack of desktop tools that represent a true end solution for visualization and prioritization of genetic variants that not only help researchers to identify the most relevant variants but also allow genetic data storage and sharing in a protected manner according to the GDPR. In this context, we present ExomeLoupe, an intuitive and user-friendly Windows platform to help with the prioritization and interpretation of genetic variants in a secure environment. ExomeLoupe requires as input a GEMINI database and offers the user the possibility to encrypt the database using SQLCipher according to the Advanced Encryption Standard 256 bit (AES256). Once encrypted, ExomeLoupe interacts directly with the database without the need for complete decryption, displaying variant annotation and searching for variants according to the filters defined by the user. Furthermore, ExomeLoupe can be used to encrypt files produced during data processing through PyCrypto, enabling users to securely store and share this sensitive genetic information complying with the GDPR. ExomeLoupe is the first software to our knowledge that provides the user the tools to work in an encrypted secure way. This work was funded by the In2Genome project, ref. CENTRO-01-0247-FEDER-017800, CENTRO 2020, Portugal 2020 and European Union, through the European Regional Development Fund (ERDF) and by GenomePT project, ref. POCI-01-0145-FEDER-022184, co-funded by FCT/MEC (PIDDAC) and ERDF through COMPETE – Operational Programme Competitiveness Factors (POFC).

**Time-course expression QTL-atlas of 301 pregnant Japanese women in Maternity Log Study.** M. Nagasaki<sup>1,2</sup>, R. Yamashita<sup>1</sup>, T.F. Shibata<sup>1</sup>, J. Kawashima<sup>1,3</sup>, Y. Tsunemoto<sup>1,2</sup>, D. Ochi<sup>1,2</sup>, T. Yamauchi<sup>1,2</sup>, S. Kumatani<sup>1,2</sup>, Y. Harada<sup>1,3</sup>, T. Mimori<sup>1,3</sup>, F. Katsuoka<sup>1,3</sup>, N. Minegishi<sup>1,3</sup>, O. Tanabe<sup>1,3</sup>, S. Hiyama<sup>2</sup>, J. Sugawara<sup>1,3</sup>, Maternity Log Study Group. 1) Tohoku Medical Megabank Organization, Tohoku University, Tokyo, Japan; 2) NTT DOCOMO, INC., Yokosuka, Japan; 3) Tohoku University Graduate school of Medicine, Sendai Japan.

In Japan, about 200,000 people are affected each year by pregnancy-related diseases including hypertensive disorders of pregnancy, gestational diabetes, and premature delivery. Pregnancy-related diseases are multifactorial disorders caused by a complex interaction of genetic factors and environmental factors such as lifestyle and living environments. Maternity Log Study (MLOG) is an add-on cohort project on a prospective cohort study by Tohoku Medical Megabank Organization in Japan. MLOG is designed to elucidate the associations between genomic and environmental factors and pregnancy complications using continuous lifestyle monitoring combined with multi-omics data on the genome, transcriptome, metabolome, and microbiome. MLOG has completed recruitment of 301 individuals and constructed a whole-genome reference panel of them by using the HiSeq sequencer with an average depth of 25x. We also collected 902 peripheral blood samples from them during pregnancy and after delivery with PAXgene® RNA tubes, and performed RNA-seq using the HiSeq sequencer. By combining these datasets, we have conducted time-course expression QTL (eQTL) analysis as well as differentially expressed eQTL analysis to construct a time-course eQTL-atlas of 301 pregnant Japanese women. Here, we report novel variants related to gene expression during pregnancy, and annotate those eQTL variants using public database, e.g. GTEx, GWASCatalog, and our in-house results of genome-wide association studies for omics and lifelog data in MLOG. The time-course eQTL-atlas will contribute to global research communities for genetic studies on pregnancy.

**1501T**

**Pipeline for trio analysis in StrandNGS.** A. Choudhury, M. Toufiq, A. Pal, S. Ramachandrala. Strand Life Sciences Private Limited, Bengaluru, India.

Whole genome and exome sequencing is now commonly employed as a clinical diagnostic test to identify disease-causing mutations in the affected children of seemingly unaffected parents. While the technology of sequencing itself has evolved to become simplistic and cheaper, analyses and interpretation of this data remains the bottle-neck causing delays in reporting thereby delaying the process of improved decision making. We designed a simplistic pipeline that helps in faster detection of the disease causing variants with an accuracy that is on par with the GATK pipelines. The Trio analysis pipeline in StrandNGS encompasses raw data import, pre-alignment QC, alignment, filtering reads (based on mapping quality and alignment score) and duplicate reads, SNP pre-processing (Local re-alignment and Base Quality Score Recalibration), detection of SNPs (including low frequency SNPs), and annotating the variants. For narrowing down causative mutations in the proband with unaffected parents, the software could identify SNPs that belong to either of these 3 categories: (1) homozygous recessive SNP (2) de novo SNP (3) compound heterozygote. Given that the StrandNGS platform has a robust and systematic framework for SNP prioritization, identification of the causative mutation in case of any genetic disorder is facilitated through features like (a) Find significant SNPs, to compare similar cases and identify any SNPs that recur across cases (b) SNP effect analysis, to find all the protein and non-protein effects of a given SNP and annotate it with HGVS nomenclature at genomic, transcriptomic, and proteomic levels (c) Find damaging non-synonymous (NS) variants, to identify NS variants that are damaging using popular functional prediction algorithms (d) Check for known variants, to scan the SNP list for variants that are known to cause the suspected disorder (e) Annotate SNP list to add any known metadata about a given SNP. All the above mentioned steps can be configured into pipelines with parameters of choice and run in an automated fashion for quick TAT (Turnaround Time). We intend to showcase this pipeline using data of a Wilms tumor case from 1000 Genomes Project. While there are a number of open-source pipelines that can be used to perform one or more of the above mentioned steps, to the best of our knowledge, StrandNGS is the only desktop software that provides such a comprehensive workflow that can be configured into a pipeline, all on a single platform.

**Alvar: An artificial intelligent variant classifier for clinical interpretation of genetic variants and prioritization of variants of unknown significance (VUS).** J. Luo, T. Zhou, Y. Zi, X. Li, Y. Wu, Y. Deng, A. Li, Y. Shi. TopGene Tech Co., Ltd., Guangzhou, Guangdong Province, P.R.China.

Clinical interpretation of sequence variants has been a difficult task in genetic medicine. Although the updated guidelines published by American College of Medical Genetics and Genomics and the Association for Molecular Pathology (ACMG-AMP) in 2015 provides a gold standard for germline variant interpretations, some problems remain unresolved. For example, variants of unknown significance (VUS) are commonly seen in classification which are not referable for any clinical intervention. They are classified as VUS due to the lack of conclusive evidence. Prioritizing VUS with high probability to fall in the benign or pathogenic category is the basis for further research in these variants, which can eventually result in their reclassification. Therefore, high-throughput methods for VUS pathogenicity estimation are in urgent need. To address this, we developed Alvar (Artificial-Intelligent variant classifier), a neural network model which is capable of classifying variants into either pathogenic/likely pathogenic (P/LP) or benign/likely benign (B/LB) category. Alvar's prediction capacity was verified on known data sets classified by human experts. It also showed superior performance over 7 other popular variant classification tools. More importantly, Alvar demonstrated great potential in VUS reclassification by correctly predicting 43 out of 44 former VUS. We then applied Alvar on 15,670 VUS (classified by the Clinvar expert panel). 79% of these variants were prioritized towards either P/LP or B/LB category by Alvar with at least 95% confidence. Alvar is available as an open-source program at Github <https://github.com/OpenBioWiki/Alvar>. An online version is available at <http://www.bioopenwiki.com/Alvar>. Alvar demonstrates that neural network is suitable for sequence variant classification and a promising solution to the VUS problem.

**A fast and interpretable new approach to fine mapping of genetic associations.** G. Wang<sup>1</sup>, A. Sarkar<sup>1</sup>, P. Carbonetto<sup>1</sup>, M. Stephens<sup>1,2</sup>. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Statistics, University of Chicago, Chicago, IL.

Despite near two decades of work in the area, fine mapping of genetic associations continues to pose major statistical and computational challenges, even when all potential causal variants are typed. Several tools have been developed, many based on Bayesian multiple regression (BMR). BMR has several appealing features compared with other approaches -- for example, it can assess uncertainty about which genetic variants explain an association, taking account of Linkage Disequilibrium (LD). And it can incorporate annotation information on variants through a modified prior distribution. However, BMR is computationally challenging. Some methods enumerate all possible models involving a small number of causal variants, but this quickly becomes computationally infeasible. Approaches such as MCMC and stochastic search can help, but remain computationally intensive. And it remains a major challenge to summarize and interpret their output, especially with high LD and many causal variants. Here we propose a new approach to fine mapping that is fast and gives new and more interpretable results. Our approach involves several innovations. First we introduce a new version of BMR, which we call the *Sum of Single Effects* (SuSiE) model. This model, while similar to existing widely-used models, has a different structure that makes it possible to fit via a new variational algorithm whose computation scales *linearly* with the number of causal variants. In contrast to existing variational algorithms for BMR, which are unsuited to fine mapping because of the way they deal with SNPs in high LD, our new version is ideally suited to this difficult case. The SuSiE structure also yields, by design, independent confidence sets, each designed to capture *one association signal*, making the results easy to interpret, and ideal for guiding follow-up studies. Although our initial work focuses on the simplest case, the framework is easily extended in many ways, including joint fine mapping of multiple phenotypes, incorporating functional annotations, and inference from summary data of association studies. We believe that the simplicity and power of this new approach has the potential to transform ongoing fine mapping efforts. This talk introduces SuSiE, illustrates its benefits compared with existing methods, and show several examples of fine mapping on real data.

**Evaluation of variant scoring methods in non-coding region in the context of complex traits/diseases.** G. Zheng, R. Chen, H. Yang, B. Li. Vanderbilt University, Nashville, TN. 1161 21st Ave S D3300, Nashville, TN 37232, 5th floor.

**Introduction:** An attractive alternative to Whole-exome sequencing, Whole-genome sequencing (WGS) identifies noncoding variants and mutations associated with complex human traits and diseases. However WGS introduces the challenge of discriminating functionally relevant variants from a huge number of background variants. To ameliorate this issue several scoring methods utilizing functional genomic data were created to prioritize noncoding variants. However, their performance in terms of predicting the potential as risk variants in complex diseases remains unclear. **Methods:** In this study, we aim to assess the performance of various scoring methods including DVAR, Linsight, Eigan, and CADD, on prioritizing risk variants. Specifically we used LD score regression to estimate heritability of top scoring variants and applied to GWAS summary statistics of Schizophrenia, Alzheimers, and Breast Cancer. Summary statistics were obtained through PGC, Breast Cancer Consortium, and International Genomic of Alzheimer Project. As a proof of concept we utilized DVAR as an example and extracted top scoring variants by making a list of 2 different cutoffs of 0.95 and 0.99 representing the top 95 and 99% of predicted noncoding variants on genome. These lists would then be used in ldsc to calculate the disease heritability explained by these variants and calculate their enrichment compared to background. **Results:** Preliminary results show that top scoring variants explain significantly more heritability than genome background ( $P < 0.001$ ). When comparing the two DVAR cutoffs, the top 99% of noncoding variants explain significantly more heritability than the top 95% score variants in schizophrenia (0.0001 vs 0.005). We observed similar trends in breast cancer and Alzheimer GWAS summary statistics. Further investigation will be done for other scoring methods such as CADD, Eigan, and Linsight to answer questions such as whether all scores perform well in all diseases, or they show some specific patterns in different disease or if certain scoring methods perform better for specific category of variants. Ldsc can be found at <https://github.com/bulik/ldsc>.

**How well can we create phased, diploid, human genomes? An assessment of FALCON-Unzip phasing using a human trio.** *A. Fungtammasan, B. Hannigan.* DNAnexus, Mountain view, CA.

Long read sequencing technology has allowed researchers to create de novo assemblies with impressive continuity[1,2]. This advancement has dramatically increased the number of reference genomes available and hints at the possibility of a future where personal genomes are assembled rather than resequenced. In 2016 Pacific Biosciences released the FALCON-Unzip framework, which can provide long, phased haplotype contigs from de novo assemblies. This phased genome algorithm enhances the accuracy of highly heterozygous organisms and allows researchers to explore questions that require haplotype information such as allele-specific expression and regulation. However, validation of this technique has been limited to small genomes or inbred individuals[3]. As a roadmap to personal genome assembly and phasing, we assess the phasing accuracy of FALCON-Unzip in humans using publicly available data for the Ashkenazi trio from the Genome in a Bottle Consortium[4]. To assess the accuracy of the Unzip algorithm, we assembled the son's genome using FALCON and FALCON Unzip, genotyped publicly available short read data for the mother and the father, and observed the inheritance pattern of the parents' SNPs along the son's phased genome. We found that 72.8% of haplotype contigs share SNPs with only one parent suggesting that these contigs are correctly phased. Most mis-phased SNPs are random but present in high frequency toward the end of haplotype contigs. Approximately, 20.7% of mis-phased haplotype contigs contain clusters of mis-phased SNPs, suggesting that haplotypes were mis-joined by FALCON-Unzip. Mis-joined boundaries in those contigs are located in areas of low SNP density. This research demonstrates that the FALCON-Unzip algorithm can be used to create long and accurate haplotypes for humans and identifies problematic regions that could benefit in future improvement.

**Improved dog reference assembly enables paralog-specific identification of tandem repeats in assembled gaps using Quick-mer.** *F. Shen<sup>1</sup>, A. Pendleton<sup>1</sup>, A. Boyko<sup>2</sup>, J. Kidd<sup>1</sup>.* 1) University of Michigan, Ann Arbor, MI; 2) Cornell University, Ithaca, NY.

Dogs are an emerging model system for the study of genome evolution and human disease, with over 300 heritable traits similar in humans. Ongoing studies using short-read re-sequencing data often rely on an incomplete and fragmented reference assembly. The latest version of the dog genome reference, CanFam3.1, contains 19,553 gaps on primary chromosomes as well as 3,000 unplaced contigs with a combined length of 83Mbp. To complement this assembly, we recently completed a de novo assembly of a Great Dane dog based on 50x PacBio long-read sequence data. The assembly results demonstrate a vast improvement with 20-fold increase in continuity and a drastically reduced number of gaps and unplaced contigs. We determine the sequence of most gaps in the CanFam3.1 assembly identify examples of partial or full transcript models which were previously missing. Assembly comparison identified 2595 insertions > 1kb in size totally missing from the canFam3.1 assembly. Analysis shows that these new sequences are enriched for tandem repeats. In order to efficiently genotype novel sequences identified in our assembly, we assessed copy-number in hundreds of sequenced canines using our paralog-specific CNV pipeline, Quick-mer. We have improved Quick-mer by eliminating a major portion of control k-mers, while still retaining sufficient GC correction accuracy. Our changes significantly improved its speed and reduced the memory usage. Our results suggest these novel regions are polymorphic with respect to presence and are a part of canine evolution process.

**Caring without sharing: Genome-wide association and mapping on cohorts fragmented across institutional silos.** A. Pourshafeie<sup>1</sup>, C.D. Bustamante<sup>2</sup>, S. Prabhu<sup>2</sup>. 1) Department of Physics, Stanford University, Stanford, CA; 2) Department of Biomedical Data Science, Stanford University, Stanford, CA.

The recent explosion in genomic and phenotypic data generated by new biomolecular and biometric technologies presents a great opportunity for expanding our understanding of human genetics and disease. Moreover, the available data is becoming more expansive and private in nature. This expansion, in cohort size and per-individual information can be expensive, unsafe and time consuming to generate or maintain at a single centralized facility. Meta-analysis/summary statistics techniques offer a work-around by combining summary statistics across multiple studies. Despite their overall success, these methods face a few serious limitations: (a) the shared summary statistics might be inadequate for some types of inference (e.g. estimating effects from shared two-tailed p-values), (b) subtle differences in model, assumptions and QC can introduce bias (Greco et al. 2013), (c) in each silo, the parameter estimates can be unreliable if the per-silo sample size is small compared to the number of covariates (k). (d) fine tuned population structure control is not possible. Here, we implement a logistic regression based, GWAS pipeline that allows participant data to remain fragmented across institutional silos. We show that Alternating Direction Method of Multipliers (ADMM) (Boyd et al. 2010) can be used to perform generalized-regression in a decentralized fashion. This method generalizes the intuition of averaging the per-silo estimates and iteratively solves the problem while only communicating summary statistics at each iteration. To evaluate this approach in a GWAS pipeline, we simulate phenotypes on POPRES dataset (Nelson, et al. 2008). We then perform a centralized and decentralized GWAS. Specifically, we show that centralized QC performed using Plink (Purcell, Chang 2010) is indistinguishable from decentralized QC. We then perform PCA and show that the results are both mathematically and numerically identical in both paradigm. Lastly, we perform GWAS via logistic regression correcting for the first 5 PC's and show that both effect sizes and the associated p-values are essentially identical between the two paradigms. Taken together, this shows that a GWAS pipeline can be performed in a decentralized fashion.

**Analyzing phenotype imputation effectiveness on summary statistics from the UK Biobank.** J. Rotman, E. Eskin. Computer Science Dept, UCLA, Los Angeles, CA.

Genome-wide association studies (GWAS) have been extremely effective in identifying loci associated with complex phenotypes. However, many phenotypes can be difficult to measure, or too expensive to obtain in large quantities. Since the power of a GWAS depends on sample size and accurate phenotype measurement, for many phenotypes performing a GWAS is not practical. One potential approach to this problem is through the use of phenotype imputation. The idea behind this approach is that a subset of the data that contains many phenotypes, including the phenotype of interest, is used to train a model that predicts the phenotype of interest using the other phenotypes. The model is then used to predict or impute the phenotype of interest in data which collects the other phenotypes but not the phenotype of interest. Specifically, the model uses correlation between the pairs of phenotypes and these correlations are calculated in the smaller subset of individuals. A GWAS can then be performed on the imputed phenotype. Phenotype imputation works because of pleiotropy, the phenomenon that a variant can affect more than one trait and the effect sizes of the variant on the pair of traits is correlated. In phenotype imputation, the correlation of many traits are combined with each other which results in an accurate enough prediction of the trait that a GWAS association can be discovered. While phenotype imputation has shown promising results, it is yet to be used on a large enough scale with just summary statistics. This further complicates the problem because summary statistics increase the difficulty of obtaining phenotypic correlation. By utilizing LD score regression to compute phenotypic correlation, phenotype imputation can produce an accurate estimation of SNP association for unknown phenotypes using summary statistics from other correlated phenotypes. In this work we test this method using summary statistic data from the UK Biobank. We demonstrate how our method can be used to obtain significant SNPs at a comparable level to a measured phenotype. Additionally, we show how the impact of these significant SNPs extends beyond the SNPs highly associated with correlated phenotypes.

**Short tandem repeat (STR) profile of pentanucleotide repeats and high-resolution STR typing solution for the Japanese population.** *M. Saito<sup>1</sup>, S. Hirata<sup>1</sup>, K. Kojima<sup>1</sup>, K. Misawa<sup>1</sup>, T. Mimori<sup>1</sup>, O. Gervais<sup>1</sup>, Y. Kawai<sup>2</sup>, Y. Hitomi<sup>3</sup>, K. Tokunaga<sup>2</sup>, M. Nakamura<sup>3,4</sup>, M. Nagasaki<sup>1</sup>.* 1) Division of Biomedical Information Analysis, Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Japan; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Japan; 3) Clinical Research Center, National Hospital Organization, Nagasaki Medical Center, Japan; 4) Department of Hepatology, Graduate School of Biomedical Sciences, Nagasaki University, Japan.

**Objective:** In the field of forensic, DNA typing is one of the main methods for identifying individuals. Microsatellite short tandem repeat (STR) analysis is widely used, for identifying victims in large-scale disasters as well as missing persons in criminal investigations. Since the number of repetitions of an STR is on average more diverse than a single-nucleotide polymorphism among individuals, STR typing can distinguish individuals with fewer genotyping regions. Furthermore, the use of highly polymorphic STRs in regional populations, such as the D6S1043 locus in Asian populations, has enabled higher precision in individual identification. **Result:** In this study, we used the whole-genome data from 1,070 Japanese individuals, generated using massively parallel short-read sequencing of 162 paired-end bases in Tohoku Medical Megabank Organization. For this dataset, we analyzed 106,418 pentanucleotide STR loci in human assembly GRCh37 and detected 8,771 highly polymorphic STR loci (with which at least five types of repeat numbers were observed in the 1,070 individuals). From them, we selected 53 pentanucleotide STR loci suitable both for short-read sequencing and PCR-based technologies, which would be candidates to the actual forensic DNA typing in the Japanese population. For these loci, we designed PCR primers and evaluated performance by measuring the repeat length of each individual with the electrophoresis experimental results. For the performance evaluation, we used the whole-genome sequence data of another 181 Japanese specimens owned by the National Hospital Organization Nagasaki Medical Center and calculated the STR repeat length. Consequently, we have established a reliable pentanucleotide repeat typing method for the Japanese population.

**The Encyclopedia of DNA elements (ENCODE): 2018 data portal update.** *E.T. Chan, ENCODE Data Coordinating Center.* Stanford University, Palo Alto, CA.

The Encyclopedia of DNA Elements (ENCODE) project aims to identify functional elements in the human genome. The ENCODE consortium, an international collaboration of experimental and computational research groups, has produced over 15,000 high-throughput experimental data sets since 2003. These data include transcriptome and epigenome profiles in multiple human and mouse tissues and cell lines. A data portal (<https://www.encodeproject.org>), developed by the ENCODE Data Coordinating Center (DCC), provides integrated, free access to over 600 terabytes of raw experimental, processed, and analysis data files with corresponding metadata. The portal also provides access to details of experimental protocols, computational procedures, and validations of key reagents (e.g. antibodies and genetically-modified cell lines). Additionally, the portal also provides access to data from other related projects such as Model organism ENCODE (modENCODE), Model organism Encyclopedia of Regulatory Networks (modERN), Genomics of Gene Regulation (GGR), and Roadmap Epigenome Project (Roadmap). Several new features are currently being added to the ENCODE data portal, such as a "Shopping Cart" function on the web user interface to facilitate customized data selection and download. On the back end, the search code has been refactored and the version of Elasticsearch updated to improve search efficiency and versatility. The ENCODE portal server architecture has also been updated and decentralized, improving stability and responsiveness of the application. New datasets are also continually being added as ENCODE labs submit new data and metadata meeting ENCODE standards. Of note, new to the portal will be data aimed at characterizing putative functions of identified ENCODE DNA elements using various genetic modification and perturbation methods (e.g. CRISPR-based screening). Up-to-date details on these developing features will be presented at the time of the meeting.

**GFAkluge: A toolbox for manipulating the graphical fragment assembly format.** *E.T. Dawson*<sup>1,2</sup>, *R. Durbin*<sup>1,3</sup>. 1) Department of Genetics, University of Cambridge, Cambridge, United Kingdom; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD, USA; 3) Wellcome Trust Sanger Institute, Hinxton, UK.

Graph models of genomes have become increasingly common in recent years, especially in the field of genome assembly. While FASTA has remained the dominant assembly format for several decades, it does not permit encoding any information about the assembly graph or population variation. The Graphical Fragment / Assembly format (GFA) has been proposed as a community standard for representing assembly graphs, sequence graphs, and variation graphs. To encourage uptake of the format we have developed a set of tools that replicate many of the analyses commonly performed on FASTA, such as calculating genome statistics. The toolkit contains tools for sorting and conversion that facilitate interchange between programs for assembly, read mapping and visualization. We also include a modern C++ API to encourage adoption among developers of high-performance tools. Our code is freely available at <https://github.com/edawson/gfakluge>.

**Towards reproducible, transparent, and systematic benchmarking of omics computational tools.** *S. Mangul*<sup>1</sup>, *L. Martin*<sup>1</sup>, *B. Hill*<sup>1</sup>, *A. Lam*<sup>1</sup>, *M. Distler*<sup>1</sup>, *A. Zelikovsky*<sup>2</sup>, *E. Eskin*<sup>1</sup>, *J. Flint*<sup>1</sup>. 1) UCLA, Los Angeles, CA; 2) Georgia State University, GA.

Rapid technological advances, such as the development of next-generation sequencing, are driving the need for comprehensive computational tools to analyze the wealth of generated genomic data. Systematic benchmarking has been successful in many research disciplines to help non-computational researchers evaluate the accuracy and applicability of new computational tools. Adopting a standardized benchmarking practice and following established principles for the design of new benchmarking studies could help researchers using omics data to better leverage technological innovation. Here, we summarize established principles for guiding the design of new benchmarking studies. We separately discuss challenges and limitations of benchmarking studies, highlighting domains of computational biology where it is impossible to obtain the accurate gold standard making the benchmarking impossible or extremely limited. We reviewed of 26 benchmarking efforts published across 10 relevant peer-reviewed journals from 2011 to 2017 reveals several aspects of software development unique to computational biology. Our survey of benchmarking tools revealed a large variety of techniques currently used to prepare gold standard data. According to our survey, the most popular technique (10 out of 26 surveyed benchmarking studies) for preparing gold standard data is to use various alternative technologies. Benchmarking studies performed by one research team evaluated on average 18 computational tools, competition-based studies evaluated on average 37 tools. All the data generated by a benchmarking study offer substantial value to the software development and research community — yet these data are often not shared (58% of studies failed to share benchmarking data). We designated a separate discussion of the ephemeral nature of benchmarking studies, in particular, addressing the challenge of asynchronous version changes of the benchmarked method, new tool development and obsoleting the benchmarking study results. We also discuss different strategies to optimize benchmarking, including crowdsourcing and challenge-based benchmarking. We identify and discuss aspects of challenge-based benchmarking relevant to tests performed by individual research groups. Finally, we propose step-by-step instructions for increasing reusability, transparency, and reproducibility of benchmarking studies by using containerization, common data representation, open data, and systematic parameter description..

**Leveraging patterns of purifying selection to identify clinically important non-coding sequence in human whole-genome sequence data.** *D. Vitsios, A. Platt, S. Petrovski.* AstraZeneca Centre for Genomics Research, Precision Medicine and Genomics, IMED Biotech Unit, AstraZeneca, 1 Francis Crick Avenue, Cambridge Biomedical Campus, Cambridge CB2 0AA, UK.

Elucidating functionality in human non-coding sequence is a key genomics challenge. The Centre for Genomics Research (CGR), AstraZeneca is developing tools to exploit the full value of whole-genome sequencing (WGS) data to facilitate identifying novel drug targets in the non-coding genome. We previously showed that the intolerance to variation of coding and proximal non-coding sequence is a strong predictor of human disease relevance (Petrovski et al., 2013, 2015). Here, we expand the published method by applying a tiled genome-wide Residual Variation Intolerance Score (gwrVIS) to WGS data from 15,496 individuals (Lek et al., 2016) with lower gwrVIS corresponding to greater intolerance. We verified that gwrVIS distinguishes human disease genes (OMIM-haploinsufficient; median gwrVIS=-0.51) from other protein-coding genes (median gwrVIS=-0.42), both significantly departing from intergenic sequence (median gwrVIS=-0.02;  $p < 1 \times 10^{-200}$ ). Strikingly, gwrVIS identified ultra-conserved non-coding elements as the most intolerant category (median gwrVIS=-0.62;  $p < 1 \times 10^{-320}$ ). ClinVar non-coding pathogenic regions (median gwrVIS=-0.46;  $p = 2.6 \times 10^{-89}$ ) and ubiquitous enhancers (median gwrVIS=-0.47;  $p = 3.3 \times 10^{-120}$ ) were the next most significantly intolerant distributions compared to intergenic sequence. Remarkably, the 20% most intolerant enhancers were significantly enriched for ubiquitous enhancers compared to the 20% most tolerant (2.2-fold increase,  $p = 2 \times 10^{-9}$ ). Our score captures previously inaccessible information to help prioritise genetic variants found in the human non-coding regulatory sequence of known and novel drug targets and biomarkers.

**1514F**

**ncER (non-coding Essential Regulation) score – prioritization of variants for clinical diagnosis in the non-coding genome.** *J. di Iulio<sup>1,3</sup>, A. Wells<sup>2,3</sup>, P. Mohammadi<sup>1,4</sup>, D. Heckerman<sup>3</sup>, T. Lappalainen<sup>4</sup>, A. Telenti<sup>1</sup>.* 1) The Scripps Research Institute, La Jolla, CA; 2) Stanford University, Stanford, CA; 3) Human Longevity, Inc., San Diego, CA; 4) New York genome Center, New York, NY.

Understanding the consequences of variation in the non-coding genome is crucial. We use machine learning techniques to model non-coding genome biochemical, genetic, 3D chromatin structure, gene regulatory constraint and high-throughput enhancer reporter screen data. We trained a XGBoost model, an implementation of gradient boosted decision trees, to differentiate between pathogenic and control genomic positions using 73 features, including (i) existing non-coding deleteriousness scores (e.g.: CDTS, ncEigen, FATHMM, FunSeq2, GERP, LINSIGHT and ReMM), (ii) genome essentiality (e.g.: pLI, and gene regulatory constraint from ANEVA), (iii) biochemically detected genomic interactions (e.g.: 3D chromatin structure data and histone marks) and (iv) regulatory screens (obtained with STARR-seq). The model was trained on 1225 non-coding pathogenic variants from ClinVar and HGMD, and 8093 control variants. Controls were variants present in the gnomAD dataset at an allelic frequency  $> 1\%$  and matched for the distance to nearest splice site and genomic elements. 80/10/10 percent of the variants were used respectively as training/dev/test sets. The final model achieved 83% ROC-AUC and 64% PR curve and outperforms any single deleteriousness metrics by at least 9% ROC-AUC and 12% in PR curve. The top 20 most important features in the model included nine deleteriousness metrics, four gene essentiality features, two expression features, three chromatin marks feature, one 3D chromatin structure feature and one regulatory screen feature. Interestingly, although the deleteriousness metrics showed the highest cumulative feature importance, the contribution of the additional features is considerable. Indeed, their incorporation in the model improved the ROC-AUC by 3% (from 80 to 83%) and the PR curve by 8% (from 58 to 64%), indicating the complementary benefit of each additional data source. The use of new information sources on genome structure, human constraint and functional essentiality increases the accuracy of predicting the impact of genetic variations at nucleotide resolution. This new metric – ncER score – can guide functional experimentation and prioritization of variants for clinical diagnosis in the non-coding genome.

**1515W**

**Application of a machine learning framework to prioritise genes from large-scale cohort analyses.** S. Petrovski, D. Vitsios. AstraZeneca Centre for Genomics Research, Precision Medicine and Genomics, IMED Biotech Unit, AstraZeneca, 1 Francis Crick Avenue, Cambridge Biomedical Campus, Cambridge CB2 0AA, UK.

The tools to identify causal functional variants in known disease genes have greatly improved in recent years through the development of novel scores (e.g. Kircher et al, 2014) and novel machine learning frameworks (e.g. Traynelis et al, 2017). Present day, the genomics community, including our team at the Centre for Genomics Research (CGR), AstraZeneca is generating and analysing large volumes of exome and genome sequence data to better understand the genetic architecture of rare and common complex disorders. Here, we present a multi-dimensional machine learning framework aiming to identify novel disease genes among rare-variant collapsing analyses of all protein-coding genes that rank highly in gene-based analyses but do not achieve experiment-wide significance. We have applied this framework to a number of our cohort analyses harvesting diverse types of information per gene, including cohort-level association statistic, gene expression, human disease literature, mouse phenotypes, proteomic, interactome, genic metrics of human-lineage purifying selection (e.g. Residual Variation Intolerance Score-RVIS and Missense Tolerance Ratio-MTR) and others (52 features in total). Using a collection of already known disease-specific genes, and comparing to the remainder of the currently non-trait specific (unknown) genes we train a Random Forest classifier (R Caret package;  $n=500$ ,  $mtry=8$ ) and focus on unknown genes that based on shared properties with known genes are being classified as potentially novel 'trait-associated genes'. Across different parametrisations selected after model tuning, we often converge on a priority set of < 10 potentially novel trait-associated target genes. We also assess feature importance using the Boruta algorithm to allow for a permutation-based independence testing. Certain features like disease literature annotations, mouse trait-specific/lethal phenotypes, GO annotation and metrics of genic purifying selection like gnomAD-based MTR and RVIS frequently emerge as key features. Our multi-dimensional gene prioritisation framework accepts results from any gene-based burden or collapsing analysis and is agnostic to the disease cohort, provided there is already sufficient knowledge of disease-specific genes. We propose this approach as a support framework for objectively and quantitatively triaging potential novel disease target genes that are well ranked in rare variant collapsing or burden analyses.

**Integrated DNase I hypersensitivity information to supervise cell type correction in DNA methylation analysis.** X. Fu, HW. Deng. Global Biostatistics and Data Science Department, Tulane University, New Orleans, LA.

In epigenome-wide association studies, to investigate the associations between DNA methylation and phenotypes through tissue samples, cell components could be a potential significant confounding due to the nature that each cell has its distinct methylation pattern. To adjust for this heterogeneity, two major types of algorithms have been developed, including reference-based and reference-free methods. While reference-based methods are now popular and well adapted in current studies, these methods are requiring cell individual methylation profiles are available, thus mostly limited within studies involving whole blood. Reference-free, on the other hand, offers more flexibility to deal with complex tissues, for example, most cases of cancers. However, the performance of existed reference-free methods is still arguable. DNase I hypersensitive site (DHS) is the accessible DNA regions that are sensitive to cleavage by Dnase I enzyme, which feasible the transcriptional activity of the genes. Large percentage of distinct DHSs are specific to each cell type, and most importantly, more stable in each cell type. With DHS profiles largely available through epigenomic projects, this sparse feature is highly proposed to use in methylation prediction studies. In this study, I propose to integrate DHS signals to the first DHS guided Nonnegative Matrix Factorization (NMF) in methylation studies, thus to better identify the underlying variations of cell mixture. Through simulations I demonstrate this method could outperform existed methods in several scenarios in regards of specificity and sensitivity. While applying this method in real data is still underway, it's promising to develop an advantage solution for cell-mixture heterogeneity in methylation studies by integrating other DNA regulation information into reference-free algorithms.

Metagenomic sequencing of clinical samples have expanded our understanding of disease phenotypes and the dynamic nature of microbial flora in different body cavities. Emerging studies have shown that several microbial taxa or species were altered in the setting of immunological, cardiovascular, and gastrointestinal diseases among others. Microbial taxa identified in the setting of clinical phenotypes offer unique challenges to understand the specific functional pathways and metabolic reactions mediated by host-microbiome interactions. The collective study of microbial dysbiosis and corresponding clinical phenotypes by compiling datasets from multiple studies will be an important step toward understanding the role of microbes in health and disease. Further, it is important to perform a systematic exploration of microbial species within taxa to assess various parameters including predictive mapping from taxa to species level, co-metabolism mediated by host-microbe interactions, computational flux balance analyses, protein domain level species interaction, and prioritization using interolog evidences. To achieve this goal, we are crowdsourcing a catalog of clinical microbiome studies with details including disease phenotype or clinical trait, microbial taxa and species implicated in the phenotype and various experimental details. We envisage that the availability of an open access microbiome-phenome catalog, with its curated content, crowdsourcing features, bioinformatics utilities and information related to microbiome and clinical phenotypes, will be a useful resources for the research community interested in exploring clinical utilities of microbiome datasets. MuPhenome would also be vital for developing pharmacomicrobiome studies and microbiome-driven drug development and drug repositioning investigations. The catalog is available from the URL: <http://www.muphenome.org>.

**Testing hypotheses about the microbiome using an ordination-based linear decomposition model.** Y. Hu<sup>1</sup>, G. Satten<sup>2</sup>. 1) Emory University, Atlanta, GA, 30322, USA; 2) Centers for Disease Control and Prevention, Atlanta, GA, 30333, USA;.

**Background:** Data from a microbiome study is often analyzed by calculating a matrix of pair-wise distances between observations; ordination using principal components or multi-dimensional scaling of the distance matrix is frequently successful in separating meaningful groups of observations (e.g., cases and controls). Although distance-based analyses like PERMANOVA can be used to test association using only the distance matrix, the connection between data on individual species (or operational taxonomic units, OTUs) and the information in the distance matrix is lost. This makes it hard to know which species contribute to the patterns seen in ordination for the high-dimensional data we gather in a microbiome study. **Methods:** We introduce a novel approach called the linear decomposition model (LDM) that provides a single analysis path that includes distance-based ordination, global tests of any effect of the microbiome, and tests of the effects of individual OTUs with false discovery rate (FDR)-based correction for multiple testing. The LDM accommodates both continuous and discrete variables (e.g., clinical outcomes, environmental factors) as well as interaction terms to be tested either singly or in combination, allows for adjustment of confounding covariates, and uses permutation-based p-values that can control for correlation (e.g., repeated measurements on the same individual). The LDM can also be applied to transformed data, and an 'omnibus' test can easily combine results from analyses conducted on different transformation scales. **Results:** For global testing, our simulations indicate the LDM provides correct type I error, even with substantial confounding and/or correlations, and can have substantially higher power than existing distance-based methods. For testing individual OTUs, our simulations indicate the LDM generally controlled the FDR well. In contrast, DESeq2 had inflated FDR in the presence of confounding and inferior sensitivity with sparse OTU data; MetagenomeSeq generally had the lowest sensitivity. The exibility of the LDM for a variety of microbiome studies is illustrated by the analysis of data from two microbiome studies. **Conclusions:** We present the LDM, a method that integrates global testing of any microbiome effect and detection of differentially abundant OTUs. The LDM is generally more powerful than existing methods, and is capable of handling the confounders and correlated data that frequently occur in modern microbiome studies.

**Meta-analysis of vaginal microbiome data provides new insights into preterm birth.** *I. Kostj<sup>1,2</sup>, S. Lyalina<sup>3</sup>, K.S. Pollard<sup>4,5,6</sup>, A.J. Butte<sup>1,2</sup>, M. Sirota<sup>1,2</sup>.*

1) Institute for Computational Health Sciences, University of California, San Francisco, CA 94158, USA; 2) Department of Pediatrics, University of California, San Francisco, CA 94158, USA; 3) Integrative Program in Quantitative Biology, Gladstone Institutes, University of California, San Francisco, CA 94143, USA; 4) Department of Epidemiology & Biostatistics, Institute for Human Genetics, and Quantitative Biology Institute, University of California, San Francisco, CA 94143, USA; 5) Gladstone Institutes, San Francisco, CA 94158, USA; 6) Chan-Zuckerberg Biohub, San Francisco, CA 94158, USA.

Preterm birth (PTB) is defined as the birth of an infant before 37 weeks of gestational age. It is the leading cause of perinatal morbidity and mortality worldwide. In this study, we present a comprehensive meta-analysis of vaginal microbiome in preterm birth. We integrated raw longitudinal 16S ribosomal RNA vaginal microbiome data from five independent studies across over 3,000 samples and were able to gain new insights into the vaginal microbiome state in women who deliver preterm in comparison to those who deliver at term. We found that women who later have a preterm delivery show a higher variance in vaginal microbiome abundance, with the most significant difference observed during the first and second trimesters. Modeling the data longitudinally revealed a number specific microbial genera as associated with PTB, including several that were previously known and two newly identified as associated with PTB by this meta-analysis: *Olsenella* and *Clostridium sensu stricto*. New hypotheses emerging from such an integrative analysis can lead to novel diagnostics to identify women who are at higher risk for PTB and potentially inform new therapeutic interventions.

**Identification of microRNA target sites: In-silico screening on NGS data.** *V. Rallo, A. Angius.* Istituto di Ricerca Genetica e Biomedica, Monserrato CA, Cagliari, Italy.

MiRNAs may be biomarkers associated with the progression of several diseases and great efforts have been made to discover miRNAs, identify miRNA targets and infer miRNA functions. Different bioinformatic tools and algorithms enabled to predict miRNAs binding regions together with several databases that provided information about miRNA sequences. WGS, WES and RNAseq datasets can represent an optimal support to correlate variants with miRNA target sites at no additional cost. Our goal is to link variant calling information with a potential gain or loss of miRNAs target sites. So far, there is no simply logical and sequential procedure to do this. Using already existing software, we developed a simple pipeline that allows us to identify the impact of variants on miRNA target sites with a biological role. We created a unique database of miRNA's sequences that collected all existing miRNA databases (miRBase, tarbase, mirRNP, etc) and performed prediction analyses of target sites focused on the most performing existing algorithms (MiRanda, TargetScan). For example, starting from about 23,000 genomic variants that lie in 3'UTR region, a simple input command enabled us to select 4637 lost and 4302 gained target sites. The output is a simple tabular text file contains genomic variants, target site, variant impact, associated miRNAs, loss and gain sites and annotation data coming from different databases. The output result was designed to be used in subsequent standard software to apply filters based on the desired mode of inheritance and on sample's genotype quality and variant frequencies. This method could be particularly useful on WES data when the identification of the causal variant has failed and the involvement of miRNAs is assumed, without additional costs. This new automated sequential pipeline allows to identify, in silico, the variants involved in the miRNA targets from VCF files and to generate results easily interpreted and usable by people without bioinformatic skills.

**The IMPC: Insights into the correlation of gene essentiality and human disease.** P. Cacheiro<sup>1</sup>, V. Muñoz-Fuentes<sup>2</sup>, H. Haseli<sup>3</sup>, H. Westerberg<sup>3</sup>, S. Murray<sup>4</sup>, M.E. Dickinson<sup>5</sup>, A.M. Mallon<sup>3</sup>, T.F. Meehan<sup>2</sup>, D. Smedley<sup>4</sup>, the IMPC consortium. 1) William Harvey Research Institute, Queen Mary University of London, London, UK; 2) European Molecular Biology Laboratory, European Bioinformatics Institute, Hinxton, Cambridge, UK; 3) Medical Research Council Harwell, Mammalian Genetics Unit and Mary Lyon Centre, Harwell, Oxfordshire, UK; 4) The Jackson Laboratory, Bar Harbor, ME, USA; 5) Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX, USA.

The International Mouse Phenotyping Consortium (IMPC) is building a functional catalogue of the mammalian genome by producing and phenotyping a knockout mouse line for every protein-coding gene with over 5,000 knockout lines screened to date. One-third of these lines result in embryonic or perinatal lethality/subviability and can be compared with orthologous essential genes discovered in high-throughput screens of human cell lines. Whereas the human cell line studies have found that approximately 2,000 genes are essential for cellular life, the IMPC is on track to identify 6,000-7,000 genes necessary for organism development. In the present study we combined the information derived from studying viability at the cellular and organism level to generate different functional bins representing a spectrum of gene essentiality. A total of 3,354 genes with viability data from both cell and mouse reports and meeting strict quality criteria were subdivided into 5 functional bins: cellular essential (essential both in human cells and mice), developmental essential (non-essential in cell lines and essential in mice), subviable, viable with phenotypic abnormalities and viable with no abnormal phenotype detected. Whereas 99% of the mouse non-essential genes (viable) were also non-essential in human cells, only 36% of the genes that were lethal in mouse were also essential in cell lines. The remaining lethal genes -developmental essential- were found to be associated to biological processes involved in morphogenesis and tissue development and showed a very high enrichment for disease genes. The disease genes in each of the functional bins also showed a clear differentiation in terms of age of onset, number of physiological systems affected and mode of inheritance. Additional features such as levels of gene expression or the percentage of genes being part of a protein complex were correlated with the level of essentiality. By combining human cell and mouse viability information we are able to capture different levels of gene essentiality. Rare disease genes are not only unequally distributed among these categories, but they also present differences with respect to the type of disorders they are associated with. Practical implications emerging from these findings would include the prioritization of variants in sequencing studies and the use of machine learning to predict new lethal and disease genes based on the distinctive features they present.

**Statistical methods inferring fetal fractions promise the most powerful noninvasive prenatal screen.** M. Dang<sup>1,5</sup>, H. Xu<sup>2</sup>, Y. Guan<sup>1,3,4,5</sup>. 1) USDA/ARS Children's Nutrition Research Center, Baylor College of Medicine, Houston, TX; 2) Beijing USCI Medical Laboratory, China; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Center for Statistical Genetics and Genomics, Department of Biostatistics and Bioinformatics, Duke University, Durham, NC.

Fetal fraction plays a pivotal role in noninvasive prenatal screen (NIPS), whose aim is to detect trisomy in fetus. The fetal fraction can be estimated from sex chromosomes for male fetuses, but not for female fetuses. In addition, such estimates are inaccurate when the fetuses have sex chromosomal trisomy XXY or XYY, or monosomy X. Here we present a method that can reliably estimate fetal fractions for both male and female fetus by examining autosome coverage. First, even at low coverage, there are sizable number of 1000 genomes SNPs that are covered by more than one reads. This can be deduced simply by assuming Poisson distribution at each locus and verified by real data. Second, at those SNPs covered by at least two reads, we can define heterozygosity. Third, the heterozygosity is a function of fetal fraction, which in turn allows fetal fraction to be inferred. With a known fetal fraction, the performance of NIPS can be dramatically improved in the following aspects. First, the traditional Z-test likelihood only accounts for how far the inferred chromosomal dosage is away from the null; the inferred fetal fraction enable us to also account for how far the inferred chromosomal dosage is away from the alternative, which is the most powerful test for aneuploidy. If we treat microdeletion and microduplication as aneuploidy of a small artificial chromosome, our method promises the most powerful NIPT Plus. Second, for samples with extremely low fetal fractions we may declare "no call," which removes a major source for false negative. Third, testing aneuploidy of sex chromosomes, such as XXY, XYY, and X, becomes a simple problem when the fetal fraction is known.

**1523F****The pharmacogene variant (PharmVar) consortium and database. A.**

Gaedigk<sup>1,2</sup>, G. Twist<sup>1</sup>, M. Whirl-Carrillo<sup>1</sup>, K. Sangkuhl<sup>1</sup>, S. Casey<sup>2</sup>, T. Klein<sup>1</sup>, N. Miller<sup>2,3</sup>. 1) Division of Clinical Pharmacology, Toxicology & Therapeutic Innovation, Children's Mercy, Kansas City, Kansas City, MO; 2) School of Medicine, University of Missouri-Kansas City, Kansas City, MO; 3) Center for Pediatric Genomic Medicine, Children's Mercy, Kansas City, Kansas City, MO; 4) Department of Biomedical Data Science, Stanford University, Stanford, CA.

**Background:** Broad implementation of pharmacogenetics (PGx) requires a stable nomenclature for allelic variation in pharmacogenes. Since its inception in 2002, the Human Cytochrome P450 Allele Nomenclature Committee has been the authority for cataloging allelic variation of CYP genes. In October, 2017 the Nomenclature Database was transitioned to the PharmVar Consortium at Children's Mercy Kansas City ([www.PharmVar.org](http://www.PharmVar.org)). **Methods:** To facilitate this transition, a stakeholder group developed a plan to sustain what was agreed upon as an essential resource. The PharmVar Consortium, a NIH-funded PGRN resource ([pgrn.org/pharmvar.html](http://pgrn.org/pharmvar.html)), was established to serve as a centralized 'Next-Generation' pharmacogene variation data repository.

**Results:** The PharmVar database was launched in March 2018 featuring three high priority genes, *CYP2C9*, *CYP2C19* and *CYP2D6* with additional genes to follow in Summer 2018. PharmVar provides consistent mapping of variants across multiple reference sequences including the genomic locus reference sequence from RefSeqGene or Locus Reference Genomic (LRG) sequence if available, a representative sequence from RefSeqTranscript and genome builds GRCh37 and GRCh38. Website features include the ability to dynamically switch coordinates between counting from the sequence start or the ATG start codon, an overview page showing all haplotypes sharing a sequence variant and links to external resources such as dbSNP, NCBI Gene, HGNC and PharmGKB. Haplotype data is available for download in FASTA, VCF and TSV formats. PharmVar is developing a revised haplotype naming system that accommodates the designation of suballeles as well as an evidence code system to clearly represent the strength of evidence supporting each allele/haplotype definition. PharmVar will simplify allele submission by developing online tools for users to deposit data. Submissions will be reviewed by gene expert panels composed of PharmVar community members. Expansion to non-CYP PGx genes are also underway. PharmVar efforts are synchronized with the Pharmacogenomic KnowledgeBase (PharmGKB) and the Clinical Pharmacogenetics Implementation Consortium (CPIC) to provide the PGx community with standardized information for implementation of PGx. **Conclusions:** PharmVar provides a rich resource for the entire PGx community. PharmVar invites anyone with an interest in PGx variation to become a consortium member and actively participate to move pharmacogene nomenclature efforts forward.

**1524W****Large-scale characterization of CYP2D6 variation in African Americans using TOPMed whole genome sequencing data. S. Lee<sup>1</sup>, M.M. Wheeler<sup>1</sup>,**

J.G. Wilson<sup>2</sup>, A. Correa<sup>3</sup>, P. Anugu<sup>3</sup>, D.A. Nickerson<sup>1,4</sup>, NHLBI Trans-Omics for Precision Medicine (TOPMed) Consortium. 1) Department of Genome Sciences, School of Medicine, University of Washington, Seattle, WA, USA; 2) Department of Physiology and Biophysics, University of Mississippi Medical Center, Jackson, MS, USA; 3) Department of Medicine, University of Mississippi Medical Center, Jackson, MS, USA; 4) Brotman Baty Institute for Precision Medicine, Seattle, WA, USA.

Genotyping *CYP2D6* is important for precision drug therapy because the enzyme it encodes metabolizes about 25% of drugs, and its activity varies substantially within and between populations. Over 100 haplotypes or star alleles have been defined for *CYP2D6*. These are characterized by single nucleotide variants, insertion-deletion variants, and structural variants that include gene deletions, duplications, and hybridizations with a nearby non-functional but highly homologous paralog *CYP2D7*. Although many star alleles are known to exhibit distinct population frequencies, further investigation of *CYP2D6* variation is warranted in non-European populations because these are underrepresented in the overall estimation of *CYP2D6* genetic diversity. In this study, our goal was to comprehensively survey *CYP2D6* variation in a large African American cohort. Specifically, we performed *CYP2D6* genotype analysis of 3,418 African American samples from the Jackson Heart Study that were whole genome sequenced by the Trans-Omics for Precision Medicine (TOPMed) program. These samples were genotyped using Stargazer, a bioinformatics tool we recently developed for accurate calling of star alleles in various polymorphic pharmacogenes, including *CYP2D6*. From our samples, we found a total of 41 unique haplotypes including the decreased function *CYP2D6\*17* (16.6%) and *\*29* (7.8%) alleles that are commonly found in individuals of African ancestry and the non-functional *CYP2D6\*4* allele (3.1%). We also observed extensive structural variation ranging from zero to five gene copies and numerous *CYP2D6/CYP2D7* hybrids. That is, 22 out of 41 detected haplotypes had structural variation: 5.4% with a gene deletion (*CYP2D6\*5*), 7.0% with a gene duplication (*CYP2D6\*1x2*, *\*2x2*, *\*4x2*, *\*10x2*, *\*17x2*, *\*29x2*, *\*34x2*, *\*41x2*, *\*43x2*, *\*4N+\*4*, *\*36+\*10*, *\*68+\*4*, *\*77+\*2*, and *\*78+\*2*), 0.1% with a gene multiplication (*CYP2D6\*1x3*, *\*2x3*, *\*4x3*, *\*29x3*, and *\*34x3*), and 1.3% with a gene hybridization (*CYP2D6\*4N*, *\*36*, *\*66*, *\*68*, *\*76*, *\*77*, and *\*78*). Overall, 25.5% of the samples had at least one type of structural variation and based on diplotype calls, 1.6%, 8.9%, 84.4%, and 3.9% were predicted to be poor, intermediate, normal, and ultrarapid metabolizers, respectively. We are currently expanding our analysis to include other cohorts in the TOPMed program. These results demonstrate the importance of enhancing our understanding of *CYP2D6* genetic diversity in large and diverse datasets in order to achieve precision drug therapy.

**1525T**

**High-throughput CLIA QC pipeline for PGx EHR integration.** *M. Saylor<sup>1</sup>, N. Rafaels<sup>2</sup>, K. Crooks<sup>2</sup>, T. Brunetti<sup>2</sup>, L. Koivukoski<sup>1</sup>, B. Jackson<sup>1</sup>, N. Hurskainen<sup>1</sup>, P. Sevon<sup>1</sup>, T. Kanninen<sup>1</sup>, A. Ahonen-Bishopp<sup>1</sup>, L. Eronen<sup>1</sup>.* 1) BC Platforms, Boston, MA; 2) Colorado Center for Personalized Medicine (CCPM), Aurora, CO.

Genotyping is a powerful method for generating genetic insights for patient care and research. Compared to next-generation sequencing (NGS), genotyping is only a fraction of the cost of NGS and is already in practice facilitating population scale adoption. Additional healthcare costs caused by incorrect medication or dosage are significant, and genotype based PGx reporting has potential for major cost savings as well as improving quality of care. However, in adopting PGx on a large scale, there are challenges in maintaining high-throughput and in ensuring data production and insights from produced data are done following clinical practices (CLIA, HIPAA). We have developed an automated pipeline that enables high-throughput processing of Illumina array data, PGx reporting, and direct delivery of results to Epic. Typically, Illumina array data production depends on GenomeStudio software for QC. This pipeline automatically processes gtc files without the need to use GenomeStudio. Data is processed according to quality thresholds, both on the sample level and on the SNP level, also including visuals of SNP intensity data to assess quality. The pipeline is automated while also allowing lab director level overrides. The software supports approval of data for further processing (either for clinical and/or research use), within a high-security audited software and hardware environment. For PGx reporting, the star allele and metabolizer status for each sample and SNP is calculated by the pipeline automatically using the combination of a custom algorithm and a PGx knowledge base. An individual's predicted drug response is valuable information in patient care, this information is communicated immediately to Epic through HL7 messaging. The pipeline can be installed to a variety of environments, including utilization of object/blob storage provided by most cloud vendors, as well as utilizing on-premise infrastructure with connected calculation cluster and file storage. The pipeline is scalable for running genotype data production for biobanks or healthcare institutions targeting population scale, where daily throughput can be thousands of samples. The pipeline can also be complemented by further automated parallel imputation pipeline research purposes. This process makes it possible to produce genotype data in massive scale to be utilized for clinical reporting, population level research and biobanking.

**1526F**

**PubCaseFinder: A phenotype-driven differential diagnosis system for rare diseases based on case reports.** *T. Fujiwara<sup>1,2</sup>, Y. Yamamoto<sup>1</sup>, J.D. Kim<sup>1</sup>, T. Takagi<sup>2</sup>.* 1) Database Center for Life Science, Kashiwa-shi, Chiba, Japan; 2) Department of Computational Biology and Medical Sciences, Graduate School of Frontier Sciences, The University of Tokyo, Kashiwa-shi, Chiba, Japan.

Next-generation sequencing (NGS)-based diagnostic tests, which particularly employ clinical exome sequencing (CES), have been attempted for diagnosis of patients with suspected rare diseases. Clinical sensitivity of CES, i.e., the percentage of patients who were diagnosed by CES, is up to 40% in several studies. Unfortunately, other ~60% of patients with suspected rare diseases don't receive a diagnosis, and such patients will likely lose opportunities such as optimization of clinical management and early intervention. Recently, to aid these patients, phenotype-driven differential diagnosis systems such as Phenomizer and FACE2GENE have been implemented. These systems provide a ranked list of rare diseases based on the phenotypic similarity between a patient and rare diseases, and the top-listed diseases represent the most likely differential diagnosis. The performance of these systems is greatly influenced by the quantity and quality of underlying databases of disease-phenotype associations (DPAs). Note that these databases rely on manual curation and show a limited coverage. In the case of DPA database from Orphanet, more than half of the rare diseases (~60.5% of 6,268) are not associated with a phenotype. The development of DPA databases is based on the curation of papers by human experts, which is time-consuming and labor-intensive because of the large volume and rapid growth of life sciences papers. To address the problem, we developed a text mining approach to extend the coverage of DPAs in manually curated databases like Orphanet. By applying the approach to a million case reports from PubMed, we could increase the coverage of DPAs from Orphanet more than 2 times. Based on the extended DPA database, we also developed PubCaseFinder (<https://pubcasefinder.dbcls.jp>), a new phenotype-driven differential diagnosis system. A series of experiments which was conducted using clinical cases from PhenomeCentral showed that the performance of PubCaseFinder could substantially be improved thanks to the extension of the DPA database. Note that automatic text mining techniques are often regarded as assistive tools to help manual curation of databases, due to its potentially high chance of noisy results. However, our experimental results suggest that even before a manual screening process, text mining approach can be substantially helpful. Our proposed approach is deemed practically useful, because manual curation will take enormous time and cost.

**1527W**

**Genetic history of Russian indigenous populations and their genome medical mining.** V. Brukhin<sup>1</sup>, D. Zhernakova<sup>1,2</sup>, S. Malov<sup>1</sup>, K.P. Koepfli<sup>1,3</sup>, A. Zhuk<sup>1</sup>, P. Dobrynin<sup>1,3</sup>, S. Kliver<sup>1</sup>, N. Cherkasov<sup>1</sup>, G. Tamazian<sup>1</sup>, M. Rotkevich<sup>1</sup>, K. Krashennnikova<sup>1</sup>, I. Evsyukov<sup>1</sup>, A. Gorbunova<sup>1</sup>, E. Chernyaeva<sup>1</sup>, A. Komissarov<sup>1</sup>, D.E. Polev<sup>1</sup>, A. Glotov<sup>1</sup>, A. Novozhilov<sup>1</sup>, S.J. O'Brien<sup>1</sup>, V. Osakovsky<sup>4</sup>.

1) Dobzhansky Center for Genome Bioinformatics, St. Petersburg State University, St. Petersburg, Russian Federation; 2) University of Groningen, University Medical Center Groningen, Department of Genetics, Groningen, the Netherlands; 3) 1.Smithsonian Conservation Biology Institute, National Zoological Park, Washington, D.C. USA; 4) Institute of Health, North-Eastern Federal University, Yakutsk, Russian Federation.

Despite a large population size and high ethnic diversity, no centralized reference database of functional and endemic genetic variation has been established to date for Russian human populations. Such data are crucial for studying population history and would be essential for medical genetic purposes. The Genome Russia Project aims at filling this gap by performing a high coverage whole genome sequencing and analysis of people from the Russian Federation. A comparative analysis of whole genome sequencing (WGS) was initiated at the St. Petersburg State University. We assessed calling of SNPs, indels, copy number variations from 264 healthy adults (from 52 indigenous Russian populations), including 60 newly sequenced samples consisting of family trios from three geographic regions: Pskov, Novgorod (Western Russians) and Yakutia (Yakut). People of Russia are shown to carry known and novel genetic variants of adaptive, clinical and functional consequence that in many cases show appreciable occurrence or allele frequency divergence from the neighboring Eurasian populations. Principal component and phylogenetic analyses of overall variation revealed strong geographic partitions among indigenous ethnicities corresponding to the geographic locales where they have lived. Allele frequency spectra identified strong constraints to gene flow that correspond to the geological barriers (e.g. the Ural Mountains and Verkhoyansk mountain range). In conclusion, this study presents a genomic characterization of population-specific variation in Russia with results important for medical genetics as well as for population genetic history studies.

**1528T**

**GRAF-pop: A novel tool to quickly infer subject ancestry from multiple genotype datasets.** Y. Jin, A.A. Schaffer, M. Feolo, J.B. Holmes, B.L. Kattman. National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD.

It is essential to be able to infer subject ancestry from genetic data in genome wide association studies, since unhandled population stratification can result in false associations, and self-reported ancestries may not be accurate. Many of the commonly used methods to infer subject ancestry from genetic data rely on principal components analysis (PCA). However, PCA has two important limitations: (1) PCA results are not comparable across data sets; (2) PCA does not work when subjects have high genotype missing rates. The two limitations have become increasingly prominent since investigators now can access more and more genotypes obtained using different platforms, such as the data sets obtained from the National Center for Biotechnology Information's (NCBI) Database of Phenotypes and Genotypes (dbGaP). We have developed an ancestry inference tool, GRAF-pop, that is robust to missing genotypes, fast and easy to use. The results of GRAF-pop can be generalized across datasets obtained using different platforms. GRAF-pop is implemented as a feature of the GRAF (Genetic Relationship and Fingerprinting) software package, using pre-selected 10,000 well separated, autosomal biallelic SNPs with high minor allele frequencies to infer subject ancestry. It calculates genetic distances from each subject to several reference populations from dbGaP and projects the results to a pre-defined 2D plane without using PCA. Barycentric coordinates are used to estimate the ancestry proportions of each subject based on the relative distances to the reference populations, and to normalize the scores to overcome the problem of missing genotypes. GRAF-pop takes PLINK formatted genotypes as input, and outputs assigned populations and estimated ancestral components in tables and scatter plots. No data pre-processing, e.g., filtering SNPs and samples, removing related subjects, are needed to run the program. Results obtained from different datasets can be combined and plotted onto the same graph. GRAF-pop is fast, with runtime linear to the number of individuals. The current version of GRAF is freely downloadable from the following webpage: <https://www.ncbi.nlm.nih.gov/projects/gap/cgi-bin/Software.cgi>. This presentation will describe the algorithms and use of GRAF-pop by dbGaP staff and data submitters and users, and summarize the results of ancestry inference of over one million dbGaP subjects. .

**Uncertainty in genetic ancestry: The importance of structure in the ancestral populations.** *F.L. Mendez, M.L.A. Isaksson, S. Ruddy, W. Lee.* Helix, LLC, SAN CARLOS, CA.

Understanding how the genetic ancestry of individuals is partitioned among ancestral populations is central to the study of human population history and fundamental for the reconstruction of an individual's ancestry. In diverse and admixed populations, knowledge of the genetic ancestry may also inform medical decisions and aid the interpretation of significance of genetic variants. One of the most popular methods to characterize genetic ancestry explains the genome of individuals as the combination of genetic material originated from discrete population clusters (Structure method). For clusters obtained in unsupervised analysis, populations are typically explained as combinations of multiple clusters. Alternatively, a supervised analysis could be used to describe individuals in terms of externally defined groups; for instance, ancestral populations could represent continental ancestry and individuals from various populations within that continent would be used to create a panel for the corresponding cluster. However, when there is structure within a group, the characteristics of its cluster will depend on the relative representation of its subgroups. This may often result in discrepancies in ancestry estimates when reference panels are very dissimilar in how they weigh subgroups in a cluster. We explored the variation in ancestry estimates and its dependence on the choice of the individuals representing each of six ancestral groups: sub-Saharan Africans, East Asians, South Asians, Europeans, Indigenous Americans, and Ashkenazi Jews. Ancestry estimates exhibit different degrees of sensitivity to the choice of representatives for each group. Estimates of European, South Asian and Ashkenazi Jewish ancestry are considerably more sensitive to the choice of individuals in the reference panels. This is especially true for European ancestry: individuals with southern and southeastern European ancestry are inferred as having Ashkenazi Jewish ancestry when the European panel relies on northern or western Europeans. We use the observed variation in estimated ancestry to provide a measure of the uncertainty associated with inferring ancestry. We further use the relationship between ancestry estimates and their uncertainty to provide confidence bounds for ancestry estimates of new samples. Our research addresses a prominent reason for discrepancy in ancestry estimates: differences in population reference panels; it also provides a framework to assess its extent.

**A framework for analytical validation of SNP arrays for clinical diagnostics.** *P.F. Cherukuri<sup>1,2,3</sup>, J.M. Lubieniecka<sup>1,2,3</sup>, K.P. Lubieniecki<sup>1,2,3</sup>, S.J. Ahuja<sup>1</sup>, R. Pyatt<sup>1,2,3</sup>, C.F. Boerkoel<sup>1</sup>, L. Carmichael<sup>1</sup>.* 1) Imagenetics, Sanford Health, Sioux Falls, SD; 2) Sanford School of Medicine, University of South Dakota, Sioux Falls, SD; 3) Sanford Research Center, Sioux Falls, SD.

**Background:** High-throughput, low-cost genotyping is used for many applications in precision medicine as well as population genomics. Consortia such as the 1000 Genomes project have made available whole genome sequence data from diverse population groups that serve as reference datasets. Additionally, curation of variants causal for diseases (e.g. ACMG59), risk associations (e.g. Cardiovascular), drug metabolism (e.g. Pharmacogenomics), and other traits, have markedly improved. **Hypothesis:** We hypothesize, therefore, that genotyping arrays can be validated to screen clinically for sequence variants. **Methods:** We used the Illumina Infinium Global Screening Array (GSA), which assays >660,000 variants in a 24-sample format, to test this hypothesis. We divided the analytical validation into theoretical and empirical components. For the theoretical component, we used a Bayesian theoretical framework to calculate the expected genotyping error in the GSA-targeted genotypes based on whole-genome sequence-based variation. For the empirical component, we used orthogonal approaches including parallel whole genome sequencing (WGS) (>30x coverage), TaqMan assays, and Sanger sequencing. To improve genotyping accuracy further, the GSA data of 1,200 individuals were manually curated for quality control (QC) and used to create a reference cluster file. **Results:** Theoretical evaluation of false positives and false negatives for single nucleotide variants predicted that we will find ~ 3 true false negatives per GSA run based on WGS and GSA whole genome discordance rates. This modelling was based on a single individual replicate dataset ( $N=23$ ; NA12878) and assumed (1) a probability of variation given a true homozygous reference of 0.0038, (2) a probability of homozygous reference given a true variant was 0.0043, and (3) a prior risk of 1/1000 for genome variation. Genomic regions with higher variation rate will have higher chance of false negatives (e.g.  $2/1000 = \sim 6$  false negatives per GSA run given all probes map to highly variable regions). Empirical comparison of replicate data sets from the GSA to a truth dataset from WGS was used to refine the performance metrics (sensitivity, specificity, accuracy, precision, etc.). Preliminary empirical results show high sensitivity and specificity (>0.99) across all GSA probes passing QC. **Conclusion:** A combined theoretical and empirical approach can analytically validate single nucleotide variant arrays for clinical use.

Jarvik<sup>1</sup>. 1) University of Washington, Seattle, WA; 2) Columbia University, New York, NY; 3) Children's Hospital of Philadelphia, Philadelphia, PA; 4) Vanderbilt University, Nashville, TN; 5) University of Texas Health Science Center at Houston, Houston, TX; 6) University of Alabama at Birmingham, Birmingham, AL; 7) Mayo Clinic, Rochester, MN; 8) Kaiser Permanente Washington Health Research Institute, Seattle, WA; 9) National Human Genome Research Institute, Bethesda, MD.

**Introduction:** The Electronic Medical Records and Genomics (eMERGE) Network has developed eMERGEseq, a panel of 106 genes comprising the "ACMG 56" actionable genes and site-requested genes, as well as approximately 1500 SNVs in other genes. The goal is to eventually return actionable results and incorporate them into the electronic health record with clinical decision support for 25,000 participants. We propose assessing the correlation between interpretations of pathogenicity of genetic variants identified in the eMERGEseq cohort using three sources, with one considered the "gold standard." **Methods:** Stratifying by cancer genetics, cardiovascular genetics, and neurogenetics, we will compare pathogenicity classifications generated by 3 methods: 1. CLIA results from two clinical labs generating clinical reports for eMERGEseq; the pathogenicity interpretation (pathogenic, likely pathogenic, variant of uncertain significance, likely benign, and benign) in these reports will be considered the "gold standard;" 2. The *in silico* clinical pathogenicity interpretation tool Intervar; and 3. Crowdsourcing participating investigators for clinical interpretation using molecular annotation and phenotype indication via RedCap survey tools. We will use a Cohen's  $\kappa$  coefficient to assess qualitative correlation among the three groups. **Results:** Response to participation in the crowdsourcing project has been enthusiastic with >50 participants at the time of this proposal, including representation from eMERGE, CSER, AMIA, and NHGRI, among others. We have captured the multiple biography variables for our crowdsourcing participants. For instance, highest degree achieved is as follows: 1. MD (22.2%); 2. PhD (44.4%); 3. MD-PhD (19.4%); 4. MS (11.1%); and 5. BS (2.8%). Indication expertise is as follows: 1. Cancer (8.3%); Cardiovascular (2.8%); 3. Neurology (2.8%); 4. Immunology (2.8%); 5. Combination of two or more (27.8%); 6. Other (25.0%); 7. Not an expert (25.0%); and 8. NA (5.6%). At present, the "gold standard" variants have been collected from the eMERGE sequencing centers, and the eMERGE Coordinating Center has ensemble-called variants in ~15,000 participants. **Conclusion:** As the focus of clinical sequencing research moves from targeted panels to exomes and ultimately genomes, it will be advantageous to assess tools that can assist in the clinical interpretation on a larger scale.

**Automating variant assessment using structural features.** A.C. Chamberlin, M.S. Park, I.D. Petrik, H.M. Lu, R.B. Fenwick. Bioinformatics, Ambry Genetics Corp, Aliso Viejo, CA.

Variant assessment is rapidly becoming a significant part of clinical diagnoses in both clinical and somatic diseases. As the number of uncategorized variants continues to grow, automated classification schemes will become more and more valuable. The application and automation of simple classification schemes using sequence, and ternary-structural features will be invaluable in prioritizing variants for assessment, classification and functional studies. Structural biology can provide a variety of features for variant assessment that can be leveraged in parallel with traditional methods such as *in-silico* predictions that rely on sequence primary-structure (Baugh et al., 2016). These features can include but are not exclusive to, structural motif identification, variant location in the domain (buried, surface, or interfacial), as well as information about the local environment of the variant (hydrogen bonding, ligand binding, back-bone conformation, etc), all of which provide invaluable insight into variant pathology (Pesaran et al., 2016; Ponzoni & Bahar, 2018). Here we present an automated method for leveraging structural features for variant assessment, which can be used as a tool to both propose appropriate categories for variants of interest and allow prioritization of variants for reporting and reassessment purposes.

**1533W**

**Leveraging external variant frequency information to increase statistical power in rare variant association studies.** *J. Chen, R. Callender, R. Bohlender, Y. Yu, M. Hildebrandt, C. Huff.* MD Anderson Cancer Center, Houston, TX.

Allele frequency summary data from large public databases has been a valuable resource in the search for rare genetic variation influencing human disease. However, such information has proved difficult to fully leverage in sequence-based case-control studies. Here, we introduce a novel approach that uses external allele frequency information from a closely related population to enrich for rare variants likely to be associated with a trait in sequencing case-control studies. This approach reduces the multiple testing burden in single marker tests and increases the effective proportion of causal variants in gene-based tests, both resulting in an increase in statistical power. We benchmark this approach in a simulation study involving a wide variety of risk patterns and observe substantial increases in power in the broad majority of scenarios. For example, using a single marker test for a variant with a minor allele frequency (MAF) of 0.01 and an odds ratio (OR) of 1.6, our approach achieves 80% power compared 20% power using standard techniques ( $\alpha = 5 \times 10^{-8}$ ). In another example, using a gene-based test for variants with MAF < 0.005 and OR of 2, our approach yields a p value of  $3.7 \times 10^{-5}$ , compared to a p value of 0.0026 using standard techniques. Importantly, this approach does not inflate Type I error and is not influenced by cross-platform stratification biases under the null model. We further demonstrate the utility of this method in case-control analyses involving whole-exome sequencing data from 783 breast cancer cases, 272 ovarian cancer cases, 322 melanoma cases, and 3507 shared controls, using ExAC as the external reference panel.

**Benchmarking and visualization of short tandem repeats to enable genome-wide discovery and clinical interpretation.** *V.B. Deshpande, E. Dolzhenko, S. Chen, D.R. Bentley, M.A. Eberle.* Illumina Inc., 5200 Illumina Way, San Diego, CA-92122, USA.

Expansions of short tandem repeats (STRs) are responsible for more than 20 genetic diseases and many new pathogenic repeat expansions are likely to be discovered. Recently we presented ExpansionHunter (EH), a tool to detect pathogenic repeat expansions using PCR-free whole genome sequence data. We have applied EH to the known pathogenic repeats and the next step is to enable discovery of novel pathogenic STRs anywhere in the genome. As we extend STR genotyping to loci across the genome, we expect that many STR loci will present unique challenges and it is important to systematically assess the genotyping accuracy at each locus. For this purpose, we developed a benchmarking pipeline which reports the Mendelian consistency rate at each STR locus in 50 trios and the 17-member Platinum Genomes pedigree. Additionally, because STRs are difficult to inspect with tools such as IGV which do not display the inserted sequence, we developed a custom visualization tool that displays a pileup of all read alignments reported by the STR genotyping tool against a custom reference containing the longest repeat alleles. Our visualization tool allows rapid assessment of STR genotypes for method development and will be invaluable for the inclusion of EH into clinical pipelines. As a demonstration of this pipeline, we assessed genotype calls made by EH at 24 STR loci associated with monogenic disorders. When we observed Mendelian conflicts, we used the visualization tool to correct the individual genotype calls and finally created a curated truth set that can be used as a benchmarking resource and for regression testing. To extend this database beyond the known pathogenic repeats, and enable researchers to genotype these STRs in their genomic studies, we are now building a genome-wide database of all STRs in genic regions. We will present a review of the genome-wide STR landscape including an assessment of the performance of these variants using our Mendelian validation pipeline. In conclusion, we provide a framework to assess STR genotyping accuracy for each STR locus, a tool to curate STR predictions through visualization and a curated truth set resource for benchmarking.

**Transcriptome analysis by RNA-sequencing as an adjunct to whole genome analysis in undiagnosed genetic disease.** *N. Balanda<sup>1</sup>, M. Malicdan<sup>1,2,3</sup>, D. Adams<sup>1,2,3</sup>, W. Gahl<sup>1,2,3</sup>, Undiagnosed Diseases Network.* 1) NIH Undiagnosed Diseases Program, NHGRI, National Institutes of Health, Bethesda, Maryland, USA; 2) Medical Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, Maryland, USA; 3) Office of the Clinical Director, National Human Genome Research Institute, NIH, Bethesda, Maryland, USA.

**INTRODUCTION:** The NIH Undiagnosed Diseases Program (NIH-UDP) aims to uncover genetic causes for rare, previously undiagnosed diseases. In the 10 years since its conception, the UDP has made extensive use of genome-scale DNA sequencing, in combination with comprehensive clinical and biochemical phenotyping, to identify diagnostic hypotheses and make diagnoses. By these efforts, approximately 25% of the over 1,000 patients seen during this period have received diagnoses. Here, we employ functional genomics and expand the use of transcriptome analysis as an adjunct to DNA-based sequencing, with the aim of increasing the rate of diagnosis in our patients. We describe the progress made in a pilot study using transcriptome to augment the analysis of whole genome sequencing (WGS) in UDP participants. **METHODS:** DNA-based sequencing of patients and family members was done through whole genome sequencing. For a cohort of 130 probands without a current diagnosis, total RNA was extracted from patient-derived dermal fibroblasts, purified for cDNA library preparation, and sequenced using Illumina HiSeq. Data were then aligned to the GRCh37/hg19 human reference and analyzed using a custom built pipeline. Given the highly-heterogenous nature of the UDP cohort, transcriptome analysis was performed for each proband using all 129 other members of the cohort as controls. **RESULTS:** Agnostic reanalysis of WGS, revealed that the majority of these 130 cases harbor non-coding variants of interest with unknown significance. We thus utilized RNAseq to verify the biological consequences of these variants, and positive findings in many of these cases suggest that individual hypotheses positing a relationship between specific DNA variants and splicing, or transcriptional regulation can be supported or refuted with RNASeq data. In addition to validating WGS findings, this method contributes new variants of interest to WGS analysis by detecting association between genomic variants and aberrant splicing/expression profiles. **CONCLUSIONS:** Prioritization of DNA sequence variants for further study is a substantial undertaking for cohorts of individuals with undiagnosed diseases. Functional genomics, including the utilization of RNASeq studies, can provide additional information that is useful for specific DNA-variant-associated hypotheses, and aid in the prioritization of genetic variants. Our results support the routine use of RNASeq analysis in improving the overall diagnostic rate over time.

**1536W**

**QTR-seq: A tool for detecting quantitative trait-associated genes in RNA-seq data.** *M. Seo<sup>1,2</sup>, D. Qiao<sup>1,2</sup>, W. Qiu<sup>1,2</sup>, P. Castaldi<sup>1,2</sup>, CP. Hersh<sup>1,2</sup>.* 1) Chan-ning Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA.

Most of the statistical analysis methods for RNA-sequencing data have been developed to focus on group comparisons such as specific experimental conditions or cases and controls. The statistical methods for quantitative trait association testing are not as well established due to the practical limitations such as limited sample sizes. Herein, we present a systematic and flexible approach for detecting continuous trait-associated genes in RNA-seq data. Using simulation studies, we evaluated the variable parameter settings for detecting quantitative trait-associated genes, including effective sample size, gene filtering strategies, normalization methods, and statistical estimators. We found that robust estimators, such as M, S, and MM estimators that account for outlier effects in both measured traits and gene expression, outperform ordinary least-squares regression in terms of false positive rate. We applied the method to 1,211 blood RNA-seq samples from the Genetic Epidemiology of Chronic Obstructive Pulmonary Disease (COPDGene) study. Since cigarette smoking is a major risk factor for COPD, we tested for gene expression-by-smoking interaction associations with quantitative measures of lung function, which could not be performed in existing statistical methods for RNA-seq data. We found that 339 genes are differentially associated with the forced expiratory volumes in 1 second (FEV1) percent predicted in current compared to former smokers at q-value < 0.05. Finally, we implemented QTR-seq, a flexible R package for detecting quantitative trait-associated genes, which is able to incorporate adjustment for covariates, gene-by-environment interactions, and multivariate outcomes.

**Identification of transcriptional effects from loss of the Y chromosome (LOY) in leukocytes using single cell sequencing.** *J. Halvardson<sup>1,2</sup>, M. Danielsson<sup>1,2</sup>, J. Mattisson<sup>1,2</sup>, H. Davies<sup>1,2</sup>, B. Torhabi Moghadam<sup>1,2</sup>, J.P. Duman-ski<sup>1,2</sup>, L.A. Forsberg<sup>1,2</sup>.* 1) Immunology, Genetics and Pathology, IGP, Uppsala, Sweden; 2) Science for Life Laboratory, Uppsala University.

It is well established that one of the most common post-zygotic mutations in men is loss of the Y chromosome (LOY) in blood. Recently several studies have shown that men with LOY have a higher occurrence of non-hematological cancers and Alzheimer's disease than what would have been expected by chance. There are currently no known genetic mechanism explaining this, however, it is reasonable to hypothesise that LOY has an effect on the immune system. In order to identify cell-types affected by LOY and its impact on gene expression we use single-cell RNA sequencing (scRNAseq) of the PBMCs from affected men. In addition to this we use the Illumina Infinium QC Array on DNA from FACS sorted cells from the same men. We use clustering techniques to assign cell-type to each sequenced cell and cells with LOY are identified using the occurrence of RNA transcripts from the Y chromosome. We have currently sequenced ~30 000 cells and identified several genes whose expression are affected by LOY. Amongst these genes both autosomal genes and genes in the pseudoautosomal region are present. The fraction of LOY calculated in our single cell analysis showed a good correlation with the results from DNA arrays from the same men. These results support that LOY in blood has an impact on the gene expression of PBMCs.

**Statistical modeling and differential gene expression analysis based on single cell RNA-seq data.** *I. Mukhopadhyay, P.K. Mondal.* Human Genetics Unit, Indian Statistical Institute, Kolkata, West Bengal, India, PIN 700108.

Single Cell RNA-seq (scRNA-seq) has emerged as a promising method to measure dynamics of gene regulation at cell level. Bulk RNA-seq measures average gene expression level over cells but introduces Simpson's paradox that results in qualitative difference in trends between single cell level and bulk transcriptome data. Large amount of scRNA-seq data generated from recent high-throughput technologies encounter inappropriate modelling in differentiating gene expression, in two types of cells from two different experimental conditions. Although many studies use bulk RNA-seq analysis methods for scRNA-seq data, they do not address the special characteristics and problems of analysing scRNA-seq data that shows higher variability than its corresponding bulk data. Moreover, there are large outliers and drop-out events resulting from failure in proper amplification and low amount of initial number of transcript. Further, transcriptional bursting that causes on and off switching in gene expression level in individual cells leads to its bimodality and complexity of the analysis. The probability of drop-out event in an individual cell depends on the absolute value of the expression level and the quality of library for that particular cell. These events are considerably higher in certain cells indicating that different cells have different effects on drop-out probabilities. Also transcriptional profile of a gene depends on ongoing cellular processes and interaction with other cells. No method developed for single cell differential expression is known to address all these issues simultaneously. Taking all these into consideration, we develop a novel statistical method using maximum likelihood approach that also removes subpopulation effect in differential expression analysis. We use latent variables with random effects for each cell that makes the model more robust and realistic in capturing the two modes in the data. We also estimate the probability of drop-out events in two different peaks. We tackle the computation efficiently, which is very challenging due to lack of any compact form of the estimators. Real data analysis based on our method could identify the two modes, wherever present, and model the gene expression, validating our model with high accuracy. We have developed robust and powerful statistical tests to differentiate scRNA-seq data under two different conditions. Extensive simulations confirm our claim.

**1539W**

**Integrative differential expression and gene set enrichment analysis in single cell RNAseq studies.** S. Sun, X. Zhou. University of Michigan, Ann Arbor, MI.

Single cell RNA sequencing (scRNAseq) has been widely applied for transcriptomics analysis. One important analytic task in scRNAseq is to identify genes that are differentially expression (DE) between different cell types or cellular states and to perform subsequent gene set enrichment analysis (GSEA) to detect biological pathways that are enriched in the identified DE genes. These two types of analytic tasks -- DE analysis and GSEA -- are often treated as two sequential steps in commonly used analytic pipelines. However, these two tasks are intermingled with each other: while DE results are indispensable for detecting enriched gene sets and pathways, the detected enriched gene sets and pathways also contain invaluable information that can in turn improve the power of DE analysis. Therefore, integrating GSEA and DE analysis into a joint statistical framework can potentially improve the power of both. Here, we develop such a computational method to integrate GSEA and DE analysis. Our method is based on the Bayesian sparse linear mixed model that is commonly used for association analysis, automatically accounts for expression correlation across genes, and with a newly developed computationally efficient algorithm, adapting it to performing joint and scalable GSEA and DE analysis in single cell RNAseq studies. With simulations, we show that, by integrating GSEA with DE, our method dramatically improves the power of DE analysis and the accuracy of GSEA over commonly used existing approaches. We also illustrate the benefits of our new method with applications to four published scRNAseq data sets.

**1540T**

**Genetic regulation across 1,500 human induced pluripotent stem cell lines.** C. Smail<sup>1</sup>, M.J. Bonder<sup>2</sup>, D. Jakubosky<sup>3</sup>, L. Frésard<sup>4</sup>, C. Brown<sup>4</sup>, E.N. Smith<sup>2</sup>, K.A. Frazer<sup>2</sup>, O. Stegle<sup>2</sup>, S.B. Montgomery<sup>1</sup>, i2QTL Consortium. 1) Stanford University, Stanford, CA, United States; 2) EMBL-EBI, Hinxton, United Kingdom; 3) UCSD, San Diego, CA, United States; 4) University of Pennsylvania, Philadelphia, PA, United States.

Human induced pluripotent stem cells (iPSC) are a powerful system to assay the molecular impact of genetic variants. Recent studies have shown that iPSCs provide broader resolution of genetic effects on gene expression than differentiated cell-types thereby offering new potential to study variants involved in complex and rare diseases in unique cellular and developmental contexts. To facilitate this effort, we have assembled the largest resource of iPSC genetic and transcriptomic data described to-date - the i2QTL resource - comprising genetic and RNA-sequencing data from 1,001 individuals (comprising 1,515 cell lines) with whole genome sequencing for 478 individuals. We find eQTLs in 14,272 genes (60% of tested genes), including 10,510 protein coding genes (FDR<5%). The dramatic increase in power compared to previous studies further reveals 603 trans-eQTLs, including 177 cis-eQTLs with trans-acting regulatory effects and 155 disease variants previously identified through GWAS. By comparison to GTEx eQTLs, we discovered 68% of all cis-eGenes in GTEx are discovered in i2QTL and we increased the number of eQTL/GWAS overlaps by 4%. From the set of known protein coding non-eGenes in GTEx, 208 could be tested in i2QTL; of these, 101 genes (49%) were found to be eGenes in i2QTL. This set of genes with iPSC-specific eQTL is enriched for developmental processes, with 30/101 (30%) genes annotated with a GO term under this category. For example, iPSC-specific eQTLs were identified for *CRX*, which causes Leber Congenital Amaurosis and is characterized by severe retinal dystrophy, as well as *PRDM13* (neurogenesis), *FOXB1* (somitogenesis), and *FOXB2* (anatomical structure morphogenesis), which are all involved in early embryo development. In addition, the combination of RNA-sequencing and WGS in our sample allowed us to identify rare variants underlying expression outliers and compare the relative discovery power between iPSCs and differentiated tissues. Interpretation of rare variants in iPSCs provides a unique opportunity to study their impacts in a developmental cellular context. For example, we observed that for OMIM disease gene sets, we find expression in 90% of OMIM genes overall, and 95% in OMIM neurology genes in iPSCs. Together, the i2QTL resource is unique in its large sample size and in its extensive data, including WGS, allowing for the creation of a comprehensive map of common and rare regulatory variants in a pluripotent cell type.

**1541F****Machine learning and network topological approaches to predict the pathogenicity of loss of function mutations.**

*D.J. Rhodes<sup>1</sup>, P. Cacheiro<sup>1</sup>, O. Makinde<sup>1</sup>, D. Smedley<sup>1</sup>, M. Caulfield<sup>1</sup>, D. MacArthur<sup>2</sup>, D. van Heel<sup>3</sup>, M.R. Barnes<sup>1</sup>.* 1) William Harvey Research Institute, Queen Mary University of London, London, United Kingdom; 2) Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Blizard Institute, Queen Mary University of London, London, United Kingdom.

Loss of function (LoF) mutations result in the partial or complete inactivation of gene products and are frequently implicated in disease. A large number of LoF mutations resulting in no overt deleterious phenotype have been identified through the study of Scandinavian populations and highly consanguineous populations of Pakistani ancestry. These benign LoF mutations are potentially attractive drug targets based on preliminary analysis that highlighted increased development success of genes with known benign LoF mutations. We hypothesise that gene non-essentiality may correlate with more favourable drug target side effect profiles. Resources such as the Genome Aggregation Database (gnomAD) are comprehensively collating data from exome and genome sequencing projects, including LoF mutations, but the observed or predicted pathogenicity of LoF mutations have not yet been systematically examined. To this end, we have curated a comprehensive snapshot of homozygous LoF variants in 6,902 genes, and used this to identify features associated with LoF pathogenicity. Based on data from human, animal model and in vitro studies, 1720 benign LoF, and 1800 deleterious LoF mutations have been identified, with the remaining 3382 classified as undetermined. From this a protein-protein interaction network has been created using the database StringDB. Topological features of the network show clear differentiation between benign and deleterious LoF mutations, with benign LoF genes exhibiting a lower degree of connectivity (median 10 vs 28), reduced centrality and betweenness. Benign LoF genes are also expressed in fewer tissues (median 22 vs 52) in GTEx data. When compared to orthologous mouse gene essentiality data from the International Mouse Phenotype Consortium, only 8% of genes containing putative benign human LoF mutations were found to be essential in mice, consistent with a conservation of core network topology across species. Conversely, a large proportion (41%) of human deleterious LoF genes resulted in viable phenotypes in mice. We are combining these data with other features such as expression data in order to apply machine learning methods to predict LoF pathogenicity, using the python TPOT framework enabling naive feature selection and construction, and model selection to more accurately predict LoF pathogenicity.

**1542W****Genome-wide discovery of large repeat expansions in whole-genome sequence data.** *M.A. Eberle<sup>1</sup>, E. Dolzhenko<sup>1</sup>, D.R. Bentley<sup>2</sup>.* 1) Illumina, San Diego, CA; 2) Illumina UK, Little Chesterford, UK.

Expansions of short tandem repeats (STRs) are responsible for over 30 rare Mendelian disorders and undoubtedly many more pathogenic repeat expansions are yet to be discovered. Detection of repeat expansions is a challenging problem that was only demonstrated to be feasible for high throughput whole-genome sequence data very recently. Existing methods for identifying repeat expansions are either targeted or require realignment of reads to a special reference which places constraints on the nucleotide composition of detectable repeats. A comprehensive search for novel repeat expansions requires an efficient method that (1) does not rely on a pre-annotated set of repeat loci and (2) places as few constraints on the composition of the repeat sequence as possible. We developed a software tool called Expansion Hunter DeNovo that identifies repeat expansions by locating reads produced by stretches of tandem repeats longer than the read length. Compared to other methods for repeat expansion discovery, Expansion Hunter DeNovo is not limited to short repeat units (i.e. less than 6bp) and can reliably identify repeat units up to 20 bp. To demonstrate that this tool can enable discovery of novel pathogenic repeat expansions, we applied it to samples harboring expansions that cause fragile X syndrome (FXS), Friedreich Ataxia (FRDA), Myotonic Dystrophy type 1 (DM1), Huntington's disease (HD) and 150 controls. Using a straightforward case-control analysis we were able to correctly rediscover both the locus and the repeat unit for each of these repeat expansions. Lastly, we identified eight control samples with evidence of long repeats that were not observed in any of the other controls. We estimate that the expanded repeats in these eight samples range between ~670 and ~4,870bp in length. In particular, one of these repeats is consistent with an expansion that causes Myotonic Dystrophy type 2 (DM2). This finding is currently being validated by an external lab. Combined, these results demonstrate that Expansion Hunter DeNovo can facilitate discovery of novel repeat expansions and, more generally, can be used to characterize landscape of long repeats present in a collection of samples.

**1543T**

**Variant calling from RNA-seq data for Mendelian disorders needs both reference genome and reference transcriptome.** A. Jazayeri<sup>1,2</sup>, S. Pajouhanfar<sup>1</sup>, L. Youssefian<sup>1,3</sup>, A.H. Saeidian<sup>1</sup>, S. Sotoudeh<sup>3</sup>, S. Zeinali<sup>4</sup>, H. Vahidnezhad<sup>1,4</sup>, J. Uitto<sup>1</sup>. 1) Thomas Jefferson University, Philadelphia, PA, USA; 2) Drexel University, Philadelphia, PA; 3) Tehran University of Medical Sciences, Tehran, Iran; 4) Pasteur Institute of Iran, Tehran, Iran.

RNA-Seq is considered as a standard approach for expression analysis, differential expression quantification, and transcriptional isoform discovery. Data analysis includes read mapping, transcriptome reconstruction, and expression quantification. For each step, numerous tools have been developed to cope with the complexities of this process. Although genome/exome sequencing are common in diagnosing Mendelian diseases, more than half of all patients remain undiagnosed by these methods. Recently, variant calling from RNA-Seq data has shown to bridge this gap to some extent. In this study, a next generation sequencing panel composed of 21 genes for a patient diagnosed as epidermolysis bullosa (EB) was developed. The variant calling was performed and two homozygous mutations were detected as disease-causing: a homozygous nonsense mutation c.5422C>T, p.R1808\* in *EXPH5*, and a homozygous c.202delA, p.T68Lfs\*106 in *COL17A1*. The pathogenicity of both variants was confirmed with different laboratory methods. The latter mutation is located on the coordinate of the last base of an exon of *COL17A1* creating a splice junction variant. Therefore, RNA-Seq was performed to identify the consequences of this mutation. As a parallel effort, it was tried to detect these mutations from RNA-Seq reads mapped to the reference genome. It was revealed that due to splicing right before the second mutation, the most common splice-aware mapping tools were unable in mapping this mutation, as the remaining part of the sequence reads are mapped to the adjacent exon, and this base is considered as an unread nucleotide. However, when the WGS/WES mapping tools were used with reference transcriptome instead of reference genome the variant was successfully detected. On the other hand, using the reference transcriptome for mapping reads resulted in mapping quality equal to zero in the region of mutation in *EXPH5*, meaning that the corresponding reads can be aligned to multiple locations equally well. This implies that this mutation either is ignored by variant callers because of the low mapping quality or the false positive rate increases. Using both (or an optimized combination of) the reference genome and transcriptome seems to be the ideal approach for variant calling from RNA-Seq data, supported by the case discussed in this study showing that using either of them alone can result in missing one of the disease-causing mutations.

**Sensitive detection of low-allele fraction structural variants in clinical cancer samples.** E. Lam, A. Pang, T. Anantharaman, J. Wang, T. Wang, X. Zhang, J. Lee, H. Sadowski, A. Hastie, M. Borodkin. Bionano Genomics, San Diego, CA.

Tumors are often comprised of heterogeneous populations of cells, with certain cancer-driving mutations at low allele fractions in early stages of cancer development. Effective detection of such variants is critical for diagnosis and targeted treatment. Short reads from next-generation sequencing platform provide fragmented information and limited power to detect complex structural variants (SVs). Based on specific labeling and mapping of ultra-high molecular weight (UHMW) DNA, Bionano's single-molecule platform has the potential to detect disease-relevant SVs and give a high-resolution view of tumor heterogeneity. We have developed a pipeline that effectively detects structural variants at low allele fractions. The pipeline uses and merges information from a single-molecule analysis and a *de novo* assembly to detect candidate variants. The single-molecule analysis can be done in mere hours; it includes both single-molecule based SV calling and fractional copy number analysis. The *de novo* assembly, while more computationally intensive, allows for more complete characterization of complex rearrangements. The candidate variants are then annotated and further prioritized based on control data and publically available annotations. Preliminary analyses using simulated and well-characterized cancer samples showed high sensitivity for variants of different types at as low as 5% allele fractions. The streamlined pipeline is fully compatible with the new Direct Label and Stain (DLS) chemistry and can be run on cluster environments and on the cloud.

**1545W****Creating a graph-based Arab reference genome using whole read overlap assembly for accurate SV genotyping.**

Y. Mokrab<sup>1</sup>, A.C. English<sup>2</sup>, L. Herta<sup>2</sup>, E. Aliyev<sup>1</sup>, J. Bruestle<sup>2</sup>, S.N. Shekar<sup>2</sup>, K.A. Fakhro<sup>1</sup>. 1) SIDRA Medical and Research Center, Doha, Ar-Rayyan, Qatar; 2) Spiral Genetics, Inc., Seattle, WA, USA.

Recent exploration of ancestral populations' genomes has shown that the widely used Human reference genome (GRCh37/GRCh38) lacks the diversity needed to represent populations of specific ethnicities (Fakhro et. al. 2016. Hum Genome Var. 3:16016). By incorporating Single Nucleotide Variants (SNVs) and indels found by alignment-based variant calling into GRCh37, a population-representative reference can be created which increases the proportion of alignable reads from an individual of the same population. Incorporating structural variants (SVs) would further improve alignment. To more thoroughly capture structural variation in a sequenced individual would in principle require aligning their reads to a continually updated reference graph of all previously called variation. To avoid introducing erroneous variation, such a graph must be made up of accurate breakpoints. Currently, the detection of SVs from short-read data using inference methods can lead to inaccurate breakpoints, unresolved insertion sequences and high false discovery rates (English AC, et. al. 2015. BMC Genomics. 16:286). Using a rapidly assemblable read graph-genome representation, BioGraph has been shown to detect SVs with high sensitivity, low false discovery rate and exact sequence of breakpoints and insertions (Parikh H et al 2016. BMC Genomics. 17:64). In a study of SVs within a family using BioGraph Assembly (BGA), over 97% of the detected SVs were shown to follow mendelian inheritance (Shekar et al, 2016 unpublished). Here, we observe the accuracy of breakpoints using BGA as an assembly based method compared to the Parliament method of consolidating breakpoints across inference SV callers using a cohort of 100 individuals with Qatari ancestry with the aim of further enhancing the Arab reference genome (Fakhro et. al. 2016. Hum Genome Var. 3:16016) with SVs having a high population frequency. We use Truvari to first identify those variants that are common between the Parliament calls and the BioGraph calls. For these common calls, we observe that a greater proportion of the BioGraph Assembly calls have evidence in the data set of the sequence spanning the breakpoint (30mers) compared to the Parliament calls. This suggests that called SVs using assembly is more suitable for characterizing structural variation in a population in a variant graph that can aligned to for the purpose of rapid accurate genotyping of SVs.

**1546T****A reference haplotype panel for genome-wide imputation of short tandem repeat variants.**

S. Saini<sup>1,2</sup>, M. Gymrek<sup>1,2</sup>. 1) Computer Science and Engineering, University of California, San Diego, La Jolla, CA; 2) School of Medicine, University of California, San Diego, La Jolla, CA.

Short Tandem Repeats (STRs) are involved in dozens of Mendelian disorders and have been implicated in a variety of complex traits in humans. Available STR datasets are limited to at most a few thousand samples for a given trait since STR genotyping currently requires either expensive next-generation sequencing data or low-throughput capillary electrophoresis techniques. On the other hand SNP genotype array data is available for hundreds of thousands of samples. A framework to impute STRs into existing SNP array datasets would enable testing STR associations across large sample sizes across hundreds of traits. However imputing STRs is challenging due to complex relationship between STRs and SNP haplotypes induced by rapid STR mutation rates and the high rate of recurrent mutation. Here, we leverage 500 quad families sequenced to 30X coverage as part of the Simons Simplex Collection (SSC), to genotype SNPs and STRs and phase STRs onto SNP haplotypes. We validated the accuracy of our calls and phasing results using Sanger sequencing and evaluated imputed haplotypes by comparing to fosmid and long-read data for the NA12878 genome. Imputation using our panel achieved an average of 97% concordance between true and imputed STR genotypes in an external dataset, with most errors concentrated in STR loci with highest heterozygosity. Using simulated data, we show that imputed STRs capture 20% more variation in STR length compared to individual SNPs, greatly increasing the power to detect associations due to underlying STRs. Finally, we demonstrate using GTEx data that imputed STRs can identify novel signals not revealed by SNP analysis alone. We have released a phased SNP-STR haplotype panel for 1000 Genomes Project samples as a community resource to facilitate large scale studies of STR associations in existing SNP datasets. Our framework will enable testing for STR associations with hundreds of traits across massive sample sizes without the need to generate additional data.

**Real-time genomic analysis with IOBIO tools.** A. Ward<sup>1,2</sup>, M. Velinder<sup>1</sup>, A. Ekawade<sup>1</sup>, C. Miller<sup>1,2</sup>, T. Di Sera<sup>1</sup>, G. Marth<sup>1,2</sup>. 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Frameshift Genomics, 129 Newbury Street, 2nd floor, Boston, MA.

Diagnostic exome/genome sequencing is becoming increasingly common, and ultimately, will become a standard clinical tool. Typically, bioinformaticians undertake genomic analysis, since it requires UNIX command line tools and computational expertise. These bioinformaticians, however, do not generally possess the clinician's experience, familiarity with the patient's family history, disease presentation and course that is often critical for arriving at accurate diagnosis. We are developing powerful, intuitive web tools to enable clinicians to analyze their own patients' genomic data at the point of care. This system is built on our IOBIO suite of web tools, designed to engage as many users as possible, including clinicians, in the analysis and interpretation of genomic data. Our tools allow users to rapidly and easily evaluate sequencing data and variant call quality, without requiring an understanding of opaque genomic data file formats. Users can generate lists of genes associated with the disorder or phenotype under study, and visually examine and prioritize candidate variants using multiple annotations and predictions (e.g. ClinVar, population allele frequencies, SIFT, PolyPhen etc.). All these tasks can be carried out in real-time from a standard web browser by accessing and analyzing only the necessary portions of the underlying data, i.e. genes likely to harbor diagnostic variants. A team of clinicians from multiple disciplines (e.g. diagnostic pathologists, subspecialty pediatricians, medical geneticists) are involved in refining these tools, and adapting them for deployment at the point of care. Utilization of these tools on undiagnosed clinic disease cases has led to the identification of previously unrealized quality problems (requiring regeneration of raw sequencing data), as well as positive solutions for previously intractable cases.

**Robust detection of differential splicing and transcription events for RNA-seq data.** J. Hu, Y. Hu, M. Li. University of Pennsylvania, Philadelphia, PA.

RNA sequencing offers unprecedented opportunities to study alternative splicing and transcription, a major mechanism for transcriptome diversity. An important application of RNA-seq is to identify genes that are differentially spliced or transcribed under different biological conditions, as these genes may reflect information on disease susceptibility. Most existing methods for differential splicing/transcription analysis only use junction reads and suffer from power loss for genes with many isoforms. To incorporate all mapped reads, we previously developed PennDiff (Hu et al. 2018 Bioinformatics), a statistical method that makes use of information on gene structures and pre-estimated isoform relative abundances. Although PennDiff has shown promising performance, it does not explicitly model estimation uncertainty of exon-inclusion level, a quantity utilized in downstream differential analysis. Empirical studies indicate that the dispersion of exon-inclusion levels is reversely correlated with the abundances of those transcripts that contain the target exons, suggesting that modeling the genome-wide distribution of exon-inclusion levels may improve the performance of PennDiff. Motivated by this, we develop PennDiff2, a successor to our PennDiff method. PennDiff2 uses shrinkage estimators for dispersion and exon-inclusion level difference to improve accuracy of the estimates and interpretability of the tests. Specifically, smooth curves are fitted by regressing the exon-wise dispersion estimates and exon-inclusion level difference estimates onto the abundance of related transcripts across all exons and all samples. Then, PennDiff2 employs an Empirical Bayes procedure to shrink these estimates. Hypothesis testing for exon-based differential splicing/transcription analysis is performed based on the shrinkage estimates. PennDiff2 is also able to detect gene-based differential splicing/transcription by combining all exons within a gene using a variance-component score test. The performance of PennDiff2 is evaluated by both simulations and analysis of RNA sequencing data from the Genetics of Evoked Response to Niacin and Endotoxemia Study.

**Mutation maps as a tool for understanding deep learning models in biology: Branchpoint prediction as an example.** *R. Srinivasan, S. Gupte.* Innovation Labs Hyderabad, Tata Consultancy Services Ltd., Hyderabad, TS, India.

**Background:** Deep Learning (DL) models have been shown to match or exceed traditional Machine Learning (ML) approaches in several prediction tasks in computational biology. However, DL models which learn features automatically, unlike ML derived models which build upon expert provided features, do not afford easy interpretation of factors that are important for successful prediction. To address this issue we developed a method called mutation maps (MutMap) that is useful in instances where the input to the DL method is a set of biological sequences (DNA/RNA/Protein). We apply DL to the problem of predicting the location of a branchpoint in an intron and show that MutMap can reveal crucial factors learned by the DL model in achieving successful predictions. **Methodology:** To illustrate our method we took up the task of predicting the location of the splicing branchpoint in a pre-mRNA sequence. We used a branchpoint dataset published by Mercer et al to create a DL model that is able to identify branchpoints using only the sequence around the branchpoint as input. The DL model used a combination of convolutional and recurrent layers to extract both local and global features automatically. We then created new sequences by mutating every nucleotide position in each of the input sequences to the other 3 possible nucleotides (e.g. A>G, A>C and A>T). These sequences were used to generate a map of nucleotide mutation vs effect of the mutation as predicted by our DL model. **Results:** The DL model we trained compared favorably to other ML based approaches such as Branchpointer and SVM-BPfinder. We obtained a higher F-Score (DL 0.706; Branchpointer 0.673; SVM-BPfinder 0.555 ) and a higher Area under Precision-Recall Curve (0.748, 0.708 and 0.537 respectively). The mutation maps generated by our model showed that the TNA motif is an important factor in branchpoint prediction. Furthermore, the maps also identify a Poly-pyrimidine tract following the branchpoint as a critical feature. Mutations which disrupt the splice site or create new AGs are also shown to have an impact. **Conclusion:** We describe a general method for extracting features learned by DL models through the creation of mutation maps. These maps help visualize important sequence regions as illustrated by the branchpoint prediction study. This is a promising approach that could be used in other prediction problems in genomics to discover novel insights.

**Integrating predicted transcriptome from multiple tissues improves association detection.** *A.N. Barbeira<sup>1</sup>, M.D. Pividori<sup>1</sup>, H.E. Wheeler<sup>2,3</sup>, D.L. Nicolae<sup>1</sup>, H.K. Im<sup>1</sup>.* 1) Section of Genetic Medicine, Department of Medicine, The University of Chicago, Chicago, IL, 60637; 2) Department of Biology, Loyola University Chicago, Chicago, IL, 60660; 3) Department of Computer Science, Loyola University Chicago, Chicago, IL, 60660.

Integration of genome-wide association studies (GWAS) and expression quantitative trait loci (eQTL) studies is needed to improve our understanding of the biological mechanisms underlying GWAS associations, and our ability to identify therapeutic targets. Gene-level association test methods such as PrediXcan can prioritize candidate targets. However, limited eQTL sample sizes and absence of relevant developmental and disease context restrict our ability to detect associations. Here we propose an efficient statistical method that leverages the substantial sharing of eQTLs across tissues and contexts to improve our ability to identify potential target genes: MultiXcan. MultiXcan integrates evidence across multiple panels while taking into account their correlation. We apply our method to a broad set of complex traits available from the UK Biobank and show that we can detect a larger set of significantly associated genes than using each panel separately. To improve applicability, we developed an extension to work on summary statistics: S-MultiXcan, which we show to be concordant with the individual level version. Results from our analysis as well as software and necessary resources to apply our method are publicly available.

**Detecting structural variants from Oxford Nanopore sequencing using signal-level data.** *D. Beyter<sup>1</sup>, H. Ingimundardóttir<sup>1</sup>, H.P. Eggertsson<sup>1</sup>, S. Mehringer<sup>2</sup>, K. Stefánsson<sup>1</sup>, B.V. Halldórsson<sup>1</sup>.* 1) deCODE Genetics/Amgen, Inc., Reykjavik, Iceland; 2) Algorithmic Bioinformatics (ABI), Freie Universität Berlin, Berlin, Germany.

Structural variants (SVs) are a major source of genetic variation. Long-read, single molecule sequencing presents an opportunity to greatly advance the detection of SVs. However, the high base calling error rate of this new technology makes it challenging to achieve accurate results that can be used for downstream analysis, such as phenotype associations. We present an SV detection pipeline, using signal-level raw nanopore data (squiggles) to filter a highly permissive initial SV call set. We also use Illumina sequencing data for breakpoint refinement wherever applicable. We tested our pipeline on a set of whole-genome sequenced individuals. Trio analysis suggests high accuracy levels, judging by the similarity of SVs in the proband and one or both of its parents.

**1552T**

**CtsCNV: A copy number variant detection method for clinical targeted sequencing data.** *Y. Cai, R. Shraga, M. Akana, B. Patel, M. Jansen, M. Jar-emko, O. Puig.* Phosphorus Inc., 1140 Broadway New York, NY.

Background: While several methods exist to detect Copy Number Variants (CNVs) in targeted sequencing data, they either fail to achieve the accuracy required in a clinical diagnostic setting, or are limited to detection of CNVs within specific genes. The problem of detecting CNVs is challenging because of uneven coverage across targets, bias in coverage based on GC content and target proximity, sample and batch level bias due to small changes in laboratory conditions, as well as small batch size and low read depths often present in clinical genetic testing. Methods: We have developed a ctsCNV caller, which computes average depth per sample per interval and includes several normalization procedures to remove variation in depth due to non-biological noise and can be readily used in clinical targeted sequencing (CTS) data. This procedure corrects for sample variability, batch effects, bias in GC content in the sequences, and other technical biases. After normalization (spline normalization, z score, PCA), copy number estimates per interval are computed by comparing each sample's normalized depth per interval to the median normalized depth within a batch. CNVs are called by running the widely used Circular Binary Segmentation algorithm on the interval estimates along with a permutation based significance test. Results: Initially, using a custom Roche NimbleGen targeted panel and the Illumina Hiseq 3000, 372 previously characterized DNA samples were sequenced at different depths (100-600X). These samples included 81 known CNVs sized between 200bp to 700Kbp. The performance of ctsCNV was compared to several commonly used callers including Codex,XHMM, Excavator2, and Convadng. CtsCNV achieved the highest sensitivity of 98.77%. To ensure the analysis was not biased to internal lab conditions, all callers were also tested on 90 lower depth WES samples available from the 1000 Genomes project. CtsCNV achieved the highest sensitivity, specificity, and precision as well. Now, we are able to accurately call CNVs ranging from ~300bp (median depth 1000X) to ~4Mbp Y chromosome micro-deletion (median depth 250X) in sequencing batches with as low as four samples. Our results demonstrate that ctsCNV achieves accurate CNV detection on targeted sequencing data, and it is suitable for clinical diagnosis. In comparison to other callers, ctsCNV represents considerable improvement to the current state of the art. Upon publication, ctsCNV will be freely available to download.

**Learning and interpreting gene regulatory architectures in a deep neural network framework.** *L. Chen<sup>1</sup>, J. Capra<sup>1,2</sup>*. 1) Department of Biological Sciences, Vanderbilt University, Nashville TN, USA; 2) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN, USA.

Determining the effects of non-coding mutations on phenotypes remains challenging due to the complexity of mammalian gene regulatory elements. There are several models of how combinatorial binding of transcription factors (TFs) drives enhancer activity, including the billboard, TF collective, and enhanceosome models. However, we have limited knowledge of the prevalence of these architectures across enhancers. Deep convolutional neural networks (CNNs) have achieved state-of-the-art performance in predicting gene regulatory sequences, but they have provided limited insight into the regulatory architecture due to the difficulty of interpreting the biological meaning of the complex patterns they learn. To explore the ability of CNNs to capture the regulatory architecture of enhancers, we performed several hypothesis-driven simulations. First, we trained CNNs to distinguish simulated DNA sequences with different regulatory architectures embedded in them from two negative sets: (i) random genomic sequences and (ii) sequences with equal number of randomly distributed TFs. The CNNs could accurately distinguish positives from both negative sets (auROC >0.99). Next, we used existing and novel algorithms, including maximally activating patches, neuron clustering, gradient ascent, and saliency maps, to interpret patterns learned by the neurons in CNNs. Models trained in both tasks consistently learned TF motifs in their first convolutional layer. The neurons in the internal layers of the CNNs trained against random sequences had similar activation in the presence of different TFs, suggesting that they simply learn to count occurrences of TFs instead of a specific architecture. The neurons in internal layers of the CNNs trained against TF-matched sequences showed different activation by different regulatory architectures, suggesting that they capture complex patterns. Based on these successes, we are using this approach to quantify the architecture of real enhancers. Our results highlight challenges of extracting insights from CNNs; even a highly accurate model may not learn biologically relevant patterns. The ability of CNNs to capture combinatorial patterns is dependent on the training data and is improved by designing a negative set to match relevant attributes of the positives. Our regulatory architecture simulation and visualization framework facilitate the use of deep learning models to reveal the complex combinatorial patterns in regulatory sequences.

**1554W**

**A high-quality benchmark dataset of SV calls from multiple technologies.** *S. Chen<sup>1</sup>, M. Bekritsky<sup>2</sup>, P. Krushe<sup>2</sup>, F. Sedlazeck<sup>3</sup>, E. Dolzhenko<sup>1</sup>, B. Moore<sup>2</sup>, D. Bentley<sup>2</sup>, M. Eberle<sup>1</sup>*. 1) Illumina Inc, San Diego, CA; 2) Illumina Cambridge Ltd., Little Chesterford, UK; 3) Baylor College of Medicine, Houston, TX.

Structural variants (SVs) represent a significant proportion of variability between human genomes and are overrepresented in genetic disease. While there are a variety of software tools that can identify and genotype SVs, the performance of these tools is not well quantified. Further development and optimization of these methods will require a comprehensive genome-wide catalog of high-confidence variants resolved to base pair accuracy. For this purpose, we have developed a validation pipeline that re-genotypes SVs by aligning reads to a variant-aware graph where haplotypes are represented as paths. By aggregating reads across many samples and incorporating small mismatches and gaps in the graph structure, we are able to refine the breakpoints of some input SVs. To QC variants, we test Mendelian consistency in the 17-member Platinum Genome pedigree as well as 50 trio families and also test for Hardy Weinberg Equilibrium (HWE) in 1,000 unrelated individuals of European origin. As a demonstration of our validation pipeline, we assessed ~20,000 SV calls made by Sniffles from PacBio data and ~18,000 SV calls made by Manta from Illumina NovaSeq sequence data, ~6,000 of which overlap. These include deletions, insertions, inversions, and translocations. Because the same variant may be represented differently by the two callers (Sniffles or Manta), we analyzed the two call sets independently and merged the passing variants. Ultimately, ~9,500 merged SVs passed our validation pipeline, including ~1,800 that were identified solely by Sniffles and ~5,000 that were identified solely by Manta. In further analyses of SVs that failed our validation, we determined that more than half of the original calls originated within tandem repeats and would require a different validation method. Additionally, a large proportion of the failed SV calls likely represented true variants with poorly resolved breakpoints or the incorrect/erroneous insertion sequences. We are continuing to refine these variants to breakpoint accuracy as part of our work developing a high quality SV truth set. We believe this truth set and validation methods are a valuable community resource for further development of SV calling methods for clinical genomics research.

**1555T****Binomial probabilistic principal component analysis for genotype data.**

A.M. Chiu<sup>1</sup>, B. Pasaniuc<sup>1,2,3</sup>, S. Sankararaman<sup>1,3,4</sup>. 1) Bioinformatics Interdepartmental Program, University of California Los Angeles, Los Angeles, CA USA; 2) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA USA; 3) Department of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA USA; 4) Department of Computer Science, University of California Los Angeles, Los Angeles, CA USA.

Principal Component Analysis (PCA) is one of the most commonly used techniques for inferring population structure as well as for visualizing and interpreting genotype data. However, classical PCA lacks a probabilistic generative model. Lack of a probabilistic generative model makes it challenging to apply PCA in the presence of missing data as well as in quantifying the uncertainty of the inferred principal components. While probabilistic Principal Components Analysis (PPCA) has been proposed to overcome the limitation of PCA, PPCA makes the restrictive assumption that the observed data follows a multivariate Gaussian distribution. This assumption is not appropriate for genotype data since each entry of the genotype vector takes on only one of three possible values (zero, one or two). We propose a novel binomial PPCA model that accounts for the discrete nature of genotype data. By modeling the observed data through a binomial distribution, we are able to define a generative model that better represents genotype data. Through the use of variational inference, we derive an EM algorithm to infer the principal components in our model. The binomial PPCA can further be extended to other genomic datatypes that have different characteristics (e.g. count data from RNA-Seq).

**Benchmarking of StrandNGS expression profiling pipeline.** D. Chohan, S. Ramachandrala, H. Adil, A. Pal, S. Cherukuri, M. Nagarajan. Strand Life Sciences Private Limited, Bengaluru, India.

StrandNGS, our flagship next generation sequencing analysis and data management tool has been providing extensive support for the analysis of RNA-Seq data. We support end-to-end analysis as well as facilitate the flexible import of unaligned, aligned, quantified, and processed data. Once the data is imported into StrandNGS, all downstream analysis options could be applied. Here, using GSE47774, the SEQC dataset consisting of samples with known mixing ratios (A & B were pure samples, C & D were derived by mixing A & B samples in 3:1 & 1:3 ratios respectively), we have benchmarked 4 expression profiling pipelines that are readily available in StrandNGS: 1<sup>st</sup> pipeline comprises of the import of unaligned data, alignment using COBWeb, the in-built aligner in StrandNGS, filtering, quantification, and statistical analysis. 2<sup>nd</sup> pipeline comprises of the import of unaligned data, trimming the reads to a length of 75 bp, alignment using COBWeb, filtering, quantification, and statistical analysis. 'Trimmed' expression pipeline saves time in alignment without affecting the results. 3<sup>rd</sup> pipeline comprises of the import of unaligned data, using HISAT for alignment, filtering, quantification, and statistical analysis. 4<sup>th</sup> pipeline comprises of the import of pre-aligned data (aligned using STAR), filtering, quantification, and statistical analysis. HISAT and STAR have special hardware requirements. HISAT index building requires ~200 GB of memory for human genome+transcriptome. STAR requires ~30 GB of memory to align human genome+transcriptome. Whereas, StrandNGS does not have any such requirements. Also, steps like index building are handled by StrandNGS so that these need not be done manually which isn't the case with other aligners. Based on the following 4 metrics, we conclude that the expression profiles generated using the 4 pipelines have a very high concordance across them: - Number of genes passing the statistical tests - The titration order of each of the genes across samples - A test to assess the A/B mixing ratio recovery in C and D samples - Pearson correlation coefficients of sample-wise expression profiles across pipelines Given that STAR and HISAT are the commonly used and well-tested aligners for transcriptomics studies, we conclude that COBWeb, our proprietary aligner performs on par with them. Additionally, the trimmed-read alignment pipeline in StrandNGS helps in saving NGS data aligning, processing, and analysis times without affecting the accuracy of results.

**1557W**

**CookHLA: Accurate HLA imputation.** S. Cook<sup>1,2,3</sup>, X. Jia<sup>4</sup>, Y. Luo<sup>5,6,7</sup>, P. Bakker<sup>8</sup>, S. Raychaudhuri<sup>5,6,7,10</sup>, J. Rho<sup>1,2</sup>, B. Han<sup>3</sup>. 1) Department of Convergence Medicine, University of Ulsan College of Medicine, Seoul, Korea, Republic of; 2) Asan Institute for Life Sciences, Asan Medical Center; 3) Department of Medicine, Seoul National University College of Medicine; 4) Department of Neurology, University of California–San Francisco, San Francisco, CA USA; 5) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, UK; 6) Division of Genetics and Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, USA; 7) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 8) Department of Genetics, Center for Molecular Medicine, University Medical Center Utrecht, Utrecht, The Netherlands; 9) Department of Epidemiology, Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, Utrecht, The Netherlands; 10) Broad Institute of MIT and Harvard, Cambridge, MA, USA.

**Background:** Human leukocyte antigen (HLA) genes in the major histocompatibility complex (MHC) region influence many disease phenotypes. It is our utmost interest to investigate as to which HLA alleles or amino acids are driving the diseases. Because HLA genes are highly polymorphic and the whole MHC region exhibits linkage disequilibrium (LD), fine-mapping disease-causing variations often requires HLA typing in tens of thousands of samples. However, classical HLA genotyping is prohibitively costly to be applied to a large-scale cohort. To solve this challenge, recent studies developed computational approaches to impute HLA from intergenic SNP genotype data. These HLA imputation methods have been widely used to fine-map HLA for many immune phenotypes. **Results:** In this study, we present a novel HLA imputation method, CookHLA. CookHLA is superior to previous approaches in accuracy and efficiency. The limitation of the predecessor approach, SNP2HLA, was that the markers defined to indicate HLA alleles were put in a specific (center) position of the gene. Thus, imputation accuracy degraded in distinguishing alleles that differ in the exon sequences far from the center position due to LD decay. To achieve high accuracy, CookHLA makes duplicate sets of markers and embeds each set in each of the highly polymorphic exons. The predictions are then calculated from the consensus posterior probabilities of the duplicate marker sets. To further improve accuracy, CookHLA adaptively learns population-specific and reference panel-specific genetic distance parameters between the markers. In the simulation experiments in which we cross-validate the European reference panel (N=5,225) from the Type 1 Diabetes Genetics Consortium (T1DGC), CookHLA superbly achieved 96.8% average 4-digit accuracy of six HLA genes, where SNP2HLA only achieved 93.9% accuracy, resulting in 2-fold reduction in error rate. A notable accuracy gain occurred at HLA-DRB1 (92.9% vs. 88.5%), which was encouraging because HLA-DRB1 is an important risk factor for many immune diseases. CookHLA is fast and memory-efficient and allows use of large reference panels. Applying the largest-to-date panel (N=10,689) to impute 3,000 individuals takes only 3 hours and 3Gb memory in a personal computer. CookHLA is freely available at <http://software.buhaman.com/COOKHLA/>.

**A balancing act: Aiming for stability in human gene nomenclature.** P. Denny, B. Braschi, K. Gray, T. Jones, R. Seal, S. Tweedie, B. Yates, E. Bruford. HUGO Gene Nomenclature Committee (HGNC), EMBL-EBI, Hinxton, United Kingdom.

The HUGO Gene Nomenclature Committee (HGNC, [www.genenames.org](http://www.genenames.org)) is the only global organisation designating standardized gene symbols and names to all human genes. As precision genetic medicine is increasingly applied in the clinic, it's critical that everyone knows exactly which gene is being discussed. Stable gene identifiers (IDs) underpin these discussions, but are not as human-friendly as the gene symbols and names which are used in everyday communication, but may change. As part of the Transforming Genetic Medicine Initiative (TGMI), we are aiming to minimise the number of gene symbol changes to achieve symbol stability in the long term. What are the characteristics of a "good", stable gene symbol and name? Symbols should be unique, memorable, short and ideally, pronounceable; names should be explanations of a symbol or function and more descriptive and informative. Some of these characteristics are subjective and not easily assessed in an automated fashion. We have chosen four metrics for an initial semi-automated assessment of our gene symbols: 1) is the symbol a placeholder? This class of symbol, e.g. with the root *C#orf#*, *FAM#* or *KIAA#*, is intended to be temporary because it is neither descriptive nor informative; 2) are the HGNC gene name and UniProt protein name similar? It's ideal if proteins are named the same as the genes that encode them; 3) is the gene a member of an HGNC gene family? This often means the family members will share a root symbol; and 4) has a human gene symbol and name been assigned to its chimpanzee ortholog? In our wider role as coordinators of vertebrate gene nomenclature (<https://vertebrate.genenames.org/>), we have curated human gene symbols and names prior to transfer to chimpanzee, based on consensus orthology and conserved synteny. During this process, where possible placeholder symbols have been replaced, e.g. *C2orf71*, '*chromosome 2 open reading frame 71*' > *PCARE*, '*photoreceptor cilium actin regulator*' and human-centric symbols and names changed, e.g. *CECR1*, '*cat eye syndrome chromosome region, candidate 1*' > *ADA2*, '*adenosine deaminase 2*'. We have been applying these four metrics to the ~3000 genes associated with disease in the TGMI Gene-Disease Map and will present our latest findings.

**1559F**

**Prototyping computational tools for human genetics research in NCBI hackathons.** A. Dillman<sup>1,5</sup>, S. La<sup>2</sup>, A. Goncarenco<sup>1,5</sup>, F.J. Sedlazeck<sup>3</sup>, D. Timmons<sup>4</sup>, L. Phan<sup>1,5</sup>, L. Federer<sup>3</sup>, B. Busby<sup>1,5</sup>. 1) NCBI, Bethesda MD; 2) Simon Fraser University, Vancouver BC; 3) Baylor College of Medicine, Houston TX; 4) University of Colorado, Boulder CO; 5) National Library of Medicine, Bethesda MD.

Over the past three years, NCBI has run or been involved in 25 data science hackathons. In these hackathons, participants assemble into teams of five or six to work collaboratively for three days on pre-scoped projects of general interest to the bioinformatics community. On average, about 80% of teams produce an alpha or beta working prototype, and approximately ten percent ultimately publish a manuscript describing their work. NCBI hackathons have generated over 150 products, some of which continue to be developed. A selection can be found at <https://ncbi-hackathons.github.io>. In addition to the production aspect, hackathons provide an immersive learning environment and promote networking opportunities. We will discuss four functional prototypes for human genetics research developed in these hackathons. The first allows the user to interrogate a number of SNPs from either fastqs at rest, or streaming from public datasets. The second packages this functionality into automated containers, which simply take a list of SNPs and can be distributed to owners of other repositories. The third takes in a list of SNPs and returns both all co-mentioned terms in PubMed abstracts, as well as generating a D3 graph depicting relationships between SNPs and publications. This is particularly useful for looking at a number of GWAS studies in a given field. Finally, we have made DangerTrack, a public blacklist of regions in the human genome where short variant calls may be inaccurate due to a high frequency of structural variants or other genome instability factors. We continue to use and build upon these tools in hackathons, especially as we partner with community patient-centered hackathons..

**Prediction of regulatory SNPs affecting transcription factor binding using RegulomeDB.** S. Dong<sup>1</sup>, AP. Boyle<sup>1,2</sup>. 1) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Evidence from Genome Wide Association Studies (GWAS) has provided us with insights into human phenotypes by identifying variation statistically associated with disease. However, it is desirable to extend these studies beyond association to an understanding of biological impact. Unfortunately, determining the function of these variants is a major challenge, especially for single-nucleotide polymorphisms (SNPs) in the non-coding regions of the genome where most of these variants fall. To functionally annotate SNPs, computational tools have been developed by using functional genomics data, which are specifically related to regulatory elements and transcription factor (TF) binding. These computational tools provide powerful ways to narrow down from a huge list of candidates to the causative SNPs leading to human disease. One example of such computational tools is RegulomeDB (<http://www.regulomedb.org>). Here, we show a prediction model to improve the current scoring system in RegulomeDB by applying machine learning methods. We generated our training data by calling allele-specific TF binding SNPs from ChIP-seq data. The final model takes advantage of functional genomics data as well as sequence context in order to more accurately predict function. We show the feasibility of this method with training results in a lymphoblastoid cell line (GM12878). Furthermore, we are collecting training data from other cell types, and we expect our new scoring method to predict novel regulatory SNPs disrupting TF binding in a variety of cell types.

**Efficient curation and real-time querying of clinical and genomic data for 500,000 samples.** *H. Edgren, H. Garritzen, M. Roccato, S. Suhonen, H. Lodenius.* MediSapiens Ltd, Helsinki, Uusimaa, Finland.

Recent research using the data from projects such as the UK Biobank has emphasized the power of large, well curated and harmonized sets of clinical and genomic data in making groundbreaking discoveries on the genetic bases of health and disease. This approach, however, presents two significant challenges: the need to curate and harmonize large amounts of clinical and phenotypic data, as well as subsequent management and efficient analysis of this together with the genomic information. To address these challenges, we developed Accurate™ and Genius™, cloud-based and highly elastic solutions for efficient curation and real-time analysis of large genomics cohorts. We present results showing the significant time savings achieved with Accurate™ in data cleanup, standardization and ontology encoding of both structured and natural language data. Results include both specific benchmarking of the machine-learning natural language analytics on the MIMIC III data set, as well as of the whole data curation process on a large heterogeneous clinical dataset. We also present methods for and results on achieving efficient and low latency complex queries on clinical and genomic data of over 500.000 samples with Genius™, at low fixed costs. In summary, we here present highly intuitive and efficient solutions for curation and analysis of large sets of clinical and genomic data for biomedical research and healthcare, emphasizing enrichment of data using ontologies, fine grained access control, full audit trail of all curation operations and scalability to millions of samples.

**MegaQC: Continuous monitoring of bioinformatics metrics.** *P.A. Ewels<sup>1</sup>, D. Moreno<sup>1,2</sup>.* 1) Department of Biochemistry and Biophysics, Science for Life Laboratory, Stockholm University, Stockholm 106 91, Sweden; 2) Inivata Limited, Granta Park, Cambridge, CB21 6GS, United Kingdom.

Large-scale data analysis is becoming increasingly commonplace in both research and clinical practice. To ensure quality, metrics must be tracked and actively monitored to spot trends and identify outliers. Previously, we developed MultiQC - an open-source package for the aggregation and visualization of results from bioinformatics tools (<http://multiqc.info>, Ewels *et al.* Bioinformatics, 2016). MultiQC can parse output from over 60 different bioinformatics programs, generating a HTML report with summaries and plots for all samples in a project and all tools used in the analysis. This enables fast and accurate evaluation of results. MultiQC has been widely adopted by the bioinformatics community and is now a standard step in analysis pipelines all over the world. However, the reports it creates are generated on a per-project basis, making it difficult to track long-term trends and metrics. Here, we present MegaQC (<http://megaqc.info>) - an interactive web tool to collect parsed output from MultiQC runs over time. Installed on a server, it allows fast and easy monitoring of custom trends and interactive investigation of patterns in data. Dynamic filtering and a drag-and-drop interface makes it easy to quickly build custom dashboards with key metrics. Automated alerts can raise the alarm when samples exceed given thresholds. These make MegaQC a perfect tool for clinical genomics groups and sequencing facilities who need to keep a close eye on data quality. MegaQC can visualise data from any of the programs supported by MultiQC, making it in incredibly flexible; statistics can describe data quality, genome coverage, variant counts or any custom input given to MultiQC. The tools require very little configuration and easily complement existing systems. MegaQC has been developed at the Swedish National Genomics Infrastructure, part of SciLifeLab. It is in use across a number of other clinical facilities and research institutes. It promises to democratise large-scale analysis of bioinformatics results, opening up access to previously unused data.

**Updating and expanding the resources from the 1000 Genomes Project in the International Genome Sample Resource (IGSR).** *S. Fairley, A. Gall, E. Haskell, E. Lowy, B. Moore, E. Perry, L. Clarke, P. Flicek.* European Molecular Biology Laboratory - European Bioinformatics Institute (EMBL-EBI), Wellcome Genome Campus, Hinxton, CB10 1SD. United Kingdom.

The 1000 Genomes Project generated the largest fully public catalogue of human genetic variation and produced a set of valuable reference resources that remain widely used. Through the International Genome Sample Resource (IGSR), we provide continued access and support to users of the 1000 Genomes data resources, while also building on those resources. Resources from the 1000 Genomes Project have been updated to the current reference genome, GRCh38, with sequence data being aligned to the genome and call sets generated using BCFtools, FreeBayes and GATK's Unified Genotyper, leading to the creation of a combined call set, called directly on GRCh38. Data from the 1000 Genomes Project has been added to, with data from technologies including Oxford Nanopore, PacBio and 10X Genomics being added for some samples from 1000 Genomes. Further, we continue to work to add available high coverage Illumina data generated on 1000 Genomes samples. IGSR is also working to add populations that were not represented in 1000 Genomes. Data from the Gambian Genome Variation Project (GGVP), HG-DP-CEPH collection and the Simons Genome Diversity Project (SGDP) have been added and we continue to work with collaborators to increase the number of populations represented in the resources. As the data sets in IGSR grow, we are developing the project website, which includes a data portal, to aid discoverability, navigation and interpretation of the data sets. Further, we continue to collaborate with Ensembl to assist users in browsing the 1000 Genomes data in genomic context and providing tools which enable users to work with the underlying files. IGSR is open to collaboration with groups generating openly consented genomic data, including providing assistance in ethical review, coordination of data and alignment to the reference genome, with a strong desire to add new populations to the resources.

**Detection of structural variants using linked-reads with novel algorithms.** *I.T. Fiddes, A.M. Barrio, S. Williams, P. Marks, S. Garcia, S. Maheshwari, D.M. Church.* 10x Genomics, Pleasanton, CA.

Variation in genomes range from single nucleotide variants (SNVs) to whole chromosomal arm aberrations. Structural variants (SVs) encompass both copy number altering and copy number neutral changes, such as inversions and translocations. Structural variation is increasingly being seen as the molecular explanation for complex phenotypes and disease etiology. Standard short-read approaches struggle to identify SVs, cannot access repetitive regions of the genome and fail to resolve the human genome into its two haplotypes. Incorporating haplotype information has been previously shown to improve SV detection sensitivity, especially for heterozygous variants (Huddlestone et al., 2016). We have developed a novel data type known as 'Linked-Reads', constructed by partitioning limiting amounts of high molecular weight DNA and producing barcoded libraries. We also developed a handful of algorithms that leverage barcode information to detect deletions in the 50bp-30kbp range as well as detect very large structural events including translocations, inversions, duplications and deletions. These libraries allow for long range haplotype reconstruction, detecting complex SVs on both Whole Genome (WGS) and Whole Exome (WES). Here we demonstrate the power of Linked-Reads to resolve SVs in control samples as well as samples with known, validated events. We performed 30x Linked-Read genome sequencing on a set of 23 samples obtained from Coriell with known large (>30Kb) balanced or unbalanced SVs. 27 of the 29 known events were detected and another event was called as a candidate. Sequence downsampling was performed on a subset to determine the lowest sequence depth required to detect variations. Copy-number variants can be called with as little as 1-2x sequencing depth (5-10Gb) while balanced events require on the order of 10x coverage for variant calls to be made, although specific signal is clearly present at 1-2x sequencing depth. Additionally, we sequenced the Genome In A Bottle consortium (GIAB) reference sample NA24385 to 84.4x coverage, and compared the results to the GIAB v0.5.0 SV truth set. We detected 4,321 deletion events  $\geq$  50bp, with 78% precision and 31% recall. This is comparable to 67% precision and 44% recall seen in the merge of seven different short read callers. Future algorithmic improvements can increase the sensitivity and specificity of Linked-Read based SV calling..

**1565F**

**Whole exome sequencing for exon-level copy-number variation in small-sample clinical settings.** *D.L. Filer<sup>1,2</sup>, F. Kuo<sup>3</sup>, C. Bizon<sup>2</sup>, K. Robasky<sup>2</sup>, J.S. Berg<sup>1</sup>, J.L. Tilson<sup>2</sup>, J.P. Evans<sup>1</sup>, K.C. Wilhelmsen<sup>1,4</sup>.* 1) Department of Genetics, UNC School of Medicine, Chapel Hill, NC; 2) Renaissance Computing Institute, Chapel Hill, NC; 3) Memorial Sloan Kettering Cancer Center, New York, NY; 4) Department of Neurology, UNC School of Medicine, Chapel Hill, NC.

As whole exome sequencing (WES) integrates into clinical practice, we should make every effort to utilize all information generated. Copy-number variation can lead to Mendelian disorders, but small copy-number variants (CNVs) often get overlooked or are obscured by underpowered data collection. Many groups have developed methodology for detecting copy-number variants from WES, but existing methods perform poorly for small CNVs and rely on large sample numbers not always available to clinical laboratories. Here we present sequencing approaches to remove capture variation and a novel depth-based statistical method for accurate detection of CNVs in small-sample clinical settings. First, using data from the NCGENES project, we demonstrate how pooling samples prior to capture greatly reduces sample-to-sample variation. Second, we show simple simulations based on the multinomial distribution replicate the distribution of observed pooled samples. Third, we perform large-scale simulations demonstrating the ability to discriminate small CNVs as a function of read depth and variant size. For each simulation condition we generated 200 pools of 16 samples with 172,000 exons and 215 expected CNVs per sample. We considered 100 conditions, varying sequencing depth (in millions of mapped reads) from 10 to 200 and variant size from single exons to five exons. Simulation results suggest an average depth of 35 million mapped reads per sample can discriminate single-exon variants with  $71.5 \pm 3.6\%$  sensitivity with  $3.4 \pm 1.3\%$  incorrectly positive calls (MCC of  $0.83 \pm 0.02$ ). For two-exon variants, the sensitivity increases to  $98.3 \pm 0.3\%$  with  $1.3 \pm 0.6\%$  incorrectly positive calls (MCC of  $0.98 \pm 0.003$ ). Taken together, our results provide a framework for researchers and clinical laboratories to assess CNV calls from WES and methodology to accurately and efficiently utilize WES for CNV detection in small-sample clinical settings.

**Benchmark: An unbiased, genetic-data-driven benchmarking strategy for gene and variant prioritization algorithms using LD score regression.** *R.S. Fine<sup>1,2,3</sup>, T.H. Pers<sup>4,5</sup>, J.N. Hirschhorn<sup>1,2,3</sup>.* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Division of Endocrinology and Center for Basic and Translational Obesity Research, Boston Children's Hospital, Boston, MA; 3) Broad Institute of MIT and Harvard, Cambridge, MA; 4) Novo Nordisk Foundation Centre for Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark; 5) Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark.

Genome-wide association studies (GWAS) have successfully identified numerous loci underpinning hundreds of traits, but determining the causal variants and genes within these loci remains challenging. To address this issue, algorithms to prioritize the most likely causal variants and genes have been developed (for example, prioritizing genes with shared protein-protein interactions or variants with similar profiles of epigenetic marks). However, it is not easy to compare, or "benchmark," the performance of these methods and assess which of them produce the most accurate results. The most common benchmarking approach uses "gold standard" genes (i.e. genes with a known link to the trait of interest), which relies on incomplete information and may punish a method that successfully discovers novel biology. We propose a novel benchmarking method inspired by cross-validation, Benchmarker, which avoids relying on known biology by using the GWAS data itself as its own control. In the Benchmarker strategy, we utilize a "leave-one-chromosome-out" strategy, where we prioritize genes or variants on each chromosome using GWAS data for all other chromosomes. Then, we combine the prioritization results across all 22 chromosomes and apply LD score regression to compare the heritability explained by each set. We applied Benchmarker to compare two gene set enrichment analysis methods, DEPICT and MAGMA, using several well-powered GWAS such as height, body-mass index, and schizophrenia. We defined "prioritized genes" as genes within the enriched gene sets found by each method. We found that while both methods clearly performed better than chance, DEPICT and MAGMA generally performed similarly despite prioritizing fairly distinct groups of genes (average percentage overlap = 32%). We also used Benchmarker to compare two different data sets as input to DEPICT, a gene set membership matrix and a tissue expression matrix, assessing their efficacy in prioritization (where prioritization is done on the basis of a gene's similarity to other genes across the input matrix). Similarly, we found that none of these methods demonstrated clear superiority. These results suggest that evaluation of prioritization algorithms likely should be done on a case-by-case basis, as different prioritization strategies may be optimal for different traits.

**Association testing and estimation of variant effects in multiple traits.** *L. Gai<sup>1</sup>, E. Eskin<sup>1,2</sup>*. 1) Department of Computer Science, University of California, Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA.

Many variants identified by genome-wide association studies (GWAS) have been found to affect multiple traits either directly or through shared pathways, a phenomenon known as pleiotropy. For this reason, analyzing multiple traits at once can increase power to detect and estimate shared variant effects. However, the degree to which traits share variant effects is often not known, and traditional meta-analysis methods can be underpowered compared to univariate analysis when applied to studies in different traits. In addition, recent studies have suggested that pleiotropy is extremely widespread across the human genome and affects a large portion of human phenotypes. This suggests a need for formal models of pleiotropy. Here we present a flexible framework for association testing and modeling of genetic effects in multiple traits from summary statistics. Using simulated data, we show our method increases power when an effect is present in a subset of traits. We then apply our method to two publicly available GWAS data sets, the Northern Finland Birth cohort and UK Biobank, and discover novel loci in a variety of metabolic traits. We also use this framework for joint estimation of effect sizes across multiple traits and improved prediction of polygenic risk scores for quantitative traits.

**A straightforward method to improve variant calling sensitivity for a *MSH2* splicing mutation (c.942+3A>T) using GATK tools.** *A. Gerasimova<sup>1</sup>, S.H. Rosenthal<sup>1</sup>, D.A. Wolfson<sup>1</sup>, A. Smolgovsky<sup>1</sup>, A. Grupe<sup>1</sup>, A. Buller-Burckle<sup>1</sup>, F.L. Lacbawan<sup>1</sup>, E.J. Moler<sup>1</sup>, C.D. Elzinga<sup>2</sup>*. 1) Quest Diagnostics Inc, 33608 Ortega Hwy, San Juan Capistrano, CA 92675; 2) Quest Diagnostics Inc, 200 Forest St, Marlborough, MA 01752.

Calling variants in low-complexity and homopolymer regions is a well-known problem for next-generation sequencing (NGS) technologies, due to biochemical and analytical limitations. A specific example in clinical NGS is a pathogenic splice-defect mutation located in a 25-bp homopolymer that is part of *MSH2*; this mutation can be missed by some existing pipelines. We present a straightforward method to increase sensitivity of a Genome Analysis Tool Kit (GATK)-based pipeline to call this particular mutation. We found that HaplotypeCaller alone has a tendency to call noisy deletions in this region, and occasionally misses the *MSH2* c.942+3A>T variant. With HaplotypeCaller, the variant was missed in 5 of 16 known positive samples. With UnifiedGenotyper, using default parameters and input sequence, we observed better but still inconsistent results: it was missed in 3 of 16 known positive samples. In these 3 cases, HaplotypeCaller made an accurate call, but neither method was able to provide consistent results in isolation. However, running UnifiedGenotyper and forcing calls at each site (--output\_mode EMIT\_ALL\_SITES) resulted in an accurate call in 16 of 16 known positive samples. In order to maximize GATK sensitivity to this variant (and potentially others with similar characteristics) we suggest using UnifiedGenotyper with --output\_mode EMIT\_ALL\_SITES parameter in addition to HaplotypeCaller. .

**Multi-omics integration of metagenomic and DNA methylation data using sparse canonical correlation analysis.** *J. Greenbaum, H.W. Deng.* Center for Bioinformatics and Genomics, Department of Global Biostatistics & Data Science, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA, USA.

It is well known that both host genetics and the gut microbiome composition each influence the risk of developing many complex diseases, however the relationship between these factors remains largely unexplored. In addition to the existing evidence for associations between SNPs and the microbial taxa, there is a growing appreciation for the role of interactions between the microbiome and the host epigenome. In this analysis we aim to detect associated features between metagenomic relative abundance data and DNA methylation data measured on the same set of subjects. There are several important challenges to integrating these multiple omics layers including heterogeneous data types and high dimensionality. Conventional techniques for integrating multiple data types such as canonical correlation analysis (CCA) are not effective for analyzing omics data with small sample sizes and a large number of biological features. These issues may be addressed by introducing a sparsity penalty into the CCA model (sCCA). This allows us to incorporate feature selection into CCA to detect the correlation between a smaller subset of important variables. We designed a simulation study using a latent variable model approach to assess the performance of sCCA incorporating various different regularization terms such as LASSO and Elastic Net. We found that on average LASSO seems to identify more true positives and produce a sparser solution, while Elastic Net shrinks fewer coefficients to zero but has a more stable performance. The results are encouraging for the utility of sCCA, a technique traditionally used in the analysis of brain imaging data, to correctly select the correlated features between these two data types. Further exploration of the relationship between the gut microbiome and other omics may have important implications for understanding the biological mechanisms underlying various complex diseases.

**Proteome PheWAS browser: Graph-based interactive platform allowing visualisation of thousands of estimates from Mendelian randomization analyses.** *V. Haberland<sup>1</sup>, J. Zheng<sup>1</sup>, D. Baird<sup>1</sup>, A. Gutteridge<sup>2</sup>, B. Elsworth<sup>1</sup>, J. Dopierala<sup>2</sup>, J. Staley<sup>1</sup>, B.B. Sun<sup>1</sup>, A. Butterworth<sup>1</sup>, J. Yarmolinsky<sup>1</sup>, C. Laurin<sup>1</sup>, V. Walker<sup>1</sup>, J. Liu<sup>2</sup>, K. Estrada<sup>2</sup>, M.R. Nelson<sup>2</sup>, R.A. Scott<sup>2</sup>, P. Haycock<sup>1</sup>, G.D. Smith<sup>1</sup>, G. Hemani<sup>1</sup>, T.R. Gaunt<sup>1</sup>.* 1) MRC Integrative Epidemiology Unit, Population Health Sciences, University of Bristol, Bristol, BS8 2BN, United Kingdom; 2) GlaxoSmithKline plc., Gunnels Wood Road, Stevenage, Hertfordshire, SG1 2NY, United Kingdom; 3) Translational Genome Sciences, Biogen, 225 Binney Street, Cambridge, MA 02142, United States; 4) MRC/BHF Cardiovascular Epidemiology Unit, Department of Public Health and Primary Care, University of Cambridge, Cambridge, CB1 8RN, United Kingdom.

Proteins can be targeted by drugs for disease prevention and treatment, and a major goal is to improve the efficiency of this process, potentially by eliminating those candidate targets destined to fail earlier in the developmental process. Mendelian randomization (MR) has been widely used to estimate the causal effect of an exposure, e.g. specific plasma protein levels, on specific outcomes, e.g. Alzheimer's disease (AD), using genetic variants as instrumental variables. These analyses can be conducted using existing platforms such as MR-Base ([mrbase.org](http://mrbase.org)), but proving causality can be difficult as MR relies on several assumptions. Visualizing and interpreting vast numbers of results is also challenging, particularly for non-expert users. However, when combined with appropriate sensitivity analyses, MR is potentially valuable for showing which putative associations are unlikely to be causal. To address these challenges, we have developed a novel proteome PheWAS browser (database and Web interface platform), which allows easy access to precomputed two-sample MR results, including SNP associated information (e.g. effect allele frequency) and results from advanced sensitivity analyses in an interactive format. The database includes MR analysis results for levels of 1449 plasma proteins from four recent protein GWAS against 1483 outcomes (including diseases, risk factors, metabolites) and employs the Neo4J graph-based platform at its core, which can smoothly be translated into an intuitive visual representation of causal dependencies. As an example, we demonstrate the MR results for ADAM11 plasma levels instrumented by the trans-SNP (rs7412) in *APOE*. Here, five associations for this protein putatively influence traits related to various lipid measures and also AD risk ([epigraphdb.org/pqtl/?query=ADAM11](http://epigraphdb.org/pqtl/?query=ADAM11)) after multiple testing correction ( $p < 0.28 \times 10^{-7}$  for 1,778,473 tests). However, sensitivity analyses for causal directionality and genetic colocalisation either discount or place a warning for most of these putative associations, and all of them are also flagged as being instrumented by the trans-SNP. This example demonstrates how easily and efficiently the user can look up and visualise hypothesised associations and provides guidance on filters to highlight potentially unreliable MR results. In the future, we intend to populate this platform with more omics-related MR results and results from additional analytical methods as they continue to be developed.

**Enhanced clinical copy number variant calling with sample-specific sensitivity.** *S. Hong, G. Hogan, P. Kaleta, J. Li, D. Muzzey, K. Haas.* Counsyl Inc., South San Francisco, CA.

**Introduction** Accurate structural variant calling, especially for copy number variants (CNVs) that can range in size from a single exon to an entire gene, is critical for clinical germline screening. However, intrinsic variation in sequencing data coupled with insufficient quality control (QC) measures can imperil high CNV-calling accuracy. We combined an enhanced hierarchical Bayesian algorithm for CNV identification with an online simulation framework—embedded in our production bioinformatics pipeline—to improve sample-specific CNV-calling accuracy and flag samples that do not achieve required performance. **Methods** CNVs were called by observing sequencing depth, which reflects the copy number, for ~100 base-pair segments tiled along the targeted region of interest (ROI). The likelihood of each observed depth value was modeled by a parameterized negative binomial distribution with expected depth and variance dependent on the particular sample-segment pair. An additional Bernoulli mixture model automatically disregards spurious depth signals resulting from technical artifacts. A Hidden Markov model (HMM) was used with transition coefficients based upon the prevalence and observed average length of CNVs. Trust Region Newton Conjugate Gradient and Expectation Maximization were used to determine all model parameters. Copy number calls were obtained by running the Viterbi algorithm and noting contiguous non-wildtype segments. Deletions and duplications of one, two, or four exons in size across the ROI were modeled from empirical depth values via down-sampling and oversampling, respectively. HMM calling was then rerun and the sample-specific sensitivity was determined by weighing the size and type of variant by its clinically established prevalence. **Results** The algorithm achieved perfect concordance, emitting positive calls for 50 orthogonally confirmed CNVs and negative calls for 685 samples not known to have CNVs in the ROI. The online simulation of 2,400 deletions/duplications in every sample revealed >99% sensitivity. The algorithm showed invariance to a range of model hyper-parameters, as well as robustness to 5x variation in sample depth. Retrospective ROC analysis of >10,000 recent random production samples showed an order-of-magnitude improvement in the false-negative rate for batches with high sample variability. **Conclusions** We developed a refined algorithm and complementary sensitivity QC metric to ensure clinical-grade calling of important copy number variants.

**1572W**

**Cox regression outperforms logistic regression for detecting genotype-phenotype associations in genetic data linked to electronic health records.** *J.J. Hughey<sup>1,2</sup>, S.D. Rhoades<sup>1</sup>, Q. Chen<sup>1,2,3</sup>.* 1) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Biological Sciences, Vanderbilt University, Nashville, TN; 3) Department of Biostatistics, Vanderbilt University Medical Center, Nashville, TN.

Linking genetic data with routinely collected clinical data has enabled genome-wide association studies across the human phenome. Nonetheless, although clinical data are generally longitudinal, most approaches for detecting genotype-phenotype associations in such linked data (notably logistic regression) were originally intended for case-control study designs, and thus do not handle the time dimension gracefully. Here we explored the advantages of quantifying associations using Cox (proportional hazards) regression, which can account for the age at which a patient first visited the healthcare system (left truncation) and the age at which a patient either last visited the healthcare system or acquired a particular phenotype (right censoring). We scanned for genotype-phenotype associations using logistic regression and Cox regression on the electronic health records of approximately 30,000 genotyped individuals. We compared the output from each method to known associations from the NHGRI-EBI GWAS Catalog. Our results suggest that, compared to logistic regression, Cox regression has greater power and equivalent Type I error. The difference in power is largely independent of minor allele frequency, but greater for phenotypes with at least 1,000 cases and for SNP associations whose odds ratio is between 0.6 and 1.6. In terms of effect sizes, the hazard ratios estimated by Cox regression are nearly identical to the odds ratios estimated by logistic regression. Our empirical findings are supported by the results of comprehensive simulations. As longitudinal health-related data continue to grow, Cox regression may improve our ability to identify the genetic basis for a wide range of human phenotypes.

**An accurate CNV model for clinical exome sequencing.** *S. Kapil, P. Shaw, S. Nair, J.T. George, S.M. Sakthivel Murugan, V. Ramprasad, R. Gupta, R. Gupta.* MedGenome Lab Ltd., Bangalore, India.

Identification of deletions and amplifications (CNV) from targeted sequencing has become one of the key requirements in genetic testing of Mendelian disorders. Recent reports have shown that accurately detecting CNV results in increasing the diagnostic yield. Although several methods have been developed in past, accurate identification of CNV from targeted sequencing at exon level is still a very challenging task. Among different CNV callers, the read depth approaches are widely used. One of the primary requirement for these methods is the collection of reference or control samples. Due to lack of reference/gold standard dataset, the actual performance of the CNV callers for targeted sequencing is largely unknown. In this study, we have (a) developed a simulator for CNV event creation, (b) benchmarked eight different CNV detection tools (Contra, Exome-Depth,XHMM, ExomeCopy, Cn.mops, Excavator, Control-Freec and Convading) and identified the best performing tool, (c) constructed a sensitive gender specific copy number model for our targeted clinical exome panel of 20Mb size covering coding region of ~6900 known disease causing genes sequenced at an average depth of 100X, (d) validation of CNV model on known MLPA tested samples, (e) improved the run-time execution of the CNV detection tool. We first performed the benchmarking of eight different tools using ~500 CNV events generated using our CNV simulator. The CNV event includes deletion/amplification of single exon to four exons, heterozygous deletion in different proportion, 1 to 3 copies amplifications. The reference samples were selected from our clinical samples satisfying the following criteria: (i) known pathogenic SNP/Indel matching with clinical symptoms identified in the sample, (ii) average read depth of the targeted region ~100X, (iii) passed our all quality metrics (alignment, duplicate percentage, average base quality, on-target read percentage). Overall, we obtained 100 reference samples each for male and female. Our analysis revealed that the exome-depth is the most sensitive program with an overall sensitivity of ~ 75%. Further, we found that the model sensitivity exceeds 90% for the target regions with an average depth >= 100X. Validation of 27 samples using MLPA technique achieved sensitivity of 74.07%. Using our pre-calculated depth model, the runtime of exome-depth for a clinical exome sample was reduced from 4 hours to 15 minutes.

**1574F**

**A computational framework for real time analysis and sharing of large next generation sequencing population datasets.** *H. Karten<sup>1</sup>, M. Haime<sup>2,3</sup>, T. Tilly<sup>2,3</sup>, S. Gräf<sup>3</sup>.* 1) Genalice Core BV, the Netherlands; 2) University of Cambridge, UK; 3) NIHR BioResource - Rare Diseases, UK.

Significant progress has been made in collecting large amounts of genetic data combined with patient information. This has led to the generation of several large repositories that are being used as 'reference' data sets. Depending on ethnicity and volume, these datasets are being used for quality control on smaller cohorts and serve as background to find variants that could be associated with rare diseases. These larger cohorts, however, themselves also exist in a context of accelerated increasing knowledge requiring an almost continuous update of variants and their annotations to be able to serve as a knowledge resource. We have created a real time analysis framework that allows for continuous data analysis and mining using AVRO files. With this framework we migrated one of the largest rare disease cohorts in the world comprising more than 13,000 whole genomes of the NIHR BioResource -- Rare Diseases to the latest human genome reference assembly. We deployed our framework on 10 compute nodes of the University of Cambridge High Performance Computing cluster. The framework uses the Genalice NGS secondary analysis suite for sequencing read alignment, population scale genotyping and preparation of the Hadoop AVRO dataset. All genomes are processable within 14 days (read mapping: 12 days; genotyping: 2 days). Subsequently, the variants are exported to AVRO files and annotated in a distributed Hadoop filesystem. The above described process scales linearly with the number of nodes and samples. The otherwise computationally expensive merging of variants is efficiently performed at the population calling stage. Variants at the same location can be represented with the AVRO file format. The data is ready for further analysis in this format and does not need to be imported into a Hadoop HBase database. Our framework significantly advances research groups to keep pace with the accelerating growth of knowledge and to maintain datasets. This will contribute to the research of others.

**1575W****Genomic multilateration.** *K. Kim<sup>1,2</sup>, H. Baik<sup>3</sup>, E. Eskin<sup>4,5</sup>, J. Noh<sup>1,2</sup>, B. Han<sup>6</sup>.*

1) Asan Medical Institute, Seoul, Korea, Republic of Korea; 2) Department of Convergence Medicine, University of Ulsan College of Medicine & Asan Institute for Life Sciences, Asan Medical Center, Seoul 05505, Republic of Korea; 3) Department of Mathematical Sciences, KAIST, Daejeon 34141, Republic of Korea; 4) Department of Computer Science, University of California, Los Angeles, Los Angeles, CA 90095, USA; 5) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA 90095, USA; 6) Department of Biomedical Sciences, Seoul National University, Seoul, Republic of Korea.

In engineering, many applications use distances between multiple objects. Multilateration is one of the localization technique which uses distances from a node at unknown position to reference nodes at known positions to estimate the spatial coordinates of the node. In the application of the radio navigation of an aircraft, the distances from the aircraft to satellites are used for mathematically calculating the position of the aircraft. We present a framework called *genomic multilateration* where we apply the multilateration technique to genomic data. We consider an individual as a node in a multi-dimensional space where each polymorphic locus becomes an axis. In this space, pairwise distance between nodes represents genetic distance between individuals. Individuals from open data become our satellites with known positions. In contrast to the multilateration where one pinpoints the target position using 4 satellites in the 3-dimensional space, the goal of genomic multilateration is not identifying the exact location. Conversely, we intentionally keep the individual's exact position unidentifiable by making the number of dimension exceeds the number of satellites. This unidentifiability allows us to freely share distances to satellites (*distance vectors*) between institutions or studies without disclosing the genetic contents, thereby protecting privacy. Distance vectors can be shared for two purposes. First, distance vectors can detect duplicate individuals between institutions. We developed a statistical framework to capture duplicates using distance vectors between two datasets without transferring the genetic contents of individuals, which turns out to be highly powerful. The second application of using distance vectors is 2-D mapping. We show that distance vectors of an individual to satellites hold enough information to infer one's geographic origin. Previous studies used principal component analysis (PCA) on genotype data to geographically map individuals, but this required sharing of genotype data. With distance vectors only, our estimated projection closely resembles the plot based on the PCA result of the corresponding data and the geographical map of the Europe.

**1576T****FALCON-Phase integrates PacBio and HiC data for *de novo* assembly, scaffolding and phasing of a diploid Puerto Rican genome (HG00733).** *S.B. Kingan<sup>1</sup>, Z.N. Kronenberg<sup>2</sup>, G.T. Concepcion<sup>1</sup>, S.T. Sullivan<sup>2</sup>, R.J. Hall<sup>1</sup>, P. Peluso<sup>1</sup>.* 1) PacBio, Menlo Park, CA; 2) Phase Genomics, Seattle, WA.

Haplotype-resolved genomes are important for understanding how combinations of variants impact phenotypes. The study of disease, quantitative traits, forensics, and organ donor matching are aided by phased genomes. Phase is commonly resolved using familial data, population-based imputation, or by isolating and sequencing single haplotypes using fosmids, BACs, or haploid tissues. Because these methods can be prohibitively expensive, or samples may not be available, alternative approaches are required. *de novo* genome assembly with PacBio Single Molecule, Real-Time (SMRT) data produces highly contiguous, accurate assemblies. For non-inbred samples, including humans, the separate resolution of haplotypes results in higher base accuracy and more contiguous assembled sequences. Two primary methods exist for phased diploid genome assembly. The first, TrioCanu requires Illumina data from parents and PacBio data from the offspring. The long reads from the child are partitioned into maternal and paternal bins using parent-specific sequences; the separate PacBio read bins are then assembled, generating two fully phased genomes. An alternative approach (FALCON-Unzip) does not require parental information and separates PacBio reads, during genome assembly, using heterozygous SNPs. The length of haplotype phase blocks in FALCON-Unzip is limited by the magnitude and distribution of heterozygosity, the length of sequence reads, and read coverage. Because of this, FALCON-Unzip contigs typically contain haplotype-switch errors between phase blocks, resulting in primary contig of mixed parental origin. We developed FALCON-Phase, which integrates Hi-C data downstream of FALCON-Unzip to resolve phase switches along contigs. We applied the method to a human (Puerto Rican, HG00733) and non-human genome assemblies and evaluated accuracy using samples with trio data. In a cattle genome, we observe >96% accuracy in phasing when compared to TrioCanu assemblies as well as parental SNPs. For a high-quality PacBio assembly (>90-fold Sequel coverage) of a Puerto Rican individual we scaffolded the FALCON-Phase contigs, and re-phased the contigs creating a *de novo* scaffolded, phased diploid assembly with chromosome-scale contiguity.

**Utilizing IGV.js to visualize genomic variation from trio clinical whole genome sequencing.** BR. Lajoie<sup>1</sup>, V. Gainullin<sup>1</sup>, A. Halpern<sup>1</sup>, A. Warren<sup>1</sup>, A. Gross<sup>1</sup>, E. Dolzhenko<sup>1</sup>, N. Johnson<sup>1</sup>, F. Mullen<sup>1</sup>, A. Chawla<sup>1</sup>, V. Rajan<sup>1</sup>, SS. Ajay<sup>1</sup>, M. Eberle<sup>1</sup>, DR. Bentley<sup>1</sup>, RJ. Taft<sup>1</sup>. 1) Illumina Inc., 5200 Illumina Way, San Diego, CA, USA; 2) Illumina Cambridge Ltd., Chesterford Research Park, Little Chesterford, UK.

Clinical whole genome sequencing (cWGS) has the potential to be a comprehensive platform for the genomic evaluation of patients with unresolved genetic disorders. As both the number and types of variants continues to increase, the need for dynamic, flexible and intuitive genome visualizations increases. Here we describe our deployment and customization of the publicly available Integrated Genome Viewer (IGV.js) to support the visualization of SNVs, INDELS, CNVs, SVs and STRs in the context of trio cWGS. IGV.js is a web-based, embeddable interactive genome visualization tool, capable of interacting with modern data object-store architectures (amazon s3, google cloud). IGV.js was integrated as part of the Illumina iResolve research program, a continuously enrolling study of more than 200 persistently unsolved RUGD cases. The iResolve IGV.js instance allows users to visualize genomic variation across a wide range of commonly used genomic file types. Users can visualize both reads and small variants through the existing support for genomic file formats (BAM, VCF and gVCF). To improve upon the existing IGV.js features, we added support for both additional data types and novel plotting methods. Copy number variants (CNVs) and structural variants (SVs) are visualized via color-coded intervals provided via BED files and confidence intervals around the event breakpoints are displayed to emphasize the ambiguity of the call. A tint is applied to events to visually demarcate the filter status. Depth support for CNV events is represented by a genome-wide normalized depth vector visualized as a color-coded point plot. Read support for SV events is depicted by a BAM pileup of anomalously-aligning reads (>1,000bp insert size or mates mapping to different chromosomes). Basepair resolution quality metrics are displayed by 12 color-coded tracks to aid in evaluation of the overall quality of any given genomic interval. The iResolve IGV.js instance also adds support for visualizing population event aggregates of healthy control samples. These aggregate visualizations help to visually inspect frequencies of both common and rare events along with positional variation in the observed population.

**1578W**

**A-Lister: A tool to identify the most important '-omics' entities across multiple sample groups.** S. Listopad, T.M. Norden-Krichmar. University of California, Irvine, Irvine, CA.

A-Lister is a downloadable freeware tool with an intuitive graphical user interface (GUI) intended to help genomics researchers identify the most important (A-list) entities in their '-omics' data. There are several tools available that perform pairwise group comparisons, but there are very few tools with easy to use GUIs that find both similarities and differences across multiple group comparisons. To address this need, we have developed an open source tool called A-Lister that identifies differences and similarities across multiple lists of data. For example, if the input data files contain gene names, A-Lister will output the gene names that were found in the intersection and union between the groups. Besides exact matching of gene names, A-Lister also provides "fuzzy" matching of gene names based on several metrics, in order to expand the list to potentially match gene names in the same gene families. If differential gene expression files containing fold change values are input, then A-Lister can also be configured to match a user-specified pattern of up- or down-regulation between the groups. The tool was originally conceived to aid in the analysis and integration of differential gene expression data from RNA sequencing generated across multiple biospecimen sample types and multiple disease groups by the Southern California Alcoholic Hepatitis Consortium. While A-Lister has been utilized in our work with transcriptomics data, it could easily be expanded to handle many different types of '-omics' data, such as proteomics, methylomics, and metabolomics. A-Lister could also be integrated into an existing bioinformatics pipeline to facilitate data analysis.

**1579T****A preliminary assessment of long-read structural variant calling software.**

*J. LoTempio<sup>1,2</sup>, S. Bhattacharya<sup>2</sup>, H. Barseghyan<sup>2</sup>, E. Delot<sup>1,2</sup>, E. Vilain<sup>1,2</sup>.*

1) Institute for Biomedical Sciences, George Washington University, Washington, DC; 2) Children's Research Institute, Children's National Medical Center, Washington, DC.

**Background:** The human genome reference completed in 2003 leveraged short-read capillary sequencing; subsequent drafts, too, have made use of short-reads from sequencing by synthesis. These initial drafts were closely followed by the initial reports in 2004 and 2005 of the feasibility of long-read sequencing technology platforms, specifically single-molecule real-time sequencing and nanopore-based sequencing, developed by PacificBiosciences and Oxford Nanopore, respectively. Nearly a decade and half later, these technologies are bearing fruit for our understanding of the structure and sequence of previously dark or repetitive regions of the genome. Another benefit to this technology is the high-accuracy with which genomic structural variation (SV) can be assessed. **Objective:** Establish an alignment → mapping → SV calling pipeline and a set of best practices after evaluation of extant software for long-read SV calling across available platforms. **Methods:** We intend to leverage the Genome in a Bottle healthy female sample, NA12878. Sequence data from short- and long-read platforms, as well as next generation mapping data are available on the NCBI FTP site or Amazon Web Services for this individual. At present, there are five software programs designed specifically for long-read SV calling, including PBHoney, Sniffles, NanoSV, SMRT-SV, and SVAnalyzer; the result of each of these programs is dependent on, and tailored to, a specific mapping algorithm. Here, we compare the results from four SV callers on four mapping algorithms, including BWA-MEM, minimap2, NG-MLR, and LAST. **Conclusions:** The use of gap-aware mapping algorithms greatly increases the detection of real SV, as determined by confirmation of common SV across long read and next generation mapping platforms.

**1580F****Comparison of indel callers and metrics to evaluate performance of new tools.**

*S. Marwaha<sup>1,2</sup>, E. Ashley<sup>1,2</sup>, M.T. Wheeler<sup>1,2</sup>.* 1) Division of Cardiovascular Medicine, School of Medicine, Stanford, CA, USA; 2) Stanford Center for Undiagnosed Diseases, Stanford, CA, USA.

**Background:** Next-generation sequencing is increasingly being used both clinically and for discovering new gene-disease associations and thus it is critical to have accurate and efficient variant calling tools. Although most of the current tools call SNPs with high accuracy, there is low concordance between different indel callers. **Methods:** We compared four current state of art variant callers - DeepVariant, GATK4 Haplotype Caller (HC), Real Time Genomics (RTG), Samtools using Genome In A Bottle (GIAB) dataset. GIAB provides high-confidence variant calls and regions for several well-characterized human genomes from publicly available cell lines and DNA, which can be used as 'gold truth' for evaluating a variant caller. We saw high discordance between variant evaluation results by different tools. This is due to discrepant representation of same set of variants by different algorithms, for example, indels and complex variants; consecutive SNPs and MNPs. For our analysis, we chose GA4GH benchmarking tool which allows user to select between vcfEval or hap.py, tools that use sophisticated matching algorithms to handle complex call representation correctly. We used Recall (Truth.TP / (Truth.TP + Truth.FN)), Precision (Query.TP / (Query.TP + Query.FP)) and F1-score (2\*Recall\*Precision / (Recall + Precision)) as metrics to evaluate the performance of each caller. Further, we investigated variants where most callers performed poorly and how the performance varied with different properties of genomic region. **Results:** We found that DeepVariant outperformed other tools with Recall of 93.10% and Precision of 89.96%, closely followed by GATK4 HC. We also discuss how different genomic metrics affect the performance of the various indel callers. For example, even though DeepVariant had highest F1 score of 0.915 for calling all indels, it performed suboptimally in detecting complex indels (Recall of 8.07% and 16.18% for Complex variants of length 1-5 (C1-5) and 6-10 (C6-10) respectively) as compared to the other callers like RTG (Recall of 95.07% and 97.06% for C1-5 and C6-10 respectively). **Conclusion:** Our work highlights the discordance among tools used for benchmarking variant callers and provides useful insights and guidelines for selecting indel callers for clinical and research goals.

Evaluation of Indel Calling Tools			
Tool	Sensitivity (%)	Precision (%)	F1-score
RTG	92.32	77.59	0.843
DeepVariant	93.1	89.96	0.915
GATK4 HC	90.66	89.66	0.902
Samtools	62.58	72.94	0.674

**Create a reproducible paper with FireCloud.** *T. Miller, G. Van der Auwera, K. Noblett, I. Rosenberg, Data Sciences Platform (DSP).* Broad Institute, Cambridge, MA.

The lack of portability and reproducibility of analysis methods limits the effectiveness with which biomedical researchers can benefit from the democratization of genomic analysis. Many analysis tools have complex requirements, making them difficult to utilize without advanced computational training. Conversely, it is difficult for the authors of new methods to share their work in a way that is readily reproducible by others. Method developers or consumers can bypass these challenges by using FireCloud, an open-source, freely accessible cloud-based analysis platform developed at the Broad Institute. Three parts of the platform work together to make method sharing and reproducibility of analysis easy: workspaces, batch analysis (pipelines), and interactive analysis with Jupyter Notebooks. A workspace is a stand-alone computational sandbox that provides a secure collaborative place to organize data, run and monitor analysis pipelines, and develop notebooks. Pipeline results can be queried in the notebook with whatever data analysis or visualization module the researcher wants to import. The notebook will record the steps the researcher takes to process raw data to generate a plot or graph that may be used in a paper. In summary, a researcher can share their workspace URL, and anyone with permission can re-run the batch analysis pipeline and re-execute the notebook steps to produce the same results or even apply this analysis on a different dataset.

**Unifying copy number variant calling and imputation from SNP arrays.**

*T. Mimori<sup>1</sup>, Y. Kawai<sup>2</sup>, K. Ueno<sup>1</sup>, S. Khor<sup>2</sup>, Y. Hitomi<sup>2</sup>, O. Gervais<sup>1</sup>, K. Tokunaga<sup>2</sup>, M. Nagasaki<sup>1</sup>.* 1) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University Organization, Tohoku University; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo.

Copy number variants (CNVs), including deletions and duplications of genomic segments, affect a considerable amount of base pairs in the human genome. As CNVs can cause Mendelian or sporadic traits, or be associated with complex diseases, sensitive and accurate calling of individual CNVs is an important task for genetics and human health studies. With the advent of SNP array technology, the genome-wide detection of large CNVs, which extend across multiple array probes, has become possible. Although high-throughput sequencing (HTS) technology enables more comprehensive detection of CNVs with higher resolution, SNP array is still the primary choice for large sample studies because of its cost advantage. To complement genotypes of unobserved SNPs, genotype imputation has been regularly used in genome-wide association studies. Also, there have been several studies that impute structural variants including CNVs. However, CNV imputation, particularly for duplications, has been a challenging problem partly because of a lack of good tag SNPs for CNVs. To improve CNV prediction accuracy from SNP arrays, it is important to make use of both linkage disequilibrium (LD) structures in reference panels and raw probe signals obtained from SNP arrays. However, traditional genotype imputation methods need reliable tag SNPs outside of CNVs and cannot use raw probe signals at CNV loci. We propose an approach that unifies CNV calling and imputation processes to overcome this limitation. For evaluation, we constructed a population-specific reference panel including CNVs by using high-depth HTS data from 418 Tokyo Healthy Controls (THC) samples. The concordance between reference and predicted copy numbers considerably improved with this approach. In our presentation, we provide the details of this method and describe the performance evaluation results.

**1583F**

**Locus Reference Genomic (LRG): A resource for reporting clinically relevant sequence variants.** *J. Morales<sup>1</sup>, A. Astashyn<sup>2</sup>, R. Bennett<sup>1</sup>, C. Davidson<sup>1</sup>, A. Frankish<sup>1</sup>, L. Gil<sup>1</sup>, V. Joardar<sup>1</sup>, M. Kay<sup>1</sup>, J. Loveland<sup>1</sup>, K. McGarvey<sup>2</sup>, A. McMahon<sup>1</sup>, G. Threadgold<sup>1</sup>, T. Murphy<sup>2</sup>, F. Cunningham<sup>1</sup>.* 1) European Molecular Biology Laboratory - European Bioinformatics Institute (EMBL-, Cambridge, Cambridgeshire, United Kingdom; 2) National Center for Biotechnology Information, National Library of Medicine, Bethesda, MD, U.S.A. 20894.

The correct interpretation of clinically relevant variants is dependent on accurate and unambiguous annotation of genes and transcripts. Central to this is the reference sequence against which a variant is reported. Ongoing changes to the reference assembly, the existence of numerous versioned reference sequences and the use of legacy reporting systems present challenges in the clinic. The Locus Reference Genomic (LRG), a manually curated resource designed specifically for the reporting of clinically relevant variants, addresses these challenges. Each LRG record provides a stable and non-versioned genomic DNA sequence for a region of the human genome, establishing a coordinate system that is independent from upgrades to the reference assembly. The records also contain a minimal set of stable transcripts to be used as reference standards. Only transcripts for which there is currently good biological understanding are selected for inclusion. Together with RefSeq (NCBI) and Ensembl/GENCODE (EMBL-EBI), our goals for 2018/2019 include faster convergence on key high value annotations in order to ensure identity between RefSeq and Ensembl for transcripts included in LRGs and used for variant reporting. LRGs are manually curated and created in consultation with locus-specific experts in the diagnostic and research communities to ensure that each record fulfils the unique demands of each specific locus. We have recently released a new version of the LRG website to enhance the display of records and improve functionality. LRGs have been recommended by HGVS and other key organisations. Their widespread use will ensure consistent variant reporting over time. LRGs are created jointly by the NCBI (and EMBL-EBI (<http://www.ebi.ac.uk>), are available on the LRG website (<http://www.lrg-sequence.org/>) and can be visualised in all genome browsers. This work was supported in part by the intramural research program of the National Library of Medicine, National Institutes of Health.

**1584W**

**Systematic meta-analysis of structural variation and CNV algorithms calling performance using short read sequencing.** *J.A. Morales-Rosado<sup>1,2,3</sup>, F. Vairo<sup>1,2,3</sup>, C. Wang<sup>1,2,3</sup>, E.W. Klee<sup>1,2,3</sup>.* 1) Center for Individualized Medicine, Mayo Clinic, Rochester, MN; 2) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 3) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester.

**Introduction:** An impressive plethora of bioinformatics tools exists for structural variant (SV) and copy-number variation (CNV) detection with a consistent yearly output of a dozen new tools. Therefore: (1) We try to understand heterogeneity of CNV/SV detection performance with respect to size-limit. (2) Evaluate translational potentials/applicability of existing popular tools. **Methods:** We have performed a systematic review with meta-analysis of SV and CNV algorithms to address the strengths and limitations in currently published tools from 2009 – 2017. (1) We selected the 10 most popular tools within 2009-2017 (based on citations per year extracted from the Web of Science database). (2) We summarize citations content and usages of tools. (3) Evaluated performance measurements with respect to size range. (4) Carried out a detailed examination of NA12878, NS12911 and HS1011 call set use as ground-truth for validation methodology. Statistically, we determined the overall performance of the most used algorithms using regression of concordance rates with the used truth-sets when the exact number of calls was reported or could be extrapolated from reported values. **Results:** The top 5 most popular tools currently used are: Pindel, Breakdancer, CNVnator, Delly, and Lumpy. We identified a series of tools that have reached a plateau of use and others that have fallen into disuse and attempted to uncover some of the factors influencing such trends. Variant size-based performance is currently underreported. Variant size-based reports available demonstrate a broad interval, 40-70% false-discovery rate (FDR), among calls made in the 50bp-1kb size-range. There is high heterogeneity in the use of gold-standard calls from unique sources and consistent omission of calls generated by algorithms during literature comparison with other tools. **Conclusion:** Taken as a whole, our large scale systematic meta-analysis of SV and CNV calling tools yield important recommendations to the bioinformatics and clinical genomics areas on several key aspects: (1) Algorithms performance reports need to be standardized for peer-review and clinical users, with attention to variant size effects. (2) Harmonized and consensus ground-truth sets are highly needed to ease future CNV/SV algorithm development and validation.

**1585T**

**Prioritizing SNPs for functional experiments using available annotations as a feature selection problem.** A. Mousas<sup>1,2</sup>, M.A. Cole<sup>6</sup>, L. Pinello<sup>3,4,5</sup>, D.E. Bauer<sup>6</sup>, G. Lettre<sup>1,2</sup>. 1) Department of Medicine, University of Montreal, Montréal, Québec, Canada; 2) Montreal Heart Institute, Montréal, Québec, Canada; 3) Molecular Pathology Unit, Massachusetts General Hospital, Charlestown, MA, USA; 4) Cell Circuits and Epigenomics Program, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 5) Department of Pathology, Harvard Medical School, Boston, Massachusetts, USA; 6) Division of Hematology/Oncology, Boston Children's Hospital, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Harvard Stem Cell Institute, Department of Pediatrics, Harvard Medical School, Boston, Massachusetts, USA.

**Background.** Genome-wide association studies have identified thousands of variants associated with complex human phenotypes. One outstanding challenge remaining is to prioritize for functional experiments variants that are in strong linkage disequilibrium. We explored this issue through a feature selection problem by analyzing a dataset of 5,592 SNPs functionally tested by CRISPR-Cas9 for their role in red blood cell biology. **Methods.** As features, we considered various relevant annotations such as erythroid enhancers, ATAC-seq peaks, GATA1 binding motifs, and eQTLs. We divided the CRISPR dataset in two distinct and mutually exclusive subsets: the training set (80%) and the test set (20%). We monitored model performance using various metrics including accuracy, area under the receiving (AUC) curve, sensitivity and specificity. We used 10-fold cross-validation in the training set to tune our models, and sub-sampled the held-in data to account for the extreme class imbalance. We tried two different feature selection methods. For the “filter” method, which disentangles the selection criterion from the model's performance, we pre-selected significantly associated predictors using Fisher's exact test and subsequently fitted a logistic regression and a random forest model. We performed recursive feature elimination with a random forest maximizing AUC for the “wrapper” method. After selecting the important features, we created a per-SNP score counting into how many annotations each SNP falls inside (“voting”). The top scoring SNPs were selected and the corresponding loci were identified. **Results.** We were able to extract 4 and 6 important features of total 23 for the filter and wrapper approach, respectively. These top annotations included erythroid enhancers and ATAC-seq peaks. All 4 selected features were included in the 6 annotations picked by the random forest wrapper. The additional features included plastic regions for chromatin states. In summary, 36 and 41 out of the 308 unique loci were identified by our method with a maximum overlap of 67% while model performance reached approximately AUC = 0.6 with the non-linear wrappers reaching the highest. **Conclusions.** The integration of available annotations to identify causal SNPs is an important problem. We have presented a simple yet principled approach to guide future functional experiments that aim to characterize discoveries from human genetic studies.

**Pedigree-based analysis pipeline (PBAP) v.2: An upgraded version with additional capabilities.** A.Q. Nato<sup>1</sup>, N.H. Chapman<sup>1</sup>, M. Saad<sup>2</sup>, H.K. Sohi<sup>1</sup>, C.Y.K. Cheung<sup>3</sup>, A.R.V.R. Horimoto<sup>1</sup>, R.A. Nafikov<sup>1</sup>, K. Kunji<sup>2</sup>, E. Ullah<sup>2</sup>, H.D. Nguyen<sup>1</sup>, E.M. Wjisman<sup>1,4,5</sup>. 1) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA; 2) Qatar Computing Research Institute, Hamad Bin Khalifa University, Doha, Qatar; 3) Center of Biologics Evaluation and Research, US Food and Drug Administration, Washington DC, USA; 4) Department of Biostatistics, University of Washington, Seattle, WA; 5) Department of Genome Sciences, University of Washington, Seattle, WA.

Availability of next generation sequencing technologies now makes dense genetic data very common. Most genetic analysis software has been developed for population-based studies, but recognizing the importance of rare variants has again made smaller pedigree-based studies common. We formerly developed a pedigree-based analysis pipeline (PBAP) v.1 that allows users to perform several procedures for pedigree-based genetic analysis. These procedures include manipulating files, sub-selecting markers from a dense panel, validating pedigree structures, and sampling inheritance vectors (IVs), which specify the flow of founder alleles in a pedigree. Here, we describe a second version of PBAP with new capabilities that set up files to make use of the IVs for downstream analyses. PBAP v.2 performs the following analyses by preparing files and accessing different programs: a) parametric linkage analysis including options for tailoring marker allele frequencies to admixed populations, b) variance components linkage analysis, c) family-based genotype imputation, and d) genotype-based kinship estimation that allows use of external allele frequencies. Additional tools have also been added to the pipeline that allow the user to: a) calculate pairwise kinship coefficients based on the sampled IVs, b) visualize spacing of the sub-selected panel of markers, c) perform family-based imputation using structural variant data, and d) compute kinship estimates between unsampled individuals with imputed data from possibly different pedigrees to enable association testing in the presence of background relatedness. These additional tools in PBAP v.2 extend its capabilities and give users more options to make maximal use of their data for family-based analyses.

**A novel deep-learning approach to predict phenotype from genotype and its applications to Japanese direct-to-consumer genetic testing.** S. Nogawa<sup>1</sup>, T. Kuo<sup>2</sup>, K. Saito<sup>1</sup>, S. Takahashi<sup>1</sup>, J. Sese<sup>2</sup>. 1) Genequest Inc. , 5-29-11. Siba, Minato-ku, Tokyo 108-0014, Japan; 2) National Institute of Advanced Industrial Science and Technology, 2-4-7. Aomi, Koto-ku, Tokyo 135-0064, Japan.

More than 3,000 genome-wide association (GWA) research studies have been published which enable Direct-to-Consumer (DTC) genetic testing companies to provide trait phenotype of subjects from their genomic data. However, GWAS studies generally perform statistical screening of single nucleotide polymorphisms (SNPs) and not for phenotype prediction, the prediction of trait phenotype using genomic data remains one of the most challenging problems in human genetics research. The present study aims to explore the accurate prediction of phenotype while considering the interaction of multiple SNPs with deep-learning (DL) methods. In contrast to numerical analysis using DL for image processing or signal processing tasks, there are more difficulties in applying DL to the accurate and stable analysis of genotype data because the information is discrete, with the presence or absence of variants. In this study, we have developed a new DL model and hyper-parameter tuning method which enables an accurate and stable analysis of genotype data and the prediction of trait phenotype from genome-wide SNP data. Genome-wide SNP data of more than 10,000 Japanese subjects from the Japanese DTC genetic testing company, were used in a phenotype prediction analysis using the new DL model and method. The phenotype inquiry information obtained from subjects on ABO blood group and eye color were used for the evaluation of the prediction as these traits are already known with regards to their association to genetic data. From the results of the DL analysis, the phenotypes were successfully predicted with a high accuracy of more than 95%. These results were validated with a different population using the public genome information, which suggests high accuracy and good versatility in the new DL model and method. Furthermore, the predictions of some complex and challenging traits were evaluated, including taste preferences and proficiency in types of sports, for which the association to genetic data has not been previously identified. The results of this study suggest a great potential for applying our new DL model and method to the accurate prediction of phenotype from genomic data and contribute to solving one of the most challenging problems in human genetics research.

**1588T**

**Unifying primary, secondary, and tertiary genomic analytics in a scalable analytics platform.** F.A. Nothaft, H. Davidge, D. Lin, R. Sriharsha. Databricks, Inc, San Francisco, CA.

As the size of genomic cohorts continues to grow, many organizations are turning to the cloud to alleviate their computational burden. While cloud computing promises elasticity and scalability, traditional bioinformatics tools are designed for single node architectures and cannot effectively leverage cloud computing. This impedance mismatch leads bioinformatics researchers to spend lots of time crafting complex and monolithic pipelines which are slow to run and difficult to share. Simultaneously, this architecture prevents bioinformaticians, computational biologists, and translational analysts from accessing the same dataset from a common infrastructure. To address this problem, researchers have turned to scalable systems like Apache Spark, and tools like Hail, GATK4, ADAM, SparkSeq, and VariantSpark. These tools provide high level APIs that simplify implementing algorithms for analyzing large genomic datasets. Since these tools are built on Apache Spark, they can be scaled to thousands of cores, achieving a scale necessary for processing contemporary genomics cohorts. While these tools present a significant advancement over single-node genomics tools, there is a great opportunity to enhance the state-of-the-art. In this talk, we present a unified analytics platform for processing genomics data. This platform achieves a 100x improvement in performance over the current state-of-the-art, which enables a dramatic improvement in processing speeds for batch analyses like variant calling, while unlocking novel tertiary analyses. We will illustrate how these optimizations allow us to reduce the latency of calling variants using the GATK to under one hour for a 30x coverage whole genome sequencing run, while achieving computational cost that is competitive with state-of-the-art variant calling pipelines and addressing the concordance issues in the GATK4's Spark-based Haplotype-Caller implementation. This approach is not restricted to GATK4, and can be used to scale other variant callers (such as FreeBayes) to thousands of cores. We then describe how these performance optimizations are able to unlock tertiary analyses and interactive visualization use cases that query read and variation data across 10,000+ sample cohorts. This unified platform enables scaling traditional genomics analyses to thousands of cores while providing bioinformaticians, computational biologists, and translational scientists access to a uniform view of the datasets within their organization.

**1589F****Shellflow: Shell-script like scientific workflow management system.**

Y. Okamura<sup>1</sup>, S. Tadaka<sup>2</sup>, K. Kinoshita<sup>1,2,3</sup>. 1) Advanced Research Center for Innovations in Next-Generation Medicine, Tohoku University, Sendai, Miyagi, Japan; 2) Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 3) Graduate School of Information Sciences, Tohoku University, Sendai, Miyagi, Japan.

Current bioinformatics analyses are built on combination with a lot of tools. To manage these complex workflow, a lot of computational workflow management systems, such as Nextflow, Snakemake, Luigi or Cromwell, were proposed. These systems aimed at reproducibility, scalability and reusability. Since they were designed for scaling with cloud services, and reusing parts of sub-workflow in many workflows, the syntaxes of workflow are complex and hard to learn for new users. For example, Common Workflow Language (<https://github.com/common-workflow-language/common-workflow-language>) requires 7 lines to run "echo hello, world". Other workflow management systems also require many lines to run even if we want to run simple command. Here, we propose Shellflow, easy-to-write, shell-script like workflow management system. To run "echo hello, world", shellflow requires only one line because the syntax of shellflow is almost identically with the shell-script. Shellflow automatically recognizes dependency of commands from simple annotation, and submits to local executor, Grid Engine or other job scheduling systems. This software also has all executed command history and rerun commands if data or command arguments are changed. Since Shellflow focused on rapid development of scientific workflow, simpleness and reproducibility, not to scalability and reusability, Shellflow does not support cloud services, and sub-workflow. In conclusion, Shellflow provides easy and simple workflow management, and traceability of works.

**Kibio.science: Unify and visualize life sciences massive data.** R. Ongaro-Carcy<sup>1</sup>, M. Leclercq<sup>1</sup>, A. Dessemond<sup>1</sup>, H. Ceril<sup>1</sup>, M.P. Scott-Boyer<sup>1</sup>, F. Belleau<sup>2</sup>, O. Perin<sup>2</sup>, A. Droit<sup>1</sup>. 1) CHU de Québec Research Center - Université Laval, Québec city, Québec, Canada; 2) L'Oréal Research and Innovation.

Biological datasets have grown exponentially in size and complexity. Representations of biomolecules like DNA/RNA/protein sequences and structures and functional information generated by Omics research (e.g. genomics, metagenomics, transcriptomics, proteomics and metabolomics) amount to tremendous quantities of data. These data are currently organized and made available in hundreds of bioinformatics repositories. However, these repositories, or databases, are disparate and most are specialized in certain biological entities or biological fields. Researchers constantly have to navigate from a database to another to perform their analyzes. They often have to adapt their data through various handmade scripts and softwares to make their data analyzable. Moreover, publicly available online resources to analyze data generated by last generation technologies, combine them with clinico-pathological and phenotypic data and link them easily with online knowledge are still lacking. To fill this need, we have developed **Kibio**, a biohub dedicated to the biology and bioinformatics sciences communities. Kibio provides a central view to explore, visualize, and analyze the overall content of repositories such as PubMed, ChEMBL, GTEX, KEGG, snpDB or UniProt simultaneously. Kibio is based on Elasticsearch search engine and Siren, a visualization tool, which allows relational searches between databases. Kibio also contains an integration program that has been developed to convert biological databases into Elasticsearch format for optimal use. It offers advanced filtering and dynamic web visualizations to analyze biological knowledge. Simultaneously mining many databases is a strong core-tightened feature, which allows to deepen the exploration of potentially new biological functions and lead to novel interpretations and discoveries. During exploration, each interaction updates automatically all graphs or statistics built in every linked database. All these features and options offered by Kibio require no programming skills and have been designed to be user-friendly, rapid and flexible. In the near future, Kibio will allow users to import their own datasets, connect them to the desired repositories and create their own visualizations. We aim to make Kibio a great resource to explore, visualize, and analyze multidimensional Omics data. Finally, to enhance the analytical power of Kibio, specialized visualizations dedicated to medical or research purpose will be implemented.

**1591T**

**Exploring bias in ATAC-seq experiments with ataqv, an interactive quality control tool for ATAC-seq data.** *P. Orchard, Y. Kyono, J. Hensley, J. Kitzman, S. Parker.* University of Michigan, Ann Arbor, MI.

The assay for transposase-accessible chromatin using sequencing (ATAC-seq) has become the preferred method for mapping chromatin accessibility, due to its speed and low input material requirements. However, it can be difficult to evaluate data quality when processing many samples. Here we uniformly processed >1,500 published ATAC-seq samples across 27 studies. We identified considerable heterogeneity in the data even within single studies. To facilitate ATAC-seq quality control (QC) we created ataqv, a software package for quantifying and dynamically visualizing ATAC-seq bias. Ataqv enables comparison of diverse QC metrics across samples, including a new fragment length distribution (FLD) reference metric. Ataqv produces both machine-readable metrics (JSON format) and an interactive human-readable report (HTML format). Chromatin structure differs across classes of regulatory elements, and different chromatin structures yield different local ATAC-seq FLDs. We therefore hypothesized that FLD-influencing technical noise, such as over- or under-transposition, will obscure true biological signals. In order to test this, we performed ATAC-seq on GM12878 cells using seven different Tn5 concentrations with six replicates per concentration (42 libraries total), while holding the number of nuclei constant at 50K. In addition to predictably shifting the FLD towards shorter fragments, Tn5 concentration positively correlated with enrichment of reads around transcription start sites and in peaks, and negatively correlated with the percentage of mitochondrial reads. Using a negative binomial generalized linear model (NB-GLM), we identified 60,392 (of 92,104) peaks showing an increase in signal with increasing Tn5 concentration (5% FDR). Furthermore, peaks positively associated with increasing Tn5 concentration are more enriched in strong enhancer, active promoter, and weak promoter chromatin states, and more depleted in repressed chromatin regions. This suggests that ATAC-seq experiments performed specifically for the purpose of identifying enhancers and promoters will achieve better signal-to-noise with increasing Tn5 concentration. Importantly, employing our FLD reference metric as a covariate in the NB-GLM effectively corrected for the controlled technical bias (different Tn5 concentrations) we introduced. We conclude that ataqv will help control for technical bias and produce more reliable ATAC-seq analysis results.

**Data visualization feature of Analyst Portal-A distributed real-time data query system.** *H. Qiu<sup>1</sup>, F. Mentch<sup>1</sup>, P.M.A. Sleiman<sup>1,2</sup>, H. Hakonarson<sup>1,2</sup>.* 1) Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA.

Analyst Portal is a distributed and integrative web tool developed in-house that supports complex queries across data modalities including but not limited to Electronic Medical Records (EMR), laboratory workflow information, genotyping and next generation sequencing (NGS) data. Analyst Portal uses distributed database links to query different source databases on the fly, without the need for a centralized data store. Since production 8 years ago, Analyst portal successfully assisted researchers in data exploration, hypothesis generation and discovery making. Data visualization is the presentation of data in a graphical format to help users see and understand data. In recent years, JavaScript HTML5 charting has gained popularity in visualizing data on web pages. We evaluated several popular JavaScript charting libraries. We identified two initial areas in Analyst Portal to implement web charting. First, we created customizable, interactive dashboard for key Laboratory workflows, to improve real time progress tracking and status reports. Second, for patient cohort exploration, after a cohort meeting some criteria is returned after search, the patient demographics (gender, race, age distribution) charts will be shown simultaneously. A patient's specific lab measurement such as white blood cells count, or IgE level is visualized with the reference distribution created in real time from live data. Here we report our current experience with interactive web data visualization, and discuss how it makes Analyst Portal more interactive and intuitive to use.

**1593W**

**GARFIELD-NGS: Genomic variants filtering by deep learning models in NGS.** *V. Ravasio<sup>1</sup>, M. Ritelli<sup>2</sup>, A. Legati<sup>2</sup>, E. Giacomuzzi<sup>2</sup>.* 1) Department of Molecular and Translational Medicine, University of Brescia, Brescia 25123, Italy; 2) Unit of Molecular Neurogenetics, Fondazione IRCCS Istituto Neurologico 'Carlo Besta', Milan 20126, Italy.

Exome sequencing approach is extensively used in research and diagnostic laboratories to discover pathological variants and study genetic architecture of human diseases. Even if present platforms produce high quality sequencing data, false positives variants remain an issue and can confound subsequent analysis and results interpretation. Here, we propose a new tool named GARFIELD-NGS (Genomic vARiants Filtering by dEep Learning moDEls in NGS), which is based on deep learning models to dissect false and true variants in single sample exome sequencing experiments performed with Illumina or ION platforms. GARFIELD-NGS consists of 4 distinct models tested on NA12878 gold-standard exome variants dataset (NIST v.3.3.2): Illumina INS/DELS, Illumina SNVs, ION INS/DELS, and ION SNVs. AUROC values for each variants category are 0.9269, 0.7998, 0.9464, and 0.9757, respectively. GARFIELD-NGS is robust on low coverage data down to 30X and on Illumina two-colour data, as well. Our tool outperforms previous hard-filters, and calculates for each variant a score from 0.0 to 1.0, allowing application of different thresholds based on desired level of sensitivity and specificity. GARFIELD-NGS processes standard VCF file input using Perl and Java scripts and produces a regular VCF output. Thus, it can be easily integrated in existing analysis pipeline. Availability: GARFIELD-NGS is available at <https://github.com/gedoardo83/GARFIELD-NGS>.

**1594T**

**Development of a clinical summary tool that reduces clinical note review time and standardizes phenotype terminology.** *J.S. Salvo, W. He, F. Xia.* Baylor Genetics, Houston, TX.

Clinical laboratory testing requires accurate evaluation of physician notes to interpret patient phenotypes. This has become especially important with whole exome sequencing (WES), as it can be used in the molecular diagnosis of a wide range of diseases. As WES testing continues to become more prevalent, a need arises for both efficient clinical note interpretation, and standardization of phenotype terminology. We have developed a computer application, the Clinical Summary Clerk (CSC), that improves the rate and accuracy of clinical note interpretation using autocomplete entry fields and phenotype synonym matching. By using the terminology provided by the Human Phenotype Ontology (HPO), the CSC combines synonyms and standardizes patient phenotypes. Phenotype language is important for patient database consistency and using HPO terms improves querying ability by reducing the number of missed patients due to unknown synonymous or misspelled phenotypes. Additionally, variant prioritization software, such as Codified and Emedgene, often require a list of HPO terms to describe patient phenotypes. The CSC helps provide these terms without any additional time input, as list files are automatically generated. With the reduced time for HPO term or synonym lookup, quick phenotype list editing, and automated file generation, the CSC can reduce time spent summarizing clinical notes by more than 30%. While human interaction is still required for clinical interpretation, it is important to have tools like the CSC to reduce human error and improve efficiency.

**1595F**

**New features facilitating search and analysis of models of human disease at Mouse Genome Informatics and The Alliance of Genome Resources.** *C.L. Smith, The MGI Curation and Software Team.* Mouse Genome Informatics, The Jackson Laboratory, Bar Harbor, ME.

Mouse Genome Informatics (MGI) is an internationally recognized community knowledgebase for the laboratory mouse. MGI integrates mouse genotype-phenotype datasets from biomedical publications and large-scale projects with genomic, mutation, expression, functional and human disease model data to accelerate correlative discoveries and inform genetic disease etiology and therapeutics. New MGI functionality reinforces the semantic acquisition, annotation, integration and display of phenotype and disease model information, and facilitates comparison of disease-related data across all model organism databases of the Alliance of Genome Resources ([www.alliancegenome.org](http://www.alliancegenome.org)). Recent enhancements include a new MGI Human Phenotype Ontology browser, incorporation of human disease-phenotype relationships from Orphanet, and new mouse embryonic lethal phenotype data from the DMDD consortium. Importantly, MGI has adopted the Disease Ontology (DO), a hierarchical classification of standardized disease concepts with cross-references to OMIM, MeSH, SNOMED and other clinical terminologies. that is also used by all members of the Alliance of Genome Resources. MGI disease model annotations have been translated from OMIM terms to DO terms to optimize searches, and grouping and display of disease classes in relevant detail pages. The MGI Quick Search tool, Human-Mouse Disease Connection (HMDC), and advanced query forms now support searches by DO terms or IDs. Furthermore, the HMDC grid groups phenotype and disease data by top-level terms to enhance visualization of these data. Finally, an improved DO Browser allows users to traverse the ontology tree or graphical view, examine a selected term's definition, IDs and hierarchical relationships, identify all genes and mouse models annotated to that disease or any of its subtypes, and access the unified Alliance multi-species disease report and related data from other species.

**1596W**

**Reproducible workflows for genomics data analyses.** *W. Souza<sup>1,3</sup>, B. Carvalho<sup>2,3</sup>, I. Lopes-Cendes<sup>1,3</sup>.* 1) Department of Medical Genetics, School of Medical Sciences, University of Campinas, UNICAMP, Campinas, SP, Brazil; 2) Department of Statistics, Institute of Mathematics, Statistics and Computer Science, University of Campinas, UNICAMP, Campinas, SP, Brazil; 3) Brazilian Institute of Neuroscience and Neurotechnology (BRAINN), Campinas, SP, Brazil.

New sequencing technologies have improved our abilities to collect biological information for large-scale population studies. The availability of public datasets and the rise of federated genomic databases have allowed researchers to find rare genomic variants. An increasing computing power is required to produce meaningful scientific contributions from high-dimensional genomic data. Cloud services have become affordable and popular among bioinformatics groups for computational-intensive tasks. The combination of large-scale datasets and cloud environments has resulted in new challenges to make genomic research more reproducible, which means the ability of other researchers to achieve the same results of the original analysis. Task-specific bundles of software called containers have been used to guarantee that tools will always give the same results regardless of the computing environment. Domain-specific languages for describing tools and workflows have helped documentation and automation of bioinformatics data analysis protocols. To make our genomic data analyses more reproducible, we have changed the methods we used to describe bioinformatics tools and workflows, and how we execute large-scale data processing tasks. We created several Docker container images for bioinformatics tools. We also wrote description files for those tools using the Workflow Description Language (WDL), which is platform-independent and follows open standards. Docker images and WDL files were submitted to Dockstore, a web service that provides bioinformatics tools and workflows. Described tools and workflows have been used by our Biostatistics and Computational Biology Laboratory (BCBLab) for performing RNA-seq, small RNA-seq, whole-genome bisulfite sequencing and exome sequencing data analyses. Validation tests showed that our workflows always generate the same results when executed in different computing environments. All tools and workflows are reusable reducing the effort to perform new analyses. Processing time was reduced since the entire analysis is performed automatically using optimized software executors capable of dynamically manage available computing resources. Disk space required to store genomic data was minimized because intermediary analysis files can be removed after execution and recovered whenever they are required. Docker and WDL files are available at <https://github.com/labcb/rnnr>.

**ReQTL: An allele-level measure of variation-expression genomic relationships.** L.F. Spurr<sup>1</sup>, N. Alomran<sup>1</sup>, P. Slowinski<sup>2</sup>, M. Li<sup>3</sup>, P. Bousounis<sup>3</sup>, Q. Zhang<sup>3</sup>, J. Seini<sup>4</sup>, K. Tsaneva-Atanasova<sup>2,4</sup>, A. Horvath<sup>1,3,5</sup>. 1) McCormick Genomics and Proteomics Center, School of Medicine and Health Sciences, The George Washington University, 20037, Washington, DC, USA; 2) Department of Mathematics & Living Systems Institute, University of Exeter, Stocker Road, Exeter, EX4 4QD, UK; 3) Department of Biochemistry and Molecular Medicine, School of Medicine and Health Sciences, George Washington University, 20037, Washington, DC, USA; 4) EPSRC Centre for Predictive Modelling in Healthcare, University of Exeter, Exeter, EX4 4QJ, UK; 5) Department of Pharmacology and Physiology, School of Medicine and Health Sciences, The George Washington University, 20037, Washington, DC, USA.

Through association of genotypes with gene expression levels, expression quantitative trait locus (eQTL) analyses have been instrumental in mapping of thousands of single nucleotide variants (SNVs) that affect the gene expression. We propose an eQTL modification, termed **ReQTL**, **RNA-eQTL**, which substitutes the DNA allele count with a continuous metric derived from the expressed variant allele frequency (VAF) at expressed SNV loci in the transcriptome ( $VAF_{RNA} = n_{var} / (n_{var} + n_{ref})$ ), where  $n_{var}$  and  $n_{ref}$  are the variant and reference read counts estimated from the RNA sequencing data, respectively. In comparison to DNA allele count,  $VAF_{RNA}$  supports several distinct types of assessments. First,  $VAF_{RNA}$  provides phenotype- (as compared to genotype-) level information and is thus a close proxy for the actual allele content in the studied system. In addition,  $VAF_{RNA}$  can reveal allele-level expression regulation, including imprinting. Moreover,  $VAF_{RNA}$  can reflect expression regulation mediated by RNA-binding molecules and post-transcriptional events such as RNA-editing. Finally, as compared to DNA alleles, correlations of RNA alleles with gene expression provides several technical advantages. Because  $VAF_{RNA}$  constitutes a continuous measure (as compared to the DNA allele count), it offers increased measurability. Furthermore, since  $VAF_{RNA}$  and gene expression levels can be retrieved from a single source of transcriptome sequencing data, ReQTL analyses naturally control for measurement differences between samples. Related to the above, ReQTLs do not require matched DNA data and are thus directly applicable on the vast amount of existing transcriptome sequencing data across species and conditions. Our presented results on subsets of several GTEx tissue types show that ReQTL analyses: (1) are computationally feasible and can identify variation-expression relationships solely from RNA-sequencing data, (2) identify more than half of the eQTL-identifiable variants, and (3) identify additional SNV loci which we found to be enriched in RNA-editing sites. Given the quickly growing accessibility of RNA-sequencing data, ReQTLs have considerable potential to facilitate the discovery of novel molecular interactions. ReQTL toolkit is available from: <https://github.com/HorvathLab/ReQTL>.

**The ENCODE pipeline architecture: Reproducible and portable analysis tools for ChIP-seq, RNA-seq, DNase-seq, ATAC-seq, HiC, ChIA-PET, and whole-genome bisulfite experiments.** J.S. Strattan<sup>1</sup>, U.K. Baymuradov<sup>1</sup>, N.C. Durand<sup>2</sup>, I. Gabdank<sup>1</sup>, K. Graham<sup>1</sup>, B.C. Hitz<sup>1</sup>, O.A. Jolanki<sup>1</sup>, J.W. Lee<sup>1</sup>, E.T. Chan<sup>1</sup>, J.A. Hilton<sup>1</sup>, K. Onate<sup>1</sup>, E.L. Aiden<sup>2</sup>, A. Kundaje<sup>1</sup>, J.M. Cherry<sup>1</sup>, ENCODE Data Coordinating Center. 1) Stanford University School of Medicine, Department of Genetics, Stanford, CA; 2) Baylor College of Medicine, Department of Genetics, Houston, TX.

Consortia like ENCODE need uniform bioinformatics pipelines to avoid technical artifacts that can confound subsequent integrative analyses of experiments done in different labs or at different times. Such artifacts can be introduced when primary data are analyzed using different software versions, parameters, or run platforms. The ENCODE Data Coordinating Center (DCC) have developed a general containerization and deployment architecture for complex bioinformatics pipelines that produces portable, internally-validating compute environments that run identically in cloud, HPC, and local platforms for the analysis of core ENCODE experiments. Docker, Workflow Description Language (WDL), and continuous integration technologies are used to compose commonly-used bioinformatics tools and purpose-built code into portable, tested workflows. These analysis pipelines produce the uniform ground-level annotations ENCODE applies to the epigenome and transcriptome from ChIP-seq, RNA-seq, DNase-seq, ATAC-seq, HiC, ChIA-PET, and whole-genome bisulfite experiments. By virtue of their portability, both the pipelines and the pipeline architecture itself are of value to other consortia and investigators who need to compare their results to ENCODE's or deploy their own tools in portable ways. Through collaborations with the Roadmap Epigenomics project and the International Human Epigenomics Consortium (IHEC), the ENCODE pipelines are used to produce data and annotations that are compatible across consortia. The ENCODE DCC pipelines and architecture are free and open-source and are documented at <https://encode-dcc.github.io/wdl-pipelines/>. The DCC codebase is at <https://github.com/ENCODE-DCC>. ENCODE analyses are distributed through the ENCODE Portal at <https://www.encodeproject.org/>.

**Wikidata for biomedical knowledge integration and curation.** G.S. Stupp<sup>1</sup>, A. Waagmeester<sup>2</sup>, T.E. Putman<sup>3</sup>, L.M. Schrimp<sup>3</sup>, A.I. Su<sup>1</sup>. 1) The Scripps Research Institute, San Diego, CA; 2) Micelio, Belgium; 3) University of Maryland, Baltimore, MD; 4) Oregon Health and Science University, Portland, OR.

The sum total of biomedical knowledge is accumulating at an explosive rate. Unfortunately, however, the entirety of that knowledge is not easily accessible. In most cases, biomedical knowledge is locked away in free-text research articles, which are very difficult to use for querying and computation. In some cases, that knowledge has been deposited in structured databases, but even then the fragmented landscape of such databases is a barrier to knowledge integration. Wikidata is an openly-accessible, community-maintained knowledge base that is editable by anyone and has a large, active user base. We have seeded Wikidata with data on key biomedical entities, including genes, proteins, diseases, drugs, genetic variants, and microbes. To ensure source databases are properly credited, we have implemented a standardized model for referencing and attribution. These data, combined with other data sets imported by the broader Wikidata community, enable powerful integrative queries that span multiple domain areas via the Wikidata SPARQL endpoint. In addition, we have designed a system to monitor, filter, and prioritize changes made by Wikidata contributors to biomedical items. The identified changes are coordinated with the primary resource's curation team through GitHub tickets, reviewed by a curator and integrated into the primary resource where appropriate. Through this process, in collaboration with the Disease Ontology, we have established a new crowdsourcing model for targeted curation and integration of knowledge into Wikidata and the DO. Furthermore, we have developed web applications (WikiGenomes and Chlambase) that facilitate the consumption and curation of genomic data by the entire scientific community, based on Wikidata, with the goal of aggregating published knowledge into a free and open database. WikiGenomes empowers the individual genomic researcher to contribute their expertise to the curation effort and integrates the knowledge into Wikidata, enabling it to be accessed by anyone without restriction. Wikidata can serve as a foundation for other bioinformatics applications and analyses and the code developed to execute this project is available as Open Source software. This suite of code includes modules for populating Wikidata, for automatically synchronizing with source databases, and for creating domain-specific applications to engage specific user communities.

**Dissecting components of genetic associations across 2,138 phenotypes in the UK Biobank.** Y. Tanigawa<sup>1</sup>, J. Li<sup>2</sup>, J. Justesen<sup>1,2</sup>, H. Horn<sup>3,4</sup>, M. Aguirre<sup>1</sup>, C.M. DeBoever<sup>1,5</sup>, M. Morri<sup>2</sup>, C. Chang<sup>6</sup>, B. Narasimhan<sup>1,7</sup>, G. Bejerano<sup>8,9,10</sup>, K. Lage<sup>3,4,11</sup>, T.J. Hastie<sup>1,7</sup>, E. Ingelsson<sup>2</sup>, M.A. Rivas<sup>1</sup>. 1) Department of Biomedical Data Science, Stanford University, Palo Alto, CA; 2) Division of Cardiovascular Medicine, Department of Medicine, Stanford University School of Medicine, Stanford, CA; 3) Department of Surgery, Massachusetts General Hospital, Harvard Medical School, Boston, MA; 4) Broad Institute of MIT and Harvard, Cambridge, MA; 5) Department of Genetics, Stanford University, Stanford, CA; 6) Grail, Inc., 1525 O'Brien Drive, Menlo Park, CA; 7) Department of Statistics, Stanford University, Stanford, CA; 8) Department of Developmental Biology, Stanford University, Stanford, CA; 9) Department of Computer Science, Stanford University, Stanford, CA; 10) Department of Pediatrics, Stanford University School of Medicine, Stanford University, Stanford, CA; 11) Institute for Biological Psychiatry, Mental Health Center Sct. Hans, University of Copenhagen, Roskilde, Denmark.

Population-scale biobanks combined with genomic and health data are critical for generating effective therapeutic hypotheses and understanding the genetic role of disease predisposition. Pervasive pleiotropy and polygenicity, the presence of genetic effects of a variant across multiple phenotypes and multiple variants across a single phenotype, test our understanding of the genetics of human diseases. To address this, we apply an unsupervised statistical learning approach: matRix Decomposition of Genetic Effects (RIDGE), to matrices of summary statistics derived from genome-wide association analysis across 2,138 phenotypes in 337,199 White British individuals in the UK Biobank study. We systematically identify key components and quantify the contribution of variants, genes, and phenotypes. For example, we identify the first component is mainly driven by body mass measurements accounting for the "healthy part" (33%) including whole-body fat-free mass and genetic variants in *FTO* and *DLEU1* loci (1.9% and 0.64%) whereas the second component is driven by fat-related measurements (62%) and genetic variants in *FTO* and *ADCY3* loci (1.5% and 0.31%). To investigate the genetic architecture of complex traits, we apply RIDGE to body mass index (BMI), myocardial infarction, and gallstones. We find the top three key components for these traits combined explain 69%, 36%, and 41% of genetic effects, respectively. For each key component, we apply a variant of NetSig protein-protein interaction and GREAT genomic region analysis for mouse MGI phenotype ontology and demonstrate significant relevant enrichment. For example, we find an interacting network of proteins including *DLGAP1*, 2, and 3 (p-value < 2.5x10<sup>-5</sup> each), brachypodia (MP:0002772, abnormally short feet, p-value = 1.3x10<sup>-23</sup>), and abnormal pancreas topology (MP:0013861, p-value = 8.8x10<sup>-12</sup>) for the top key component for BMI. Finally, we identify three putative loss of function variants, rs114285050 (*GPR151*), rs150090666 (*PDE3B*), and rs137891647 (*LIPT1*), which contribute substantially to the components of genetic effects of obesity through RIDGE and PheWAS analysis. We demonstrate their effects on adipocyte formation by siRNA-mediated gene silencing followed by expression quantification of adipogenic markers with RT-qPCR. Our approach to dissect the components of genetic effects across human phenotypes will accelerate biomedical hypothesis generation by providing insights on latent structures previously unexplored.

**OptimIR: An alignment workflow that integrates genetic variations in miRNA sequencing data.** F. Thibord<sup>1,2</sup>, C. Perret<sup>1,2</sup>, M. Roux<sup>1,2</sup>, P. Suchon<sup>3,4</sup>, M. Ibrahim<sup>3,4</sup>, L. Goumid<sup>5</sup>, M. Germain<sup>1,2</sup>, J-F. Deleuze<sup>5</sup>, P-E. Morange<sup>3,4</sup>, D-A. Trégouët<sup>1,2</sup>, GENMED consortium. 1) Sorbonne Universités, Université Pierre et Marie Curie (UPMC Univ Paris 06), Institut National pour la Santé et la Recherche Médicale (INSERM), Unité Mixte de Recherche en Santé (UMR\_S) 1166, Team Genomics & Pathophysiology of Cardiovascular Diseases, 75013 Paris, France; 2) Institute for Cardiometabolism and Nutrition (ICAN), 75013 Paris, France; 3) Laboratory of Haematology, La Timone Hospital, Marseille, France; 4) Institut National pour la Santé et la Recherche Médicale (INSERM), Unité Mixte de Recherche en Santé(UMR\_S) 1062, Nutrition Obesity and Risk of Thrombosis, Center for CardioVascular and Nutrition research (C2VN), Aix-Marseille University, Marseille, France; 5) Centre National de Recherche en Génomique Humaine (CNRGH), Direction de la Recherche Fondamentale, CEA, Institut de Biologie François Jacob, Evry, France.

MiRNAs belong to a class of small (~22nt) non coding RNAs known to regulate post transcriptional expression and to associate with several human diseases. Because of its high detection sensibility and higher quantification accuracy, miRNA profiling by Next-Generation Sequencing (miRSeq) has gained recent interest to identify disease-associated miRNAs. A crucial step in the bioinformatics analysis of miRSeq data consists in aligning sequenced reads to a reference library of mature miRNAs. This step may be challenging because of the variability of mature miRNAs sequences due to post transcriptional editing mechanisms and genetic variations. We here propose a new bioinformatics workflow, OPTIMIR (for pOlymorPhism in Tegratlon for MIRna data alignment), for miRSeq data alignment aimed at improving the accuracy of miRNA detection and quantification by simultaneously integrating the information on post-transcriptional editing and genetic variations data available in reference databases. In the context of miRSeq profiling applied to large cohorts of individuals, it is difficult to validate post-transcriptional editing induced variations. Conversely, the impact of genetic variations on miRSeq alignment can be assessed in individuals that have also been genotyped for DNA array. OPTIMIR was evaluated on a sample of 391 participants of the MARTHA study that have been profiled for plasma miRNAs and typed for genetic variants using Illumina genotyping array. In this sample, we identified 82 genetic variants located in miRNA sequence. The application of OPTIMIR to MARTHA samples revealed a 99.12% concordance between imputed homozygous genotypes and miRNA sequence deduced genotypes. Sanger sequencing validation of the discordant situations (8 events, i.e ~0.88%) identified one wrongly imputed genotype and suggested improper miRSeq data alignment for the 7 other cases. For heterozygous variants, our analysis revealed that both alleles are not equally expressed. Most of the miRNAs harboring a polymorphism in their sequence preferentially expressed one of the two alleles, not necessarily the most frequent one. Very few miRNAs had a balanced expression of both isoforms. In conclusion, using OPTIMIR, we showed that the detection/quantification of miRNAs by miRSeq are hardly impacted by the presence of genetic variations in the miRNAs sequences. In addition, we suggested that allele specific-expression of miRNAs could also hold as previously reported for gene expression.

**TogoVar: A comprehensive Japanese genetic variation database including 183,884 SNP-array and 125 whole exome sequence based data.** L. Toyo-oka<sup>1</sup>, N. Mitsuhashi<sup>1</sup>, M. Kawashima<sup>1</sup>, T. Fujiwara<sup>2</sup>, S. Katayama<sup>2</sup>, S. Kawashima<sup>2</sup>, Y. Tateishi<sup>1</sup>, T. Takagi<sup>2,3</sup>. 1) National Bioscience Database Center, Japan Science and Technology Agency, Tokyo, Japan; 2) Database Center for Life Science, Joint Support-Center for Data Science Research, Research Organization of Information and Systems, Japan; 3) Department of Biological Sciences, Graduate School of Science, the University of Tokyo.

To conduct a genetic analysis, it is essential to have amount of well-qualified genetic variation data in the targeted population. One of the successful contributions to the human genetics is the Exome Aggregation Consortium (ExAC) which has been providing quality controlled allele frequency information in several populations. However, for Japanese population, the Human Genomic Variation Database (HGVD) and the Integrative Japanese Genome Variation Database (iJGVD) are mainly used because the number of Japanese population in the ExAC is limited. On the purpose of providing the amount of allele frequency data of Japanese and compare with that of different populations, we launched the TogoVar database (<https://togovar.biosciencedbc.jp/>). Two new Japanese allele frequency datasets are included to the database in addition to HGVD, iJGVD, ExAC and ClinVar data; (1) JGA-SNP, consisted of 183,884 samples genotyped by SNP-array method and (2) JGA-NGS, consisted of 125 samples produced by whole exome sequencing method. Both of these datasets are constructed from the data deposited to the NBDC Human Database, which is a repository for sharing Japanese genomic data in cooperation with the DNA Data Bank of Japan since 2013. Because about half of variants derived from JGA-SNP, JGA-NGS, HGVD, iJGVD, ExAC and ClinVar did not have the corresponding rs number, another identifier independent from genomic assembly was required. Thus we assign a new identifier named TogoVar ID to all the genetic variants. The total number of assigned genetic variants is up to 67 million. After excluding the assigned genetic variants with low allele frequency due to avoiding individual identifiability, more than 19 million unique variants are included in the public TogoVar dataset. The TogoVar web site provides a query interface for searching variants by a genomic position or region, a TogoVar or dbSNP ID, a gene name, or a disease name with auto-completion. Then user can narrow down the result set by filtering variants by datasets, allele frequencies, variant types and clinical significances. Detailed information of each variant is shown in the variant report page with the corresponding allele frequency data by population, genetic information annotated by Variant Effect Predictor (VEP), citations of relevant literature from PubMed and clinical significance from ClinVar.

**ViVa (Visualization of Variants):VCF (Variant Call Format) file visualization tool.** A. Uzun<sup>1,2,3</sup>, G. Tollefson<sup>1</sup>, J. Schuster<sup>1,2</sup>, A. Ragavendran<sup>4</sup>, I. Restrepo<sup>4</sup>, F. Gelin<sup>4</sup>, P. Stey<sup>4</sup>, J. Padbury<sup>1,2,3</sup>. 1) Dept. of Pediatrics, Brown University Warren Alpert Medical School, Providence, RI; 2) Dept. of Pediatrics, Women and Infants Hospital, Providence, RI; 3) Center for Computational and Molecular Biology, Brown University, Providence, RI; 4) Data Science Practice, Brown University, Providence, RI.

ViVa is a software tool designed to visualize data from VCF (Variant Call Format) files. A VCF file is a text file format that contains information about the genome. The file contains data about sequenced samples represented in columns and gene variant positions represented in rows. It is difficult to draw conclusions from this densely filled data structure without writing computer scripts. Because whole genome sequencing is becoming increasingly accessible to researchers and clinicians due to rapidly lowering costs of Next Generation Sequencing technologies, the need to easily extract insights from VCF files is growing in demand. We present a tool that flexibly generates publication quality graphics for the purposes of variant analysis and quality control of sequencing experiments. We offer users flexibility, efficiency, and ease of use compared with similar existing tools. In order to achieve this, we use the Julia programming language: a high-level, high-performance, dynamic programming language for numerical computing. Users can view trends in VCF fields such as sequencing read quality or genotype values across all samples and variant positions to identify regions of interest in an experiment. ViVa is designed to visualize millions of variant positions on the genome-wide to chromosome-region scales and is supported by rigorous filtering options. In addition to generating publication quality, scalable visualizations of data, users can manipulate and export filtered VCF files for downstream analysis. ViVa is comprised of three elements: a command line executable for bioinformaticians, an interactive user interface for clinicians and non-programmers, and a Julia language package for developers to collaborate. Additional plotting features include generation of line plots of read depth across both samples and variant positions. For instance, users can visualize read depth across all samples at a particular gene variant position. This allows analysts to remove samples with poor sequencing quality from queries involving discrete sets of genes. Similarly, users can visualize average read depth across all variant positions to identify poorly captured regions that may be excluded from further analysis.

**Bayesian hierarchical modeling of clustered or longitudinal RNA sequencing experiments.** B.E. Vestal<sup>1</sup>, C.M. Moore<sup>2</sup>, T. Fingerlin<sup>1</sup>, L. Saba<sup>3</sup>, K. Kechris<sup>3</sup>. 1) Center for Genes, Environment and Health, National Jewish Health, Denver, CO; 2) Department of Biostatistics, National Jewish Health, Denver, CO; 3) Department of Biostatistics and Informatics, University of Colorado Denver, Denver, CO.

The continued increase in accessibility to RNA sequencing (RNA-Seq) technology has led to more complicated study designs that demand analysis methods beyond the scope of what current methods were designed to handle. For example, studies that take repeated measurements of subjects over time would typically require Generalized Linear Mixed Models (GLMMs) or Generalized Estimating Equation methods for robust analysis. The most popular analysis tools for RNA-Seq data, edgeR and DESeq2, are designed for use on studies that only include fixed effects, and thus do not contain the machinery to account for the correlation between repeated measurements/clustered samples or other random effects. One solution that has been suggested is to include individual subjects as fixed effects when using edgeR or DESeq when there are repeated measurements on individuals, but this strategy can lead to complications with estimating specific parameters (e.g. a difference between two groups is not estimable in this scenario). In this work, we propose using a Bayesian hierarchical model for analyzing RNA-Seq data that will naturally allow for the inclusion of random effects. Since RNA-Seq data is quantified as counts, we use the commonly chosen Negative Binomial (NB) distribution with a log link to model the observed data. Model parameters are estimated using Markov Chain Monte Carlo (MCMC) methodologies with a Weighted Least Squares proposal distribution for better mixing of regression parameters (available in the MCMSeq R package). Additionally, by including the NB dispersion parameter in the MCMC sampling, the regression coefficients and their credible intervals take into account the fact that the dispersion is also being estimated. Both edgeR and DESeq2 treat this value as fixed and known when testing, and this has been posited to contribute to hypothesis tests on regression coefficients not attaining their nominal type I error rate for these methods. We compare the MCMC results to edgeR, DESeq2, and traditional generalized linear mixed models (GLMMs) in terms of power, type I error rates, false discover rate (FDR), and mean squared error (MSE) of regression coefficients for data sets simulated under a GLMM framework (paired observations per individual). Preliminary results show that the Bayesian model better controls type I errors and FDR, while edgeR, DESeq2, and the traditional GLMM fits show inflated false positive rates and inflated FDRs.

**Structural variation detection and validation pipelines for whole genome sequencing association studies and diagnostic testing.** H.Z. Wang<sup>1</sup>, B.B. Currall<sup>1,2,3</sup>, M.R. Stone<sup>1</sup>, X. Zhao<sup>1,2,3</sup>, R.L. Collins<sup>1,3,4</sup>, C. Antolik<sup>1</sup>, J.T. Glessner<sup>5</sup>, M.J. Waterman<sup>6</sup>, M.E. Talkowski<sup>1,2,3,7</sup>, H. Brand<sup>1,2,3</sup>. 1) Center for Genomic Medicine and Department of Neurology, Massachusetts General Hospital, Boston, MA; 2) Department of Neurology, Harvard Medical School, Boston, MA; 3) Program in Medical and Population Genetics and Stanley Center for Psychiatric Research, Broad Institute, Cambridge, MA; 4) Program in Bioinformatics and Integrative Genomics, Division of Medical Sciences, Harvard Medical School, Boston, MA; 5) The Center for Applied Genomics, Abramson Research Center, Children's Hospital of Philadelphia, PA; 6) Department of Biology, Eastern Nazarene College, Quincy, MA; 7) Departments of Pathology and Psychiatry, Massachusetts General Hospital, Boston, MA.

Detection of structural variation (SV) from whole-genome sequencing (WGS) remains highly inconsistent across studies with variable reporting of counts, SV classes, functional annotations, and validation methods. Numerous signatures of SV can be captured from WGS: anomalous paired-end (PE) reads signifying a rearrangement, split reads (SR) crossing a breakpoint, and changes in read depth (RD) indicating alterations in DNA dosage. Few algorithms jointly consider all signatures, hampering accurate variant discovery. We have developed a multi-stage SV detection and classification pipeline (<https://github.com/talkowski-lab/SV-Adjudicator>), which incorporates an array of established PE/SR and RD algorithms to discover an extensive list of candidate SV loci, then adjudicates each predicted variant with a joint statistical analysis across all samples. Candidate copy number variant (CNV) intervals are verified by testing for statistically significance differences in RD between samples predicted to harbor a CNV and those individuals that are diploid for the segment. Putative SV breakpoints are also assessed with an equivalent test of PE/SR evidence. The refined SVs from each algorithm are then clustered and stitched together to resolve both balanced and complex SV events based on 20 previously identified signatures. This method routinely identifies ~6000 SVs per individual and 0.2 *de novo* SVs outside of repetitive sequences and multi-allelic CNV copy gains. We have further developed a high throughput validation approach (BPP3) that can test single nucleotide variants (SNVs), indels, and SV rearrangements detected from WGS. PCR primers are designed via a custom script that integrates Primer3, *in silico* PCR and BLAT to implement strand and orientation aware primers. Our script automatically chooses the appropriate validation strategy according to the type and size of variant, then iteratively adjusts constraints to arrive at optimal experimental conditions, and QCs the resulting primer set to yield the best possible primer pair (<https://github.com/talkowski-lab/bpp3>). PCR products are ligated with Illumina adapters, pooled and then paired-end sequenced at 250 bp on an Illumina MiSeq. Sequencing reads are aligned to with BWA-MEM and variants are screened with bam-readcount, Vardict, blat, and bamstat, followed by manual conformation in IGV. All PCR reactions are performed on 96-well plates to permit efficient scaling to hundreds of variants.

**SeQuiLa: An elastic, fast and scalable SQL-oriented platform for processing and analyzing genomic data.** M. Wiewiórka, A. Szmurlo, T. Gambin. Institute of Computer Science, Warsaw, Poland.

Efficient processing of massive amount of genomic data generated by biological assays became possible thanks to the application of big data technologies in bioinformatics pipelines. Traditionally, next generation sequencing (NGS) secondary analysis pipelines, have been designed and performed in a file-centric manner, resulting in multiple drawbacks, including but not limited to inefficient data processing and re-analysis, lack of fine-grained security, and inconsistent data representation. Our solution combines distributed computing engine based on extended Apache Spark Catalyst query optimizer with a Structured Query Language (SQL) interface for handling large-scale processing and analysing of NGS datasets in a consistent tabular form. It facilitates the following aspects of genomics data handling: Definition of Apache Spark compatible datasources that map the existing file formats such as BAM, ADAM or VCF into easy to query unified table abstractions. Data access to both single and multiple samples is optimized using partition and column pruning strategies. It makes combining results from many stages of bioinformatics pipelines both straightforward and efficient. Genomic interval queries which are crucial to many bioinformatics analyses were optimized through a distributed implementation of interval forests that can be expressed in a form of regular SQL range joins which are automatically transformed into the most efficient physical execution plan using input datasets statistics. Coverage computations are also included in a SQL syntax using table-valued functions and optimized by a distributed implementation that eliminates the unnecessary data shuffling between computing nodes. User defined functions including shift, resize, flank that streamline genomic records operations and parameters maxGap and minOverlap for additional overlap configuration. Straightforward interoperability with existing analytics tools using a widely-adopted JDBC standard. To test the efficiency of our platform, we performed multiple tests on both a single node and on a cluster. In particular, we demonstrated that our range join strategy is significantly (~22x) faster than Apache Spark one and outperforms other state-of-the-art tools for genomic intervals processing. The project documentation and source code is available at <http://biodatageeks.org/sequila/>.

**A high-throughput computational quality control pipeline for exome and genome data for rare disease studies.** *M. Wilson<sup>1,2</sup>, G. Tiao<sup>1,2</sup>, K. Laricchia<sup>1,2</sup>, L. Francioli<sup>1,2</sup>, K. Karczewski<sup>1,2</sup>, B. Weisburd<sup>1,2</sup>, D. MacArthur<sup>1,2</sup>.* 1) The Broad Institute of MIT and Harvard, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA, United States.

Every year over 500,000 babies are born with a Mendelian disorder, but current diagnostic approaches provide a diagnosis for less than half of all patients with genetic disease. To increase diagnostic rates for patients with rare Mendelian disorders, we have developed the software platform *seqr*, which allows analysts to efficiently and systematically search for candidate disease-causing variants in patients' sequencing data. By providing multiple resources in an easy-to-use interface, *seqr* enables users to search variant calls by filtering on variant type, functional class, allele frequency, allele count, inheritance mode, deleteriousness predictions, and genomic location to discover variants possibly related to a Mendelian disease. Standard analysis procedures, such as identifying familial inheritance patterns, prioritizing candidate genes, filtering variant calls, and querying online databases and papers typically take days to complete but can be accomplished in minutes within the *seqr* interface, allowing analysts to review and identify more candidate disease-causing variants with less effort. Successful searches for causal disease variants in *seqr* depend on the quality of the sequencing data and the accuracy of sample annotations, including labeling of familial relationships and individual metadata. To ensure data quality and to increase the probability of variant discovery and diagnosis, we have built a computational quality control pipeline for *seqr* using Hail (<https://github.com/hail-is/hail>), an open-source, scalable framework for exploring and analyzing genomic data. The quality control pipeline is written entirely in Python using the Hail library and capitalizes on Hail's ability to handle large genomic datasets for efficient processing. The pipeline flags samples with elevated rates of contamination, chimeric reads, and low coverage. Sex, exome capture platform, and ancestry are all inferred and checked against available sample metadata supplied by clinicians. The pipeline also provides a direct estimate of consanguinity and reconstructs family pedigrees computationally, allowing analysts to check family structures against reported pedigrees. By providing analysts with quality sequencing data and accurate sample metadata, we are actively working to increase the diagnostic rates of rare Mendelian disease.

**Determining sanger confirmation necessity of NGS variants using a data-driven model.** *C. Wu<sup>1</sup>, K.B. Pechter<sup>1</sup>, E.J. Romasko<sup>1</sup>, X. Zhao<sup>1</sup>, M.A. Diaz-Miranda<sup>1</sup>, C.U. Silva<sup>2</sup>, K. Cao<sup>1</sup>, M.C. Dulik<sup>1,3</sup>, A.N. Abou Tayoun<sup>1,3,4</sup>, M. Sarmady<sup>1,3</sup>.* 1) Division of Genomic Diagnostics, The Childrens Hospital of Philadelphia, Philadelphia, PA, USA; 2) GenoMed Inc., Instituto De Medicina Molecular, University of Lisbon, Lisbon, Portugal; 3) Department of Pathology and Laboratory Medicine, The University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, USA; 4) Al Jalila Childrens Specialty Hospital, Dubai, UAE.

Next generation sequencing (NGS) is increasingly the preferred technology for sequence-based clinical genetic tests. The quality of NGS calls may vary widely, with a small fraction of the detected variants needing orthogonal confirmation despite the majority of the calls being accurate and reliable. Orthogonal confirmation can be costly and increase turnaround time for tests. Therefore, many clinical labs are moving towards a quality control strategy to identify only the 'low quality' variants that require orthogonal confirmation. Here, we report the development of our bioinformatics method to differentiate between these two groups of variant calls: 1) not requiring orthogonal confirmation (high confidence) and 2) requiring additional testing (low confidence). Since the vast majority of the detected mutations are single nucleotide variants (SNVs), we derived a set of rules incorporating several features of the characteristics and call quality to determine if an SNV was detected at high or low confidence. Here, a true positive is defined as a variant called in NGS and confirmed by Sanger sequencing, whereas a false positive is a variant called in NGS yet rejected by Sanger. The challenge is to classify all of the false positive calls as 'low confidence', while categorizing most true positive calls as 'high confidence'. We studied 474 SNVs detected by clinical NGS exome capture, including 460 SNVs that were Sanger confirmed and 14 Sanger rejected, and extracted sequencing and quality attributes of each of the variants. Then we performed feature selection based on information entropy to remove features that did not separate the two classes well. Finally, we derived a set of rules to determine the confidence of a detected SNV. As a result, we label a SNV as 'low confidence' if any of the criteria is met: Quality by Depth (QD) < 11; Phred-scaled p-value using Fisher's exact test (FS) > 5; Allele Ratio (AF): Homozygous < 67% and Heterozygous < 33%. Applying this set of rules, 281 out of the 460 true positives are labeled as 'high confidence' (61.1%) while all 14 false positives are labeled as 'low confidence' (100%). To further investigate its clinical utility, we performed additional validation on 'borderline' variants and consolidated the set of criteria. In summary, we present a bioinformatics approach to accurately identify SNVs requiring additional confirmation using quality metrics for clinical implementation to reduce the need for confirmatory testing.

**Performance evaluation of assembly-based structural variation discovery in the human genome.** C. Xiao<sup>1</sup>, H. Hong<sup>2</sup>, SEQC2 Germline Working Group. 1) NCBI/NIH, Bethesda, MD 20894; 2) NCTR/FDA, 3900 NCTR Road, Jefferson, AR 72079.

Structural variations (SVs) are widely known to contribute to genetic diversity of human populations, affect biological functions, and cause various human disorders. However, accurately identifying SVs with correct sizes and locations in the human genome remains a challenge due to the complexities of the human genome, limitations of sequencing technologies, and drawbacks of analysis methods. Recent advancement of next-generation sequencing technologies has significantly reduced the sequencing cost, while substantially increased the lengths of the sequencing reads. Therefore, using *de novo* assembly based approaches for discovering a full spectrum of SVs in human genome becomes appealing. While various assembly methods have been developed and proposed for general use by the community, the relative efficiency and predictive accuracy of SVs calling based on these assembly methods have not been fully evaluated. In this study, we applied several popular *de novo* assembly tools to the sequencing read data that were generated using multiple sequencing technologies with technical replicates for NA12878/HG001 and a Chinese Quartet. Assemblies and SVs callsets were generated for each of the five samples, and repeatability in the SVs of the technical replicates and reproducibility across sequencing sites were evaluated. Preliminary results showed that there were substantial variabilities between SVs callsets based on various assemblies within sequencing platform. We also observed considerable variabilities between assembly-based SVs callsets and alignment-based SVs callsets. The sources of these variabilities will be further discussed. These results allow better understanding of the impacts of *de novo* assembly methods on SVs calling, thus providing a better insight to precision medicine.

**CRISPRO identifies functional protein coding sequences based on genome editing dense mutagenesis.** Q. Yao<sup>1,2,3,4</sup>, V.A.C. Schoonenberg<sup>1,2,3</sup>, M.A. Cole<sup>1,2,3</sup>, C. Macias-Trevino<sup>1,2,3</sup>, F. Sher<sup>1,2,3</sup>, P.G. Schupp<sup>1,2,3</sup>, M.C. Canver<sup>1,2,3</sup>, T. Maeda<sup>5</sup>, L. Pinello<sup>3,4</sup>, D.E. Bauer<sup>1,2,3</sup>. 1) Boston Children's Hospital, Boston, MA; 2) Dana-Farber Cancer Institute; 3) Harvard Medical School, Boston, MA; 4) Massachusetts General Hospital, Boston, MA; 5) Kyushu University Hospital, Fukuoka, Japan.

CRISPR/Cas9 pooled screening permits parallel evaluation of comprehensive guide RNA libraries to systematically perturb protein coding sequences *in situ* and correlate with functional readouts. For the analysis and visualization of the resulting datasets we have developed CRISPRO, a computational pipeline that maps functional scores associated with guide RNAs to genome, transcript, and protein coordinates and structure. No available tool has similar functionality. The ensuing genotype-phenotype linear and 3D maps raise hypotheses about structure-function relationships at discrete protein regions. Machine learning based on CRISPRO features improves prediction of guide RNA efficacy. The CRISPRO tool is freely available at [gitlab.com/bauerlab/crispro](https://gitlab.com/bauerlab/crispro).

**Cell type clustering tools evaluated in six single cell chromatin accessibility experiments.** *E. Urrutia<sup>1</sup>, L. Chen<sup>2</sup>, Y. Jiang<sup>1</sup>*: 1) University of North Carolina, Chapel Hill, NC; 2) Auburn University, Auburn, AL.

Single-cell assay of transposase-accessible chromatin followed by sequencing (scATAC-seq) is an emerging new technology for the study of gene regulation with single-cell resolution. Unlike the conventional ChIP-seq, DNase-seq and ATAC-seq technologies, scATAC-seq measures regulatory element activities within each individual cell, which circumvents the averaging artifacts associated with traditional bulk population data, yielding new insights into the cellular heterogeneity. The data from scATAC-seq are unique – sparse, binary, noisy with biases and artifacts, and highly variable even within cell types. As such, neither methods developed for bulk ATAC-seq nor single-cell RNA-seq are appropriate. Here, we propose Destin, a bioinformatic and statistical framework for comprehensive scATAC-seq data analysis. We evaluate performance of Destin using scATAC-seq data of 19,000 cells from six experiments. The experiments show diversity, ranging from 500 to 3,000 cells, from 100,000 to 150,000 accessible regions, and from 2 to 12 cell types. The experiments also span multiple technologies, including one based on physical isolation of single cells using microfluidics, and one by a two-step combinatorial indexing strategy that avoids single-cell reaction volumes. Destin is benchmarked against seven existing methods using the known cell identities presented by the original authors and is shown to have the best performance across all datasets. Specifically, we show that proper normalization for sequencing depth accounted for a 25-50% improvement in clustering in every scATAC-seq experiment. Furthermore, Destin incorporates weights for chromatin accessible regions based on previous annotations and bulk epigenomic profiles, which (i) give higher weights to long-range regulatory elements (i.e. enhancers, repressors/silencers and insulators, while down-weighting accessible promoter regions) and (ii) up-weight rare accessible regions and down-weight common accessible regions as determined by previous bulk chromatin-accessibility experiments. We show that incorporating the above weights to our recommended best practice resulted in clustering accuracy at least as strong as unweighted in every scATACseq experiment and accounted for up to a 15% improvement. .

**1612T**

**Differences in GWAS findings driven by using ethnically-matched and mixed imputation reference panels.** *M. Kalsi<sup>1,2</sup>, K. Lälli<sup>1,2</sup>, T.T. Sikka<sup>1</sup>, A. Paldie<sup>3,4</sup>, A. Metspalu<sup>1,5</sup>, P. Palta<sup>1,3</sup>, R. Mägi<sup>1</sup>, SISu Project*. 1) Estonian Genome Center, Institute of Genomics, University of Tartu, Tartu, Estonia; 2) Institute of Mathematics and Statistics, University of Tartu, Tartu, Estonia; 3) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 4) Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 5) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia.

Over last decade genome-wide association studies (GWAS) have been most frequent tool to identify genes involved in complex diseases. Input of GWA studies requires high-quality genetic imputation and imputation accuracy depends on underlying imputation reference panel (IRP). Although genotype imputation can be performed relatively well for common and low-frequency variants with publicly available ethnically more heterogeneous IRPs like the 1000 Genomes Project (1000GP) and the Haplotype Reference Consortium (HRC), the imputation of rare variants has been shown to be significantly more accurate when the used reference panel and target dataset are ethnically matched or if population-specific reference panel is used for genotype imputation. Notwithstanding, the genome-wide downstream differences and consequences of using international mixed and ethnically matched reference panels have not been yet comprehensively explored. In this study we determined and quantified these differences by performing several comparative evaluations of the following biologically motivated analysis scenarios by using genome-wide genotype array data of ~52,000 Estonians imputed with both ethnically-matched and 1000GP imputation reference panel. Firstly, a variant-wise GWAS of confidently imputed (INFO > 0.8) variants was performed on seven complex diseases (bipolar disorder, Crohn's disease, coronary artery disease, hypertension, rheumatoid arthritis, type 1 diabetes, and type 2 diabetes). A logistic regression model using Firth's bias reduction method was applied to model genotype dosages. Although several previously reported common variant associations were replicated in both imputed datasets, no major differences were observed in the results of variant-wise GWAS or in fine-mapping effort of associated loci. Secondly, a gene-wise GWAS was performed using SKAT-O test to determine the joint contribution of rare (MAF < 1%) nonsynonymous variants. In this analysis, significant differences were observed in favor of ethnically-matched imputation, where 10-fold statistically significant genes were discovered as compared to the 1000GP-based imputation. Our results clearly demonstrate that although there are no major differences in common variant imputation and consequent GWAS findings, the usage of ethnically-matched imputation reference panel can enable superior imputation of rare variants, facilitating significantly higher number of findings in gene-based rare variant GWAS scans.

**1613F**

**Clinotator: Analyzing ClinVar variation reports to prioritize reclassification efforts.** R.R. Butler<sup>1,2</sup>, P.V. Gejman<sup>1,2</sup>. 1) Genomic Health Initiative, NorthShore University HealthSystem, Evanston, IL; 2) Department of Psychiatry and Behavioral Neuroscience, Pritzker School of Medicine, University of Chicago, Chicago, IL.

While ClinVar has become an indispensable resource for clinical variant interpretation, its sophisticated structure provides it with a daunting learning curve. Often the sheer depth of types of information provided can make it difficult to analyze variant information with high throughput. Clinotator is a fast and lightweight tool to extract important aspects of criteria-based clinical assertions; it uses that information to generate several metrics to assess the strength and consistency of the evidence supporting the variant clinical significance. Clinical assertions are weighted by significance type, age of submission and submitter expertise category to filter outdated or incomplete assertions that otherwise confound interpretation. This can be accomplished in batches: either lists of Variation IDs or dbSNP rsIDs, or with vcf files that are additionally annotated. Using sample sets ranging from 15,000–50,000 variants, we slice out problem variants in minutes without extensive computational effort (using only a personal computer) and corroborate recently reported trends of discordance hiding amongst the curated masses. With the rapidly growing body of variant evidence, most submitters and researchers have limited resources to devote to variant curation. Clinotator provides efficient, systematic prioritization of discordant variants in need of reclassification. The hope is that this tool can inform ClinVar curation and encourage submitters to keep their clinical assertions current by focusing their efforts. Additionally, researchers can utilize new metrics to analyze variants of interest in pursuit of new insights into pathogenicity.

**1614W**

**Prediction of missense variant function polarity using machine learning.** A. Ghosh<sup>1,2,3</sup>, A. Navarini<sup>1,2,3</sup>. 1) Department of Dermatology, University Hospital Zurich, Zurich, Switzerland; 2) Faculty of Medicine, University of Zurich, Zurich, Switzerland; 3) Competence Center Personalized Medicine, University of Zurich and ETH Zurich, Zurich, Switzerland.

*Introduction:* Functional interpretation is crucial when facing on average 20,000 missense variants per human exome, as the great majority are not associated with any underlying disease. *In silico* bioinformatics tools can predict the deleteriousness of variants or grade their functional impact by assigning scores such as SIFT, PolyPhen2 and CADD. In addition, consensus scores such as Condel aim to further refine the predictions by aggregating weighted single scores. For functional experiments seeking to confirm biological relevance, an as yet unanswered question is whether a missense variant in question results in loss or gain of function at the protein level. *Objectives:* To develop a new classifier for damaging genetic variants allowing to predict their gain or loss of function polarity. *Material and Methods:* 1,543 loss of function (LOF) and 518 gain of function (GOF) variants with supporting evidence in terms of literature texts, clinical reports and research projects were extracted from ClinVar. All damaging variants as annotated by Condel and CADD were selected to develop the classifier. Boosting algorithm was preferred over other machine learning algorithms because of its additive model approach. *Results:* Our results showed two peaks of mean Condel scores across GOF and LOF variants ( $p < 0.01$ ) indicating a non-random difference. The classifier adapted a weighted boosting approach to address the variant class imbalance and therefore ROC curve was used to assess its performance. The discriminative power of the tool was found to be very high with an area under the ROC curve of  $>0.82$ . *Discussion:* Function polarity prediction was found to be possible using available prediction algorithms' data in this new classifier. Even though no prediction has perfect accuracy, these results may help to guide biological experiments on the clinical relevance of damaging genetic variants. The algorithm, named BioPol, is available online. A weakness of our approach is that the great majority of available missense variants have not been investigated with biological experiments.

**DeepSweep: A novel neural model to localize signals of positive selection.** S.J. Gosai<sup>1,2</sup>, J.J. Vitt<sup>2,3</sup>, S.K. Reilly<sup>2,3</sup>, P.C. Sabeti<sup>2,3</sup>. 1) Department of Biological and Biomedical Sciences, Harvard University, Boston, Massachusetts 02115, USA; 2) Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 3) Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, Massachusetts, USA.

As humans migrated out of Africa over the past 200,000 years and encountered novel environments, diets, and pathogens, distinct sub-populations have been exposed to various selective pressures. The emergency of whole-genome sequences from diverse human populations has allowed us to search for the adaptive human variants that are a response to these selective pressures. However, only a handful of putative adaptive variants (PAVs) have been convincingly linked to evolutionarily advantageous traits. Progress has been hindered by the challenges of pinpointing PAVs amongst numerous variants in linkage disequilibrium (LD), meaning humans neutral variants almost certainly drastically outnumber adaptive ones. Methods to precisely identify variants under selection by minimizing false discovery rate would drastically reduce these challenges. Here, we present deepSweep, a deep neural network used to localize signals of selection in humans to individual variants. Previous methods are able to localize signal to large loci approximately 100kb in size with tens to hundreds of variants. However our model achieves >70% top-1 and >95% top-10 accuracy when searching for individual adaptive variants with derived allele frequency (DAF) >20% in simulated hard-sweeps. Moreover, our model is able to detect simulated adaptive variants with DAF as low as 10%, albeit at reduced sensitivity and selectivity. Our model is trained to identify drivers of both “soft- sweeps” and “hard- sweeps” and can be directly applied to data generated from any population. To our knowledge, this is the first deep-learning approach to scans for adaptive variation in humans. We used this tool in conjunction with Composite of Multiple Signals (CMS) method for Bayesian identification of regions under positive natural selection to scan the 1000 Genomes Phase 3 dataset. Using a two tiered approach, we identify 650 regions with evidence of positive evolutionary selection and identify ~65000 candidate variants for further analysis.

**The Monarch HIPPO: Deriving insight from the medical literature by fuzzy semantic searches over diseases and phenotypes.** T. Groza<sup>1</sup>, A. Muaz<sup>1</sup>, A. Azarkhish<sup>1</sup>, P.N. Robinson<sup>2</sup>, C.J. Mungall<sup>3</sup>, N.L. Harris<sup>3</sup>, J.A. McMurry<sup>4</sup>, M.A. Haendel<sup>5</sup>. 1) Garvan Institute of Medical Research, Darlinghurst, NSW, Australia; 2) The Jackson Laboratory for Genomic Medicine, Farmington, CT, USA; 3) Lawrence Berkeley National Laboratory, Berkeley, CA, USA; 4) Department of Medical Informatics and Clinical Epidemiology, Oregon Health and Science University, Portland, OR, USA; 5) Dept of Environmental and Molecular Toxicology, Oregon State University, Corvallis, OR, USA.

It takes a clinician substantial time to search for publications relevant to a given patient case, and such searches are often unsuccessful. For example, using PubMed to find all publications that might mention genes responsible for “macrocephaly” and “developmental delay” requires tedious review of numerous abstracts in order to surface those that actually mention a gene relevant to a patient’s diagnosis. Most available full-text search applications provide basic string matching of full text; they usually also leverage what little curated meta-data exists (e.g., MeSH terms). However, to further improve literature search it is necessary to mine specific entities from the text and to leverage what is already known about how they are related to each other. We have developed a high-throughput pipeline to extract clinically relevant knowledge from the literature and present it to users in novel ways. The new application, HIPPO ([hippo.monarchinitiative.org](http://hippo.monarchinitiative.org)) enables researchers to perform fine-grained searches for abstracts mentioning concepts of interest: phenotypes (from Human Phenotype Ontology), diseases (MONDO) and genes (HGNC), and soon for drugs (DrugBank), variants (in HGVS notation) and signs and symptoms (SNOMED-CT). Because these entities are also structured in a hierarchy with synonyms, queries can find all relevant records, e.g., “brain cancer” will automatically retrieve any records that mention “glioblastoma” even if they do not mention “brain” or “cancer”. Similarly, a search for FANCD1 also retrieves abstracts for BRCA1 as these are synonymous. Moreover, the recognized entities in HIPPO are linked out to the corresponding page in the main Monarch application so that users can explore the landscape of published associations between an entity of interest and other diseases, genes, and phenotypes. We are crowdsourcing manual curation of each text-mined entity via a simple “thumbs-up/thumbs-down” voting integrated within the user interface. Finally, the entire pipeline is re-run on a weekly basis, pulling not only the latest abstracts, but also the latest lists of genes, phenotypes, diseases etc. We have also introduced a query subscription service for users to track phenotypes and other related entities of interest. HIPPO can help clinicians find what they need to help diagnose patients while staying updated with the latest developments for their query of interest.

**ForestQC: Variant quality control based on random forest model.** J. Li<sup>1</sup>, S.K. Service<sup>2</sup>, B. Jew<sup>2</sup>, L. Zhan<sup>1</sup>, S. Hwang<sup>2</sup>, G. Coppola<sup>2</sup>, N.B. Freimer<sup>1,2</sup>, J.H. Sul<sup>1</sup>. 1) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA; 2) Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA; 3) Bioinformatics Interdepartmental Program, University of California, Los Angeles, Los Angeles, CA; 4) Molecular Biology Institute, University of California, Los Angeles, Los Angeles, CA.

Next generation sequencing (NGS) technology enables discovery of nearly all genetic variants present in a genome. A subset of these variants, however, may have poor sequencing quality due to biases and errors in sequencing technologies, alignment biases caused by inconsistent mappability of reads, or inaccurate and discordant variant calling algorithms. For example, concordance among different variant callers was 57.4% in SNVs detection and 26.8% in indels discovery. In genetic studies that analyze a large number of sequenced individuals, it is critical to detect and remove those variants with poor quality as they may cause spurious findings. In previous studies, either filtering approaches or machine learning approaches are used for variant quality control (QC). In this paper, we developed a statistical approach for performing QC on variants identified from NGS data by combining a filtering approach and a machine learning approach. Our method uses information on sequencing quality such as sequencing depth, genotyping quality, and GC contents to predict whether a certain variant is likely to contain errors. We applied our method to two different whole-genome sequencing (WGS) datasets whose study designs include family and unrelated individuals. The first WGS dataset consists of 449 individuals from a large extended pedigrees ascertained for bipolar disorder (BP). It has about 25 million SNVs and 4 million indels, whose average coverage is about 40X. The second WGS dataset is based on a sequencing study for progressive supranuclear palsy (PSP). It includes 495 unrelated subjects who were sequenced at average coverage of 29X, generating about 33 million SNVs and 5 million indels. Results indicate that our method outperforms widely used methods for variant QC such as GATK-VQSR by considerably lowering Mendelian error rate, missing rate and genotype discordance rate and improving Ti/Tv ratios of variants to be included in the analysis. Our approach is very efficient that it takes 20-30 minutes to finish processing the two WGS datasets, which is 15 to 20 times faster than GATK-VQSR. Hence, it is scalable to large-scale sequencing datasets. We conclude that combining a machine learning algorithm trained with sequencing quality information and the filtering approach is an effective approach to perform QC on genetic variants detected from sequencing.

**DECA: Scalable XHMM exome copy-number variant calling with ADAM and Apache Spark.** M. Linderman<sup>1</sup>, D. Chia<sup>1</sup>, F. Wallace<sup>1</sup>, F. Nothhaft<sup>2,3</sup>. 1) Department of Computer Science, Middlebury College, Middlebury, VT; 2) AMPLab, University of California, Berkeley, Berkeley, CA; 3) Databricks, Inc., San Francisco, CA.

**Background:**XHMM is a widely used tool for copy-number variant (CNV) discovery from whole exome sequencing (WES) data, but can require hours to days to run for large cohorts. A more scalable implementation would reduce the need for specialized computational resources and enable increased exploration of the configuration parameter space to obtain the best possible results. **Methods and Results:**DECA is a horizontally scalable implementation of the XHMM algorithm using the ADAM framework and Apache Spark that incorporates novel algorithmic optimizations to eliminate unneeded computation. DECA automatically parallelizes XHMM on both multi-core shared memory computers and large shared-nothing Spark clusters. We performed CNV discovery from the read-depth matrix for the s=2535 1000 Genomes Phase 3 exomes in 31 minutes on a 16-core workstation (10.6x speedup vs. XHMM), 23.2 minutes using 40 executor cores on a Spark cluster (10.3x speedup vs. XHMM), and 18.45 minutes using 48 executor cores on Databricks on the Amazon cloud (approximate cost of \$0.53). We performed CNV discovery directly from the BAM files in 292 minutes using 640 executor cores on a 56-node Spark cluster. Of 16512 XHMM CNV calls in a subset of 500 samples, 99.92% have an overlapping DECA call with same copy number and 93% have identical breakpoints. The breakpoints of most partially overlapping calls differed by 1 target (65.7%) with a mean difference of 3.3 targets. We do not expect identical results due to differences in the numerical behavior of multiplying small probabilities. We describe lessons learned, including the importance of library choice - the XHMM PCA step can be sped up 3.9x by switching to an optimized LAPACK library - and algorithmic optimizations. DECA implements an iterative algorithm for PCA normalization that produces the same results as XHMM, but typically reduces the amount of memory required for any one computer by 10x thus increasing the size of the cohort than can be analyzed on commodity hardware. **Conclusions:**ADAM and Apache Spark are a performant and productive platform for implementing large-scale genome analyses that are scalable by default, but efficiently utilizing large clusters can require algorithmic optimizations and careful setting of Spark's many configuration parameters.

**1619F****metro and hudson: R packages to leverage the utility of Manhattan plots.**

A. Lucas<sup>1</sup>, A. Verma<sup>1</sup>, M.A. Hall<sup>2</sup>, M.D. Ritchie<sup>1</sup>. 1) Department of Genetics, Institute for Biomedical Sciences, University of Pennsylvania, Philadelphia, PA; 2) College of Agricultural Sciences, The Pennsylvania State University, University Park, PA.

As genome-, phenome-, and exposome-wide analysis studies (GWAS, PheWAS, EWAS) increase in size and complexity, there is need to further develop visualization techniques for the presentation of results. We have developed a pair of ggplot2-based R packages, metro and hudson, which augment basic Manhattan plots with the aim of improving result communication and interpretation. The metro package allows users to quickly create static, interactive, or animated Manhattan plots for GWAS, PheWAS, and EWAS results. Though the package was designed to cater to SNP (GWAS/PheWAS) and exposure (EWAS) data, it will accept any data that can be mapped to chromosome and position, such as genes, while EWAS plots are suitable for analyses with many results organized into categories, such as tissues or pathways. Further, while Manhattan plots traditionally visualize p-values, our flexible framework allows the user to plot other data, such as beta or intensity values instead. Within metro, adding threshold lines, highlighting points by either name or numeric value, and assigning colors or shapes to groups are common to all plotting functions. Static images allow for additional text annotation while the animated plotting functions, which output GIF files, enable the user to map an additional layer of information to an animation frame. For example, a user can see how a GWAS landscape changes based on population or the model assumed when encoding SNPs. This is potentially more impactful than comparing two static images as it highlights nuance and could reduce change blindness. Interactive plots, which can be shared as an HTML file, making them particularly useful for collaboration and translation of results, allow the user to include meta-information viewed by hovering over the data points as well as link the points to websites or databases, such as dbSNP or the NHGRI-EBI GWAS Catalog, upon mouse click. The counterpart to metro, hudson, can be used to create mirrored Manhattan plots for the position by position comparison of results between two datasets, e.g. discovery and replication, or two features of a dataset, e.g. subsets of SNPs by direction of effect. The Hudson plots are static images characterized by a shared x-axis and diverging y-axis, and contain the same annotation features as described in the metro package. Together these packages enhance traditional Manhattan plots providing for comprehensive visualization of increasingly larger scaled and more detailed analyses.

**A bioinformatics pipeline for next-generation sequencing of the killer cell immunoglobulin-like receptor gene complex.** W.M. Marin<sup>1</sup>, P.J. Norman<sup>2</sup>, R. Dandekar<sup>1</sup>, J.A. Hollenbach<sup>1</sup>. 1) Neurology, UC San Francisco, San Francisco, CA; 2) SOM-MED, UC Denver, Denver, CO.

The killer cell immunoglobulin-like receptor (KIR) complex (Chr19) encodes receptors expressed on the surface of natural killer (NK) cells, which may have either activating or inhibitory effects on NK cell activity, resulting in a finely tuned reactivity. The KIR region is marked by highly homologous loci, extensive structural variation, and high levels of polymorphism, all of which serve to significantly confound genotype determination. Variation in KIR gene-content has been implicated in numerous immune-mediated and infectious diseases, but more detailed interrogation of these loci has been thwarted by the complexity of the region. To facilitate study of KIR variation, we have developed a novel bioinformatics pipeline that allows for high-throughput, accurate determination of high-resolution KIR genotypes from next-generation sequencing data. A gene content determination method identifies sequence motifs that are unique to individual KIR loci, then searches over the sequencing data of a sample for these unique motifs to determine which KIR loci are present. Many KIR loci are copy number variable, and this method allows for the determination of locus presence and copy number, which is vital for accurate read mapping and genotype calling. A read filtration method resolves highly-homologous sequence through a series of read mapping steps that separate reads from homologous loci. The first step is a permissive positive filter, to isolate reads that map to specific KIR loci, which is followed by a stringent negative filter, to discard reads that map strongly to other KIR loci, and the remaining reads are used for final mapping. The negative alignment step reduces genotypic ambiguity through multiple rounds of read mapping to highly divergent haplotype references, which are constructed to most completely represent the variation found within the KIR loci. Combining the results of multiple rounds of mapping allows the identification of variants that might be missed by a single mapping, but more importantly, it allows the exclusion of alleles that contain variants that were not found in any round of mapping. Together, these methods solve the issues preventing the accurate determination of KIR genotypes. The pipeline implementing these methods is open source and has been validated and developed for large-scale analysis of targeted, as well as whole-genome and -exome sequencing data, enabling population level studies investigating the role of KIR genes in disease.

**Accurate fetal DNA variant calling in the presence of maternal cell contamination.** *E. Nabieva, Y. Kapushev, A. Chernomorov, S. Mishra Sharma, D. Vinogradov, G. Bazykin, D. Yarotsky.* Skolkovo Institute of Science and Technology, Moscow, Russian Federation.

High-throughput sequencing of fetal DNA is a promising and increasingly common method for the discovery of all (or all coding) genetic variants in the fetus, either as part of prenatal screening or diagnosis, or for genetic diagnosis of spontaneous abortions. In many cases and depending on the tissue and the laboratory technique used, the fetal DNA (from chorionic villi, amniotic fluid, or abortive tissue) can be contaminated with maternal cells, resulting in the mixture of fetal and maternal DNA. This maternal cell contamination (MCC) undermines the assumption, made by traditional variant callers, that each allele in a heterozygous site is covered, on average, by 50% of the reads, and therefore can lead to erroneous genotype calls. We present a panel of methods for reducing the genotyping error in the presence of MCC. All three methods start with the output of GATK HaplotypeCaller on the (contaminated) fetal sample and sequencing data for either one or both of the parents, and additionally rely on information about the MCC fraction (which itself can be readily estimated from the HTS data). The first of these methods uses an explicit formula based on simple probabilistic assumptions to “recalibrate” the fetal genotype calls produced by MCC-unaware HaplotypeCaller. The second method employs machine learning to recalibrate the HaplotypeCaller genotype calls in the presence of MCC; it trains on variant calls for fetal samples with and without simulated MCC, the latter being used as true labels. The third method adapts the model of GATK PhaseByTransmission to calculate the genotype posteriors in the presence of MCC using fetal and parental read data. We use simulated contaminated fetal data to show that all three methods lead to substantially improved accuracy when compared with the original MCC-unaware HaplotypeCaller calls, as judged by the concordance with genotype calls made on uncontaminated child data. We discuss the drawbacks and advantages of each of the presented methods.

**Confounding variable analysis of transcriptomics sequencing samples.** *M. Nagarajan, S. Ramachandrala, M.W. Saifi, R. Bettadapura, D. Chohan.* Strand Life Sciences Private Limited, 5th Floor, Kirtoskar Business Park, Bellary Road, Hebbal, Bangalore 560024 INDIA.

The purpose of RNA analysis is often to reveal sources of differential expression between various biological groups. It relies on the dogma that phenotype could be inferred from the patterns of gene expression. However, sequencing analysis, starting from the lab and moving on up to bioinformatics and interpretation, despite years of standardization, is notoriously difficult to be made error free. While random errors are unpreventable and acceptable, systematic errors are to be avoided. Some systematic errors are known and preventable, while others creep in, especially, in large data sets. Biologists often use simple batch-correction methods but are largely unaware of more mathematical approaches to find underlying systematic errors and correct for them. To address this problem of known and unknown confounders that affect expression matrices, we have developed an intuitive framework for Confounding Variable Analysis (CVA) in StrandNGS, our comprehensive NGS data analysis and management software. Any gene list could be used as an input and on providing biological variables and known (if any) technical variables, confounders could be identified and corrected. The spread of the data before and after the correction can be visualized. The sample behavior is captured using Principal Component Analysis (PCA) plots while the gene expression distributions are shown as box-whisker plots. An f-test is applied to find differentially expressed genes and genes whose expression values are affected/not-affected by the identified confounders. This corrected expression matrix is available for all downstream analyses. We intend to illustrate the utility of this feature in StrandNGS using 3 data sets: GSE87194 - Set of post-mortem brain samples from Schizophrenic patients and age-matched controls. The paper reported batch-effects and the batch information was not published. We could find the batches and correct for them using CVA. GSE77288 - Set of pan-cancer blood platelet samples and controls. While most tumor samples were from older patients, all control samples were from healthy young individuals. Using CVA, the confounding effect of age could be corrected. GSE22521 - Set of primate prefrontal cortex samples collected from multiple species after post-mortem assayed using microarrays and expression values reported at gene level. Given the varied collection and processing times, this dataset showed a lot of underlying confounders that could be identified and corrected using CVA.

**1623W****Prediction of pathogenic non-coding variants associated to monogenic Mendelian diseases through an integrative supervised learning approach mining signals of recent and ongoing purifying selection in human.**

A. Rausell<sup>1,2</sup>, B. Caron<sup>2</sup>, Y. Luo<sup>2</sup>. 1) INSERM UMR 1163, Institut Imagine, 24 boulevard du Montparnasse, 75015 Paris, France; 2) Paris Descartes – Sorbonne Paris Cité University, Institut Imagine, 24 boulevard du Montparnasse, 75015 Paris, France.

The study of rare Mendelian diseases through exome sequencing typically yields incomplete diagnostic rates (~8-70%), depending on the disease type. Whole genome sequencing of the unresolved cases allows addressing the hypothesis that causal variants could lay in non-coding regions with damaging regulatory consequences. Computational methods are then needed to score the pathogenicity potential of the large amount of rare and singleton variants found in each individual genome. However, state-of-the-art methods to prioritize non-coding variants have been characterized on sets largely composed of trait-associated polymorphisms and associated to common diseases. In this work we first curated a collection of  $n=737$  high-confidence pathogenic non-coding single-nucleotide genetic variants in proximal cis-regulatory regions associated to monogenic Mendelian diseases. We then systematically evaluated the ability to predict causal variants of an exhaustive set of genomic features extracted at three levels: the affected position, the flanking region and the affected gene. In addition to epigenetic features and inter-species conservation scores, a complete set of ongoing purifying selection signals in human was explored. This represents a main novelty allowing to exploit sequence constraints potentially associated to recently acquired regulatory elements in human. A supervised learning approach using gradient tree boosting on the previously described sets of features reached a predictive performance characterized by an area under the ROC curve = 0.84 and an area under the Precision-Recall curve = 0.53. These figures represent, respectively, a relative improvement of >12% and >51% upon the performance of current state-of-the-art methods for prioritizing non-coding disease variants. The approach consistently outperformed reference methods under multiple configurations of the sets of variants used for learning and independent testing. A detailed comparative benchmark is presented and results discussed in terms of the type of the targeted regulatory region.

**1624T****Scripting support in StrandNGS.** M.W. Saifi, S. Ramachandrala, S.C. Cherukuri. Strand Life Sciences Pvt. Ltd., Bangalore, Karnataka, India.

Analyzing Next Generation Sequencing (NGS) data involves multiple teams from varied backgrounds. Also, for most comprehensive analysis, generally multiple approaches are used to compare and contrast the results to derive valid conclusions. However, given that bioinformaticians and biologists use different approaches, the collation of their respective analyses becomes cumbersome. StrandNGS is an NGS data analysis software designed for the biologists. It provides this flexibility in the form of scripting support within the framework of the tool. This ensures that the same inputs/data could be used to perform various analyses using different techniques in the software as well as store and compare results on the same. StrandNGS provides support for Jython & R scripting. We intend to showcase this functionality using example study workflows on how one could use scripting to: 1. Integrate HISAT, an open-source software that helps in transcriptome alignment. This flexibility ensures that researchers can continue to use their lab-specific practices while taking advantage of the data management and visualization capabilities of StrandNGS. Also, the aligned files could then be used for all downstream analyses available in StrandNGS. 2. Use pre-packaged R-scripts for multiple differential expression analyses (using external R packages) in the same experiment. This eliminates the need for preparing the data set multiple times to suit the input needs as required by various packages. 3. Write custom scripts to perform vital steps in the workflow. Given that sequencing data is primarily used for answering a myriad of biologically relevant research questions, no software could singularly provide all options readily. Therefore, this option helps researchers to dynamically customize the software for their specific use. Moreover, one can also integrate these scripts in a custom pipeline to either perform additional analysis or replace existing techniques with the pertinent latest external techniques to obtain faster and accurate results or interface with third-party tools. We aim to showcase the technical strengths and robustness of StrandNGS which enables effortless and smooth integration of customized scripts in to the tool. This all-encompassing ability of StrandNGS ensures that multidisciplinary research teams can make the best use of their space, time, and resources to answer diverse biological research problems through a collaborative utilization of this integrated platform.

**Comparison of African genome resource and 1000-Genomes imputation.** *M. Schmidt<sup>1</sup>, B. Kunkle<sup>1</sup>, K.L. Hamilton-Nelson<sup>1</sup>, M. Jean-Francois<sup>1</sup>, F. Rajabli<sup>1</sup>, A.J. Griswold<sup>1</sup>, G. Beecham<sup>1</sup>, G.D. Schellenberg<sup>2,4</sup>, C. Reitz<sup>2</sup>, M.A. Pericak-Vance<sup>1</sup>, E.R. Martin<sup>1,3</sup>.* 1) University of Miami, Leonard M. Miller School of Medicine Dr. John T. Macdonald Foundation Department of Human Genetics Miami, FL; 2) Columbia University; 3) Alzheimer's Disease Genetics Consortium (ADGC); 4) University of Pennsylvania, Perelman School of Medicine.

The African Genome Resource (AGR, S. McCarthy et al. 2016) recently released a data from a large sample of African individuals to help improve imputation in individuals with African ancestry. The goal of our investigation is to determine if AGR works better for imputing African genomes than the widely used 1000 Genome Project (1KGP, The 1000 Genome Project Consortium, 2015). In addition we also investigate the impact of SNV confidence thresholds, “.gen” probability cutoffs and minor allele frequency (MAF) on the accuracy of the imputed data. We selected a group of individuals with African heritage from the Alzheimer's Disease Genetics Consortium (ADGC) that were genotyped with genotype-wide arrays (GWAS), whole genome sequencing (WGS) and whole exome sequencing (WES). Using genotype array data as a backbone, genotypes were imputed twice, once using the 1KGP reference panel and the AGR. In each imputed set, we separated positions into two disjoint groups, GWAS-only and purely imputed positions. Then we intersected the positions of all three sets, AGR, 1KGP with either WGS or WES to determine the positions common to all. For both groups, imputed and GWAS, we conducted a pairwise comparisons between all three sets to determine concordance. Our results show the concordance of the GWAS data and of the purely imputed data versus the sequencing data under various thresholds and MAFs. Initial results on chromosome 22 show that AGR yields better quality results for subjects with African ancestry.

**1626W**

**Quantifying the unknown unknowns in molecular genetic assays.** *D. Siegel<sup>1</sup>, O. Le Tonqueze<sup>1</sup>, A. Biton<sup>1,2</sup>, D. Erle<sup>1</sup>, N. Zaitlen<sup>1</sup>.* 1) University of California, San Francisco, San Francisco, CA; 2) Pasteur Institute, Paris, France.

Transformative advances in molecular technologies, such as massively parallel reporter assays (MPRAs) and CRISPR screens, can efficiently characterize the effects of genetic and genomic variation on cellular phenotypes such as gene expression, growth, and chemical resistance. These technologies complement genetic association studies by providing direct identification of causal factors, an important step towards mechanistic understanding. To date, analyses have proceeded in a bottom-up fashion, identifying individual genomic regions or genetic variants that perturb phenotypes of interest. In this work, we seek to determine the overall contribution of sequence variation to phenotypic variation in massively parallel experiments and to demonstrate how this can lead to an improved understanding of mechanistic biology. To achieve these goals we developed a method to determine the fraction of variance in molecular assays explained by the included sequences, as opposed to other sources of variability such as technical factors and statistical noise. We can apply this method to the entire assay, akin to estimating the “heritability” of the experiment; or to subgroups of sequences, akin to enrichment analyses for regions of interest. We have applied this approach to several simulated and real data sets. In our MPRA for 3'UTR function (Fast-UTR), we show that 63% of the variance in phenotype (reporter RNA level) is explained by sequence variability; while at most 10% can be explained by any single known 3'UTR category. That is, the function of the 3'UTR is mostly unknown. Then we show that the flanking sequence of a known 3'UTR functional element (an AU-rich element (ARE)) accounts for 16% to 56% of the variance of the effect of a killer mutation, depending on the length of the ARE. This illustrates the critical importance of genetic context to the effect size of a mutation. Finally we will discuss the applicability of this method to related assays like CRISPR screens. Our method is implemented as a free and open source software package and can be used in any barcoded molecular assay, as it is based on holding out or resampling over barcoded clones within a dataset, and it does not require parametric model assumptions. Going forward, this method will set an upper limit to the expected performance of prediction methods, and provide a better estimate of the relative importance of various classes of motif- and sequence-based factors in massively parallel experiments.

**1627T**

**A fast and accurate open-source variant caller.** *M.A. Simpson<sup>1</sup>, S. Thiem<sup>1</sup>, A. Dorr<sup>1</sup>, E. Sanders<sup>1</sup>, A. Rimmer<sup>1</sup>, J. Penn<sup>2</sup>, X. Bai<sup>2</sup>, J.G. Ried<sup>2</sup>, S. Teasdale<sup>1</sup>, A. Heger<sup>1</sup>, G. Lunter<sup>1</sup>.* 1) Genomics plc, Oxford, United Kingdom; 2) Regeneron Genetics Center, Tarrytown, NY, USA.

The use of short-read sequencing for whole exome and whole genome analysis is now routine for genetic research and clinical applications. The accurate identification and genotyping of positions at which an individual's genome varies from the reference genome is a critical step in drawing inference from such data. In addition to accuracy, as sample sizes grow to hundreds of thousands of individuals there is a requirement for computationally efficient approaches to variant calling. Whilst many solutions for variant calling have been developed in academia and industry, they are often either limited by accuracy or by computational performance, inhibiting deployment across many thousands of genomes. *weCall* is an open-source variant caller developed by Genomics plc. *weCall* capitalises on highly performant algorithm to enable variant detection and genotyping of aligned short read sequencing data with low CPU, memory and I/O usage while achieving high accuracy. The software, implemented in C++11, undertakes local re-alignment of sequencing reads, identifies and handles duplicate reads, calls and determines the locally phased genotypes of variant positions, and performs quality filtering, all in a single pass of an input BAM file. The performance of *weCall* has been evaluated internally by Genomics plc and externally as part of a beta testing program. It consistently outperforms other variant calling approaches in terms of sensitivity, specificity of detection and genotyping SNPs, MNPs and notably short (<80 bp) indels. In addition, *weCall* is able to call larger indels up to ~100 kb by analysing read pairs, which further helps to improve the specificity of SNP calling. *weCall* will be the primary variant calling tool deployed in the Regeneron Genetics Center-led consortium to exome sequence the UK Biobank participants.

**Sharing aggregate genomic data on the web: re-engineering and extending the gnomAD browser.** *M. Solomonson<sup>1,2</sup>, N. Watts<sup>1,2</sup>, T. Singh<sup>1,2</sup>, H. Huang<sup>1,2</sup>, F.K. Satterstrom<sup>1,2</sup>, B. Weisburd<sup>1,2</sup>, K.J. Karczewski<sup>1,2</sup>, M.J. Daly<sup>1,2</sup>, D.G. MacArthur<sup>1,2</sup>.* 1) Analytic and Translational Genetics Unit (ATGU), Massachusetts General Hospital, Boston, MA, USA; 2) Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA.

Increasing the accessibility of aggregate genomic data can have an immediate impact on human health. For example, online access to variant frequency resources such as ExAC and gnomAD has proven critical for gene discovery and diagnosis in rare disease. As genomic resources continue to grow in scale and complexity, it is becoming increasingly challenging to engineer and maintain the technical infrastructure necessary to share them with the broader community. A centralized, community-driven, open-source suite of developer tools is needed for the construction of portals that share and display aggregate data of diverse types. Such tools should include a library of robust, modular web components geared for data visualization which serve as elemental building blocks in the creation of complex web applications. This toolkit must support extremely large genomic datasets stored in the cloud and should integrate with scalable genomic analysis software. Here, we describe a general framework for sharing aggregate genomic data on the web. We showcase the framework by demonstrating a suite of portals, beginning with an updated version of the gnomAD browser. We have re-engineered the gnomAD browser, future-proofing it for an eventual dataset of more than 1 million exomes and genomes. We also present the SCHEMA consortium exome results browser, which displays summary statistics from a case-control sequencing study of over 25,000 schizophrenia exomes and 50,000 controls. The exome results browser is designed to be extendable to other large-scale genotyping and sequencing studies of other disorders. Finally, we present a prototype for dbLoF, a catalogue of loss-of-function variants and associated phenotypic data from large human populations, for leveraging gene-inactivating mutations to explore the function of uncharacterized human genes.

**1629W**

**Systematic discovery of conservation states for single-nucleotide annotation of the human genome and variant interpretation.** A. Sperlea, J. Ernst. University of California, Los Angeles, Los Angeles, CA.

Effectively annotating the non-coding human genome is a key challenge to being able to interpret and prioritize potential disease associated genetic variants. Comparative genomics based annotations have been an important source of information for whole genome annotation, but have focused primarily on scores or binary elements of evolutionary constraint. In this work we present a novel computational method, ConsHMM, for systematically annotating entire genomes into one of a number of different 'conservation states'. ConsHMM learns 'conservation states' based on the combinatorial and spatial patterns of which species align to and match a reference genome in a multiple-species DNA-sequence alignment using a multivariate hidden Markov model. We applied this approach to a number of different whole genome multiple species alignments, including a 100-way vertebrate alignment annotate the human genome at single nucleotide resolution into one of 100 conservation states. ConsHMM states show diverse enrichments for orthogonal genomic annotations. Both locations called as constrained and those called as non-constrained by existing constraint measures are heterogeneous in their assigned conservation state. Conservation states also had greater or complementary information than constraint scores or elements for predicting external annotations. Specific conservation states exhibited enrichments for common human variants, while a different set of states exhibited enrichments for variants in the Genome-Wide Association Studies catalog relative to common variation. We demonstrate that bases within constrained elements can have substantially different enrichments for phenotype-associated heritability depending on which set of conservation states they overlap. We also show how the conservation state annotations help clarify the relationship between inter-species constraint and the recently introduced context-dependent tolerance score for identifying intra-species constraint, which were previously reported to have limited overlap. We identify conservation states that strongly enrich for bases prioritized by both approaches as well as uniquely by each approach. In addition to annotating the reference genome, we developed an approach to accurately estimate the conservation state assignment for every possible nucleotide at every base in the genome. These variant specific conservation states give additional information to identify and interpret potential disease-associated variants.

**Quality assessment and comparison of exome data from neonatal dried blood spot DNA with whole blood data.** U. Sunderam<sup>1</sup>, K. Kundu<sup>1</sup>, A.N. Adhikari<sup>2</sup>, Y. Wang<sup>2</sup>, D. Vaka<sup>3</sup>, R.J. Currier<sup>2</sup>, J.M. Puck<sup>2</sup>, P-Y. Kwok<sup>2</sup>, S.E. Brenner<sup>2</sup>, R. Srinivasan<sup>1</sup>. 1) Tata Consultancy Services, Hyderabad, TS, India; 2) University of California, Berkeley, CA, USA; 3) University of California, San Francisco, CA, USA.

Several countries and American states routinely collect and store neonatal dried blood spots (DBS) through their newborn screening (NBS) programs. These archived collections of DBS provide a potential DNA and analyte source for a large cohort of healthy and affected individuals for scientific inquiry. In order to use DBS samples for DNA analysis, including variant discovery, the quality of the DNA sequence obtained from these should be comparable to those from whole blood. In our study, we compared the DNA sequence quality of exomes of a large cohort of 180 DBS archived between 2006 and 2011 with that of 35 whole blood samples sequenced between 2013 and 2014 at the same facility. The de-identified DBS were obtained from the California Department of Public Health under an approved IRB protocol. In the absence of matched samples, we performed an extensive analysis to assess the quality of DNA extracted from DBS. We compared 16 metrics that can be categorized broadly into 3 categories - evaluation of how effectively the reads mapped to the reference genome, the degree of DNA damage, and assessment of the variants that were ultimately called for the samples. Additionally, we evaluated these parameters for a smaller set of DBS samples that were archived between 1980 and 1982, and had been stored for over 30 years. Our assessment showed that DNA sequenced from DBS mapped with similar efficiency as reads from whole blood, while considering parameters such as number of unmapped reads, reads mapped to different chromosomes, uniformity of coverage, and gene level coverage. The overall DNA damage rates, measured by the mismatch rate with the reference genome, were also comparable across the 3 sets of samples. While examining single nucleotide changes that may have arisen from DNA damage related nucleotide mis-incorporation, the A>T and T>A changes were higher in the DBS samples. However, this does not appear to have impacted the accuracy of variant calling. DBS samples yielded a comparable number of high quality SNVs and comparable numbers of indels were observed in samples sequenced with at least 50x coverage. The Transition-Transversion ratios were found to be comparable and in the expected range indicating adequate quality of the variants. Overall, we conclude that dried blood spots, stored desiccated and at -20 degrees C, provided exomes of sufficient quality for clinical interpretation.

**Construction and benchmarking of a multi-ethnic reference panel for the imputation of the HLA.** *M. Wendorff, F. Degenhardt, M. Wittig, A. Franke.* Institution of Clinical Molecular Biology, Christian-Albrechts-University of Kiel, Kiel, Schleswig-Holstein, Germany.

Genotype imputation of the human leukocyte antigen region (HLA) is a cost-effective means to infer classical HLA alleles from inexpensive and dense SNP array data. In the research setting, imputation helps to avoid costs for wet lab-based HLA typing and thus renders association analyses of the HLA in large cohorts feasible. Yet, most HLA imputation reference panels are targeting Caucasian ethnicities and multi-ethnic panels are scarce. Here, we present a high-quality multi-ethnic reference dataset based on genotypes measured with Illumina's Immunochip genotyping array including samples from Europe, China, India, Iran, Japan, Korea, Malta and an admixed African American dataset. We HLA-typed more than 1,300 samples from the afore-mentioned eight different ethnic groups using a high-resolution next generation sequencing approach. Manually curated 4-digit level alleles for the classical HLA class I and II loci were included in the reference panel. Using extensive cross validation and different combinations of reference datasets, we benchmarked the imputation using the HLA imputation tool HIBAG across our multi-ethnic reference and an independent, previously published, dataset for the subpopulations of the 1000 Genomes project. We combined HLA data from 1000 Genomes with our multi-ethnic reference to create references with a full 4-digit HLA context for our own multi-ethnic samples alone and at G group level for the combined dataset for all classical HLA class I and II genes as well as the *HLA-DRB3/4/5*. We achieve high average imputation accuracies across *HLA-A*, *-B*, *-C*, *-DQA1*, *-DQB1*, *-DPA1*, *-DPB1*, *-DRB1* and the *-DRB3/4/5* within a 5x cross-validation framework with our own multi-ethnic data and the 1000 Genomes data. We also present an overview of the current literature on *HLA-DRB3/4/5* and show that the imputation of these loci should be considered with care. In conclusion, our new multi-ethnic reference dataset allows for high resolution HLA imputation for all of the classical HLA class I and class II genes as well as the *HLA-DRB3/4/5* for different ethnicities.

**Introducing Aneris: A hadoop cluster for bioinformatics at scale.** *N.R. Wheeler<sup>1</sup>, M. Warfe<sup>2</sup>, W. Bush<sup>1</sup>.* 1) Institute for Computational Biology, Department of Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 2) Institute for Computational Biology, Division of University Technology, Case Western Reserve University, Cleveland, OH.

Human genetics datasets are expanding in size, variety, and number at an accelerating rate, and the integration of multiple data types is becoming a more critical component of genetics research. For example, the Alzheimer's Disease Sequencing Project is generating whole-genome sequencing data on thousands of individuals across multiple studies, many of which have orthogonal high-dimensional data of their own like gene expression and neuroimaging values. While the accumulation of biological data of this magnitude presents lucrative opportunities for data analysis, it also creates new burdens for data storage, manipulation, and processing. Just as novel analytical approaches help to address the new statistical issues inherent to these datasets, new data processing and analytical systems are needed to handle this incoming deluge of data, all while maintaining the reproducibility of scientific studies at scale. Here we demonstrate a scalable analytics platform we call ANERIS based on the Hadoop software ecosystem, which addresses these challenges through the application of feature rich and widely used open source technologies. By leveraging distributed storage and processing across a cluster of powerful computational nodes, bioinformatics questions can be asked interactively, providing useful insight from large-scale data at unprecedented speeds. ANERIS provides researchers the ability to work collaboratively across numerous and massive biological datasets in ways that would not be possible with conventional computational methods. Building upon the open-source HAIL software, currently supported applications include the storage and retrieval of large datasets, effortless GWAS style statistical modeling, and fast SQL table operations for variant annotation processing. Extended operations with Spark enable annotation-based analyses to run orders of magnitude faster, with sequences of operations that take several days using traditional SQL processing being completed in only minutes on ANERIS. Presently, over 90TB of data has been uploaded and formatted for easy access by researchers for downstream processing and use in reproducible genomic studies. Taken together, the shift from serial analysis operations to distributed parallel processing provides more stable, rapid, and reproducible workflows for genomic and bioinformatics data processing.

**A computational approach to detect site specific change in read patterns from high resolution sequencing assays.** *N. Yamada, S. Mahony.* Department of Biochemistry & Molecular Biology, Pennsylvania State University, University Park, PA.

Recent developments in high throughput sequencing assays enable us to profile biological activities genome-wide. Genome-wide sequencing assays such as ChIP-exo and ATAC-seq utilize nuclease digestion with or without chromatin immunoprecipitation. Dense mapping of nuclease cleavage sites identifies small regions protected from digestion by the presence of a bound transcription factor. We seek to take advantage of DNA footprint shapes and perform analysis beyond finding peak locations and signal strength in high resolution sequencing assay technology data. Specifically, we develop a computational method to detect site specific change in DNA footprinting shape and read enrichment levels in different biological conditions such as development stages and disease and healthy conditions. Such analysis will define a set of factors that are responsible for changing biological activities and provide us per site quantification of the molecule activity differences. Our computational analysis method may provide novel insights into precise regulatory elements interactions exist in the genome.

**KMgene: A unified R package for gene-based association analysis for complex traits.** *Q. Yan<sup>1</sup>, Z. Fang<sup>2</sup>, W. Chen<sup>1,2</sup>.* 1) Division of Pulmonary Medicine, Department of Pediatrics, Children's Hospital of Pittsburgh of UPMC, University of Pittsburgh, Pittsburgh, PA; 2) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA.

The gene-based tests are becoming an attractive complement to the single variant tests used in GWAS. Compared to single variant tests, gene-based tests are able to identify weak individual signals by combining the effects of variants in the same gene, and greatly reduce the number of multiple testing. One widely used gene-based test is the sequence kernel association test (SKAT) based on a Kernel Machine (KM) regression framework. Although SKAT was first developed for testing rare variants, it could be easily applied to common variants. After SKAT was introduced for testing independent samples with continuous and binary traits, a number of methods and corresponding tools have been developed to extend the approach to complex traits, such as familial, multivariate and longitudinal traits. These methods are based on a GLMM framework. Since SKAT has imbalanced power performance when the single variant effects are in the same direction (i.e., all rare alleles are risk or protective) or in different directions, the optimal version, SKAT-O, was developed to balance these two scenarios. However, most of the extended SKAT methods do not consider the optimal tests balancing genetic effects. In addition, those programs have different input and output formats, making it difficult to use in practice for bioinformaticians with limited genetics knowledge. Therefore, in this report, we introduce KMgene, a one-stop solution that combines SKAT-type methods for complex traits and extends them to include their corresponding optimal tests. KMgene can perform association tests between a set of genetic variants and familial, multivariate, longitudinal or survival traits.

**1635W**

**Homozygosity mapping provides evidence of pathogenicity in recessive Mendelian disease.** *M.N. Wakeling<sup>1</sup>, T.W. Laver<sup>1</sup>, C.F. Wright<sup>1</sup>, E. De Franco<sup>1</sup>, K.L. Stals<sup>2</sup>, A. Patch<sup>3</sup>, A.T. Hattersley<sup>1</sup>, S.E. Flanagan<sup>1</sup>, S. Ellard<sup>1,2</sup>, DDD Study.* 1) Institute of Biomedical and Clinical Science, University of Exeter, Exeter, England, United Kingdom; 2) Department of Molecular Genetics, Royal Devon & Exeter NHS Foundation Trust, Exeter, UK; 3) QIMR Berghofer, Herston, Queensland, Australia.

One of the greatest challenges currently facing those studying Mendelian disease is identifying the pathogenic variant from the long list produced by a next generation sequencing test. The ACMG guidelines provide a framework for variant classification using all available evidence. Homozygosity mapping has been previously used to guide the identification of pathogenic variants in recessive disease in consanguineous populations. Using 179 homozygous pathogenic variants from three independent cohorts, we investigated the predictive ability of homozygosity mapping for identifying the regions likely to contain the causative variant. We demonstrate that pathogenic variants are not randomly distributed among the regions of homozygosity, but are disproportionately likely to be found within the largest regions of homozygosity. The size and rank of the region of homozygosity can thus be used as supporting evidence of pathogenicity. The maximal predictive power is achieved in patients with <8% homozygosity and variants >3Mb from a telomere, this gives an AUC of 0.735 and results in 92% of the causative homozygous variants being in one of the top 10 largest regions of homozygosity in a sample. Only 62% of benign rare homozygous variants fulfil the same criterion. This predictive power is comparable to SIFT or PolyPhen. The number and size of homozygous regions within an individual's genome is influenced both by ancestral population effects and by recent consanguineous events. It is important to differentiate the two cases as disease causing variants are likely to be in regions of recent homozygosity – variants in ancestral regions of homozygosity have been exposed to selection in a homozygous state for sufficient time for selection to act on them. Ancestral regions of homozygosity are likely to be smaller than homozygous regions which are the result of recent consanguinity. This can explain why variants which cause recessive Mendelian disease are contained in the largest regions of homozygosity. This method can be used to prioritize the list of candidate variants in gene discovery studies. When classifying a homozygous variant using the ACMG guidelines, the size and rank of the region of homozygosity in which the candidate variant is located can be considered as supporting evidence for pathogenicity.

**1636T**

**Limit of detection study of targeted sequencing for germline copy number variation.** *Q. Cai, T. Kuang, X. Meng.* WuXi NextCODE, Shanghai, Shanghai, China.

The whole exome or panel based NGS method is promising to detect the copy number variation (CNV) of exons due to its low cost comparing to whole genome sequencing. However, methodological difficulties still exist considering biases during library construction and sequencing process. Barely a study worked carefully to assess the factors that influence the detection limit of the method. When it comes to clinical diagnostic applications, the detection limit of the CNV types across the whole panel and its validation is demanding for genetic counselors and doctors to make accurate diagnosis. We developed a CNV detection software iConer: it integrated multiple depth-of-coverage methods to achieve a high sensitivity; it also incorporated B-allele frequency information to filter out false positives. With further clinical phenotype information, 100% precision could be achieved. Five main factors were included to investigate the CNV calling accuracy: CNV length, ploidy, sequencing depth, batch effect, and pseudogene. In total, 10 samples with spike-in CNVs, 25 CNV positive cell line samples, and 67 clinical blood/saliva samples were used for validation in this study. According to the results: 1) CNV length: for the 10 Mb panel with average read depth 150x, sensitivity increased with the CNV length; > 90% sensitivity could be achieved for CNV length > 5 kb, and ~100% sensitivity could be achieved for CNV length > 100 kb; 2) Ploidy: deletion was easier to be called than duplications; homologous/heterozygous deletion was detected as small as 500 bp/5 kb with ~100% sensitivity, respectively; the detection limit for duplications was about 100 kb with ~100% sensitivity. 3) Sequencing depth: at least 100x average coverage was required for effective CNV calling at single exon level; 4) Batch effect: the results varied a lot due to different evenness among batches; thus, quality controls were introduced before the pipeline; 5) Pseudogene: The mapping problem of pseudogenes could be mitigated by using more specific genomic markers on or near the target regions. In conclusion, our study provided an accurate CNV calling pipeline for targeted sequencing data and valuable assessment of the factors that influence the limit of detection of the method.

**1637F****Exome CNV calling improves diagnostic yield in rare disease families.**

*K.R. Chao<sup>1,2,4</sup>, J.K. Goodrich<sup>1,2,4</sup>, A.S. Lee<sup>6,7</sup>, M. Babadj<sup>6</sup>, S.K. Lee<sup>8</sup>, A. Smirnov<sup>6</sup>, M. Lek<sup>3</sup>, H.L. Rehm<sup>1,2,4</sup>, D. MacArthur<sup>1,2,4</sup>, A.H. O'Donnell-Luria<sup>1,2,4,5</sup>.* 1) Broad Institute Center for Mendelian Genomics, Broad Institute of MIT and Harvard, Cambridge, MA; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 3) 16 Department of Genetics, Yale School of Medicine, New Haven, Connecticut, USA; 4) Center for Genomic Medicine, Massachusetts General Hospital, Boston, MA; 5) Division of Genetics and Genomics, Boston Children's Hospital, Boston, MA, USA; 6) Department of Neurology, Children's Hospital Boston, Boston MA; 7) Department of Neurology, Harvard Medical School, Boston, MA; 8) Methods Group, Data Sciences Platform, Broad Institute of MIT and Harvard, Cambridge, USA.

The Broad Institute Center for Mendelian Genomics (CMG) has sequenced over 2,600 families with rare genetic diseases since 2016. A diagnosis has been identified for 27% of these families through exome analysis of rare single nucleotide variants (SNVs) and small indels. Additional copy number variant (CNV) analysis may contribute to diagnosis of families that remain unsolved after initial exome analysis. Traditionally, CNVs that are too large to be identified through standard exome analysis have been detected using array comparative genomic hybridization (CGH) or whole genome sequencing (WGS). However, the combination of small indel detection during standard exome analysis and large CNV detection via array testing fails to capture a class of mid-sized CNVs. A number of tools (xHMM, CoNIFER, CNVnator, etc.) have been developed in the past few years to detect medium sized CNVs in whole exome sequencing (WES) data. GATK's new CNV tool, the Germline CNV (gCNV) caller, incorporates and improves upon many features of these existing tools and uses a probabilistic framework to infer both rare and common CNVs from read depth data in the presence of systematic bias. The Broad CMG ran gCNV on over 5,000 samples from 20 different rare disease cohorts. After applying modest CNV quality score filtration, gCNV detected an average of 25 CNVs per exome. gCNV diagnosed 22 previously unsolved cases and found an additional 23 candidates across the CMG cohorts by detecting two duplications and 45 deletions, including several that involved only a single exon. The CNVs ranged from 122 base pairs to 356,701 base pairs in size and involved a median of two exons. Due to their relatively small size, the majority of the pathogenic CNVs called by gCNV would not have been found by standard clinical CGH arrays. In addition, WGS validated several CNVs, and defined breakpoints, but was not required to detect any of the CNVs in these samples. Our results with gCNV demonstrate that exome CNV callers can increase diagnostic yield for existing WES data for individuals that remain undiagnosed after standard analysis approaches, providing a more comprehensive approach, with higher sensitivity, than ordering a separate array, and a more cost-effective option than moving directly to whole genome sequencing.

**1638W**

**A public benchmarking resource of 194,731 CNV calls generated from a combination of short reads, linked long reads and true long read technologies.** *X. Chen<sup>1</sup>, S. Chen<sup>1</sup>, A. Gross<sup>1</sup>, F.J. Sedlazeck<sup>1</sup>, M. Bekritsky<sup>1</sup>, DR. Bentley<sup>1</sup>, MA. Eberle<sup>1</sup>.* 1) Illumina Inc., San Diego, CA; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

High throughput whole-genome sequencing (WGS) allows for rapid identification and classification of all variant types. While high quality benchmarking datasets exist for small variants such as SNPs and indels, the ability to systematically call structural variants and copy number variants (CNVs) is less well characterized since we lack high quality benchmarking datasets. To address this problem for CNVs, we have developed a targeted software pipeline that genotypes previously characterized common CNVs. This approach consists of several stages. First, we aggregate reads across multiple samples to refine the variant boundaries. We then perform targeted calling using these refined boundaries by normalizing read counts against a baseline of reference samples negative for each variant. We test the variant calls using Mendelian errors and Hardy Weinberg Equilibrium (HWE) across the 17-member Platinum Genomes pedigree, 50 Polaris trios and 957 samples of European ancestry. We show the utility of this method by analyzing 3,818 CNVs called in these 1,124 samples by Canvas/Manta and an additional 46 CNVs independently identified from PacBio data in NA12878. 2,441 of these CNVs were common enough that they could be positively assessed by Mendelian inheritance and HWE tests. Of these, we identified 2,083 deletions (257 longer than 10kb) and 146 duplications (64 longer than 10kb) that pass both validations. To further validate these CNVs, we also sequenced 87 of these samples using linked reads produced by the 10x Chromium platform and use the per-haplotype depth as an additional validation of our calls. For example, a deletion should only have reads from one haplotype in the deleted region. Among the CNV calls in these samples, the median ratio between read counts of the minor and major haplotype is 0.014, 0.858 and 0.548 for heterozygous deletion (CN1), reference (CN2) and duplication (CN3) calls, respectively, consistent with their copy number states (one haplotype deleted, both haplotypes present, and one haplotype duplicated). Of the samples analyzed here, 313 are consented for public release and the raw sequence data (40x depth HiSeqX data for all samples and an additional 30x depth linked read data for 87 samples) and their CNV calls are publicly available as a community resource (<https://github.com/Illumina/Polaris>). This CNV truth set includes 194,731 total CNV calls and is a valuable public resource for algorithm benchmarking and clinical genetics research.

**Genome-wide structural variant identification from PromethION long read sequencing data.** *W. De Coster<sup>1</sup>, A. De Roeck<sup>1</sup>, T. De Pooter<sup>2</sup>, S. D'Herf<sup>2</sup>, P. De Rijke<sup>2</sup>, M. Strazisar<sup>2</sup>, C. Van Broeckhoven<sup>1</sup>.* 1) Neurodegenerative brain diseases group, Center for Molecular Neurology, VIB & University of Antwerp; 2) Neuromics Support Facility, Center for Molecular Neurology, VIB & University of Antwerp.

The Oxford Nanopore PromethION is an emerging platform for affordable long read whole genome sequencing, including human genomes. Long read sequencing enables structural variation detection with unprecedented resolution, especially in repetitive regions complicating their discovery using currently dominant short read sequencing technologies. For benchmarking of the device and evaluation and development of bioinformatic tools we have sequenced the Yoruban reference genome NA19240 to 80x coverage. We discuss the characteristics and accuracy of the obtained data and the results of a de novo assembly. Making use of the plethora of sequencing and variant data available for this individual we evaluate alignment and structural variant calling software and describe their performance. Additionally, we provide a flexible and efficient computational workflow for cohort-based genome-wide structural variant detection and annotation from long read datasets integrating multiple state-of-the-art tools and provide recommendations for its application in identification of pathogenic structural variation.

**1640F**

**Comprehensive benchmarking of structural variant callers.** *R. Littman<sup>1</sup>, S. Mangul<sup>1</sup>, V. Sarwal<sup>1</sup>, M. Distler<sup>2</sup>, E. Eskin<sup>1</sup>, J. Flint<sup>2</sup>.* 1) Computer Science Dept, UCLA, Los Angeles, CA; 2) Semel Institute for Neuroscience and Human Behavior, UCLA, Los Angeles, CA.

Structural variance (SV) in genomics including insertions, deletions, copy number variation, translocations, and inversions, have varying pathogenicity of disease. The detection of these variants is necessary for both the detection and treatment of disease. Currently there are no benchmarking studies available, making it difficult to choose proper SV discovery software. The wide spectrum of effects of SV in the genome provides a necessity to discover the most accurate SV detection software. We compared over 70 SV detection tools' abilities to detect deletions, to determine which tools have the best sensitivity and precision. We detected the performance of these tools on 8 different strains of inbred mice in which all SV on chromosome 19 have been detected and confirmed by PCR. Since we have high coverage on these mouse strains we have been able to subsample our data with varying coverage (54x - 1.5x), to determine the effects of coverage on each tool's accuracy. We randomly subsampled ten times to increase the validity of our results. We determined the resolution of each tool by varying the resolution threshold by 100, 1000, and 10,000 base pairs of our gold standard. The resolution is determined as the distance between the gold standard deletion coordinate and that determined by the computation method. As we increase the required distance from the gold standard, generally precision decreased, and sensitivity increased. Generally as coverage increased, precision decreased, and sensitivity increased. The effect of coverage was much more significant between 1.5x and 22x, rather than between 22x and 54x. Many methods reach sensitivity of 100% with precision of 0%, these tools have both a high true positive and false positive rates. Clever is the only sv tool that has a good balance between sensitivity and PPV. Many other tools have high sensitivity, and low PPV, or low sensitivity and high PPV. Our recommendations can help researchers choose the best SV detection software, as well as inform the developer community of the challenges of SV detection, especially with regard to low coverage WGS data.

**1641W**

**FusorSV: An algorithm for optimally combining data from multiple structural variation detection methods.** A. Malhotra, L. Lochoovsky, C. Lee. Jackson Laboratory for Genomic Medicine, Farmington, CT.

Despite the large scope and potential for critical impact on human biology Structural Variations (SVs) remain poorly characterized primarily due to the lack of comprehensive methods for SV detection. To the best of our knowledge, no algorithm comes close to identifying all types of SVs and across all size ranges in human genomes. For example, DELLY and LUMPY appear similar in methodology and produce very similar deletion calls but diverge significantly for inversion calls. To overcome this issue, more recently, certain genome consortia studies have combined multiple SV-calling algorithms into a single pipeline to generate a unified SV callset comprising of primarily overlapping calls. However, the optimized way to combine SV calls from multiple algorithms still remains unclear. As a solution we present Structural Variation Engine (SVE), a computational infrastructure that currently includes an ensemble of eight popular SV calling methods and a novel algorithm – *FusorSV* to merge the SV calls from the ensemble. *FusorSV* employs a data-mining approach to characterize the performance of a group of SV callers against a given truth set. The aim is to select all possible combinations of callers that satisfy a performance threshold. By utilizing 27 deep-coverage human genomes from the 1000 Genomes Project we developed a data fusion model for merging SVs. For these 27 genomes, we identified 843 novel SV calls that were not reported by the 1000 Genomes Project. Experimental validation of a subset of these calls yields a validation rate of 86.7%. These results highlight the power of the *FusorSV* approach and we believe that it has the potential to become a new gold standard for SV calling from short read whole genome sequencing datasets. Currently we are planning to add features to *FusorSV* that will make it easy for users to use any reference genome. *FusorSV* will then be useful for analyzing newer hg38-based datasets as well as model organisms such as the mouse. Furthermore, we wish to train a new *FusorSV* model using newer truth datasets, with a particular focus on using more comprehensive set of SV calls predicted using long read sequencing data. We will deeply investigate the integration of new SV calling methods and the interplay amongst the method to develop a more lightweight version *FusorSV* that can be applied at scale to thousands of genomes. Finally, we will explore the use of machine learning in *FusorSV*'s SV scoring and merging methods to improve performance.

**SV-INFERNO: A Spark based pipeline for INFERRing the molecular mechanisms of NONcoding structural variants.** E.E. Mlynarski<sup>1,2,3</sup>, A. Amlie-Wolf<sup>1,2,3,4</sup>, P.P. Kuksa<sup>1,2,3</sup>, O. Valladares<sup>1,2,3</sup>, G.D. Schellenberg<sup>1,3</sup>, L.-S. Wang<sup>1,2,3</sup>. 1) Penn Neurodegeneration Genomics Center, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA., Select a Country; 2) Institute for Biomedical Informatics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 3) Department of Pathology and Laboratory Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 4) Genomics & Computational Biology Graduate Group, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA.

The GTEx consortium recently demonstrated that noncoding structural variants (SVs) can substantially alter gene expression and are enriched at regulatory elements, highlighting the importance of noncoding SVs in disease pathology. However, such noncoding SVs are poorly understood in part because the few tools available for SVs primarily focus on protein coding genes or previously reported variants, and largely ignore potentially causal noncoding structural variants. Here we introduce SV-INFERNO, the first Spark-based annotation and analysis pipeline for structural variants. SV-INFERNO expands upon our INFERNO method (<http://inferno.lisanwanglab.org/>), which provides a principled approach to harmonize information from diverse data sources across tissues types using a tissue categorization system to prioritize causal noncoding single nucleotide variants and identify the affected regulatory mechanisms, tissue contexts, and target genes in a hypothesis-free manner. Spark, coupled with the INFERNO tissue categorization schema, enables us to efficiently query millions of SVs in a distributed manner against >300 functional genomic datasets in parallel. The pipeline currently includes the following data sources and we will continue to integrate new functional datasets as they become available: enhancers from the Roadmap Epigenomics and FANTOM5 consortia; GTEx eQTLs; TFBS from HOMER and Factorbook; ncRNAs from DASHR (Database of small RNAs, <http://dashr2.lisanwanglab.org/>); and predicted miRNA binding sites from TargetScan. SV-INFERNO converts the SV-annotation queries to Spark RDDs and uses distributed Spark join operations to efficiently identify loci with multiple types of overlapping functional annotations in a tissue context specific manner. The Spark RDDs corresponding to each annotation type/source are then joined to form the SV annotation feature matrix for subsequent SV classification and prioritization using the TensorFlow deep learning framework. SV-INFERNO also includes traditional GSEA, pathway and gene network analyses using overlapping protein coding genes +/- the predicted target genes from applicable functional annotation types. SV-INFERNO is implemented in Python/pyspark and will be available as a webserver and as a Docker container that can be run on any Spark cluster (<http://lisanwanglab.org/SV-INFERNO>).

**A novel approach for structural variant calling: Combining data from whole genome next-generation sequencing and optical mapping.** Y. Porat<sup>1</sup>, O. Lev<sup>1</sup>, M. Einhorn<sup>1</sup>, O. Shani<sup>1</sup>, E. Vilain<sup>2</sup>, H. Barseghyan<sup>2</sup>, S. Bhat-tacharya<sup>2</sup>, N. Paz-Yaacov<sup>1</sup>. 1) Genoox, Palo Alto, CA 94306, USA; 2) Center for Genetic Medicine Research, Children's National Health System, Children's Research Institute, Washington, DC 20010, USA.

Structural variant (SV) detection via short-read sequencing is typically characterized by high false-positive rates and considerable uncertainty regarding variant breakpoint position, owing to the size of alterations typically far exceeding the read length. Thus, alignment patterns between short reads and the reference genome often can provide only limited evidence for the existence of a variation. In addition, variant calling and genotyping employ probability inference surrounding combined alignment signals, which carries inherent uncertainty surrounding exact breakpoint positions and confidence. Optical mapping technology for SV detection results in high sensitivity and specificity but often carries limited certainty of breakpoint positions. We validated a novel joint pipeline for SV detection that integrates next-generation sequencing (NGS) raw data with optical mapping-based SV calls using an advanced reference graph structure. By applying the reference graph structure throughout the analytical pipeline, evidences from both technologies can be considered simultaneously to provide increased breakpoint accuracy and confidence. The novel SV-calling pipeline was validated for deletions and insertions larger than 500bp, using sample data and high-confidence SV truth sets available for NA12878 in Genome in a Bottle (GIAB; <http://jimb.stanford.edu/giab>), by comparing NGS-only, optical-mapping-only, and combined technologies calling. Per optical-mapping-only data, 817 deletions and 1,670 insertions had high breakpoint uncertainty (tens of thousands bp). With application of the combined technologies, the uncertainty of accurate breakpoint positions for the 0-75th percentile of the 756 (92.5%) deletions and 1,248 (75%) insertions called was reduced to only 4bp and 140bp, respectively. Further, results of a specificity evaluation using *in silico* simulations on regions that did not overlap the GIAB truth set indicated 99.3% (971/978) specificity for deletions and 94.3% (910/965) for deletions. As such, the respective false-positive rates were 0.7% (7/978) and 5.7% (55/965). A novel joint pipeline integrating NGS raw data with optical mapping provided SV calls characterized by precise breakpoint positions and low false-positive rates, suggesting the advanced graph structure could have considerable utility in clinical practice.

**Precise common and rare germline CNV calling with GATK.** A.N. Smirnov<sup>1</sup>, M. Babadi<sup>1</sup>, S.K. Lee<sup>1</sup>, L.D. Gauthier<sup>1</sup>, M.E. Talkowski<sup>2</sup>, H. Brand<sup>2</sup>, X. Zhao<sup>2</sup>. 1) Broad Institute of MIT and Harvard, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA.

We propose, implement, and evaluate a novel method (GATK gCNV) for the accurate discovery of rare and common copy-number variations (CNVs) from read-depth data derived from either whole exome sequencing (WES) or whole genome sequencing (WGS) data. GATK gCNV particularly outperforms other read-depth methods on whole exome sequencing (WES) data due to a sophisticated Bayesian approach that learns bias factors arising from sequencing and library preparation. GATK gCNV consists of two models - an initial model that infers the ploidy of sex chromosomes and the presence of autosomal aneuploidies, and a primary model that infers bias factors and CNVs, treating GC bias probabilistically and automatically determining the necessary level of model complexity in a data-driven manner. In analyses performed to date, GATK gCNV maintains a high level of sensitivity in common CNV regions due to a hierarchical hidden Markov model used for accurate genotyping of multi-allelic loci. Furthermore, GATK gCNV performs bias modeling and CNV discovery simultaneously and self-consistently, resulting in significantly improved sensitivity and precision. Our implementation of GATK gCNV utilizes the PyMC3/Theano framework for performing automatic differentiation variational inference (ADVI). In addition, GATK gCNV automatically scatters large tasks across multiple machines using the Cromwell/WDL framework, enabling the scalable processing of large cohorts. We have evaluated the ability of GATK gCNV to detect both rare and common coding CNVs in neurodevelopmental disorder cohorts and are continuing the process of benchmarking its sensitivity, precision, and reproducibility for clinical diagnostic applications by direct comparisons to short-read and long-read WGS datasets. GATK gCNV is available in the GATK framework and provides a research tool that could have significant implications for clinical diagnostic genetic testing.

**1645T**

**A deep learning method to increase the accuracy of copy number variation detection from whole-genome sequencing data.** *B. Trost<sup>1</sup>, L. Lee<sup>1</sup>, S. Walker<sup>1</sup>, E.J. Higginbotham<sup>1</sup>, C.M. Nguyen<sup>1</sup>, S.W. Scherer<sup>1,2,3</sup>.* 1) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 3) McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada.

Copy number variations (CNVs) are major sources of genetic diversity and have been associated with many disorders. Several algorithms for detecting CNVs from whole-genome sequencing (WGS) data are available; however, they have high false discovery rates (FDRs), making it difficult to separate true CNVs from false positives. Previously, we identified ERDS and CNVnator as the most accurate read depth-based CNV-detection algorithms and presented a workflow that reduced the FDR substantially with only a modest reduction in sensitivity. Our workflow partially relied on various simple filters for eliminating false positives, such as using only CNVs identified by both ERDS and CNVnator and discarding CNVs rich in repetitive genetic elements. In this study, we hypothesized that a deep learning model could be used to achieve more accurate prioritization of true CNVs. To test this hypothesis, we developed a method called DNN-CNV that uses a deep neural network to separate real CNVs from false positives based on several features: CNV size and type (deletion or duplication), whether a CNV was detected by ERDS and/or CNVnator, read-depth data, and the repeat elements in and around the predicted CNV. Six genomes with corresponding CNV benchmarks were used to train and test our model. DNN-CNV improved upon the accuracy of previous filters for most combinations of CNV size and type and was particularly effective for duplications, which have the highest false positive rate. For instance, DNN-CNV detected 22% more true and 58% fewer false duplications between 10 and 100 kb compared to the best simple filter. For 5-10 kb deletions, DNN-CNV had the same sensitivity as the best simple filter but a lower FDR (13% versus 17%). Besides increasing accuracy, DNN-CNV offers several other benefits: it obviates the time-consuming process of determining appropriate simple filters; it simplifies the filtering process itself by eliminating the need to use different criteria depending on CNV size and type; and it facilitates modifying the sensitivity/FDR balance depending on application-specific requirements. DNN-CNV should thus prove useful for disease-association studies, population-genetics studies, and other work that depends on reliable CNV detection. DNN-CNV is freely available either as a web server or downloadable source code at <http://dnn-cnv.tcag.ca>.

**DeepCNV: A deep learning approach for detecting copy number variants.** *Z. Wei<sup>1</sup>, X. Hou<sup>1</sup>, J. Glessner<sup>2</sup>, M. Khan<sup>2</sup>, P. Sleiman<sup>2</sup>, H. Hakonarson<sup>2,3</sup>.* 1) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ 07102; 2) The Center for Applied Genomics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA 19102.

Copy number variants (CNVs) represent the largest component of structural genomic variations. The recent high-throughput technologies, such as high-density SNP genotyping and DNA sequencing, have made it possible to compressively identify and catalog CNVs. Detection of CNVs has become routine in many genetic studies of disease susceptibility. As a result, many computational methods have been proposed for detecting CNVs. However, it has been shown that the current CNV detection tools still have limited performance, due to the complexity of biological samples, and high level of noise and biases in the high-throughput data. We applied a deep learning approach to overcome these challenges and improving CNV detection performance over existing approaches. To this end, we have compiled a large sample size of manually annotated and validated 4839 CNVs and 9062 controls. We divided these samples into 70:15:15 for training, validation, and testing, respectively. We developed a novel deep neural network named DeepCNV for recognizing CNVs from blood or saliva-derived DNA samples. It is capable of automating feature engineering and eliminates the need of human feature engineering. We obtained an overall AUC of 0.942, MCC of 0.873, and accuracy of 0.943 on the testing dataset. Specifically, for the 788 testing CNVs, DeepCNV has a precision of 0.947, recall of 0.885 and F1 score of 0.915, and a precision of 0.941, recall of 0.974 and F1 score of 0.957 for predicting the 1361 samples. In comparison, SVM using carefully handcrafted features has only an accuracy of 0.905.

**Evaluation of the performance of copy number variation prediction tools for the detection of deletions from whole genome sequencing data.** *W. Whitford*<sup>1,2</sup>, *K. Lehnert*<sup>1,2</sup>, *R.G. Snell*<sup>1,2</sup>, *J.C. Jacobsen*<sup>1,2</sup>. 1) School of Biological Sciences, The University of Auckland, New Zealand; 2) Centre for Brain Research, The University of Auckland, New Zealand.

Whole genome sequencing (WGS) has seen both an increase in popularity and concurrent decrease in cost over the past decade, rendering this approach a viable and sensitive method for variant detection. In addition to its utility for single nucleotide variant detection, WGS data has the potential to detect Copy Number Variants (CNV) to fine resolution. Many CNV detection software packages have been developed which exploit four main types of data: read pair, split read, read depth, and assembly based methods. The aim of this investigation was to evaluate the efficiency of each of these main approaches, including a commonly used combinatorial approach. WGS and CNV location data for the individual NA12878 from the Genome in a Bottle consortium was used as the benchmark dataset. The performance of Breakdancer (read pair), CNVnator (read depth), Delly (read pair and split read), FermiKit (assembly), and Pindel (split read) was assessed by comparing the accuracy and sensitivity of deletion calls  $\geq 1\text{kb}$  made by each software package. There was wide variability in the outputs of the different WGS CNV detection programs. The best performance was seen from Breakdancer and Delly, with 92.6% and 96.7% sensitivity, respectively and 34.5% and 68.5% false discovery rate (FDR), respectively. In comparison, CNVnator, FermiKit, and Pindel were less effective with sensitivities of 66.0%, 15.8%, and 69.1%, respectively and FDR of 69.0%, 31.7%, and 91.3%, respectively. Concordance across software packages was poor, with only 27 of the total 612 benchmark CNVs identified by all five methodologies. The WGS based CNV detection tools evaluated show disparate performance in identifying deletions  $\geq 1\text{kb}$ , particularly those utilising different data input characteristics. Software that exploits read pair based data showed the highest sensitivity, namely Breakdancer and Delly. Breakdancer also displayed the second lowest false discovery rate. Therefore, in this analysis read pair methods (Breakdancer in particular) were the optimal approach for the identification of deletions  $\geq 1\text{kb}$ , balancing accuracy and sensitivity. There is clear potential for improvement in the detection algorithms, particularly in reducing FDR. This analysis has validated the utility of WGS based CNV detection software to reliably identify deletions, and these findings will be of use when choosing appropriate software for CNV detection, for use in both research and diagnostic medicine.

Salit*<sup>14</sup>, *Genome in a Bottle Consortium*. 1) National Institute of Standards and Technology, Gaithersburg, MD; 2) Cancer Genetics and Comparative Genomics Branch, National Human Genome Research Institute, Rockville, MD; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 4) Pacific Biosciences, Menlo Park, CA; 5) Spiral Genetics, Seattle, WA; 6) National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD; 7) Nabsys, Providence, RI; 8) BioNano Genomics, San Diego, CA; 9) 10x Genomics, Pleasanton, CA; 10) Max Planck Institute, Munich, Germany; 11) University of Southern California, Los Angeles, CA; 12) Boston University Medical School, Boston, MA; 13) DNAnexus, San Francisco, CA; 14) Joint Initiative for Metrology in Biology, Palo Alto, CA.

The Genome in a Bottle Consortium (GIAB) has characterized an Ashkenazi trio from the Personal Genome Project (NIST Reference Material 8392) with short, long, and linked read sequencing and optical/nanopore mapping methods. In this open science project, a community of experts has contributed public data and analyses of structural variants (SVs). Experts contributed SV calls from over 30 mapping- and assembly-based variant callers from 5 technologies. Sequence-resolved insertions and deletions were integrated using sequence-based, repeat-aware clustering methods in SVanalyzer. We have evaluated support for the merged calls using svviz with Illumina paired-end and mate-pair reads as well as 10x Genomics and haplotype-partitioned PacBio. We used BioNano and Nabsys to confirm size predictions of large insertions and deletions. We launched the web-based SVCurator.com platform to enable a community manual curation of our candidate SVs. The community has evaluated multiple iterations of draft benchmark SV calls for their utility, which has led to our current benchmark callset with two tiers: (1) ~13,000 isolated, non-complex, sequence-resolved SVs, and (2) ~7,000 likely SV regions that are complex with multiple calls or with unresolved size or sequence. In addition, we have used four diploid assemblies to develop the first "high-confidence regions" for SV benchmarking, covering ~2.7 Gbp of the genome in which our characterization of SVs is close to comprehensive, which allow users to assess false positives as well as false negatives when benchmarking. We have developed a tool truvari to enable users to compare any SV callset to our benchmark calls and regions at a user-defined sequence-based, size-based, or type-based stringency. Calls are annotated as tandem repeat expansions/contractions, mobile element insertions, etc. to enable stratification of performance by variant type, size, and genome context. These results represent a significant step in GIAB work towards improved benchmarking of large variants in research and clinical settings. These benchmarks are already enabling technology and bioinformatics development, optimization, and demonstrations. All data, analyses, and benchmark calls are publicly available and will continue to be improved based on user feedback and as sequencing data and analysis methods improve.

**Polaris: Extensive resources from multiple technologies for next generation sequencing analysis.** *M.A. Bekritsky<sup>1</sup>, J. Leng<sup>3</sup>, L. Janin<sup>1</sup>, N. Johnson<sup>2</sup>, B. Lajoie<sup>2</sup>, A. Moshrefi<sup>2</sup>, T. Truong<sup>2</sup>, E. Jaeger<sup>2</sup>, F. Chen<sup>2</sup>, G.P. Schroth<sup>2</sup>, D.R. Bentley<sup>1</sup>, M.A. Eberle<sup>1</sup>.* 1) Illumina Cambridge Ltd., Chesterford Research Park, Saffron Walden, Essex, CB10 1XL, United Kingdom; 2) Illumina Inc., 5200 Illumina Way, San Diego, CA 92122, USA; 3) Illumina Inc., 200 Lincoln Centre Drive, Foster City, CA 94404, USA.

As next generation sequencing becomes more commonplace, increasing access to whole genome sequencing data becomes an imperative. As has been previously demonstrated by Illumina's Platinum Genomes and the NIST Genome in a Bottle Consortium, readily available sequencing data drives improvements to downstream analysis as informatics developers are able to train and test their methods on the most current data. The goal of the Polaris project is to provide the research community with access to readily available sequence data. To do this, we sequenced DNA from 270 samples obtained from the Coriell Institute that are consented for full release of personally identifiable genetic information. These samples were originally collected as part of the HapMap, 1000 Genomes, and Personal Genomes projects and have been sequenced to an average of 40x depth using Illumina's HiSeqX platform with TruSeq PCR-Free sample preparation. We have grouped our current samples and publicly released this data in four panels (ENA Study IDs are in parentheses): 1. **Diversity Panel (PRJEB20654)**: 150 unrelated samples from 3 super-populations (European, East Asian, and African) 2. **Trio Panel (PRJEB25009)**: 50 children whose parents are part of the Diversity Panel, enabling extensive trio analyses 3. **PGx Panel (PRJEB19931)**: 70 samples with extensive orthogonal characterizations of pharmacogenetic variants performed as part of the CDC's GeT-RM program 4. **PGx 10X<sup>©</sup> Panel (PRJEB26950)**: PGx panel samples that have been prepared with 10X's Chromium controller and sequenced on the HiSeq4000, providing linked read information. The sequence data for every sample from these panels is available on ENA as part of the Polaris umbrella project (PRJEB23074) and we will continue to add more sequence data for additional samples and new technologies under this umbrella project. Updates to this project will enable novel analyses and validation methods on new platforms. We will also be making these WGS panels available on BaseSpace along with the variant calls made using the latest bioinformatics pipelines developed by Illumina, including Edico's Dragen platform. As the pace of genomic innovation continues to accelerate, Illumina's Polaris project will enable researchers from diverse backgrounds and with varying access to sequencing resources to explore, understand, and contribute to our shared understanding of the role of genomics in human health.

Bustamante<sup>6</sup>, Clinical Genome Resource (ClinGen).* 1) Department of Biomedical Data Science, Stanford University, Stanford, CA; 2) Laboratory for Molecular Medicine, Partners Healthcare Personalized Medicine, Cambridge, MA; 3) Renaissance Computing Institute, University of North Carolina, Chapel Hill, NC; 4) Geisinger Health System, Danville, PA; 5) Baylor College of Medicine, Houston, TX; 6) Center for Genomic Medicine, Massachusetts General Hospital, Boston, MA; 7) Brigham and Women's Hospital, Boston, MA; 8) Harvard Medical School, Boston, MA; 9) Broad Institute, Cambridge, MA.

Over the coming decade, clinical genome sequencing will identify millions of genetic variants and query their potential association with disease phenotypes. Therefore, it is imperative for us as a community to create gold-standard curation of individual variants at scale in the context of clinical care, a task made more challenging by "data silos." Central to the mission of the Clinical Genome Resource (ClinGen; [clinicalgenome.org](http://clinicalgenome.org)) is breaking down these silos and allowing for the accurate and consistent curation of the clinical relevance of genes and variants to inform precision medicine and research. ClinGen's Variant Curation Interface (VCI) is designed to support routine application of the ACMG/AMP Guidelines as well as application of gene and disease specifications of the ACMG/AMP Guidelines by ClinGen's Expert Panels, and thus serves as a platform for gold-standard curation of clinical variants. It achieves this by aggregating evidence in a normalized manner from external resources and by supporting the manual curation of evidence in a structured manner. The VCI is now also publicly accessible to any user wishing to interpret the clinical relevance of genetic variants using, as well as contributing to, a shared evidence pool. We describe here 1) efforts aimed at large-scale identification and "tagging" of relevant literature with standardized terminologies to scale curation efficiency within the VCI, and 2) a ClinVar submission workflow supported by ClinGen's common data model, establishing the VCI as a thoroughfare for curation and submission/resubmission of standardized variant interpretations to ClinVar. The above workflow facilitates the collection of shared, normalized variant evidence from and across a vast array of publications, clinical and research laboratories, clinicians, and genomics databases, providing an ideal forum for discrepancy resolution and a rich dataset for subsequent machine learning that will feed back to further increase curation efficiency. Importantly, the VCI integrates curation and ClinVar submission by programmatically converting the ACMG/AMP criteria evaluations and supporting evidence into a ClinVar submission format. This facilitates submission to ClinVar, a public resource, and therefore public access to standardized interpretations of clinical variants and the supporting evidence behind them.

**Resources for archiving, sharing and analysis of controlled-access human data at DDBJ Center.** Y. Kodama<sup>1</sup>, O. Ogasawara<sup>1</sup>, A. Fukuda<sup>1</sup>, J. Mashima<sup>1</sup>, M.T. Minowa<sup>2</sup>, M. Kawashima<sup>2</sup>, L. Toyo-oka<sup>2</sup>, N. Mitsuhashi<sup>2</sup>, K. Okubo<sup>1</sup>, Y. Nakamura<sup>1</sup>, T. Takagi<sup>1,2</sup>, M. Arita<sup>1</sup>. 1) DDBJ Center, National Institute of Genetics, Shizuoka 411-8540, Japan; 2) National Bioscience Database Center, Japan Science and Technology Agency, Tokyo 102-8666, Japan.

The Japanese Genotype-phenotype Archive (JGA, <https://www.ddbj.nig.ac.jp/jga>) provides authorized access to individual-level phenotype and genotype data as a centralized repository in collaboration with the National Bioscience Database Center (NBDC) of the Japan Science and Technology Agency (<https://humandbs.biosciencedbc.jp>). NBDC has established the ethical guidelines and policies, and its Data Access Committee (DAC) grants data submission and data access requests to JGA. JGA accepts metadata, raw and processed data from array-based and next-generation sequencing platforms, clinical images, and phenotype data associated with data samples. For submitted studies and metadata, JGA assigns stable, unique identifiers prefixed with 'JGA'. Summaries of available JGA studies are listed at <https://ddbj.nig.ac.jp/jga/viewer/view/studies>. As of 4 June 2018, total 85 studies are available. The JGA system is connected to our secure supercomputer through a high-speed network so that users can smoothly download and analyze data with pre-installed bioinformatics tools on the supercomputer. The computing system is compliant with the NBDC security guidelines. To enhance researchers' collaboration through sharing and analyzing pre-publication data, we also started a new service "DDBJ Group Cloud (DGC)" since February 2017. The first use is the "AMED Genome Sharing Database (AGD)" for human genomes among researchers funded by AMED (Japan Agency for Medical Research and Development). Because AGD and JGA use the same data model, users can easily transfer the AGD data to JGA upon publication. In the poster, we present recent developments of our systems for archiving, sharing and analysis of controlled-access human data.

**Data integration techniques to elucidate connections between environmental factors, genetic variants, and human diseases.** M.B. Kosnik<sup>1,2,3</sup>, A. Planchart<sup>1,3,4</sup>, D.M. Reif<sup>1,2,3,4</sup>, C.J. Mattingly<sup>1,3,4</sup>. 1) Toxicology Program, North Carolina State University, Raleigh, NC; 2) Bioinformatics Research Center, North Carolina State University, Raleigh, NC; 3) Department of Biological Sciences, North Carolina State University, Raleigh, NC; 4) Center for Human Health and the Environment, North Carolina State University, Raleigh, NC.

Addressing the complex relationship between genetic influences on disease development and environmental factors is a challenge that requires multiple types and sources of data. Chemical exposure data from high-throughput screening (HTS) efforts such as the Tox21/ToxCast program identify chemical hazard using *in vitro* assays to probe toxicity. While most of these assays target specific genes, assessing how these chemicals exert effects through genetic interactions remains challenging. Integration with datasets like the Comparative Toxicogenomics Database (CTD), a publicly available database that builds networks of chemical, gene, and disease information from curated literature sources, may help to resolve these questions by providing broader biological context to HTS data. Further context for the interplay of gene-environment (GxE) interactions can be provided to disease connections formed between HTS data and CTD by joining the resulting chemical-gene-disease associations to resources like ClinVar, an archive of clinically relevant genetic variants implicated in disease conditions. By linking these datasets together, new chemical-disease associations can be found leading to new hypotheses for GxE interactions involved in disease progression. Here, we developed a technique for integrating these three resources together by linking elements common to the databases and used these integrated data to identify new associations between environmental factors, diseases, and genetic variants to promote discovery. By statistically testing disease enrichment using chemical-gene data from HTS and gene-disease data from CTD, we identified new chemical-disease associations between 2,781 chemicals and 776 diseases, with a median of 129 new, statistically significant ( $p < 0.01$ ) disease associations per chemical. For 833 of these chemicals, we also found new, statistically significant ( $p < 0.01$ ) genetic support for existing chemical-disease associations in a median of 44 diseases per chemical. We connected these new chemical-gene-disease associations to ClinVar gene-condition-variant data and identified a median of 5 variants per chemical-gene-disease association across 61 unique gene-disease combinations to form new hypotheses about GxE interactions involved in disease progression. Thus, we demonstrate a novel method to integrate existing biological data and identify new associations between environmental factors, diseases, and genetic variants to promote discovery.

**1653W**

**NCBI services for variation normalization, remapping, and annotation.** *L. Phan, E. Moyer, E. Ivanchenko, D. Revoe, H. Zhang, W. Qiang, E. Shekhtman, D. Shao, M. Ward, A. Glodek, J.B. Holmes, B.L. Kattman.* National Center for Biotechnology Information, U.S. National Library of Medicine 8600 Rockville Pike, Bethesda MD, 20894 USA.

Variant normalization and annotation are crucial steps to understanding the genetic basis of their effects on disease and biological functions. Normalizing variants and matching them with data in public variation databases, such as dbSNP and ClinVar, are central to the discovery efforts to identify known and novel variants. However, this process can be difficult because identical variants can be represented differently by variation resources and tools leading to duplications and complicating downstream analysis and annotation. Various tools have been proposed to address variant normalization but they are not robust handling variants in different formats and reporting on different reference sequence coordinates. Here we present a suite of NCBI variation tools (<https://www.ncbi.nlm.nih.gov/projects/variation/services/v0/>) that 1) normalizes representation of genetic variants from dbSNP rs IDs, HGVS expressions, and VCF formats for matching existing variants in dbSNP and other public resources and to identify novel variants, 2) remapping of variants between assembly versions and between coordinates on mRNA, protein, and genomic sequences to a normalized sequence coordinate, and 3) provide annotations from dbSNP and ClinVar. The tools employ a new algorithm and data model called Sequence Position Deletion Insertion (SPDI) to describe sequence changes and variant normalization which allow for:

- Producing a contextual allele, a new feature of our SPDI format that corrects left/right-shifting or shuffling for insertions or deletions
- Transforming data into right-shifted HGVS
- Transforming data into left-shifted VCF fields
- Remap (or lift-over) a variant to all available locations based on the alignment dataset used by ClinVar and dbSNP
- Remap (or lift-over) to a canonical representative at a single location that you can use to group identical variants

Acknowledgments Work at NCBI is supported by the NIH Intramural Research Program and the National Library of Medicine.

**MyVariant.info: Community-aggregated variant annotations as a service.** *J. Xin<sup>1</sup>, S. Lelong<sup>1</sup>, C. Afrasiabi<sup>1</sup>, M. Cano<sup>1</sup>, B. Jeon<sup>1</sup>, G. Tsueng<sup>1</sup>, S. Mooney<sup>2</sup>, A. Su<sup>1</sup>, C. Wu<sup>1</sup>.* 1) Department of Integrative Structural and Computational Biology, The Scripps Research Institute, LA JOLLA, CA; 2) Department of Biomedical and Health Informatics, University of Washington, Seattle, WA.

The accumulation of genetic variant annotations has been increasing explosively with the recent advance of the high-throughput sequencing technology. These annotations are sprinkled across dozens of data repositories like NCBI, Ensembl, UniProt, and hundreds of other specialized databases. While the volume and breadth of annotations is valuable, their fragmentation across many data silos is often frustrating and inefficient. Bioinformaticians everywhere must continuously and repetitively engage in data wrangling in an effort to comprehensively integrate knowledge from all these resources, and these uncoordinated efforts represent an enormous duplication of work. We created a platform, called MyVariant.info, to aggregate variant-specific annotations from community resources and provide high-performance programmatic access. Annotations from each resource are first converted into JSON-based objects with their id fields as the canonical names following HGVS nomenclature (genomic DNA based). This scheme allows merging of all annotations relevant to a unique variant into a single annotation object. A high-performance and scalable query engine was built to index the merged annotation objects and provides programmatic access to the developers. MyVariant.info is an open source project and we are actively expanding the coverage by engaging community efforts. Integrating a new variant annotation resource into MyVariant.info is extremely simple, which is to build a parser to convert from the original data source file into a JSON document, with the primary key represented by HGVS ID. And the parser could be contributed not only by the data provider but basically anyone who is interested. Once a parser is contributed, the sophisticated query-engine we built can save users effort to build their own infrastructure, which provides the incentive for them to contribute. As of today, we are able to aggregate annotations for around 900 million unique variants from 19 diversified resources, including well-known resources like dbSNP, ClinVar, as well as specialized ones like CIVIC and GRASP. In addition, we have built a scheduling system that automates the updates for each data source according to its own schedule. Queries to MyVariant.info can be performed through our web-based API at <http://myvariant.info> or by using data access libraries for Python, R or JavaScript. MyVariant.info currently handles more than 1.3 million monthly user queries from thousands of unique IPs.

**Genetic variation influences ground state pluripotency in mouse embryonic stem cells through a hierarchy of molecular phenotypes.** D.A. Skelley<sup>1</sup>, C. Byers<sup>1</sup>, A. Czechanski<sup>1</sup>, C. Spruce<sup>1</sup>, K. Choi<sup>1</sup>, D.M. Gatti<sup>1</sup>, S. Aydin<sup>1</sup>, A. Stanton<sup>1</sup>, D. Porter<sup>2</sup>, T. Choi<sup>2</sup>, G.A. Churchill<sup>1</sup>, S.C. Munger<sup>1</sup>, C.L. Baker<sup>1</sup>, L.G. Reinholdt<sup>1</sup>. 1) The Jackson Laboratory, Bar Harbor, ME 04609; 2) Predictive Biology, Inc., Carlsbad, CA 92010.

The influence of genetic variation on differentiation propensity of human pluripotent stem cell lines has important consequences for regenerative medicine and the study of early development. Mouse embryonic stem cells (mESCs) grown under controlled conditions occupy a ground state where pluripotency-associated transcriptional and epigenetic circuitry are highly active. We observed variability in expression of core pluripotency genes in genetically diverse mESCs grown in media lacking inhibitors that reinforce the ground state. To dissect the genetic basis of this variation in stability of ground state pluripotency, we conducted genetic analysis of gene expression and chromatin accessibility in mESCs grown under sensitized conditions (LIF + GSK3 inhibitor). We profiled gene expression and chromatin accessibility in 185 lines derived from genetically heterogeneous Diversity Outbred mice. We mapped thousands of loci that affect chromatin accessibility (caQTL) and/or transcript abundance (eQTL). We found eleven instances where distant QTL co-localized in clusters, suggesting a common regulator. One locus on chromosome 15 controlled the expression of 208 genes including many with known roles in maintenance of pluripotency. We applied causal mediation analysis and identified *Lifr* (leukemia inhibitory factor receptor) transcript abundance as the causal intermediate for these eQTL. Moreover, a joint mediation analysis of gene expression with chromatin accessibility yielded a single peak upstream of *Lifr* containing one SNP with a strain distribution pattern matching founder haplotype effects on *Lifr* downstream targets. Functional assays confirmed that *Lifr* genotype influences self-renewal capacity in an orthogonal set of mESCs derived from recombinant inbred lines. Furthermore, allele swap experiments in mESC lines with opposing alleles upstream of *Lifr* verified that the SNP we identified strongly influences mESC pluripotency. Thus, we detected a causal chain of molecular events: a single SNP modulates regulatory element accessibility, which affects *Lifr* expression, leading to large-scale transcriptional shifts including known and novel pluripotency-associated genes. These results reveal mechanistic details underpinning variability in stability of ground state pluripotency in mESCs, highlight the power of diverse mouse populations for dissecting molecular regulatory networks, and represent a resource for study of molecular events driving early development.

**Identification of novel epigenetically regulated genes and pathways involved in high myopia.** C. Uppala<sup>1</sup>, K.I. Lakhtaria<sup>1</sup>, S.S. Chettiar<sup>2</sup>, S. Visweswaraiah<sup>3</sup>, U. Radhakrishna<sup>3</sup>. 1) Computer sciences, Gujarat University, Ahmedabad, Gujarat, India; 2) Department of zoology, School of sciences, Gujarat University, Ahmedabad-9, India; 3) Department of Obstetrics and Gynecology, Oakland University William Beaumont School of Medicine, Royal Oak, MI, USA.

Myopia or nearsightedness is the most prevalent form of refractive error. In myopic subjects, the image of distant objects falls in front of the retina and either the eye is too long (axial myopia), the cornea is too convex, or the index of refraction of the lens is too high (refractive myopia). The risk of threats to vision can also occur in patients with moderate and/or high-grade myopia. In United States, about 24% of the >40 years aged population is affected by myopia and the estimation predicts that, myopia will affect about 45 million US people by 2050 and about 5 billion people would be myopic globally. However, the prevalence of myopia varies with age, sex, race, occupation, ethnicity, and environmental effects. Its highest prevalence rates are in East Asians, in whom between 80 to 90% of the young adult populations are myopic confirming that both genetic and environmental factors influence the incidence of myopia. Until now there are no genome-wide epigenetic association studies related to high myopia subjects were reported. To elucidate the molecular mechanism(s) underlying the pathophysiology of high-grade myopia, we have conducted a genome-wide methylation analysis on 18 high myopia subjects and an equal number of controls using Illumina epic array. We identified 1544 CpG sites in 1782 unique genes that were differentially hypermethylated (at least 2.0-fold or higher) in high myopia subjects compared to healthy controls. Among the 1544 unique targets, the top 10 hypermethylated targets were cg26526312 (*LINGO1*), cg27541540 (*PTPN11*), cg00609363 (*ZNRD1*), cg24877391 (*PEX-13;PUS10*), cg21790796 (*KIF20A;BRD8*), cg14282407 (*TRAPPC1;CNTROB*), cg18191664 (*ERLIN2*), cg08048517 (*KIAA0528*), cg10646633 (*ZNF224*) and cg14694176 (*TCEA1*). This study will shed light on the etiology of myopia and eye growth patterns and thus has considerable public health application, as the high prevalence of myopia in the world is a formidable health care challenge. Furthermore, the identification of myopia causing genes will be important for improving myopia diagnosis and counseling, promoting the development of therapeutic strategies and increasing our understanding of the normal and abnormal development of the affected tissues. .

**NGS studies on non-model organisms using StrandNGS.** *V. Chakraborty, S. Ramachandrala, D. Chohan, A. Adewar, S. Cherukuri.* Strand Life Sciences Private Limited, Bengaluru, Karnataka, India.

Next Generation Sequencing (NGS) is constantly growing and becoming a popular tool for quantitative studies. Model organisms are widely used in this research methodology as they are well studied which helps researchers answer various biological questions. As the cost of sequencing techniques continue to plummet, more researchers are leaning towards sequencing of non-model organisms to identify interesting genetic traits. Sequencing analysis of non-model organisms addresses questions related to genetic evolution, comparative genetics, genetic breeding, ecology, and so on. However, as these species have less gene annotations and functional knowledge, the analysis is a much more technically involved process. We elaborate an intuitive and user friendly way to perform sequencing analysis with non-model organisms using the StrandNGS bioinformatics software. In StrandNGS, the Annotation Manager is a central interface for updating, deleting, or adding custom annotations and it also contains a repository of annotations for various organisms. The software is flexible and supports creation of custom builds using text, GenBank and fasta files coming from various sources namely NCBI, Ensembl, UCSC or any other source. For this case study, we analyzed two types of datasets from *Callithrix jacchus* (Marmoset): (A) 12 RNA-Seq raw samples generated using Illumina platform (B) already analyzed data present in text format. These datasets were a part of a bigger study from the publicly available dataset GSE50747. The reference build was created using the fasta and the annotations were updated using gtf files from Ensembl. An end to end analysis including alignment, quantification, filtering, and differential analysis was performed. A multi-omics approach was then applied to understand the correlation between the results obtained from the two types of datasets. The significant genes identified by our analysis matched with some genes highlighted by the research group and reported to be conserved among other mammalian species. To further perceive the conservation of these genes, pathway analysis was done by mapping these genes to pathways of model mammalian organisms. This was accomplished in StrandNGS by enhancing the HomoloGene annotations which primarily identifies homologs of a gene in diverse organisms. As the study of non-model organisms is trending, our intention was to showcase StrandNGS as a tool to effortlessly perform a comprehensive analysis on these organisms.

**Optimal correction for hidden covariates improves eQTL-based characterization of disease risk variants.** *M.J. Gloudemans<sup>1</sup>, N.R. Gay<sup>2</sup>, B. Liu<sup>3</sup>, A.S. Rao<sup>4</sup>, S.B. Montgomery<sup>2,5</sup>.* 1) Biomedical Informatics Training Program, Stanford University, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Department of Biology, Stanford University, Stanford, CA; 4) Department of Bioengineering, Stanford University, Stanford, CA; 5) Department of Pathology, Stanford University, Stanford, CA.

Recent dissemination of publicly accessible results from genome-wide association studies (GWAS) has enabled functional investigation of putative disease risk variants. For example, a GWAS risk variant that also affects gene expression as an expression quantitative trait locus (eQTL) may affect disease risk through a mechanism involving the regulated gene. The quality of eQTL calling is often hindered by both biological and technical batch effects including known and unknown covariates, such as the subject's age, or tissue sampling heterogeneity. Using the method PEER to identify and correct for such covariates increases the number and significance of identified eQTLs (Stegle et al. 2012); therefore, application of PEER or related methods has become standard practice for eQTL analysis. However, it remains unclear to what extent the inclusion of PEER covariates in an eQTL model affects the overlap of eQTLs with disease-relevant GWAS variants, as well as exactly how many PEER factors should be included to achieve optimal interpretation. To answer these questions, we evaluated the overlap between eQTLs and disease risk variants for 15 recent GWAS with high SNP density, large study sample size, and many genome-wide significant hits. We called eQTLs in 922 human whole blood RNA-seq samples from the Depression Genes and Networks (DGN) study and in the GTEx project, including every number of PEER factors from 0 to 60. We then ran several commonly used GWAS-eQTL colocalization tools (eCAVIAR, coloc, SMR) at every level of correction (Hormozdiari et al. 2016, Giambartolomei et al. 2014, Zhu et al. 2016). Strength of colocalization increased at some loci and diminished at others with respect to the number of modeled PEER factors. Furthermore, we observed considerable differences between the behavior of the three colocalization methods, suggesting that the choice of colocalization method is a critical factor for interpreting GWAS variants. Our results illustrate that eQTL pipelines should carefully consider the extent of hidden covariate removal, in order to optimize not only the total number of eQTLs identified, but also the biological relevance of these eQTLs in relation to known disease risk variants. To address this, we propose a new method to optimize colocalization discoveries by identifying and removing hidden covariates significantly associated with sample genotypes, and we demonstrate its utility by discovering robust eQTL-GWAS colocalizations.

**An ultra-fast approach to identify eQTLs with many tissues leveraging a linear time mixed-model algorithm.** *B. Jew<sup>1</sup>, B. Han<sup>2</sup>, S. Sankararaman<sup>3,4</sup>, J.H. Sul<sup>5</sup>.* 1) Bioinformatics Interdepartmental Program, University of California, Los Angeles, CA, USA; 2) Department of Medicine, Seoul National University College of Medicine, Seoul, Korea; 3) Department of Computer Science, University of California, Los Angeles, CA, USA; 4) Department of Human Genetics, University of California, Los Angeles, CA, USA; 5) Department of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, CA, USA.

Large scale generation of genotyping and gene expression data allows researchers to better understand the genetic basis for traits and disease by identifying genetic variants linked to gene expression levels, or expression quantitative trait loci (eQTLs), that can reveal key insight into the regulatory architecture that drives complex phenotypes. Regulation of gene expression varies by tissue and cell type and to study this variation, the Genotype-Tissue Expression (GTEx) project is generating genotype and tissue-specific gene expression measurements. This data has allowed researchers to significantly expand our understanding of local (cis-eQTLs) and distal (trans-eQTLs) effects on traits, and evidence suggests that sample size is a limiting factor in identifying these regulatory elements. One approach to increase power to detect eQTLs is to combine the tissue-specific measurements from each individual across multiple tissues to simulate larger sample sizes. Meta-Tissue (Sul et al. PLOS Genetics, 2013) is a statistical framework that effectively utilizes multiple tissue samples in these datasets for identifying eQTLs through linear mixed model and meta-analytic methods. However, the feasibility of this method diminishes with increasing sample sizes due to computational time that grows cubically with each sample. For example, Meta-Tissue in current implementation will take years of computational time to analyze the latest GTEx dataset. The main computational bottleneck is estimating a variance component of each SNP-gene pair in the linear mixed model (LMM) framework. To overcome this challenge, we propose an efficient algorithm to estimate variance components in LMM. Our method leverages the structured format of data in LMM because gene expression measurements are usually collected from many tissues in each individual. Our algorithm scales linearly with sample size and generates results identical to Meta-Tissue when all tissues are collected from each individual. At current sample sizes, this method is thousands of times faster than the current Meta-Tissue implementation, and hence will enable detection of eQTL from many tissues like those in GTEx. We are currently extending the algorithm to consider a situation when different sets of tissues are collected from individuals. This method will accommodate current and future studies with increasing sample sizes required to identify novel eQTLs from many tissues.

**The eQTLs catalog and LinDA browser: A platform for determining the effects on transcription of GWAS variants.** *S. Onano<sup>1,2,3</sup>, F. Cucca<sup>1,2</sup>, M. Pala<sup>2</sup>.* 1) Department of Biomedical Science, Università degli Studi di Sassari, Sassari, Italy; 2) National Research Council (CNR) Institute for Genetic and Biomedical Research (IRGB), Cagliari, Italy; 3) Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor (MI), USA.

The expression Quantitative Traits Loci (eQTLs) are genetic polymorphisms associated with changes in gene expression levels. They have been successfully used to prioritize the target genes of the variants associated with complex traits and diseases (GWAS variants). Up to date a few eQTLs databases exist and they collect only a small portion of the available datasets. We thus planned to build the largest publically available catalog of eQTLs, coupled with a browser, to optimize and simplify their interrogation. We collected and manually curated 51 eQTL public studies ranging from 2007 to date, corresponding to more than 94 sample types and 15 human populations for a total of 285,157 cis-eQTLs and 33,374 genes with at least one cis-eQTL (cis-eGenes). Most of the eQTLs studies were conducted in blood samples from healthy individuals of European ancestry. We found that for 93% of the known protein-coding genes were eGenes, 22% of them intersecting ( $r^2 \geq 0.8$ ) with the NHGRI-EBI GWAS Catalog and 26% of whom considered as druggable. Furthermore, for those GWAS variants for which at least an eGene was known, we found that the NHGRI-EBI GWAS Catalog proposed at least one of the same genes as candidate target only for the 68% of the times. Our eQTL-Catalog can be used as a reference to measure the degree of novelty for future eQTLs studies; it is provided within a platform with a web interface (LinDA) that we plan to implement with other types of quantitative traits (i.e. epigenetic, proteomic, metabolomics and microbiota) to better dissect the pleiotropy of the GWAS variants.

**Design and analysis of FACS-based CRISPR screens.** C.G. de Boer, J. Ray, C. Fulco, N. Hacohen, A. Regev. Broad Institute, Cambridge, MA.

CRISPRi (interference) and CRISPRa (activation) can be used to ectopically activate or repress regulatory regions such as enhancers. Here, a cleavage-defective Cas9 protein tethered to a transcriptional activation or repression domain is targeted to a locus with complementary guide RNAs. Combining pooled CRISPR screens with a gene expression output is a powerful approach to identify regulators<sup>1</sup>, and regulatory regions<sup>2,3,4</sup> controlling gene expression, by allowing us to test potential associations for many genes/loci in a single experiment. Here, I will discuss considerations in experimental and library design, and introduce models and tools for the analysis of FACS-based CRISPR screens. 1. Parnas O et al. A Genome-wide CRISPR Screen in Primary Immune Cells to Dissect Regulatory Networks. *Cell*. 2015 Jul 30;162(3):675-86. doi: 10.1016/j.cell.2015.06.059. Epub 2015 Jul 16. 2. Simeonov DR et al. **Bioinformatics approaches for quantifying endogenous and transgene mRNA expression by RNA sequencing in gene therapy studies.** E.K. Tsang, J.T. Gray, C. Chaivorapol. Audentes Therapeutics, South San Francisco, CA.

Gene therapy has demonstrated profound clinical benefit for patients with serious, life-threatening rare genetic diseases, and AAV vectors are the most advanced tool for delivering genetic payloads to terminally differentiated somatic cells in liver and muscle. Clinical development of these products will benefit from a more precise understanding of transcriptional changes induced by the vector in tissues, including characterization of mRNA expression of the endogenous mutated gene and of the transgene. RNA-seq is a cost-effective way to simultaneously measure transgene and endogenous gene expression and the effects of gene therapy at a transcriptome-wide level. A challenge with ascertaining transgene expression simultaneously with that of the endogenous gene is that the two sequences may or may not differ significantly in sequence, and quantification methods must work in the context of wide genetic variation across patients with the same disease, ranging from single nucleotide mutations to deletions and skipped exons. Here, we present bioinformatics approaches for quantifying endogenous and transgene expression from RNA-seq data at varying levels of sequence divergence between the two transcripts. Using a combination of *in silico* simulations and data from animal studies, we assess two methods for distinguishing endogenous from transgene expression: 1) estimating transcript abundances with Salmon, and 2) directly counting reads that align to sequences where the transgene and endogenous transcripts differ. We find that Salmon works well when the two sequences are sufficiently different, but it incorrectly partitions transgene and endogenous expression when the sequences are similar. The more targeted counting approach works even when the sequences differ by a single nucleotide, but only provides coverage at a limited number of sites that may be influenced by sequencing platform and alignment algorithm biases. To guide when each approach should be used, we quantify the level of sequence divergence for Salmon to provide accurate transcript abundance estimates. Our results demonstrate that RNA-seq can be used to reliably assess transgene expression even when the endogenous and transgene sequences have a single nucleotide difference across the entire gene. Our work provides insight into the applications of a common transcript estimation tool and a direct counting method for estimating transcript abundance in gene therapy.

**Miscall estimation for pathogenic variants in genomic direct-to-consumer microarray data.** G. Lennon, M. Cariaso. SNPedia, Potomac, MD.

Direct-to-Consumer (DTC) genomic products based on microarray technology are relatively inexpensive and have been used by millions of consumers. Many of these microarrays report on rare variants that have significant clinical associations based on the scientific and medical literature. The false positive rate for reported pathogenic variants in DTC products is important to establish. As a significant provider of independent, third-party literature retrieval reports based on uploaded DTC data, Promethease is in a unique position to compare variant frequencies in such data to expected frequencies observed in large-scale sequencing projects such as gnomAD and TOPMED. Here, we report our findings based on raw genotype data from microarray DTC products generated by companies such as 23andMe, Ancestry, and MyHeritage. In addition, thousands of individuals have data for their own genomes from two or more DTC companies, allowing us to calculate reproducibility between companies. Overall, we find high reproducibility and very good correlation between microarray data frequencies and sequencing frequencies. For genes with high medical interest such as BRCA1 and BRCA2, we are able to estimate the number of variants likely to be miscalled. Based on the ability to estimate miscall likelihood, we are developing a new feature in Promethease reports allowing users to systematically identify and filter specific genotypes likely to be incorrect. This feature is based on statistical analysis of company- and platform-specific frequency data. We believe this feature will empower DTC users to more confidently assess their data and the relevant literature.

**1664F**

**MiniScrub: De novo long read scrubbing using approximate alignment and deep learning.** N. LaPierre<sup>1</sup>, R. Egan<sup>2,3</sup>, W. Wang<sup>1</sup>, Z. Wang<sup>2,3,4</sup>. 1) University of California, Los Angeles, Los Angeles, CA; 2) Department of Energy Joint Genome Institute, Walnut Creek, CA; 3) Lawrence Berkeley National Laboratory, Berkeley, CA; 4) University of California, Merced, Merced, CA.

Long read sequencing technologies such as Oxford Nanopore can greatly decrease the complexity of de novo genome assembly and large structural variation identification. Currently Nanopore reads have high error rates, and these errors, if not corrected, may result in poor quality assemblies. Correcting these errors dramatically improves assembly quality, but requires prohibitive experimental or computing cost. Here we developed a novel Convolutional Neural Network (CNN)-based method, called MiniScrub, for de novo identification and subsequent "scrubbing" (removal) of low-quality Nanopore read segments. MiniScrub first generates read-to-read alignments by MiniMap, then encodes the alignments into images, and finally builds CNN models to predict low quality segments that could be scrubbed based on a user defined quality cutoff. Applying MiniScrub to in-house Nanopore control datasets under several different parameters, we show that it robustly improves overall read quality, which in turn leads to dramatic improvements in the speed and/or accuracy of de novo genome assembly. When applying MiniScrub as a preprocessing step before assembly with MECAT, the percentage of genome assembled increases from 87.92% to 99.71%, the NGA50 increases from 315,975 to 438,077, and the number of misassembled contigs decreases from 18 to 14. As a preprocessing step for Canu, MiniScrub results in similar percentage of genome assembled but enables Canu to run 9 times faster by eliminating excess poor-quality data. We propose MiniScrub as an essential tool for preprocessing Nanopore long reads, and its design makes it generalizable across a variety of datasets and similar sequencing technologies.

**1665W**

**A massive collection of Japanese full-length class-I HLA sequences enhanced the accuracy of HLA genotyping from WGS data.** *Y. Wang<sup>1</sup>, T. Mimori<sup>1</sup>, S. Khor<sup>1</sup>, Y. Hitomi<sup>2</sup>, O. Gervais<sup>1</sup>, K. Misawa<sup>1</sup>, Y. Kawai<sup>2</sup>, K. Tokunaga<sup>2</sup>, M. Nagasaki<sup>1</sup>.* 1) Division of Biomedical Information Analysis, Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo.

The human leukocyte antigen (HLA) system, which is the most variable gene region in the entire genome, encodes the major histocompatibility complex (MHC) proteins in humans on chromosome 6 and has been reported to be associated with numerous immune-mediated diseases. HLA calling from whole genome sequencing data (WGS) remains to be challenging due to the incompleteness of population specific references. We have previously described the construction of Japanese reference sequences of HLA genes (ToMMo HLA sequences). This study aim to evaluate the accuracy of HLA calling from WGS when the in-house ToMMo HLA sequences were used in conjunction with the IPD-IMGT reference sequences to estimate the most likely HLA genotypes. To assess the usefulness of population-specific HLA references in HLA type estimation, we compared the performance of different sets of references (with and without ToMMo HLA sequences) across HLA-A, HLA-B and HLA-C alleles by using HLA-VBSeq, a flexible software which allows the use of arbitrary reference sequences. In addition, we compared HLA-VBSeq with another widely-used HLA typing software, HLA\*PRG:LA. We evaluated their performances by using 418 Japanese samples (Tokyo Healthy Controls, THC) as testing data, in which HLA genotypes were determined with Luminex technology. All of the tests were implemented based on 4-digit resolution. As a result, the performance of HLA calling in the Japanese population significantly increased when we included ToMMo HLA sequences as reference sequences. In conclusion, we suggest that including the sequences obtained from regional population samples is an effective way to improve the accuracy of HLA calling from WGS dataset. Given that this study was performed based on 4-digit resolution, in the future we intend to assess the accuracy of HLA-VBSeq with ToMMo HLA sequences at the 6-digit and 8-digit level resolutions.

**1666T**

**Linkage-disequilibrium regularized support vector machines for genome-wide association studies.** *M. Sudarshan, L. Subramanian.* Courant Institute of Mathematical Sciences, NYU, New York, NY.

It is of great interest to perform whole genome analyses (WGA) in order to determine the causal single nucleotide polymorphisms (SNPs) for a particular outcome without manually subsampling the large genome. However, in many experiments, researchers focus only on a small portion of the genome [He and Lin, 2011], [Wu et al., 2010], and [Fan and Lv, 2008]. This may be done to mitigate the effect of spurious correlations between certain SNPs and the outcome. We hypothesize that by considering block structures in the Linkage Disequilibrium (LD) [Slatkin, 2008] matrix of the data, we can return a significantly smaller set of significant SNPs without a large drop in prediction accuracy. LD is a property observed in genomics where adjacent SNPs take on highly correlated values. Our main contribution is a two-step procedure in which we first determine blocks in the LD matrix using a constrained spectral method, then regularize an SVM model based on these blocks. We apply a separate L2 norm for each block of SNPs and an overall L1 norm to enforce a small number of SNPs being returned as relevant. We observe that this model selects blocks of SNPs with high pairwise LD that are significantly predictive of the phenotype. Furthermore, the model selects only the SNPs within each block that are the most significant in terms of predicting the outcome. We also observe that despite a slightly larger set of SNPs being returned in the block-regularized case, the percentage of SNPs that are significant are better than or equal to the L1-regularized models. The use of a max-margin classifier over logistic regression improves classification accuracy by around 6% while returning a set of highly significant SNPs.

**1667F**

**Fine mapping chromatin contacts in capture Hi-C data.** C. Eijsbouts<sup>1,2</sup>, O. Burren<sup>1</sup>, P. Newcombe<sup>2</sup>, C. Wallace<sup>1,2</sup>. 1) Department of Medicine, University of Cambridge; 2) MRC Biostatistics Unit, University of Cambridge.

Capture Hi-C (CHI-C) uses high-throughput sequencing to map physical interactions between chromatin regions (HindIII digestion fragments) in cell nuclei. The technique is suitable for the discovery of regulatory interactions at high resolution, which is achieved by targeting only interactions involving defined regions of interest (baits). However, in a typical CHI-C analysis, the evidence for each of a bait's putative interactions is considered independently, while patterns in the evidence across neighboring regions are ignored. This tends to produce long runs of regions which appear to all make contact with the same bait. Based on peaks within the signal across these, we hypothesised that long runs of apparently interacting regions could result from a small subset of direct interactions. We propose a new method, based on a Bayesian sparse variable selection approach, which attempts to fine map these direct interactions. Our model is conceptually novel, exploiting the spatial pattern of read counts in CHI-C data, and in application to real experimental data prioritised interactions with biological properties that would be expected of true contacts. For bait fragments corresponding to gene promoters, we identify contact fragments with active chromatin that overlap those found in previously defined enhancer-target networks; conversely, for intergenic bait fragments, we identify contact fragments corresponding to promoters for genes expressed in that cell type. We show that long runs of apparently co-contacting fragments can typically be explained using a subset of direct interactions consisting of <10% of the number in the full run. Our results appear largely complementary to those from a per-fragment analytical approach, and provide an additional level of interpretation for CHI-C datasets that helps to map interactions at increased resolution.

**1668W**

**Pathoscore: A tool for unbiased evaluation of variant pathogenicity metrics.** J.M. Havrilla<sup>1</sup>, B.S. Pedersen<sup>1,2</sup>, R.M. Layer<sup>1,2</sup>, E.J. Hernandez<sup>1,2</sup>, M. Yandell<sup>1,2</sup>, A.R. Quinlan<sup>1,2,3</sup>. 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) USTAR Center for Genetic Discovery, University of Utah, Salt Lake City, UT; 3) Department of Biomedical Informatics, University of Utah, Salt Lake City, UT.

When sequencing a rare disease cohort, much of the variation will be either extremely sparse in the population, or entirely de novo. Deciding upon the best metric to evaluate the pathogenicity of each newly discovered variant can be onerous. Many variant pathogenicity predictors exist, yet determining which is most appropriate to use for a particular phenotype and its corresponding set of genes is difficult. One major complication in fairly evaluating metrics lies with ClinVar. ClinVar has numerous limitations: it changes version and its variant set constantly, the criteria for establishing pathogenicity is not consistent, benign variants are primarily common variants from population-scale datasets, and many variants are incorrectly annotated. Nearly all variant pathogenicity predictors have compared their metrics to others on ClinVar alone, and each one uses a different version or subset of the variants, with virtually no consistency between independent evaluations based on ClinVar. To address these difficulties and to aid in the evaluation of new and existing methods, we have created pathoscore, which acts both as a tool and a collection of curated truth sets and metrics. The truth sets are filtered to exclude supposed pathogenic variants that are common in the gnomAD population database. The pathoscore tool allows quickly evaluating existing methods via a simple command-line tool that utilizes the truth-sets included in the repository. Pathoscore creates an interactive HTML page for evaluating the performance of variant pathogenicity predictors on different truth sets. The HTML contains ROC curves, value distribution plots for benign and pathogenic variants for each metric, Youden's J statistic curves, precision recall curves, the number of variants each metric was able to score, and a clinical utility score. There is a detailed README and a wiki to facilitate use of this tool and help interpret the output. Our goal is not only to provide bioinformaticians with a fair and consistent way to evaluate their new tool against existing approaches, but also to provide clinicians and diagnosticians with an easy, comprehensive approach to identifying the best metric for their patients' datasets.

**1669T****IGV-Web: An application for viewing and sharing genomic datasets.**

J.T. Robinson<sup>1</sup>, H. Thorvaldsdóttir<sup>2</sup>, D. Turner<sup>1</sup>, J.P. Mesirov<sup>1,2,3</sup>. 1) University of California San Diego, La Jolla, CA; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Moores Cancer Center, University of California San Diego, La Jolla, CA.

Advances in genomic technologies are revolutionizing our knowledge and understanding of human disease. They enable the generation of diverse types of data to detect genetic variation and analyze its impact. While much of the analysis can be automated, human interpretation and judgment supported by rapid and intuitive visualization are important for gaining insight, increasing the confidence in computational results, and characterizing complex events. First released in 2008, the *Integrative Genomics Viewer (IGV)* is a high-performance desktop tool for interactive visual exploration of diverse genomic data. IGV was one of the first tools to provide next-generation sequencing (NGS) data visualization, and it currently provides a rich set of tools for inspection, validation, and interpretation of genomic datasets. The IGV supports real-time interaction at all scales of genome resolution, from whole genome to base pairs, even for very large NGS datasets. In 2016, we introduced *igv.js*, a JavaScript implementation of IGV, designed to be easily embeddable in web portals, cloud applications, and investigators' web pages. It supports many of the key features of the desktop application, including visualization of NGS alignments, germ-line and somatic variants, copy-number data, annotations, and eQTL data. This version has been widely adopted in web portals, including the cBioPortal for Cancer Genomics, Genotype-Tissue Expression (GTEx) Portal, Exome Aggregation Consortium (ExAC) Browser, and others. Here we present *IGV-Web* (<https://www.igv.org/app>), a new web-based resource based on *igv.js*. IGV-Web enables researchers to view genomic datasets using the familiar IGV user interface without the need to install any software. Importantly, it allows users to visualize and share data stored on web servers, as well as popular cloud providers such as Dropbox, Google Drive, Google Cloud Storage, and Amazon Web Services. Data is protected using the cloud provider's authorization scheme. IGV-Web encodes the exact state of the visualization in a shareable URL, making sharing a visualization of a genomic dataset as easy as sharing a YouTube video. The IGV-Web application, IGV desktop application, and *igv.js* are all open source and freely available at [www.igv.org](http://www.igv.org) and [github.com/igvteam](https://github.com/igvteam).

**1670F****What's new with NCBI tools for genome visualization and analysis.** V.A. Schneider, A. Kuznetsov, T.D. Murphy, F. Thibaud-Nissen. Information Engineering Branch, NIH/NCBI, Bethesda, MD.

To keep pace with the still-increasing number of newly sequenced genomes and offer users the sequence-level details that are now an integral part of most annotation data and browser-based analyses, NCBI introduced the Genome Data Viewer (GDV), a new genome browser, in 2016. Since then, we have continued to add functionality to GDV, making possible the retirement of the aging Map Viewer browser in May 2018. We will present recent GDV updates, which include an integration with BLAST that offers tools for graphical analysis of alignments, new track offerings that show details of assembly-assembly alignments and evolutionary conservation, and added support for the display of custom tracks representing externally hosted data, either from user-provided stand-alone remote files or those in the UCSC Track Hub format. GDV's graphical display uses the NCBI Sequence Viewer, an application that can also be integrated into web pages external to NCBI using its embedding API. Sequence Viewer offers highly customizable views of individual sequences that can include both NCBI-provided annotation tracks and custom data, and publication quality PDFs. We will also demonstrate examples of its recently added features and use. We will additionally highlight recent updates to web-based NCBI genome analysis tools, such as the Coordinate Remapping Service, which now offers improved handling for variant data in VCF format and an alpha release of a stand-alone software package, and the Genome Decoration Page (GDP) that can be used to generate publication quality images of annotated ideograms. These, and other tools, can be easily accessed from the NCBI human resources page (<https://www.ncbi.nlm.nih.gov/genome/guide/human/>). Together, these tools provide users with a comprehensive suite of resources for genomic visualization and analysis. This work was carried out by staff of the National Library of Medicine (NLM), National Institutes of Health, with support from NLM.

**Using heterogeneous networks to systematically record, model and query GWAS follow-up experiments.** *J. Barrett, J. Floyd, P. Seth, M. Suci.* Genomics plc, Cambridge, United Kingdom.

To date, more than 3300 genome-wide association studies (GWAS) have identified approximately 62,000 unique SNP-trait associations. However understanding the causal variants, genes and mechanisms underlying these associations has proven difficult. Signals of association frequently span large regions encompassing many genes, and statistical fine-mapping approaches and variant annotation often fail to identify any one variant conclusively. There has therefore been a huge amount of functional follow-up experimentation done to try to resolve these questions. These studies carry out a diverse range of experiments and typically report results for individual loci in an unstructured way in the text of publications. Researchers may be familiar with results in their disease of interest, but making systematic comparisons between disease areas is difficult. Here we present a tool to record, model and enable systematic queries of a wide variety of data types used to convincingly identify causal variants, genes and mechanisms. We represent these data as a heterogeneous network, which have been previously used to encode relationships among a wide variety of biological data types. Here we focus on creating much more detailed paths between traits and genes, which previously have been captured by generic "is associated with" edges that can vary in how confident the underlying data are. In addition to trait and gene nodes we have added variant, transcript, region (e.g. enhancer), and cell type. Edges represent experimentally validated links, such as genetic association, eQTL co-localisation, tissue-specific expression, model organism knockouts, or CRISPR perturbations in cell models. We have built upon existing graph frameworks to benefit from methods and software tools to create and query meta-nodes and meta-paths connecting genes and traits. We have implemented a user-friendly tool to enter data (e.g. while reading a paper) to help expand the database. This framework enables comprehensive analysis of a wide variety of commonly employed GWAS follow-up experiments. We will show how paths with the strongest evidence can be used as "gold standard" loci to evaluate automated algorithms for discovering new causal genes, which has historically been challenged by the absence of robust and computationally usable truth sets.

**GlobAI Distribution of Genetic Traits (GADGET): Exploring polygenic trait scores.** *A.T. Chande<sup>1,2,3</sup>, L. Wang<sup>1,3</sup>, L. Rishishwar<sup>1,2,3</sup>, A.B. Conley<sup>1,3</sup>, E.T. Norris<sup>1,2,3</sup>, A. Valderrama-Aguirre<sup>3,4</sup>, I.K. Jordan<sup>1,2,3</sup>.* 1) School of Biological Sciences, Georgia Institute of Technology, Atlanta, GA, 30332; 2) IHRC-Georgia Tech Applied Bioinformatics Laboratory, Atlanta, GA 30332, USA; 3) PanAmerican Bioinformatics Institute, Cali, Valle del Cauca, Colombia; 4) Biomedical Research Institute, Faculty of Health, Universidad Libre-Seccional Cali, Cali, Valle del Cauca, Colombia.

Genome-wide association studies (GWAS) have the power to reveal the underlying genome-phenotype associations within complex traits. Over the last decade, thousands of such associations have been discovered for hundreds of traits. Exploration and interrogation of these data in global populations has the potential to aid in the understanding of global and regional risk factors. To address this need, we have developed the GlobAI Distribution of Genetic Traits web server (GADGET <http://gadget.biosci.gatech.edu>). The GADGET web server provides users with a dynamic visual platform for exploring the relationship between worldwide genetic diversity and the genetic architecture underlying numerous human phenotypes. GADGET combines trait-associated single nucleotide polymorphisms discovered by GWAS with genotype data from the 1000 Genomes Projects and ChocoGEN to compute polygenic trait scores (PTS) for 800+ complex trait for 27 global populations. Population-specific PTS are visualized for each of the 27 global population and 5 continental super-populations. GADGET users can also analyze custom trait-associated SNP lists and visualize their distribution. GADGET was used to explore and describe the global distribution of risk for Post-Traumatic Stress Disorder and Type 2 Diabetes. We also used GADGET and its underlying technology to interrogate genetic difference among African and European ancestry individuals in Colombia.

**An exploration of the clinical phenome and the application of natural language processing for rapid and deep phenotyping of acutely ill children with genetic diseases.** *M.M. Clark<sup>1</sup>, S. Batalov<sup>1</sup>, M. Janes<sup>1</sup>, T. Defay<sup>2</sup>, S. Gilmer<sup>1</sup>, C. Yacoubian<sup>3</sup>, N. Veeraraghavan<sup>1</sup>, S.F. Kingsmore<sup>1</sup>.* 1) Rady Children's Institute for Genomic Medicine, San Diego, CA, USA; 2) Alexion Pharmaceuticals, Inc., New Haven, CT, USA; 3) Clinithink Ltd., London, UK.

**Intro:** Rapid whole-genome sequencing (rWGS) is now gaining traction for the diagnosis of neonates affected with rare genetic disorders in intensive care units. The accuracy and completeness of patient phenotypic information has a direct impact on the ability to make a timely molecular diagnosis. However, there are three issues that remain stumbling blocks: (1) textbook descriptions are incomplete for rare genetic diseases, (2) existing descriptors lack granularity, and (3) phenotyping from electronic health records (EHRs) is time-consuming, requires expert knowledge, and has a risk of bias. In a retrospective analysis, we examine how closely phenotypes derived with natural language processing (NLP) match those selected by expert analysts and physicians and how both compare to the current understanding of the diagnosed disease. **Methods:** For 76 acutely ill children diagnosed with a genetic disease, an expert reviewed the EHR and manually selected HPO phenotypes determined to be representative of the child's condition. NLP software (CLiX ENRICH, Clinithink) was adapted to extract HPO phenotypes from non-structured EHR fields without human involvement. For each patient, an automated workflow was triggered which imported clinical documents from the Epic Chronicles Database to CLiX ENRICH and automatically initiated a job resulting in a set of HPO terms. The OMIM disease descriptions were used to assess the accuracy of the existing disease-phenotype associations. These three sets of phenotypes were evaluated based on precision, recall, count, and information content (IC), a measure of term specificity. **Results:** We find that the application of NLP to ascertain a deep phenotype has 74% precision and 93% recall. In ~20 seconds, the optimized NLP software identified an average of 93 phenotypes per patient, a 20-fold deeper phenome than by expert manual curation. There was surprisingly little overlap between the observed and expected phenomes; only 3.2% of the NLP phenome matched the OMIM descriptions of those genetic diseases. Interestingly, the phenotypic overlap of OMIM and NLP had significantly higher IC than the overlap of OMIM and the manual extraction ( $p < .0001$ ). This exploration provides quantitative evidence that most acutely ill children with genetic diseases have presentations that imprecisely and noisily match textbook descriptions of disease, which has critical implications for the genetic diagnosis of affected children based on clinical phenotypes.

**Utilizing spike-and-slab Lasso models for epistasis analysis.** *J. Wen, J. Chen, X. Shi.* University of North Carolina at Charlotte 9201 University City Blvd., Charlotte, NC 28223.

Epistasis among genetic variants or genes is an important genetic mechanism in complex traits including common diseases. Many studies show that epistasis helps elucidate the genetic foundation for modeling human traits and evolution. However, it is statistically and computationally challenging to identify epistasis in large-scale and high-dimensional genomic data. The challenge lies in many intertwined aspects including (1) how to avoid overfitting induced by high-dimensional data where the number of genetic variants is typically much larger than the number of samples under investigation; (2) how to model the high collinearity or correlations in genomic data; and (3) how to reduce the search space for epistasis analysis to ensure that the computing is feasible for large scale genomic data. Recently, shrinkage based variable selection methods have showed desirable property for modeling this type of genomic data. In this study, we apply a new type of shrinkage variable selection models, namely spike-and-slab Lasso general linear models, to identify epistasis among genetic variants. We develop an iterative workflow with an interactive web portal to support data pre-processing, model training and optimization, and result presentation and visualization for epistasis analysis using these new models.

**Predicting genetic communities using frequently shared identity by decent segments.** L. Doroud<sup>1</sup>, S. Hateley<sup>1</sup>, G. Yalamanchili<sup>2</sup>, H. Guturu<sup>1</sup>, K. Noto<sup>1</sup>, E. Hong<sup>1</sup>, K. Chahine<sup>2</sup>, C. Ball<sup>1</sup>. 1) AncestryDNA, San Francisco, CA; 2) AncestryDNA, Lehi, UT.

Direct-to-consumer (DTC) genomics tests provide a unique experience for individuals interested in their family history and genetic matches. AncestryDNA estimates customers' distant and recent ancestry. The recent ancestry evaluation is powered by the Genetic Communities™ algorithm, which constructs a large Identity-By-Descent (IBD) network and clusters individuals if they share a significant amount of genome-wide IBD [1][2]. With the remarkable popularity in DTC genomics and continuous expansion of our genotype database, the IBD connections among individuals grow quadratically, leading to a "hair-ball" effect on the IBD network. To address the computational challenges inherent with a genome-wide IBD network, we propose a novel approach that investigates the significance of the IBD segments within the communities. In this study, we evaluate the impact of this method on the feasibility and accuracy of community assignments. [1] <https://www.ncbi.nlm.nih.gov/pubmed/28169989>[2] <https://www.ancestry.com/cs/dna-help/communities/whitepaper>.

**A Hadoop data lake enables genocentric mining of genetic variation associated with Mendelian disease.** A.W. Hansen<sup>1,2</sup>, L. Wang<sup>1</sup>, B.G. Palazzo<sup>1</sup>, P. Panchel<sup>1</sup>, J.R. Easton-Marks<sup>1</sup>, Z. Coban-Akdemir<sup>2</sup>, J.A. Rosenfeld<sup>2</sup>, C. Eng<sup>2,3</sup>, Y. Yang<sup>2,3</sup>, J. Posey<sup>2</sup>, J.R. Lupski<sup>1,2,4,5</sup>, M. Murugan<sup>1</sup>, R.A. Gibbs<sup>1,2</sup>. 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Baylor Genetics Laboratories, Houston, TX; 4) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 5) Texas Children's Hospital, Houston, TX.

Traditional study design for disease-gene association is 'phenocentric' and assumes that enriching a cohort for phenotypic homogeneity will also enrich for genetic homogeneity. Here we have pursued a complementary genocentric paradigm to accelerate gene discovery in Mendelian disease cohorts. We employed a Hadoop open-source platform to construct a data lake, aggregating whole exome sequencing (WES) data from more than 17,500 samples—approximately ¾ of samples are probands, ¼ are unaffected family members or other healthy exomes. The only phenotypic commonality among probands is an indication for WES due to suspected Mendelian disease. Additionally, we have loaded variant-level and gene-level annotations from a variety of sources, enabling rapid, flexible annotation through Hive or Impala joins. We flagged genes harboring recurrent ultra-rare variants (MAF < 1/10k) across at least 5 samples, placing the genes into bins according to the value of one additional filtering criteria (i.e., ExAC missense intolerance z-score between 4.0 and 4.5, etc.), creating a series of gene lists across a range of possible scores for a given parameter. The fraction of Mendelian disease genes (from OMIM) was then compared across the series of gene lists corresponding to these bins. We hypothesized that when creating these binned gene lists based on filter parameter value, outlier lists with lower-than-expected disease gene enrichment would be 'corrected' as more disease genes are reported. Accordingly, we prioritize gene lists for discovery efforts as those with lower-than-expected disease gene enrichment. Comparing gene list OMIM disease ratio in 2016 vs 2018 database versions validates this hypothesis, as gene lists with lower-than-expected OMIM disease gene enrichment in 2016 have the highest increase in reported OMIM disease-gene associations from 2016 to 2018. Our approach yielded more than 100 candidate novel dominant disease genes, which we are prioritizing for both *de novo* mutation screening and functional study. For example, we identified a Sanger-validated *de novo* variant in *POLR2A* and are collaborating to study 10 patient variants in multiple model organisms. Our approach is also valuable to the study of established disease genes, such as *DDX3X*, where we have identified multiple Sanger-validated *de novo* variants in previously undiagnosed patients.

**ClinGen's Gene Curation Interface (GCI) facilitates gold-standard consistent evaluation of the clinical relevance of genes.** *M.W. Wright<sup>1</sup>, S.S. Dwight<sup>1</sup>, J. Zhen<sup>1</sup>, C. Thomas<sup>1</sup>, B. Wulf<sup>1</sup>, S. Prabhu<sup>1</sup>, H. Wand<sup>1</sup>, D. Azzariti<sup>2</sup>, M. DiStefano<sup>3</sup>, J. Goldstein<sup>3</sup>, S. Harrison<sup>3</sup>, J. McGlaughon<sup>3</sup>, E. Rooney Riggs<sup>4</sup>, N.T. Strande<sup>5</sup>, C. Thaxton<sup>2</sup>, L. Babb<sup>2</sup>, C. Bizon<sup>5</sup>, S. Goehring<sup>6</sup>, T. Nelson<sup>4</sup>, J. Zou<sup>1</sup>, G. Bejerano<sup>1</sup>, J.S. Berg<sup>3</sup>, C.L. Martin<sup>4</sup>, S.E. Plon<sup>6</sup>, H.L. Rehm<sup>2,7,8</sup>, C.D. Bustamante<sup>1</sup>, *Clinical Genome Resource (ClinGen)*. 1) Stanford University, School of Medicine, Stanford, CA; 2) Laboratory for Molecular Medicine, Partners Personalized Medicine, Cambridge, MA; 3) University of North Carolina at Chapel Hill, NC; 4) Autism & Developmental Medicine Institute at Geisinger, Danville, PA; 5) Renaissance Computing Institute, Chapel Hill, NC; 6) Baylor College of Medicine, Houston, TX; 7) Brigham and Women's Hospital, Boston, MA; 8) Broad Institute, Cambridge MA.*

With a large increase in the number of reported gene-disease relationships in recent years, there is an urgent need to critically evaluate which associations are most clinically valid. Defining the clinical relevance of genes is one of the primary objectives of the Clinical Genome Resource (ClinGen). The ClinGen gene curation process combines an appraisal of genetic and experimental data in the scientific literature with expert review to classify gene-disease pairs into 1 of 6 categories according to ClinGen's Gene-Disease Clinical Validity Classification framework. ClinGen's Gene Curation Interface (GCI) tool ([curation.clinicalgenome.org](http://curation.clinicalgenome.org)) was specifically designed to facilitate this process, enabling curators to systematically assess the strength of gene-disease associations. The GCI guides curators through the curation process, enabling them to access and evaluate evidence for a gene's role in disease in a consistent and efficient manner. All evidence is accessible to any registered user, allowing all users to view and evaluate the same set of information (Case Level, Case-Control and Experimental evidence). Members of ClinGen expert panels (EPs) can work collectively on a Classification to edit and score/evaluate the same pieces of evidence. An automated table dynamically tallies the score and provides a calculated Classification. A detailed Evidence Summary is also available and is used by ClinGen's EPs as an integral part of their expert review process. Expert Panels can now publish their final approved Classifications to the public ClinGen website ([clinicalgenome.org](http://clinicalgenome.org)), via ClinGen's Data Exchange (a data repository that harmonizes curated ClinGen data via a common data model). Controlled vocabularies and ontologies are utilized throughout the GCI in order to promote the capture of discrete evidence that will allow downstream connections between information on the ClinGen website and to promote consistency. We also briefly describe our plans to assist curators in their capture of relevant data from publications via large-scale identification and "tagging" of literature with standardized terminologies. **A test site ([curation-test.clinicalgenome.org](http://curation-test.clinicalgenome.org)) with a "demo login" facility is available for anyone who wants to explore the functionality of the GCI . We provide extensive help documentation on how to use the GCI, and there is a detailed SOP on the ClinGen website that describes how to utilize their framework.**

**1678T**

**Xrare: A machine learning method jointly modeling phenotypes and ACMG guidelines improves rare disorder diagnosis.** *X. Ma<sup>1,2</sup>, K. Zhao<sup>2</sup>, Q. Li<sup>2</sup>, C.D. Bustamante<sup>3,4</sup>, W.H. Wong<sup>1</sup>*. 1) Department of Statistics, Stanford University, 390 Serra Mall, Stanford, CA 94305; 2) GenomCan Inc., 119 University Ave, Palo Alto, CA 94301; 3) Department of Biomedical Data Science, Stanford University, 365 Lasuen Street, Littlefield Center, Room 303, Stanford, CA 94305; 4) Department of Genetics, Stanford University, 300 Pasteur Dr., Stanford, CA 94305.

Despite the successful progress of next generation sequencing technologies brought in diagnosing the genetic cause of rare Mendelian diseases, the current diagnostic rate is still far from satisfactory with ranges from ~28% in WES to 57% in the most comprehensive family trio WGS. While standards and guidelines for the interpretation of sequence variants released by the American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP) have greatly facilitated the variant pathogenicity interpretation process, subjectivity and inconsistency are still widespread across clinical molecular genetic laboratories, with the phenotype to genotype supporting evidence being the most inconsistent among the laboratories. Even though existing computational phenotype-driven methods (e.g. Exomiser, Phen-Gen) have eased the inconsistency and gained wide applications in clinical diagnoses, the heterogeneity, imprecision and noise in disease phenotype descriptions in real clinical settings posed big challenges. To combine the strength from both approaches, we developed a machine learning method for disease causative variant prioritization. We developed a novel phenotype similarity scoring method named Emission-Reception Information Content (ERIC) highly tolerant of noise and imprecision in the clinical phenotypes and incorporated ACMG domain expert knowledge in feature extraction and learning. Extensive simulations and two real clinical datasets demonstrated that Xrare outperforms existing alternative methods (e.g. CADD, M-CAP, REVEL, Exomiser, Phen-Gen etc. ) by 10-40% at various genetic diagnosis scenarios.

**CLUMPAK 2.0: Improved alignment of replicate cluster analyses.** *N.M. Kopelman<sup>1</sup>, M. Jakobsson<sup>2</sup>, N.A. Rosenberg<sup>3</sup>, I. Mayrose<sup>4</sup>.* 1) Holon Institute of Technology, Givatayim, Israel; 2) Uppsala University, Uppsala, Sweden; 3) Stanford University, Stanford, CA; 4) Tel Aviv University, Tel Aviv, Israel.

Many model-based clustering methods have been developed for the identification of population structure. These methods take as input multi-locus genotypes of individuals, and either assign these individuals into a few presumed source populations, or – more often – estimate coefficients of membership of each individual in the various clusters, summing to 1 across clusters. Typically, model-based algorithms, among which the most popular is STRUCTURE, involve stochastic steps. Assuming  $N$  individuals and  $K$  ancestral populations, where  $K$  is a parameter that is predefined, the output of a single run of an algorithm is a matrix of membership coefficients of size  $N \times K$ , termed a "Q matrix". Due to the stochastic nature of the algorithms, a typical analysis consists of multiple runs for the same value of  $K$ . Moreover, as the "real" number of ancestral populations is generally unknown, a range of  $K$  values is investigated. Thus, many Q-matrices are produced, and a comparison of these Q-matrices, as well as a summary of the results, are required. We have previously developed CLUMPP and CLUMPAK in order to aid users in automating the analysis of the results of genotype clustering programs such as STRUCTURE. Both programs incorporate various algorithms for the alignment of multiple replicates, i.e. multiple Q-matrices, produced for the same value of  $K$ . In addition, CLUMPAK separates runs belonging to distinct clustering solutions, and aligns results across different values of  $K$ , enabling publication-quality visualization of results with different  $K$  values. In this work, we have augmented the three algorithms for the alignment of replicate Q-matrices with a new algorithm. In particular, we have added the classical Hungarian algorithm, treating the alignment problem as an assignment problem. Unlike the greedy algorithms currently utilized by CLUMPP and CLUMPAK, the order in which replicates are handled does not affect the Hungarian algorithm, thus saving the need to examine large numbers of different input orders of replicates. We compare the results and running times for the Hungarian and greedy algorithms using various datasets and species. CLUMPAK is freely available for use as a web-server, allowing users to easily analyze tens or hundreds of results produced by STRUCTURE-like programs.

**1680W**

**A novel non-linear dimension reduction approach to infer population structure for low-coverage sequencing data.** *J. Zhou<sup>1</sup>, M. Zhang<sup>1</sup>, H. Zhou<sup>2</sup>, J. Watkins<sup>1</sup>.* 1) University of Arizona, Tucson, AZ; 2) University of California, Los Angeles.

With rapid advances in DNA sequencing technologies, different sequencing designs and platforms appear and provide options balancing between accuracy and cost. As a cost-effective choice, low to medium depth sequencing allows researchers afford to sequence more samples. But this sequencing relies on linkage-disequilibrium (LD)-based methods and has lower accuracy for genotype calling, especially rare-variant identification. Downstream association analyses are advised to incorporate sequencing uncertainties in order to increase the statistical power. As a fundamental dimension reduction technique, principal component analysis (PCA) is widely adopted in genetic studies to infer population structure and to adjust the bias caused by population differences in the association testing procedures. However, PCA is not designed to reveal non-linear patterns that may arise in genetics data, for example, in low-depth genomic sequencing data. We propose an advancement of a data-adaptive approach, *MCPCA\_PopGen*. Our method uses genotype likelihoods rather than genotypes and, thus, takes into account the uncertainty of raw sequencing reads to discover the non-linear patterns. *MCPCA\_PopGenis* defined via an optimization that infers transformations of genotype likelihoods and maximizes Ky Fan norm of the transformed covariance matrix. We propose an efficient block coordinate descent algorithm to determine transformation. Moreover, we propose a distributed algorithm to compute an approximation of Maximal Correlated Principal Components for dense sequencing data by chromosomal partitions. In the simulation, we reveal two major properties of our method for low-coverage sequencing data. For a locus with a low minor allele frequency (MAF), the transformation emphasizes the uncertainty in calling between heterozygous and the major homozygous loci. On the other hand, the transformation is more linear when both variants are common. We apply *MCPCA\_PopGento* a human sequencing sample from two indigenous Siberian populations, the Nganasan (nomadic hunters, NGA) from the Taymyr Peninsula in the Arctic Ocean, and the Yakut (herders, YAK) of North-Central Siberia with 5x coverage on average. Our method can separate two groups with much higher confidence in comparison with many other existing methods, including PCA.

**1681T**

**A data broker tool to coordinate availability queries and meta-analysis in a secure, compliant environment.** *E. Sukharevsky, B. Jackson, F. Syed, N. Hurskainen, T. Kanninen, A. Ahonen-Bishop.* BC Platforms, Boston, MA.

It is a contradictory time for the scientific community: while it is acknowledged that there is a need for genomic data sharing to deliver on the promise of precision medicine, optimize outcomes and reduce costs, data security regulations are becoming stricter and can limit progress. Communicating with tens or hundreds of collections individually on a global scale has been stated as one of the biggest bottlenecks in seeking data and samples for pharmaceutical research. Academic research groups and industry alike demand an ecosystem that facilitates the sharing of data and information in a safe and secure environment. This opens the door for the role of a data broker solution that can guarantee a confidential environment for biobanks to share their data with pharmaceutical researchers who seek suitable patient cohorts within validated data clouds on a global scale. Such a global ecosystem, presented here, does exist so that researchers can efficiently search for specific cohorts of patients for population research and rare tumors. With this system, biobanks also benefit by getting access to researchers, sustaining their academic relevance and financial viability. Additionally, the ability to perform controlled meta-analysis on genomic data provides researchers with necessary tools to run feasibility studies, and to investigate the safety of specific pathway targets utilizing naturally occurring mutations in the cohorts. As the platform is highly flexible in its data model and access control, its utility in the most complex data environments is unique. .

**Undiagnosed Diseases Program Database (UDPdb) of genomic data: Development and utility.** *D.L. Ross, N.J. Balanda, N. Ten, B.N. Pusey, C. Lau, W.A. Gahl, D.R. Adams.* UDP, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

The NIH Undiagnosed Diseases Program (UDP), now part of the Undiagnosed Diseases Network (UDN), is entering its 10<sup>th</sup> year of seeking diagnoses for individuals with illnesses that remain undiagnosed despite extensive medical evaluation. The UDP's diagnostic rate is approximately 25%. Extensive phenotyping as well as genome sequencing have been critical in making these diagnoses. Bioinformatic methods have drastically advanced over the last 10 years creating a unique opportunity to reanalyze patient's genomic data. Further, the accumulation of genomic data of 500+ families with undiagnosed diseases presents another unique opportunity to discover rare diseases shared by two or more patients within the cohort. The purpose of this work is to revisit past unsolved cases en bloc in a systematic and organized fashion with the conjecture that more patients can be diagnosed by examining the cohort altogether and performing reanalysis using updated methods, tools and annotation databases. The heterogenous nature of the source data for patients creates a challenge for reanalysis and cohort-wide analyses. To address this challenge, the approximately 1700 exomes and 300 genomes were uniformly aligned and joint-genotyped using the DRAGEN V2+ pipeline (Edico Genome, San Diego, CA), thereby creating a cohort-wide variant call format (VCF) file. Annotation of variants was performed using Variant Effect Predictor (VEP) and Vcfanno (Quinlan Lab, University of Utah), incorporating a broad variety of the most current annotation sources. Finally, the variant and annotation data were loaded into the GEMINI (Genome MINing, Quinlan Lab, University of Utah) platform to enable flexible and structured data queries based on family variant segregation and annotation information. The UDPdb will provide a model for studying reanalysis approaches in our extensively-phenotyped undiagnosed-disease cohort. We have built an approach to systematically reanalyze the entire cohort using new and experimental annotation sources. The speed of the DRAGEN platform combined with the analytic flexibility of the GEMINI system allows us to update the dataset on a frequent basis. Creating a standardized and updatable sequence dataset for our cohort of undiagnosed-disease study participants has the potential to allow for rapid adaptation to new analytic approaches, providing a foundation for ongoing studies of data reanalysis.

**Seekmer: A fast and accurate tool for quantitative transcriptomic analysis at low sequencing depth.** H. Zhang<sup>1</sup>, Y. Wang<sup>2</sup>, E. Aziz<sup>3</sup>, S. Wu<sup>1</sup>, G. Omenn<sup>1,2,3</sup>, R. Mills<sup>1,2</sup>, Y. Guan<sup>1,3,4</sup>. 1) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Department of Internal Medicine, University of Michigan, Ann Arbor, MI; 4) Department of Electronic Engineering and Computer Science, University of Michigan, Ann Arbor, MI.

Low sequencing depth presents a long-term challenge for quantitative transcriptomic analysis, especially in novel single-cell RNA sequencing studies. We present Seekmer, a fast and accurate quantification tool that seamlessly combines the speed of alignment-free and accuracy of alignment-based algorithms without their corresponding shortcomings. Seekmer incorporates fast alignment algorithm into alignment-free mapping, resulting in a 95% increase in speed over alignment-based tools, and up to 15% improvement in accuracy over commonly used tools. We applied Seekmer on single-cell mRNA sequencing data of K562 erythroleukemic cell line, and identified heterogeneous expression of marker isoforms across different cell types. The Python-powered package enables interactive transcriptomic analysis using IPython notebook and Python-based data analysis packages.

**Quality control of highly structured RNA-seq data from the Multimuther Study.** M.W. Stevens<sup>1,2</sup>, M. Abdalla<sup>4,5,6</sup>, Y. Jiao<sup>4,5,6</sup>, G. Leday<sup>7</sup>, J.S. El-Sayed Moustafa<sup>8</sup>, C. Menni<sup>9</sup>, G. Nicholson<sup>9</sup>, C. Holmes<sup>9</sup>, T.D. Spector<sup>9</sup>, M.I. McCarthy<sup>4,5,8</sup>, S. Richardson<sup>7</sup>, K.S. Small<sup>9</sup>, E.T. Dermizakis<sup>1,2</sup>. 1) Institute of Genetics and Genomics of Geneva, Geneva, Switzerland; 2) Department of Genetic Medicine and Development, Faculty of Medicine, University of Geneva, Geneva, Switzerland; 3) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 4) Wellcome Centre Human Genetics, Nuffield Department of Medicine, University of Oxford, Oxford, OX3 7BN, UK; 5) Oxford Centre for Diabetes, Endocrinology and Metabolism, Radcliffe Department of Medicine, University of Oxford, Oxford, OX3 7LE, UK; 6) Department of Statistics, University of Oxford, Oxford, OX1 3TG, UK; 7) Medical Research Council Biostatistics Unit, Cambridge, United Kingdom; 8) Oxford NIHR Biomedical Research Centre, Oxford University Hospitals Trust, Oxford, OX3 7LE, UK.

We describe the steps taken in our QC'ing of the highly structured RNA-seq data set generated by the Multimuther study. This study is designed to investigate the use and determine the usefulness of longitudinal multi-omics in identifying patterns associated with clinically relevant phenotypes using the extensively phenotyped TwinsUK cohort. As part of this project, 1014 RNA-seq libraries of twin pairs at three time-points over 7 years were generated. While many large data sets are presumed to be randomly sampled from a population sample, this set is highly structured containing both family structure as well as multiple, longitudinal samples from the same individual providing additional challenges as well as opportunities. Firstly, to take into account both twin structure as well as all time points to minimize bias we processed all RNA samples together and randomized them in the process of library preparation and sequencing. Important early QC steps were taken including checking for sample mislabeling, cross-sample contamination, and PCR amplification biases, which can be estimated by comparing RNA-seq reads to genotypes at both hetero- and homozygous SNPs, as in QTLtools, MBV mode (Fort et al., *Bioinformatics*, 33(12), 2017). However, 7 subjects did not have a genome available. By using the longitudinal structure, we were nonetheless able to check for coherence between time points by extending the MBV methodology to look at similarly hetero- and homozygous variant frequencies but between two RNA-seq libraries from the same person. We characterize the effect of contamination and amplification bias on this statistic using simulations. We provide this QC step as a tool, R2R, <https://qtltools.github.io/r2r/>, for use in longitudinal studies or any study with repeated measurements on the same subject or twin pair. The highly structured nature of the data, particularly the longitudinal, allowed us to residualize the effect of the genomic variation on expression to look for association of expression levels with potential sources of bias, such as RNA quality, QC content, percent exonic reads as well as batch effects due to time of collection. We compare these associations with and without residualization.

**1685F****Deep learning in accurate cell type classification and robust surface protein abundance prediction for droplet-based single cell transcriptomic data.**

*H. Xin<sup>1</sup>, J. Ma<sup>2</sup>, Y. Jiang<sup>1,4</sup>, T. Chen<sup>3</sup>, S. Fong<sup>2</sup>, T. Ideker<sup>2</sup>, W. Chen<sup>1</sup>.* 1) Department of Pediatrics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Medicine, University of California San Diego, La Jolla, CA; 3) Department of Pathology, University of Pittsburgh, Pittsburgh, PA; 4) School of Medicine, Tsinghua University, Beijing, China.

Recent developments in droplet-based single cell gene expression profiling technologies, such as the Chromium system from 10X genomics, allow biomedical researcher to measure transcript abundance for thousands of cells simultaneously. While cells from the same cell types can be clustered together based on similarities in expression profiles using unsupervised clustering methods, we observe that such approaches often lead to limited accuracy in cell type classification, due to imperfect signature gene markers, heterogeneities across cell lineages, and inevitable dropout events. In this work, we present CytoNet, a novel supervised cell classification method that predicts the abundance of surface protein markers based on the gene expression profile of each cell; and classifies the type of each cell individually thereafter. Specifically, we employed an emerging droplet-based gene expression profiling technology, CITE-seq with cell hashing, which measures the abundance of surface proteins and RNA transcripts together for each cell. We assembled a total of 100k PBMC cells from 9 samples with both RNA expression and surface marker profile available. Then we applied deep learning methods to train a neural network that predicts the surface marker profile given expression profile and classifies each cell into 8 cell types, including CD4+/CD45RA+ T cells, CD4+ T cells, CD8+ T cells, CD8+/CD45RA+ T cells, B cells, monocytes, NK cells and hematopoietic cells. Furthermore, to mitigate input noise introduced by the low sampling rate of droplet-based gene expression profiling technologies, we applied a random-walk-based data normalization method, which averages expression levels of functionally closely-related genes. We evaluated CytoNet with 10-fold cross validation and observed that CytoNet achieves over 90% accuracy in predicting cell types. Finally, we applied CytoNet to over 200k human PBMC cells from both internal and external resources. We compared cell compositions predicted by CytoNet against flow cytometry and observed that CytoNet produces similar results to flow cytometry. We implemented CytoNet using Pytorch and built an interactive webserver at <http://www.pitt.edu/~wec47/CytoNet>, as a one-stop solution of cell type classification for single-cell research community.

**1686W****Identification and prediction of cell cycle signatures in induced pluripotent stem cells using single-cell gene expression data.**

*C.J. Hsiao<sup>1</sup>, P. Tung<sup>2</sup>, J.D. Blischak<sup>1</sup>, J. Burnett<sup>2</sup>, K.K. Dey<sup>2</sup>, K. Barr<sup>2</sup>, Y. Gilad<sup>1,2</sup>, M. Stephens<sup>1,3</sup>.* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL; 3) Department of Statistics, University of Chicago, Chicago, IL.

The cell cycle is known to control cell fate decisions in cell state transitions, during which the cell cycle is tightly regulated by a family of proteins conserved across species and cell types. However, at the transcriptional level, the effects of the cell cycle on cell fate decisions can vary between different cell types, even for cells at the same cell cycle stage. To date, the cell cycle is receiving a renewed importance due to the rapid advancement of single-cell genomics technology. Especially in the analysis of single-cell gene expression, the cell cycle plays a key role in expression variation across cell states and cell types. The current study was designed to develop effective tools for assessing and predicting the cell cycle in single-cell gene expression data analysis. We collected both Fluorescent Ubiquitination-based Cell Cycle Indicator (FUCCI) – for determining the cell cycle – and single-cell RNA-seq (scRNA-seq) data from each individual using STRT-seq on the Fluidigm C1 platform. The cells were collected from iPSCs derived from 6 genotyped Yoruba cell lines. The experimental design controlled for C1 processing batch effects, as well as individual and gender effects. Using these data, we are developing a supervised approach for predicting the cyclical ordering of single cells in the cell cycle using single-cell gene expression data. We use the FUCCI fluorescent intensities to determine a cyclical ordering of the individual cells, and to assign cell time labels for individual cells representing each cell's position in one complete cell cycle. We estimate the cyclical trend of expression levels for each gene based on the FUCCI-derived cell times, and identify candidate sets of cyclical genes for model training. We train our model in in 5-fold cross-validation and evaluate the trained model in held-out validation samples and external datasets. We will compare the prediction results with existing approaches for estimating the cell cycle using single-cell gene expression data: including unsupervised approaches to construct the cyclical ordering of single cells and approaches to categorically assign the cell cycle to individual cells. These results will provide a benchmark for assessing the cell cycle in scRNA-seq data analysis. We also expect that our results will give insights into the effects of the cell cycle on gene expression variation in stem cells.

**Imputation of single-cell gene expression with an autoencoder neural network.** R. Li<sup>1</sup>, B. Liu<sup>2</sup>, M.B. Badsha<sup>1</sup>, Y.I. Li<sup>3</sup>, N.E. Banovich<sup>4</sup>, A.Q. Fu<sup>1</sup>. 1) University of Idaho, Moscow, ID; 2) Stanford University, Stanford, CA; 3) University of Chicago, Chicago, IL; 4) Translational Genomics Research Institute, Phoenix, AZ.

Due to dropout and other technical limitations in single-cell sequencing technologies, single-cell RNA-seq (scRNA-seq) data typically contain many zero expression values, resulting in a nonzero rate that are often <20% and can be as low as just a few percent. This low nonzero rate leads to problems in downstream analyses (e.g., obscuring gene-gene relationships, and blurring differences in cell subpopulations). It is of great interest to impute the zeros (i.e., missing values) in this type of data. The idea is analogous to genotype imputation methods that have been used extensively. Whereas those methods exploit the dependence structure across the DNA sequence, we will exploit dependence in gene expression. We have developed imputation algorithms based on autoencoder, a deep learning architecture, for scRNA-seq data. Our architectures make use of the dependence structure across genes and across cells. Our LATE (Learning with AuToEncoder) algorithm trains an autoencoder of 1, 3 or 5 hidden layers de novo on the data. Our TRANSLATE (TRANSfer learning with LATE) algorithm further allows for the use of a reference gene expression panel (e.g., bulk gene expression, a larger scRNA-seq data set, or scRNA-seq data of similar cells types collected elsewhere), and employs the transfer learning technique in deep learning to provide LATE with an initial set of parameter estimates. We assess the performance of LATE and TRANSLATE on simulated and real data, and compare them to existing methods (MAGIC, SAVER, scImpute, DCA, and scVI). In terms of mean squared error, LATE and TRANSLATE perform similarly, and both outperform other methods, across multiple data sets from human and mouse with different numbers of genes and cells and different nonzero rates. Our methods recapitulate nonlinear relationships between gene pairs well; when the cells are collected during a differentiation process, these nonlinear relationships reflect the differentiation trajectory. When the cells are a mixture of cell types, LATE and TRANSLATE both capture the cell types, and TRANSLATE demonstrates better capability in capturing less frequent cell types. Additionally, LATE is highly scalable: it easily runs on a large mouse brain data set (28K genes, 1.3M cells, and a nonzero rate of 7%; from 10x Genomics), and finishes the job within 17 hours on a GPU, whereas no other method can handle this data set.

**1688F**

**BAMM-SC: A Bayesian mixture model for clustering droplet-based single cell transcriptomic data from population studies.** Z. Sun<sup>1</sup>, L. Chen<sup>2</sup>, Q. Huang<sup>3</sup>, A. Cillo<sup>4</sup>, T. Tabib<sup>4</sup>, Y. Ding<sup>4</sup>, J. Kolls<sup>5</sup>, R. Lafyatis<sup>4</sup>, D. Vignali<sup>6,8</sup>, K. Chen<sup>4</sup>, M. Hu<sup>7</sup>, W. Chen<sup>1,8</sup>. 1) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 2) Harrison School of Pharmacy, Auburn University, Auburn, AL; 3) The Dietrich School of Arts & Sciences, University of Pittsburgh, Pittsburgh, PA; 4) School of Medicine, University of Pittsburgh, Pittsburgh, PA; 5) School of Medicine, Tulane University, New Orleans, LA; 6) Tumor Microenvironment Center, UPMC Hillman Cancer Center, Pittsburgh, PA; 7) Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH; 8) Department of Pediatrics, Children's Hospital of Pittsburgh of UPMC, University of Pittsburgh, Pittsburgh, PA.

Single cell RNA sequencing (scRNA-seq) technologies have been widely used to measure gene expression for each individual cell, facilitating deep understanding of cell heterogeneity. The recently developed droplet-based technology has quickly gained popularity because of its high-throughput and low cost. It is now feasible to conduct population scale single cell transcriptomic profiling studies, where several to tens or even hundreds of individuals are sequenced. A major task of analyzing droplet-based scRNA-seq data is the identification of clusters of single cells with similar transcriptomic profile. To achieve this goal, numerous clustering methods have been developed for unbiased inference of cell types. It is unclear how these methods can be scaled up to study population scale data with tens of thousands of cells collected from many individuals and conditions. In addition, no existing clustering method is tailored for modeling multiple layers of heterogeneity imbedded in population studies. To fill in this gap, we propose a **BA**yesian **M**ixture **M**odel for **S**ingle **C**ell sequencing (BAMM-SC) to simultaneously cluster droplet-based scRNA-seq data from multiple individuals. Specifically, BAMM-SC adopts a Bayesian hierarchical Dirichlet multinomial mixture model, which explicitly characterizes three levels of variabilities (i.e., genes, cell types and individuals). BAMM-SC has the following three key advantages: (1) BAMM-SC is able to account for potential batch effect among multiple individuals, such as unbalanced sequencing depths, variable read lengths and hidden technical biases. (2) BAMM-SC borrows information across different individuals, leading to improved power for detecting individual-shared cell types. (3) BAMM-SC can account for data heterogeneity among multiple individuals, and improves the reproducibility and stability of clustering results. We have conducted comprehensive simulation studies and applied our method to three in-house scRNA-seq datasets collected from mouse lung tissue, human peripheral blood mononuclear cells (PMBCs), and human skin tissue, respectively. We further applied BAMM-SC to a dataset from CITE-seq which is a cutting-edge method that combines multiplexed protein marker detection with transcriptome profiling for single cells. We demonstrated that BAMM-SC outperforms existing clustering methods with improved clustering accuracy and reduced impact from batch effects.

**1689W****A generative model for manifold learning for single cell RNA sequencing experiments.** *A. Verma, B. Engelhardt.* Princeton University, Princeton, NJ.

Effective analysis of single cell RNA sequencing (scRNA-seq) experiments often requires dimension reduction for visualization, regularization, and efficiency. This practice is based on the manifold assumption, that expression patterns lie on a low dimensional surface that captures the space of possible high dimension gene measurements. A robust manifold learning model should account for the nonlinear and noisy nature of gene expression from single cells. We present a generative, nonlinear latent variable model with robust, heavy-tail error modeling and adaptive kernel learning to properly capture low dimensional nonlinear structure in scRNA-seq data. Each cell's expression is modeled as a noisy draw from a Gaussian process in high dimensions with latent variable weights, or the Gaussian Process Latent Variable Model. We model noise with a heavy tailed Student t-distribution to account for observed technical and biological error including dropouts. An adaptive kernel is used to automatically estimate the smoothness of the manifold and number of latent dimensions. Black Box Variational Inference is used to overcome the intractability of likelihood function for inference of the latent manifold. Batch learning enables scalable fitting for large data sets as experiments grow to hundreds of thousands and millions of cells. We demonstrate our model's ability to accurately capture clustering and developmental behavior from previously published experimental data. Preliminary results show superior separation of labeled cerebral cortex cells compared to current dimension reduction techniques commonly used for analyzing single cell experiments. The generative model also allows quantification of uncertainty in the latent positions and identification of poorly sampled regions of the manifold to inform decisions about further experiments.

**1690T****Greatly reducing the noise of single-cell RNA sequencing with transfer learning.** *J. Wang, M. Huang, G. Hu, D. Agarwah, Z. Zhou, M. Li, N. Zhang.* University of Pennsylvania, Philadelphia, PA.

Single-cell RNA sequencing (scRNA-seq) has rapidly gained popularity for profiling transcriptomes of hundreds to thousands of cells. This technology has led to the discovery of novel cell types and revealed insights into complex tissues. However, the data generation process is very noisy. There always need to be a trade-off between the number of cells and the sequencing depth. Even when the reads are deeply sequenced, efficiency loss during reverse transcription is still inevitable. We develop a fast computational method, SAVER X, which denoises and greatly improves the quality of scRNA-seq data without an extra budget to increase the number of cells or the sequencing depth. SAVER X is based on the transfer learning technique in deep learning and borrows information from public single-cell RNA sequencing data across protocols, cell types, tissues, and even species. It uses a hierarchical transfer learning framework which benefits both its wide applicability and specificity. Particularly, SAVER X builds up a complex autoencoder network that can learn both common gene networks that are widely preserved and tissue/cell type-specific gene features. The outputs are finally combined with Bayesian shrinkage and cross-validation filtering so that over-fitting is effectively reduced. As a first example, we show using down-sampling experiments of several datasets [Zeisel et.al (2015), Shekhar et.al.(2016)] that SAVER X acts as increasing sequencing depth. By borrowing information from cells in the same tissue and species but are measured with different protocols and laboratories, the down-sampled data can have comparable quality with the original data. Though neither the raw nor the imputed down-sampled data without using our pre-trained model are too poor to identify cell sub-types, these cell sub-types can clearly be detected with the SAVER X denoised data. Immune cells widely exist in many tissues. However, the cell types are very hard to identify using scRNA-seq both due to their similarity and the low total number of immune cells in a specific dataset. As a second example, we show that by pre-training SAVER X using both the half a million immune cells from Human Cell Atlas and PBMC cells from Zheng et. al. (2017), we can more accurately identify the cell types of immune cells from other tissues. Finally, using the data from Manno et. al. (2016) where the brain cells are measured in both human and mouse, we show that information across species is as well helpful. .

**1,000x faster than PLINK: Genome-wide epistasis detection with logistic regression using combined FPGA and GPU accelerators.** *D. Ellinghaus, L. Wienbrandt, J.C. Kässens, M. Hübenthal.* Institute of Clinical Molecular Biology, Christian-Albrechts-University Kiel, Kiel, Schleswig Holstein, Germany.

Logistic regression as implemented in PLINK is a powerful and commonly used framework for assessing gene-gene (GxG) interactions. However, fitting regression models for each pair of markers in a genome-wide dataset is a computationally intensive task. Performing billions of tests with PLINK takes days if not weeks, for which reason pre-filtering techniques and fast epistasis screenings are applied to reduce the computational burden. Here, we demonstrate that employing a combination of a Xilinx UltraScale KU115 FPGA and an Nvidia Tesla P100 GPU leads to runtimes of only minutes for logistic regression GxG tests on a genome-wide level. In particular, a dataset with 53,000 samples genotyped at 130,000 SNPs was analyzed in 8 minutes, resulting in a speedup of more than 1,000 when compared to PLINK v1.9 using 32 threads on a server-grade computing platform. Furthermore, on-the-fly calculation of test statistics, p-values and LD-scores in double-precision make commonly used pre-filtering strategies obsolete.

**Improving NCBI's dbSNP data quality and annotation for variant interpretation.** *M.T. Ward, L. Phan, Q. Wang, H. Zhang, G. Shekhtman, T. Murphy, C. Farrell, E. Moses, A. Astashyn, J.B. Holmes, B.L. Kattman.* NCBI/NLM/NIH, Bethesda, VA.

For nearly two decades, dbSNP - NCBI's Short Genetic Variation database - has been serving as the premier reference variation database for many disciplines of genetic research including personal genomics and medical genetics. dbSNP aggregates and annotates genetic variation data from multiple submitters, and assigns stable Reference SNP (rs) identifiers that can be used as citation in publications and for annotating and integrating with other data sources. The database houses variation and frequency data from thousands of submitters, ranging from large-scale projects including HapMap, 1000Genomes, GO-ESP, ExAC, GnomAD, TOPMED and HLI to more focused studies such as locus-specific databases (LSDB) and clinical variants in ClinVar. It has over 650 million human RS identifiers, averaging one variant every five nucleotides across the genome. In this presentation, we describe several approaches that integrate dbSNP with other NCBI resources (Genome, RefSeq, etc.) to improve the data quality and annotation of this unprecedented large variation dataset and to aid variant interpretation and prioritization. - Identify suspect Paralogous Sequence Variants (PSVs) due to sequence differences in paralogs. - Identify potential misreporting of SNVs in repeat regions by analyzing mapping results along with RepeatMasker. - Remap variants from one assembly to another in aligned regions with gaps. - Identify possible false variant calls and other data issues including differences in alleles due to assembly-to-assembly differences. - Add functional and regulatory elements including enhancers, promoters and CpG islands to variant annotation. - Compare data from multiple submitters to check for concordance and for methodological biases for both variant and allele frequencies. This work is supported (in part) by the intramural research program of the National Library of Medicine, National Institutes of Health.

**Integrate genome, phenome and transcriptome data to detect novel disease-gene association using GWAS summary data.** *B. Wu<sup>1</sup>, B. Guo<sup>1</sup>, N. Liu<sup>2</sup>.* 1) University of Minnesota, Minneapolis, MN; 2) Indiana University, Bloomington, IN.

Genetics have the great potential to personalize and improve the disease treatment by tailoring to patients' genetic profiles. In the past decade many large-scale genome-wide association studies (GWAS) have been conducted and successfully identified tens of thousands of genetic variants associated with various diseases and traits. However in total these identified genetic variants explained only a small proportion of the heritability for most traits, suggesting that there remain many more genetic variants to be discovered. This is (i) mainly due to the small effect sizes of most genetic variants, which requires very large sample sizes to achieve decent detection power; (ii) partially due to the current dominating practice of single trait and single variant association test in the field of GWAS analysis, despite the fact that most traits are polygenic in nature; and (iii) the extreme multiplicity associated with testing individual variants genome-wide. We discuss several of our recently developed methods to integrate phenome (multiple traits), genome (multiple variants), and transcriptome data to detect novel disease-gene association that need only GWAS summary data. We build statistical models to develop sound association test methods, and develop efficient and accurate numerical algorithms to quickly compute the analytical p-values for all our proposed methods without the need of resampling. Our methods nicely unify (i) pleiotropy of variants, (ii) polygenicity of traits, and (iii) transcript mediated association, into a coherent modeling framework. We demonstrate the utility of our proposed methods through rigorous numerical studies and analysis of GWAS summary data for multiple lipids traits, glycemic traits, and psychiatric disorders. Our approach identified many novel loci that were not detected by the existing methods. .

**Amplimap: An open-source analysis pipeline for targeted high-throughput sequencing data.** *N. Koelling, M. Bernkopf, E. Calpena, G. Maher, K. Miller, H. Ralph, A. Goriely, A.O.M. Wilkie.* MRC Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, United Kingdom.

Next-generation targeted sequencing, for example with PCR-based amplicons or single-molecule molecular inversion probes (smMIPs), is widely used to resequence candidate genes in large panels or to identify low-frequency mutations (<5% allele frequency) using high-coverage sequencing. This enables cost-effective screening of patient cohorts for novel pathogenic mutations and detection of somatic mutations from cancer samples or mosaic cases. While various tools exist to analyse such data, they often either require specialized bioinformatics knowledge or only support a small set of analyses. Pitfalls specific to this type of experiment, for example off-target capture events introducing false positive variant calls, are also common yet not always considered during primer design and analysis. We introduce amplimap, a free open-source pipeline to automate the processing and analysis of data from the most commonly used protocols, including standard PCR-based amplicons and probes with/without Unique Molecular Identifier (UMI) sequences. Taking raw sequencing data (FASTQ) as input, amplimap generates a variety of output files with a single command, including read alignments, per-basepair nucleotide counts (pileups) and annotated germline variant calls. By leveraging knowledge of primer sequences and their corresponding genomic regions, amplimap improves accuracy and identifies off-target capture events. It can also extract UMI sequences from reads to generate consensus pileups: particularly important in ultra-high-coverage applications, where true low-frequency variants must be distinguished from errors introduced during sequencing or PCR amplification. As a Python 3 package, amplimap can easily be installed on Linux and Mac systems. Built on top of Snakemake, it can intelligently determine which processes need to be run and take advantage of computing clusters such as LSF or SGE. Under the hood, it interfaces with commonly used tools such as BWA, GATK, Annovar and SAMtools to follow best practices. All source code is freely available from <https://github.com/koelling/amplimap> amplimap was developed in close collaboration with wet-lab scientists to ensure maximum user-friendliness and wide applicability. Here, this will be illustrated through three case studies: germline variant screening in a patient cohort, quantification of transcript abundance to detect nonsense-mediated decay and validation of low-frequency somatic mutations in a survey of testis samples.

**1695W**

**A workflow to improve variant calling accuracy in molecular barcoded sequencing reads.** *M. Tai<sup>1</sup>, C. Yin<sup>2</sup>, G. Smith<sup>1</sup>, W. Xu<sup>1</sup>.* 1) Department of Molecular Genetics, True Health Diagnostics, 6170 Research Rd. Frisco, TX; 2) Department of Mathematics, Statistics, and Computer Science, University of Illinois Chicago, Chicago, IL.

Molecular barcoded multiplexed amplicon sequencing can be used to identify and correct sequencing errors and amplification biases introduced during library preparation in low-frequency variant calling. Barcode aware variant calling algorithms can achieve higher sensitivity detecting variants at very low allelic fractions in somatic tissue. Additionally, a linear relationship between the read depth and the copy number can be more consistently established by reducing PCR duplicates to the unique templates captured during the initial enrichment stages. We propose a generic workflow to improve variant calling accuracy taking advantage of molecular barcoded sequencing reads by applying a base score correction method to duplicate or overlapping read pairs across the targeted panel. The workflow introduces a few additional steps to the typical processing pipeline. First, we strip the molecular barcode from the sequencing read and associate it with the read name for downstream processing. After alignment, we perform steps to mask the primer sequences used for enrichment and apply base score correction on discordant bases called within any overlapping or duplicate read pairs sharing the same barcode for the same primer. After the correction is applied, a deduplication step is performed to select the read pairs with the highest overall base call qualities between duplicates. We demonstrated the ability of the workflow to reduce the false positive rate of variant calls in homopolymer and repetitive regions where the sequencer commonly encounters phasing errors interfering with base calling. The analysis was focused on three specific regions within a custom QIAseq targeted DNA (Qiagen, USA) of 220 genes with high false positive rate in the clinical validation study. Uncorrected and corrected datasets were compared at targeted regions to reference calls from NIST and exome data from a reference laboratory (Macrogen, USA). The base correction method was able to remove all false positives previously identified without the correction method while retaining the true positive call in the dataset. We have shown that our workflow incorporating base correction of molecular barcoded sequencing data can be applied to germline sequencing to improve variant calling accuracy in genomic regions with certain repetitive sequence motifs.

**DeFine: Deep convolutional neural networks accurately quantify intensities of transcription factor-DNA binding and facilitate evaluation of functional non-coding variants.** *M. Wang.* Center for Bioinformatics, School of Life Sciences, Peking University, Beijing, 100871, P. R. China.

The complex system of gene expression is regulated by the cell type specific binding of transcription factors to regulatory elements. Identifying variants that disrupt the normal regulation and give rise to human diseases remains a great challenge. To address this, we built and trained sequence-based deep learning regression models that accurately predicted the cell type specific transcription factors ChIP-seq signal intensity, which measured the *in vivo* DNA sequence binding affinity of transcription factors. Unlike existing methods that just predicted the binary outcome binding/unbinding, our model was capable of predicting the continuous TF binding intensity to any sequence. We showed that the deep learning models captured known motifs of different TFs. The capability of accurately predicting the sequence binding affinity enabled us to develop the tool DeFine (Deep learning based Functional impact of noncoding variants evaluator, <http://define.cbi.pku.edu.cn>) with improved performance for assessing the functional impact of noncoding variants including SNPs and indels. Furthermore, DeFine integrates three-dimensional genome contact maps so that it is able to indicate the potential affected genes for each regulatory variant. DeFine is an effective and easy-to-use tool that facilitates systematic evaluation of functional noncoding variants.

**To bind or not to bind: A deep learning approach for explaining TF-DNA recognition.** A. Zheng<sup>1</sup>, M. Lamkin<sup>2</sup>, H. Su<sup>1</sup>, M. Gymrek<sup>1,3</sup>. 1) Department of Computer Science and Engineering, University of California San Diego, La Jolla, CA; 2) Department of Bioengineering, University of California San Diego, La Jolla, CA; 3) Department of Medicine, University of California San Diego, La Jolla, CA.

Binding of transcription factors (TFs) is one of the major transcriptional regulation mechanisms. Most TFs have intrinsic binding preferences to specific motifs. However, these motifs cannot completely explain TF binding affinity: a TF motif can occur as many as one million times across the human genome, whereas only 1% or fewer of these occurrences may actually be bound *in vivo*. To comprehensively understand TF-DNA recognition, we developed "Agent Bind", a deep learning approach, which enables both prediction and interpretation of TF binding affinity. Previously, several deep learning approaches, such as DeepSEA and DeepBind, proposed to tackle similar problems, including predicting noncoding variant effects and chromatin accessibility. However, these methods restrict analysis to regions with known binding activities and do not include regions without regulatory functions. Thus, they have limited power to identify key elements that contribute to TF-DNA recognition. Importantly, our approach incorporates regions both with and without binding activities, and pay special attention on identifying signals in the motif context that differ between these two categories. The prediction module in Agent Bind consists of a five-layer convolutional neural network (CNN). For each TF, we identified all genomic regions containing the target motif. Regions were labelled as positive or negative based on their overlap with ENCODE ChIP-seq peaks and used as input to our CNN model training. Our overall classification performance reached AUC=0.92 on average, demonstrating that sequence context contains critical additional signals beyond the core motifs for determining TF binding. For the interpretation module, we implemented deep Taylor decomposition, a state-of-the-art model interpretation method, to explain prediction decisions. This method annotates positions in every input sequence with quantitative scores according to their contributions to the prediction results. We found that 78% of the most influential bases overlap known motifs and are highly enriched for motifs recognized by pioneer factors. The additional 22% of scores are concentrated in proximal flanking regions and contain sequence features that are yet to be characterized. Overall, our results show that Agent Bind can shed light on the critical challenge of determining whether a given motif instance will be bound or unbound by its target TF and help in explaining the underlying determinants of TF-DNA recognition.

**1698W**

**Consistent variant annotation using the Clinical Annotation Reference Templates (CART).** S. Yost, M. Munz, E. Ruark, S. Mahamdallie, A. Renwick, N. Rahman, *The Transforming Genetic Medicine Initiative (TGMII)*. Division of Genetics, Institute of Cancer Research, London, United Kingdom.

NGS gene testing involves variant annotation against the reference genome. However, in clinical reports nucleotide and protein annotation against a transcript is given. This has the advantage of not changing between genome builds, but the disadvantage that no 'reference transcripts' equivalent to the reference genome is available. This leads to inconsistency because different labs use different transcripts. Moreover, most clinical labs use RefSeq NM transcripts which may not match the reference genome, whereas databases, such as ExAC use Ensembl ENST transcript releases, which match the reference genome, but change frequently. To address these problems we have integrated clinical and scientific data to define a set of Clinical Annotation Reference Templates (CARTs), which can be used to give consistent gene variant annotation and frequency data, similarly to how the reference genome is used to provide consistent genomic annotations. The CART defines the five properties required to annotate gene variation for clinical reports: 1) reference genome build, 2) strand, 3) total number of exons, 4) exon boundary positions, 5) translation start and stop positions. We also provide the ENST and related NM and if/how the NM differs from the reference genome. For each gene the CART matches an ENST, which by definition matches the reference genome and a related RefSeq NM, for which we have generated the matching reference genome sequence. For 17,957 CARTs the coding sequence is identical between build 37 and 38, and 14,350 of these have identical sequence end-to-end. For most genes, using the CART would not alter the clinical annotation, and other annotations will not be required. However, the CART annotation can and should be used in addition to other transcript annotations, where appropriate. For example annotation against tissue-specific transcripts may be appropriate in some clinical or scientific scenarios. The CART annotations aim to deliver a single consistent annotation of a variant, to facilitate accurate interchange and integration of variant calls. Having a stable, versioned, set of templates for annotation will make clinical reporting and data sharing of WES and WGS gene testing simpler and more robust. Our work has also highlighted important discrepancies that need to be addressed, for example when comparing RefSeq and Ensembl transcripts, there are 53 transcripts that match against different genes on build 37 and a further 14 mismatches on build 38.

**1699T**

**ERVcaller: Identifying and genotyping non-reference unfixed endogenous retroviruses (ERVs) and other transposable elements (TEs) using next-generation sequencing data.** X. Chen<sup>1</sup>, D. Lji<sup>2,3,4</sup>. 1) Department of Microbiology and Molecular Genetics, University of Vermont, Burlington, Vermont 05405, USA; 2) Department of Computer Science, University of Vermont, Burlington, Vermont 05405, USA; 3) Neuroscience, Behavior, and Health Initiative, University of Vermont, Burlington, Vermont 05405, USA; 4) University of Vermont Cancer Center, University of Vermont, Burlington, Vermont 05405, USA.

More than 8% of the human genome is derived from endogenous retroviruses (ERVs). In recent years more and more polymorphic (unfixed) ERVs were found to be associated with human diseases. However, it is still challenging to accurately detect polymorphic ERVs using next-generation sequencing (NGS) data. As such, development of new tools is needed to rectify this shortcoming. We designed a new tool, ERVcaller (<http://www.uvm.edu/genomics/software/ERVcaller.html>), to accurately detect and genotype non-reference unfixed transposable elements (TEs), including ERVs, in the human genome. We evaluated the tool using both simulated and real benchmark whole-genome sequencing datasets. The detection power and precision were ~98% and ~99%, respectively, and the genotyping accuracy was ~97% under 30X sequencing depth. We compared ERVcaller with four existing tools. ERVcaller consistently showed the highest sensitivity and precision for detecting and genotyping non-reference unfixed TEs, particularly ERVs, as well as produce the most accurate breakpoints at single nucleotide resolution, especially under low sequencing depths. By applying ERVcaller to the 1000 Genomes Project samples, we detected 100% of the ERVs and 95% of the TEs that were experimentally validated. In conclusion, ERVcaller is capable of accurately identifying and genotyping non-reference unfixed ERVs and other TEs using NGS data. Additionally, this tool is applicable to analyze NGS data from animals and plants.

**reGenotypeTE: A tool to improve genotype prediction for mobile element insertions.** J. Thomas<sup>1</sup>, C. Goubert<sup>2</sup>, L.M. Payer<sup>3</sup>, J.M. Kidd<sup>4</sup>, J.E. Feusier<sup>1</sup>, W.S. Watkins<sup>1</sup>, K.H. Burns<sup>3</sup>, C. Feschotte<sup>2</sup>, L.B. Jorde<sup>1</sup>. 1) Department of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT; 2) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY; 3) Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Department of Human Genetics, Department of Computational Medicine and Bioinformatics, University of Michigan Medical School, Ann Arbor, MI.

Non-LTR retrotransposons constitute more than one third of the human genome, stemming from their proliferative activity over the last 100 million years. Their continued activity in the human lineage has generated polymorphic insertions, where individuals or populations share the presence or absence of a mobile element insertion (MEI). Such polymorphic MEIs are a source of genetic variation and can lead to regulatory polymorphisms that alter gene expression. The polymorphic MEIs are also used as markers of ancestry in population genetics to understand the structure and evolution of populations. These studies depend on accurate genotyping of MEIs, thereby enabling correct estimations of their allele frequencies. However, accurate MEI genotyping using short-read alignments is inherently challenging due their repetitiveness, and dedicated tools are scarce. In addition, we found that a large proportion of MEIs genotyped in the 1000 Genomes Project (1KGP) show excess heterozygosity compared to SNPs, which contradicts expectations for such largely neutral markers. We thus have developed a pipeline called *reGenotypeTE* that aims to genotype both reference and non-reference MEIs from whole genome paired-end resequencing data aligned to the reference assembly. The pipeline analyzes the MEI breakpoints detected by other tools, such as *MELT*, for non-reference insertions. First, all mapped reads including discordant reads and their mates are extracted for each locus. The consensus sequence of MEI at each locus is either generated through a local *de novo* assembly or extracted from the Repbase database. The pipeline then identifies the hallmarks of non-LTR retrotransposition (i.e. a poly-A tail and target site duplications) and the strand orientation of the MEI. The extracted reads are then mapped to two alleles (with and without TE insertion) separately, and the genotype likelihoods are calculated using established methods. To confirm the accuracy of prediction, we compared *MELT* and *reGenotypeTE* predicted genotypes to PCR-based genotypes generated for 37 reference and 102 non-reference MEIs in 45 CEU individuals from the 1KGP. On average, our genotype predictions were 91% concordant with the PCR genotypes whereas those predicted by *MELT* v2.1.4 were 72% concordant. These data indicate that *reGenotypeTE* improves the accuracy of MEI genotype prediction and will be valuable in identifying candidate regulatory variants and markers of ancestry in population genetics.

**Refining the ability to detect human-specific LINE-1 insertions using long-read sequencing technology.** *W. Zhou<sup>1</sup>, S. Emery<sup>2</sup>, D. Flasch<sup>2</sup>, Y. Wang<sup>2</sup>, K. Kwan<sup>2,3</sup>, J. Kidd<sup>1,2</sup>, J. Moran<sup>2,4</sup>, R. Mills<sup>1,2</sup>.* 1) Department of Computational Medicine and Bioinformatics, University of Michigan Medical School, 100 Washtenaw Avenue, Ann Arbor, MI 48109, USA; 2) Department of Human Genetics, University of Michigan Medical School, 1241 East Catherine Street, Ann Arbor, MI 48109, USA; 3) Molecular and Behavioral Neuroscience Institute, University of Michigan Medical School, 109 Zina Pitcher Place, Ann Arbor, MI 48109, USA; 4) Department of Internal Medicine, University of Michigan, 1500 East Medical Center Drive, Ann Arbor, MI 48109, USA.

Long Interspersed Element-1 derived sequences (LINE-1s or L1s) comprise ~17% of the human genome. The mobilization of active L1s contributes to inter- and intra-individual genetic variation, and L1 insertions into genes occasionally can lead to human genetic disorders. Various strategies have been developed to identify human-specific LINE-1 (L1Hs) insertions from short-read whole genome sequencing (WGS) data; however, these approaches are limited in their ability to identify L1Hs insertions that reside within genomic regions containing pre-existing LINE-1 sequences. The advent of single molecule, third generation Pacific Biosciences (PacBio) DNA sequencing has allowed the direct sequencing of long stretches of contiguous DNA, permitting an additional approach to identify L1Hs insertions. Here, we describe the development of a computational pipeline (PALMER) to identify non-reference L1Hs insertions in PacBio DNA sequencing data. PALMER identified 199 non-reference L1Hs insertions in the well-characterized NA12878 sample, including 92 that were not detected using standard short-read WGS data, representing a ~2-fold enrichment of L1Hs insertions in NA12878. Using this L1Hs dataset as a gold standard, we then assessed the ability of WGS to identify germline L1Hs insertions in single-cell sequencing data obtained from four individual NA12878 cells. Approximately 66% of L1Hs insertions were not detected in our single-cell experiments and the majority of these L1Hs insertions were nested inside of reference LINE-1 sequences. We observed a wide variation in L1Hs insertion detection accuracy between individual single-cell WGS experiments. Our preliminary data further suggest that a 3' targeted L1 capture assay had a higher sensitivity and lower false discovery rate at detecting L1Hs insertions when compared to single-cell WGS. Together these results indicate that ongoing studies of mobile element insertions in bulk and single cell experiments using standard WGS approaches may underestimate the numbers of L1Hs insertions near or nested within reference LINE-1s.

**Manta: Improving the accuracy of structural variant calling.** *X. Chen, N. Narai, A. Gross, S. Ji, C. Saunders.* Illumina, Inc., 5200 Illumina Way, San Diego, CA, USA.

Manta is an open-source method designed to discover structural variants (SVs) from next generation sequencing data. Manta is optimized for rapid germline and somatic analysis, calling SVs, medium-sized indels and large insertions on standard compute hardware. Since its initial publication in 2015, ongoing development of Manta has led to improved call accuracy and expanded scope of applications such as multi-sample germline calling and tumor-only calling. A TIGRA-like, iterative assembler has been recently introduced in Manta to improve the quality of alternative contigs assembled from evidence reads. The new iterative assembler outperformed a few state-of-the-art local assemblers in our comparative analysis, and has been shown to improve the call sensitivity across SV types and sizes, and to be able to accurately assemble insertions of size larger than 500 bp with high-depth, short-read data. Furthermore, the contig aligners are tuned to improve the germline call precision in noisy and/or low complexity regions, particularly for indels of size between 51 and 200 bp and large SVs of size more than 10 kbp. This study reports improved Manta performance for both germline and somatic calling, as determined by comparison of germline calls to GIAB germline calls and comparison of somatic calls to COSMIC database variants. This study also highlights directions of ongoing Manta improvements including utilization of depth information to improve the precision of deletion/duplication calls, and recovery of unmapped reads to improve the accuracy of large insertion calls. Such improvements reflect the development work of Manta towards an accurate, fully featured structural variant caller.

**1703F**

**Highly-accurate detection of SNVs from long read sequencing with high error rates.** *P. Edge<sup>1</sup>, V. Bansal<sup>2</sup>*. 1) Department of Computer Science Engineering, University of California, San Diego, La Jolla, CA; 2) Department of Pediatrics, University of California, San Diego, La Jolla, CA.

Single molecule sequencing (SMS) technologies such as Pacific Biosciences (PacBio) Single Molecule Real-Time (SMRT) sequencing have seen increased adoption in recent years. Compared to short reads, SMS long reads have better capability for genome assembly, haplotype assembly, and resolution of large structural variations. Further, long reads are capable of uniquely mapping to more of the genome than short reads, including coding regions coinciding with gene duplications. However, the high indel error rate of SMS reads makes the detection of Single Nucleotide Variants (SNVs) more challenging than with short Illumina reads, in particular for heterozygous variants. For this reason, there are limited methods for calling SNVs in diploid organisms using SMS reads. We introduce REAPER, a realignment-based diploid SNV caller that calls haplotype-resolved SNVs from long reads. REAPER uses a realignment-based approach to allelotype and estimate quality values for potential variant sites, and iteratively refines genotypes and haplotypes using the HapCUT2 algorithm. We use REAPER to call SNVs with high precision and recall for four human individuals, and validate the calls against high-confidence variant calls from the Genome in a Bottle (GIAB) consortium. We find that REAPER calls variants with excellent precision and recall (see table), achieving 99.6% precision and 97.0% recall from 44x SMS reads for the NA12878 genome. We analyze the locations of false positive SNVs and find that 80.7% occur at true indel variant sites, indicating that classification of these sites can improve the precision even further. Further, we use simulated SMS reads to show that REAPER is capable of calling variants in highly similar (99.9% similarity) segmental duplications. REAPER called variants in these regions with a recall of 93.2% from 40x coverage simulated SMS reads, compared to 33.9% recall using 40x coverage simulated short reads. The ability to call variants in low-mappability regions allows the detection of variants in highly similar gene paralogs and more complete profiling of human genetic variation.

Table: Summary of variants called on chromosome 1 with REAPER using SMS reads for 4 GIAB individuals.						
Genome	SMS read coverage	SNVs called	Precision	Recall	Outside GIAB high-confidence	Runtime (hours)
NA12878	~44x	281,525	0.996	0.97	40,673	13:39
NA24385	~69x	277,921	0.99	0.975	42,235	20:39
NA24149	~32x	225,890	0.997	0.837	30,097	5:51
NA24143	~30x	212,458	0.997	0.767	26,415	5:31

**1704W**

**Comprehensive characterization across the spectrum of tandem repeat variants.** *H. Kang, A. Tan*. Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI.

Accurately detecting polymorphic alleles from a population of genome sequences is a very important step to comprehensively understand the genetic architecture of disease-related traits. One of the known challenges in variant calling is that Indels calls are much less reproducible than SNPs and the discordance rate of indels is particularly high in the repetitive (low-complexity) regions of genome. This is because tandem repeat variants (TRVs), which includes STRs (Short Tandem Repeats or microsatellites) and VNTRs (Variable Nucleotide Tandem Repeats or minisatellites), encompass a large proportion of indels, especially in repeat-rich regions, and they are more prone to alignment errors and misleading representations. As a result, existing callers tend to undercall TRVs or only calls a specific class of TRVs, making a comprehensive understanding of TRVs very challenging. We present a principled way to characterize TRVs across the entire spectrum of tandem repeats variants, and present a robust algorithm for comprehensively detecting and characterizing TRVs among indels. Unlike previous methods that rely only on reference genomes to identify TRVs, our algorithm integrates reference sequence and allelic variation together to infer "allelic window", which allows us to determine repeat tracts and units. Starting from an arbitrary variant call set in VCF (Variant Call Format), our method groups specific indels together based allelic window inferred jointly from reference and non-reference alleles. Using the allele windows, we were able to quantify relative abundance of observed TRVs across all allele lengths and repeat context. We found that the TRV is 10 times more enriched than average when allele window is 5, and more than 100 times enriched when allele window is greater than 10, across all allele lengths. Our results can be used to model relative mutation rates of TRVs, or to be used as priors for calling Indels and TRVs. Furthermore, our method allows us to properly integrate multiple TRVs in the presence of alignment and sequencing errors, accounting for repeat-rich sequence context, especially multi-allelic indels. Instead of dichotomously classifying indels and TRVs separately, we demonstrate that dual representation of Indels as Indel or TRV allows us to determine more accurate representation of the variant at the time of genotyping. Our algorithms are publicly available at <http://github.com/atks/vt>.

**A comparative evaluation of accelerated variant calling pipelines for human germline whole-genome sequencing data.** *S. Maciuca, T. Hickman, S. Chacko, A. Daly, K. Walter, J. Randall.* Wellcome Sanger Institute, Cambridge, United Kingdom.

The analysis of next-generation sequencing data typically starts with mapping reads to the reference genome, followed by calling small variants observed in the read pileup, in the form of SNPs and INDELS. The accuracy of this process is critical to downstream analyses of variant interpretation and disease association. A number of tools have been published, widely used and typically benchmarked against high-confidence variant calls from a small number of well-characterized human genomes, developed by projects such as *Genome in a Bottle* and *Platinum Genomes*. The limitation of these gold standard call sets is that they were built by integrating variant callers based on short reads, which biases testing towards genomic regions that are accessible to short-read technologies. More recently, a new "truth set" was built from a synthetic diploid mixture of two haploid PacBio assemblies of hydatidiform mole cell lines, which are homozygous across the whole genome. This truth set provides a less biased benchmarking framework because it was derived from a method orthogonal to the ones being tested, based on long-read sequencing data. With growing initiatives for population-scale genome sequencing (*100,000 Genomes Project*, *UK Biobank*), there is a need to evaluate variant calling pipelines in the context of computational performance. In the past year, several hardware-accelerated implementations have been released, such as **GATK4** with Intel FPGA (field-programmable gate array) and avx512 support and **DeepVariant**, with GPU (graphics processing unit) support. We evaluate these solutions against the synthetic diploid truth set, along with standard **GATK4** deployed on a public and private cloud, in order to assess their scalability to very large sample sizes, on the order of 10s to 100s of thousands of genomes. While offering a robust genome sequence to compare against, the synthetic diploid benchmark has the limitation of consisting of a single sample. For multi-sample calling, we perform testing on 3 additional data sets and compare with results obtained from independent sources. We assess concordance with genotyping chip data, Mendelian inconsistencies for a set of trios and heterozygous calls in regions of homozygosity for a set of consanguineous samples.

**1706F**

**Joint calling and PacBio SMRT Sequencing for indel and structural variant detection in populations.** *A.M. Wenger, A. Toepfer, Y. Li, L. Hickey, J. Korlach.* PacBio, Menlo Park, CA.

Fast and effective variant calling algorithms have been crucial to the successful application of DNA sequencing in human genetics. In particular, joint calling – in which reads from multiple individuals are pooled to increase power for shared variants – is an important tool for population surveys of variation. Joint calling was applied by the 1000 Genomes Project to identify variants across many individuals each sequenced to low coverage (about 5-fold). This approach successfully found common small variants, but broadly missed structural variants and large indels for which short-read sequencing has limited sensitivity. To support use of large variants in rare disease and common trait association studies, it is necessary to perform population-scale surveys with a technology effective at detecting indels and structural variants, such as PacBio SMRT Sequencing. For these studies, it is important to have a joint calling workflow that works with PacBio reads. We have developed pbsv, an indel and structural variant caller for PacBio reads, that provides a two-step joint calling workflow similar to that used to build the ExAC database. The first stage, discovery, is performed separately for each sample and consolidates whole genome alignments into a sparse representation of potentially variant loci. The second stage, calling, is performed on all samples together and considers only the signatures identified in the discovery stage. We applied the pbsv joint calling workflow to PacBio reads from twenty human genomes, with coverage ranging from 5-fold to 80-fold per sample for a total of 460-fold. The analysis required only 102 CPU hours, and identified over 800,000 indels and structural variants, including hundreds of inversions and translocations, many times more than discovered with short-read sequencing. The workflow is scalable to thousands of samples. The ongoing application of this workflow to thousands of samples will provide insight into the evolution and functional importance of large variants in human evolution and disease.

**Pluto: Ultra-fast haplotype phasing and genotype refinement tool for ultra-low coverage DNA sequence reads.** *F. Zhang, H.M. Kang.* University of Michigan, Ann Arbor, MI.

As the number of deeply sequenced genomes increases, genomes sequenced in ultra-low coverage is continuously growing in various contexts, including non-invasive prenatal testing (NIPT), targeted sequencing with off-target coverages, and ultra-low coverage genome sequencing as alternatives of SNP arrays. Insufficient coverage inflates the error rate in genotype calling, and haplotype-based genotype refinement is a critical step to obtain high-quality genotypes from ultra-low coverage sequence reads. Recently, statistical methods to leverage a large and diverse reference haplotype panel, such as Haplotype Reference Consortium (HRC) are demonstrated to be effective in haplotype phasing or imputation. However, for ultra-low coverage sequencing, existing tools are inappropriate due to either high computational cost or the lack of ability to account for genotype uncertainty. We propose an efficient statistical method *Pluto* that enables haplotype phasing and genotype refinement from individual genomes sequenced in ultra-low coverage with orders of magnitude smaller computational cost compared to alternative methods such as Beagle. Our method integrates the Positional Burrows-Wheeler Transform (PBWT) and Variable Length Markov Chains (VLMC) to build a haplotype graph from reference haplotypes to account for genotype uncertainty. We leverage statistical methods, such as Kolmogorov-Smirnov (KS) test, to accurately and efficiently build haplotype graphs for VLMC from conditional distributions rapidly obtained from PBWT. Our experiments show that our method can achieve comparable genotype accuracy with Beagle under various sequencing depth between 0.1x or 4x when using 1000 Genomes as reference haplotypes. Specifically, our initial results show that *Pluto* provides relatively lower homozygous error rate but higher heterozygous error rate than Beagle. The computational speed of *Pluto* is 8.5x faster than Beagle when evaluated in 4x whole genome sequence reads.

**Profound perturbation of the human metabolome by obesity.** *E.T. Cirulli<sup>1</sup>, L. Guo<sup>2</sup>, C. Leon Swisher<sup>1</sup>, N. Shah<sup>1</sup>, L. Huang<sup>1</sup>, L.A. Napier<sup>1</sup>, E.F. Kirkness<sup>1</sup>, T.D. Spector<sup>3</sup>, C.T. Caskey<sup>4</sup>, B. Thorens<sup>5</sup>, J.C. Venter<sup>6</sup>, A. Telenti<sup>7</sup>.* 1) Human Longevity, Inc., San Diego, CA; 2) Metabolon, Inc., Durham, NC; 3) Department of Twin Research and Genetic Epidemiology, King's College London, London, U.K; 4) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 6) J. Craig Venter Institute, La Jolla, CA; 7) The Scripps Research Institute, La Jolla, CA.

Obesity is a heterogeneous phenotype that is crudely measured by body mass index (BMI). More precise phenotyping and categorization of risk in large numbers of people with obesity is needed to advance clinical care and drug development. Here, we used non-targeted metabolome analysis and whole genome sequencing to identify metabolic and genetic signatures of obesity. We collected anthropomorphic and metabolic measurements at three timepoints over a median of 13 years in 1,969 adult twins of European ancestry and at a single timepoint in 427 unrelated volunteers. We observe that obesity results in a profound perturbation of the metabolome; nearly a third of the assayed metabolites are associated with changes in BMI. A metabolome signature identifies the healthy obese and also identifies lean individuals with abnormal metabolomes – these groups differ in health outcomes and underlying genetic risk. Because metabolome profiling identifies clinically meaningful heterogeneity in obesity, this approach could help select patients for clinical trials.

**1709F**

**Single-nucleus RNA-sequencing of human subcutaneous adipose tissue reveals a heterogeneous population of 12 cell types.** *M. Alvarez<sup>1</sup>, K. Garske<sup>1</sup>, J.N. Benhammou<sup>1,2</sup>, J.R. Pisegna<sup>1,2</sup>, K.L. Mohlke<sup>3</sup>, M. Laakso<sup>4</sup>, K.H. Pietiläinen<sup>5</sup>, P. Pajukanta<sup>1,6,7</sup>.* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA; 2) Vache and Tamar Manoukian Division of Digestive Diseases, UCLA, Los Angeles, CA, USA; 3) Department of Genetics, University of North Carolina, Chapel Hill, NC, USA; 4) Institute of Clinical Medicine, Internal Medicine, University of Eastern Finland and Kuopio University Hospital, 70210 Kuopio, Finland; 5) Obesity Research Unit, Research Programs Unit, Diabetes and Obesity, University of Helsinki, Biomedicum Helsinki, Helsinki, Finland; 6) Bioinformatics Interdepartmental Program, UCLA, Los Angeles, USA; 7) Molecular Biology Institute at UCLA, Los Angeles, CA, USA.

Adipose tissue functions as both a metabolic and an endocrine organ that plays a key role in obesity and cardiovascular disorders. Furthermore, several cell types, including adipocytes, immune cells, and mesenchymal cells, interact to affect adipose function at the tissue level. However, the detailed cellular landscape of human adipose tissue has not been precisely determined. We used single-nucleus RNA-sequencing (snRNA-seq) to identify cell types in adipose tissue based on nuclear gene expression. We isolated nuclei from human subcutaneous adipose tissue and prepared single-nuclei RNA Illumina libraries using the 10X Chromium platform. Raw reads were aligned to the hg38 human genome with the 10X CellRanger software. Utilizing Seurat to cluster nuclei based on expression, we identified 12 cell-types in the human adipose tissue, suggesting that this tissue consists of more cell types than previously reported using FACS sorting. Differential expression analysis identified signature genes specific to each cluster and pinpointed adipocyte, endothelial cell, macrophage, dendritic, T-cell, and 7 potentially novel cell-types. To further explore these 7 cell types, we searched for their pathway enrichments using DAVID. Three of the 7 clusters were enriched for extracellular matrix processes, suggesting that they are preadipocyte- and fibroblast-related cell-types. The other 4 clusters showed enrichments for muscle/contractile and mitochondrial-related processes. Lastly, we explored if these cluster-specific marker genes exhibited associations between whole adipose tissue gene expression and metabolic traits in bulk adipose RNA-seq data from the METSIM cohort (n=335). Six of the 12 cell-type clusters were enriched for genes whose expression level is correlated with  $\geq 1$  of 47 metabolic traits ( $p < 3.14 \times 10^{-5}$ ). For example, adipocyte signature genes were enriched for genes whose expression is correlated with serum triglycerides (TGs) (OR=4.82;  $p = 8.18 \times 10^{-19}$ ), and 92.9% of these genes had a negative correlation, suggesting that TGs correlate negatively with the proportion of adipocytes in METSIM adipose transcriptomes. Taken together, snRNA-seq from adipose tissue revealed a heterogeneous population of 12 cell-types, each expressing a unique set of markers. These results, leveraging bulk RNA-seq and snRNA-seq data from human adipose tissue, provide novel insight into adipose function and can be used to decompose cell-type proportions contributing to disease phenotypes.

**1710W**

**Metabolite Quantitative Trait Loci (mQTLs) provide insights into genetically driven pathobiology in asthma.** R.S. Kelly<sup>1</sup>, B.A. Raby<sup>1</sup>, B.D. Levy<sup>2</sup>, S.T. Weiss<sup>1</sup>, J.A. Lasky-Su<sup>1</sup>. 1) Channing Division of Network Medicine, Brigham and Womens Hospital, Boston, MA; 2) Department of Medicine, Brigham and Womens Hospital, Boston, MA.

Inflammatory mediators play a key, but not fully understood, role in the pathogenesis of asthma; with metabolites derived from omega-6 and omega-3 fatty acids of particular importance. *FADS2* (fatty acid desaturase 2) encodes a crucial rate limiting enzyme within these unsaturated fatty acid pathways, and has been linked to asthmatic phenotypes. Metabolomics, which captures both genetic and environmental influences and current phenotype, is ideally suited to explore the downstream functional implications of genetic variants in *FADS2* on asthmatic phenotypes. The Childhood Asthma Management Program is a randomized clinical trial investigating the long-term effects of inhaled treatments for asthma in children. Blood samples from 375 participants with asthma were submitted for mass-spectrometry based metabolomic, transcriptomic and genome-wide profiling. A metabolite Quantitative Trait Loci analysis (mQTL) was performed using the R package *matrixQTL*, to identify metabolites whose abundance was associated with a functional variant in *FADS2*; rs968567. Mediation analysis was conducted to determine whether the genetic burden of disease severity in asthma was mediated through alterations in the levels of these metabolites. Rs968567 [C>T] was shown to be associated with increased expression of *FADS2*; ( $p=6.6 \times 10^{-14}$ ); with multiple lung function metrics, including bronchodilator response ( $p=0.013$ ), and with 67 metabolites; the majority of which were omega-6 or omega-3 derived fatty acids, and which were themselves associated with asthmatic lung function. Mediation analysis revealed that archidonate ( $p < 2 \times 10^{-16}$ ); eicosapentaenoate ( $p < 2 \times 10^{-16}$ ); docosapentaenoate ( $p=0.06$ ) and docosahexanoate ( $p=0.07$ ) were mediating the relationship between the *FADS2* variant and bronchodilator response, although only a proportion of the change attributable to rs968567 was explained by these metabolites. This study leverages population-wide integrative-omic data to demonstrate *FADS2* variants may act as mQTLs driving differential abundance of key inflammatory mediating metabolites that influence asthma severity. The balance of omega-3 versus omega-6 fatty acid conversion regulated by *FADS2* in the alpha-linoleic acid pathway is crucial for the resolution of inflammation and dampening of airway hyperresponsiveness. However, mediation analysis suggests that *FADS2* may also exert its genetic influence on asthma through the regulation of additional metabolic pathways.

**Gut microbiota composition, DNA methylome and susceptibility of developing allergic diseases in children living in rural and urban.** Z. Yang<sup>1,2</sup>, Z. Chen<sup>2</sup>, Z. Zheng<sup>1</sup>, L. Zhu<sup>1</sup>, X. Chen<sup>2</sup>, C. Wang<sup>1,2</sup>, J. Li<sup>1</sup>. 1) Department of Allergy and Clinical Immunology, the National Center for Respiratory Diseases, State Key Laboratory of Respiratory Disease, Guangzhou Institute of Respiratory Health, The First Affiliated Hospital of Guangzhou Medical University, Guangzhou, China; 2) Center for Genomics and Department of Basic Sciences, School of Medicine, Loma Linda University, CA 92350, USA.

The interplay between the diet and reduced microbiome diversity has been linked to allergy diseases. Our previous study has shown a marked difference in dietary patterns between urban and rural children exposed in different environments. However, it is unknown if this different environmental exposure and diet patterns between urban and rural children will give rise to different susceptibility of developing allergic diseases. Our study is to investigate whether different environmental exposure-modulated gut microbiota and DNA methylome may be related to food allergy (FA) between urban and rural children in Guangdong, China. A questionnaire survey was performed in 11,473 children aged 7–12 years old from urban Guangzhou and rural Shaoguan, China. A nested age-matched case-control consisting of 402 children from Guangzhou city and 349 children from Shaoguan rural area was studied. Skin-prick test and serum-specific IgE to allergens were determined. We conducted 16S rRNA gene sequencing focused on V3-V4 region consisting of 226 stool samples, i.e., 92 urban FA, 53 urban control, 38 rural FA and, 37 rural controls. We also carried out metagenomic shotgun sequencing on 96 stool DNA samples from children living in urban and rural (24 samples in each group). In addition, we obtained peripheral blood DNA methylomes on 36 subjects (both FA and controls) using Illumina Human Methylation 450k beadchips. Our study showed although the self-reported food allergy prevalence (4.0% vs. 3.5%) was not significantly different between urban Guangzhou and rural Shaoguan, there was a distinct difference in dominant genus or endotype with *Prevotella* more prevalent in rural children vs. *Bacteroidetes* more prevalent in urban children. In addition, there was a significant different DNA methylation profiles between food allergy subjects and healthy controls. We identified ninety-one candidate differential CpGs in urban and rural samples. Our preliminary data suggest urbanization or long-term lifestyle may have a significant impact on gut microbiota and there is a distinct different dominant genus or endotype between food allergy and control. In addition, there is a marked different blood DNA methylation profiles between food allergy and control. Overall, different environment-modulated gut microbiota and DNA methylation may be one of the main determining factors for different susceptibility of developing allergic diseases between urban and rural children in China.

**Transcriptomics and metabolomics show the *ORMDL3* asthma gene regulates pleiotropic effects on epithelial inflammation.** Y. Zhang<sup>1</sup>, S. Willis-Owen<sup>1</sup>, S. Spiegel<sup>2</sup>, C. Lloyd<sup>1</sup>, M. Moffatt<sup>1</sup>, W. Cookson<sup>1</sup>. 1) National Heart and Lung Institute, Imperial College London, London, London, United Kingdom; 2) Department of Biochemistry and Molecular Biology and the Massey Cancer Center, Virginia Commonwealth University School of Medicine, Richmond,.

Human chromosome 17q21 locus confers the major genetic susceptibility to childhood asthma, within which asthma-associated SNPs are strongly correlated with the transcript abundance of *ORMDL3*. The locus influences disease severity and the frequency of human rhinovirus (HRV) initiated exacerbations. The mechanisms how *ORMDL3* modulates airway inflammation and infection remain unclear. In order to investigate the role of *ORMDL3* in cellular inflammation, we performed time-series of IL1B-induced inflammation in A549 cells, using cytokine production as outputs and testing effects of *ORMDL3* siRNA knockdown, *ORMDL3* overexpression, and the SPT antagonist myriocin. We replicated selected findings in primary human bronchial epithelial (NHBE) cells. We measured global gene expression and biochemical profiles in quadruplicate. Silencing *ORMDL3* led to steroid-independent reduction of IL6 and IL8 release and reduced ER stress after IL1B stimulation. Overexpression of *ORMDL3* and myriocin increased IL6 and IL8 release. Silencing *ORMDL3* reduced expression of genes regulating host-pathogen interactions, stress responses and ubiquitination, in particular strongly reduced expression of the HRV receptor *ICAM1*. Silencing led to changes in levels of transcripts and metabolites integral to glycolysis. Increased concentrations of ceramides and the immune mediator sphingosine-1-P (S1P) were also observed. The results show *ORMDL3* has pleiotropic effects during cellular inflammation, consistent with its substantial genetic influence on childhood asthma and provide potential new therapeutic targets for the disease.

**1713W**

**Pan-Immune Project: Building an integrated T cell receptor repertoire profile for immune-related diseases.** X. Liu<sup>1,2</sup>, W. Zhang<sup>1,2</sup>, J. Wu<sup>1,2</sup>. 1) BGI, shenzhen, China1BGI-Shenzhen, Shenzhen, 518083, China; 2) China National GeneBank-Shenzhen, BGI-Shenzhen, Shenzhen 518083, China.

The human adaptive immune system provides protection against internal and external environmental pressures, such as genome somatic mutation and infected pathogens. The protection function is directly triggered by the receptors on the surfaces of T cells (TCRs) and B cells (BCRs) to specifically recognize antigens. However, up to now, it is frustrating to exactly detect some immune related diseases such as autoimmune diseases, which hinder the disease prevention and treatment. Here, we proposed a pan-immunome project, building an integrated T and B cell receptor repertoire map for immune related disease, and aimed to explore and mine the disease's immune characteristics. As the early stage of this project, we have established a pan-immune-repertoire database (PIPD, <https://db.cngb.org/pird/>) in China National Genebank to store TCR and BCR repertoire data of this project. We have collected more than 10,000 patients comprising sorts of autoimmune diseases and thousands of healthy people. All samples have been amplified TCR b repertoire and sequenced using high throughput sequencer. We developed a bioinformatic pipeline to cluster the large number of discrepant TCR b clones that are associated with the same antigen. The method has been evaluated using previously reported clones associated with certain antigen. As for each disease, the disease specific clustered clones were identified from TCR b repertoire of thousands of patients using machine learning. A statistical model was generated to diagnose diseases using those disease-associated TCRs, and performed well with high specificity and sensitivity. Thus, the immune repertoire data could reflect the individual immune status and serve as a strong biomarker for molecular classification of immune related diseases, especially for autoimmune diseases that are fairly complicated for pathogenesis and have not exactly diagnostic method for early stage patients. It is worthwhile to build an enormous immune database with kinds of diseases and healthy samples, for the potential applications, such as assisting diagnosis, prognosis evaluation, early screening and risk evaluation of disease.

**1714T****Fine-mapping autoimmune disease variants in cytokine induced cell states.**

*B. Soskic<sup>1</sup>, E.C. Gamez<sup>1</sup>, D. Plowman<sup>1</sup>, N. Nakic<sup>2</sup>, D. Tough<sup>2</sup>, W. Rowan<sup>2</sup>, C. Larminie<sup>2</sup>, T. Carlson<sup>4</sup>, P.G. Bronson<sup>3</sup>, K. Estrada<sup>3</sup>, G. Trynka<sup>1</sup>.* 1) Wellcome Sanger Institute, Cambridge, United Kingdom; 2) GSK, Stevenage, United Kingdom; 3) Statistical Genetics & Genetic Epidemiology, Biogen, Cambridge, MA, USA; 4) Tempero Pharmaceuticals, GlaxoSmithKline Co., Cambridge, MA, USA.

Autoimmune disease variants are enriched in active chromatin regions of stimulated T cells and macrophages. The functional response of both cell types differs depending on the environmental cues. Here, we sought to investigate whether disease variants play a role in specific cytokine induced conditions. Therefore, we stimulated T cells and macrophages in the presence of different autoimmune disease relevant cytokines in two time points and profiled active enhancers with H3K27ac ChIP-seq and regions of open chromatin with ATAC-seq, generating a total of 54 T cell and macrophage cell states. We observed that the majority of peaks were shared across conditions, however the levels of acetylation of H3K27 and chromatin accessibility differed. Using the available SNP enrichment methods, we were unable to fine-map disease relevant cell states, as these methods are based on the binary overlap between peaks and disease variants. We therefore developed a more sensitive method that uses the changes in histone modifications and chromatin accessibility to prioritise relevant cell states. We observed that rheumatoid arthritis (RA), multiple sclerosis (MS), type 1 diabetes (T1D), Crohn's disease (CD), ulcerative colitis (UC) and inflammatory bowel disease (IBD) variants were enriched in peaks that were upregulated during early activation of naïve and memory T cells irrespective of the cytokine induced environment. At the late time point, IBD, CD and UC were specifically enriched in regulatory regions active in Th1 and Th17 cells, as well as cells stimulated in the presence of IFN- $\gamma$ . Other immune traits were not enriched in any of the conditions at the late time point. Furthermore, CD and IBD variants were also enriched in regulatory regions specific to TNF $\alpha$  and IL-23 polarized macrophages. Our method allows for discrimination between cell subsets with subtle changes in chromatin activity and predominantly points towards the effects of autoimmune variants in early T cell activation irrespective of cytokine polarization. In addition, we have demonstrated that IBD, CD and UC variants are enriched in regulatory regions active in Th1 and Th17 cells. Disclaimer: The human biological samples were sourced ethically and their research use was in accord with the terms of the informed consents under an IRB/EC approved protocol.

**1715F****Development and validation of next-generation sequencing assay for carrier screening of alpha-thalassemia.**

*C. Ye, Q. Cai, T. Kuang, X. Meng.* WuXi NextCODE, Shanghai, China.

Alpha-thalassemia ([MIM 604131]) is one of the most common genetic diseases worldwide, especially in southern China. It usually results from single or double deletions of alpha globin genes within the alpha globin gene cluster that spans about 30 kb on the genome. Conventionally, Gap-PCR or MLPA is used for alpha-thalassemia detection. However, these PCR-based methods are costly, low throughput, and difficult to identify novel variant. Recently, NGS is promising as a replacement for patient-based and population-based carrier testing in Mendelian recessive diseases. However, NGS-based carrier screening for alpha-thalassemia is challenging due to the identical coding sequences of *HBA1* and *HBA2* and its complicated genotypes. In our developed NGS assay, besides exonic regions, capture-based probes were also designed for *HBA1/2* intronic regions and UTRs. Then, the normalized read depths of the unique regions were used for CNV calling. The called CNV was further genotyped by the maximum likelihood estimation algorithm. In validation, both NGS and MLPA assays were conducted for 986 samples. All 28 carriers (heterozygous deletion) and normal samples identified by MLPA were all successfully called by NGS assay. In addition, a novel short deletion (~100bp) on exon 1 of *HBA2* was only found through NGS assay. The frequencies of alpha-thalassemia subtypes ( $\alpha\alpha/---^{SEA}$ ,  $\alpha\alpha/-\alpha^{3.7}$ , and  $\alpha\alpha/-\alpha^{4.2}$ ) in this cohort were 0.6%, 1.92% and 0.2%, respectively. Another 600 samples were enrolled in a prospective NGS carrier screening program with optional MLPA confirmation. According to NGS results: 1) 7 samples were carriers; 2) 32 samples were low confident results; 3) the rest 561 samples were high confident negatives. According to confirmations by MLPA, 1) the sensitivity is 77.8% (2 low confident results were later found as positives); 2) the PPV is 100%; 3) the estimated specificity is 100%. The performance could be improved by balancing the low sensitivity and high PPV/specificity in future. Particularly, these two false negative samples resulted from bad coverage evenness due to batch effects. The total alpha-thalassemia carrier frequency in this cohort (eastern Chinese) as a result is 1.5% (9/600). In conclusion, we have developed and validated a NGS assay for carrier screening of alpha-thalassemia. Our results also indicated that clinical application should take more factors, such as batch effects and quality problems, into consideration in addition to analytical validations.

**Functional dissection of common genetic variation in the autoimmune-associated *TNFAIP3* locus.** J.P. Ray<sup>1</sup>, C.G. de Boer<sup>1</sup>, C. Fulco<sup>1,2</sup>, R. Tewhey<sup>1,2</sup>, C. Lareau<sup>1,2</sup>, J.C. Ulirsch<sup>1,2</sup>, L. Ludwig<sup>1,2</sup>, S.K. Reilly<sup>1,2</sup>, J. Engreitz<sup>1</sup>, A. Regev<sup>1,4,5</sup>, N. Hacohen<sup>1,3</sup>. 1) Broad Institute, Cambridge, MA; 2) Harvard University, Cambridge, MA; 3) Massachusetts General Hospital, Boston, MA; 4) Massachusetts Institute of Technology, Cambridge, MA; 5) Howard Hughes Medical Institute, Cambridge, MA.

Common genetic variation has been shown to explain a significant component of the heritability for complex, non-Mendelian inheritance of many diseases, including autoimmune diseases. However, moving from disease association to causal variant is extremely difficult, in part due to linkage disequilibrium, and in most cases neither the causal variant, the cell types in which it functions, nor its mechanism of action are known. *TNFAIP3* encodes for the well-known A20 protein, which functions to attenuate NF- $\kappa$ B signaling in a multitude of immune cell populations and contexts. Here, we study 2,781 genetic variants in the *TNFAIP3* locus, which contains multiple independent haplotypes associated with at least 8 autoimmune diseases. In order to (1) nominate causal variants that could underlie these diverse autoimmune disorders and to (2) gain a more comprehensive understanding of the regulatory architecture of this important locus, we dissect regulatory variant functionality using massively parallel reporter assays, create maps of the regulatory landscape with ATAC-seq and Hi-C, and probe the functional relevance of identified regulatory elements and variants using complementary CRISPRi and CRISPRa high throughput screens across a diverse spectrum of immune cell lines under relevant stimulation conditions. Combining all evidence, we nominate several putatively functional regulatory variants that are within linkage disequilibrium blocks for genetic association with inflammatory bowel disease, systemic lupus erythematosus, and psoriasis. Several of these variants are occupied by and predicted to disrupt the binding of key immune transcription factors. Overall, our comprehensive experimental approach is applicable to the study of disease associated common genetic variants and may be used to refine the search for causal variants in a scalable manner.

**Predicting and characterizing kidney transplant rejection risk by B cell immune repertoire sequencing.** S. Pineda<sup>1,2</sup>, T. Sigdel<sup>1</sup>, J. Liberto<sup>2</sup>, M. Sarwal<sup>1</sup>, M. Sirota<sup>1</sup>. 1) Institute for Computational Health Science, UCSF, San Francisco, CA, USA; 2) Department of Surgery, UCSF, San Francisco, CA, USA.

The diversity of the B cell immune repertoire (IR) may drive humoral injury and rejection in organ transplantation (tx). We studied functionally correlated variations in the VDJ-CDR3 regions by B cell sequencing, examining 124 DNA and RNA samples from the same tx patient before tx, and at 6 and 24 mo post-tx. Three patient groups sorted into non-progressors (NP), progressors/ no rejection (PNR) and progressors/ with rejection (PR) were scored by progressive changes in the chronic allograft damage index (CADI). Pre-tx IR diversity was significantly greater in patients that went on to reject their tx (PR vs NP,  $p = 0.008$ ). Post-tx, there was a strong interaction between clinical outcome (CADI score, AR) and time, with a significant reduction in clonal diversity ( $p = 0.01$ ) in PR, and an increase in NP. We defined a network for each sample considering the clone definition (same V and J segments, same CDR3 length and 90% nucleotide identity between CDR3s). We used Gini index for quantification and found relevant changes at 24 mo post tx (PR vs. NP,  $p=0.003$  and  $p=0.001$ ). On a further evaluation of the data, we also found specific clones and an over-expression of several IGHV genes in the rejection group, which may suggest a biological driven mechanism for rejection. The diversity of recipient IR plays a major role in driving AR and progressive chronic tissue injury, and this effect can be observed even prior to engraftment of the tx organ. Selected dominant clones expand in patients who reject allografts, and the preservation of these dominant clones results in a reduction of their diversity. Pre-tx prediction of recipient risk of rejection, provides a powerful approach for precision medicine in tx.

**Genetic and environmental factors associated with the diversity and biases of immune system.** *W. Zhang<sup>1,2</sup>, X. Liu<sup>1,2</sup>, Z. Wan<sup>1,2</sup>*. 1) BGI-Shenzhen, Shenzhen, 518083, China; 2) China National GeneBank-Shenzhen, BGI-Shenzhen, Shenzhen 518083, China.

The extremely large diversity of T-cell receptor (TCR) repertoire make up of individual immune system, acting against the external Pathogenic infection and enabling individual to keep healthy. The process of germline VDJ rearrangement, that comprise of VDJ gene recombination and random nucleotides deleted or inserted during the junction of V-D and D-J regions, contribute the huge TCR diversity and is regulated by both genetic factors and environment stimulation. The genetic influence are involved during the period of negative and positive selection of T cells in thymus and external antigen presentation. Additionally, auto or exogenous antigen stimulation causes some TCRs expansion. To explore how genetic factors and environment stimulation regulate the diversity of TCR repertoire, we collected more than 1000 volunteers and all were amplified TCR  $\beta$  repertoire and sequenced using high throughput sequencer. Simultaneously, multi-dimensional data were generated, including whole genome sequences (WGS), clinical tests, metabolomes, microbiomes, tumor screen, psychological test and so on. Using all of these data, we utilized bioinformatic method to identify genetic variations from WGS data associated with TCR  $\beta$  V genes and overall clone diversity, and found many associated variations in major histocompatibility complex (MHC) region. According to comparison of TCR repertoire and internal/external environmental data, we can find which factors are strong correlated with the diversity of TCRs. Our results clearly demonstrate the genetic environmental factors regulate the diversity of TCR repertoires, which provide clues for avoiding decreasing the capacity of immune system, and prevention and therapy of immune related disease.

**Single-cell RNA-sequencing of a patient with a mosaic RUNX3 deletion reveals an aberrant T-cell repertoire in peripheral blood mononuclear cells.** *J.H. Tsai<sup>1</sup>, V. Montel<sup>1</sup>, L.C. Watson<sup>1</sup>, M. Kellogg<sup>1</sup>, J. McEachern<sup>1</sup>, B. Lajoie<sup>1</sup>, M. Bainbridge<sup>1</sup>, J. Friedman<sup>2,3,4</sup>, R.J. Taft<sup>1</sup>*. 1) Illumina, Inc, San Diego, CA; 2) UCSD Department of Neurosciences and Pediatrics, San Diego, CA; 3) Rady Children's Hospital Division of Neurology, San Diego, CA; 4) Rady Children's Institute for Genomic Medicine, San Diego, CA.

The application of whole exome and whole genome sequencing to patients with rare, undiagnosed and genetic diseases (RUGD) has led to substantial increases in diagnostic yield, but even amongst cohorts with refined selection criteria the number of patients resolved rarely exceeds 60%. Recent advances in single-cell RNA-sequencing (scRNA-seq) enable massively parallel analysis of transcriptomes across diverse cell types, which may help deconvolute previously complex genetics and improve disease understanding. Here, we applied scRNA-seq to a patient carrying a mosaic 68kb deletion in RUNX3 with progressive neurodegeneration and an unresolved clinical diagnosis. We performed scRNA-seq on isolated peripheral blood mononuclear cells (PBMCs) from the proband and both biological parents, followed by unbiased dimensionality reduction-based clustering analysis (tSNE) on at least 5000 cells to profile the PBMC subpopulation. Using canonical immune cell gene markers to annotate the subpopulations, the tSNE plot revealed a loss of a defined CD8 T-cell cluster in the proband. Comparative analysis of the proband with the biological mother showed that the subpopulation of cells with low CD8 gene expression also had low RUNX3 gene expression, consistent with the previous studies showing that RUNX3 is linked to CD8a expression. Using flow cytometry (FACS) to profile the peripheral immune cell surface protein expression, we found a higher CD4- CD8- population in the proband compared to the biological mother (35.6% versus 19.7%, respectively), but similar levels of CD8+ cells (24.4% versus 28.3%). Combined with the scRNA-seq data, we believe the CD4/CD8 canonical protein surface markers alone may not be sufficient to detect the subtle gene expression differences observed in the T-cell populations that are identified by scRNA-seq. To our knowledge, this is the first study to show that scRNA-seq may provide insight into the biological impact of a mosaic CNV. Further studies are required to understand the link between RUNX3, the immune cell phenotype and the proband's neurodegeneration.

**Droplet assisted RNA targeting by single cell sequencing (DART-seq) enables simultaneous multiplexed amplicon sequencing and transcriptome profiling in single cells.** *M.F.Z. Wang<sup>1</sup>, M. Saikia<sup>1,2</sup>, P. Burnham<sup>1</sup>, S.H. Keshavjee<sup>1</sup>, P. Moral-Lopez<sup>2</sup>, M.M. Hinchman<sup>2</sup>, C.G. Danko<sup>2</sup>, J.S.L. Parker<sup>1</sup>, I. De Vlaminc<sup>1</sup>.* 1) Meinig School of Biomedical Engineering, Cornell University, Ithaca, NY 14853, USA; 2) Baker Institute for Animal Health, College of Veterinary Medicine, Cornell University, Ithaca, NY 14853, USA.

**Background:** High-throughput single-cell RNA sequencing (scRNA-seq) technology has provided important insights into cellular complexity and transcriptome dynamics. However, current implementations of this technology are limited to capturing information from the ends of A-tailed messenger RNA (mRNA) transcripts. Here, we describe a versatile technology, Droplet Assisted RNA Targeting by single cell sequencing (DART-seq), that surmounts this limitation allowing investigation of all regions of the polyadenylated transcriptome, as well as measurement of other classes of RNA in the cell. **Method:** Barcoded primer beads that capture the poly(A)-tailed mRNA molecules in Drop-seq are enzymatically modified using a tunable ligation chemistry to target specific RNA sequences. The resulting DART-seq primer beads are capable of priming reverse transcription of poly(A)-tailed transcripts as well as any other RNA species of interest. **Results:** We first applied DART-seq to simultaneously measure transcripts of the segmented dsRNA genome of a reovirus strain, and the transcriptome of the infected cell. DART-seq captured significantly more viral RNA in T3D reovirus-infected L cells, where the T3D mRNA lack poly(A)-tails, compared to the standard Drop-seq technique. Additionally, DART-seq increased the mean coverage of the S2 gene segment in T3D virus by 430-fold compared to Drop-seq leading to the observation of a high rate of G-to-A mutations in S2. We also found a significant increase in the proportion of viral transcripts in a subset of host cells with an upregulation of mitotic related genes demonstrating DART-seq's utility in studying the single cell heterogeneity of viral genotypes and cellular phenotypes during viral infections. In a second application, we used DART-seq to simultaneously measure natively paired, variable region heavy and light chain amplicons and the transcriptome of human B lymphocyte cells. DART-seq captured the paired heavy and light variable regions in B cells more frequently than standard Drop-seq without compromising transcriptome data for other cell types. **Conclusion:** DART-seq is an easy-to-implement, high-throughput scRNA-seq technology that overcomes the limitation of 3' end focused transcriptome measurements. We have demonstrated the versatility of DART-seq with distinct assays that probe host-virus interactions during RNA virus infection and that measure the endogenously paired antibody repertoire and the transcriptome of B cells.

**Deciphering the cellular and molecular heterogeneity of the human lung airway epithelium in smokers and non-smokers with single cell transcriptomics.** *M.A. Seibold<sup>1,2,3</sup>, N.D. Jackson<sup>1</sup>, S.P. Sajuthi<sup>1</sup>, C. Rios<sup>1</sup>, J.L. Everman<sup>1</sup>, K.C. Goldfarbmuren<sup>1</sup>.* 1) Center for Genes, Environment, and Health, National Jewish Health, Denver, CO, USA; 2) Department of Pediatrics, National Jewish Health, Denver, CO, USA; 3) Division of Pulmonary Sciences and Critical Care Medicine, Department of Medicine University of Colorado-AMC, Aurora, CO, USA.

Single cell transcriptomics is a valuable tool for inferring cell type-specific expression profiles that can be used to deconvolute the various cell phenotypes present in a system, such that the functional and genetic heterogeneity underlying these phenotypes can be accurately studied. The human proximal airway epithelium plays a vital role in respiratory health and homeostasis as well as in the pathogenesis of chronic pulmonary disease. In addition to cell types, the airway epithelium is composed of many distinct cell states whose identity, molecular phenotype, and relative prevalence in the airway remain poorly described. In this study, we characterize cellular heterogeneity in the tracheal epithelium of non-smoker and smoker donors using single cell RNA-seq of >10,000 cells. Examining these data, we find three states of basal airway stem cells, several states within two types of secretory cells, four states of ciliated cells, and various transitional cell states. We also reveal previously undescribed transcriptional signatures of rare cell types within the human airway epithelium, such as pulmonary neuroendocrine cells and ionocytes, which are likely critical to asthma and cystic fibrosis. Moreover, we characterize various immune cells that contribute to epithelial inflammation and immune responses present in many chronic lung diseases. We show that ciliated cell populations are both strongly re-programmed and proportionally reduced in smoker airways. Smoking also induces cell type-specific transcriptome shifts in other cell populations that alter airway function. In addition to functional characterization, we have developed panels of diagnostic cell surface biomarkers for described cell types and states that can be used for histological identification, isolation with flow cytometry, and deconvolution of cell type proportions in bulk RNA-seq datasets. These results provide functional information and molecular tools that will aid in our understanding and further study of the distinct and interacting transcriptional programs found within the proximal airway epithelium, both in health and in chronic lung disease.

## 1722W

**Translational evaluation of a genome-wide CRISPR/Cas9 screen of acetaminophen-induced hepatocyte toxicity reveals mechanistic insights and druggable candidate genes.** K. Shortt<sup>1</sup>, D.P. Heruth<sup>1</sup>, L.Q. Zhang<sup>2</sup>, S.Q. Ye<sup>2</sup>.

1) Children's Mercy Kansas City, Kansas City, MO; 2) University of Missouri Kansas City School of Medicine, Kansas City, MO.

Acetaminophen (APAP), a commonly used analgesic, is the leading cause of acute liver failure (ALF) in the United States and Great Britain. The drug is responsible for more than 56,000 overdose-related emergency room visits annually. APAP overdose has long asymptomatic period and limited treatment options, leading to a high rate of liver failure and frequently resulting in either organ transplant or mortality. Our aim is to identify new genetic risk factors to better understand the mechanisms of hepatotoxicity and to further identify gene and pathway candidates suitable for diagnostic and therapeutic targeting of APAP overdose and ALF. We previously described a genome-wide CRISPR/Cas9 screen, which evaluated genes that were protective against or increase susceptibility to APAP-induced liver injury. The HuH7 human hepatocellular carcinoma cell line containing CRISPR/Cas9 gene knockouts were treated with 15mM APAP for 30 minutes to 4 days to simulate partial to near total cellular death. Top candidate genes were identified based on their enriched knockout (pathogenic gene) or depleted knockout (protective gene) rankings ( $p < 0.05$ ) and were further filtered by significant differential expression in gene expression data of various APAP exposures ( $p < 0.05$ ). We now describe and extended assessment of the CRISPR/Cas9 screen data and gene expression data of 3 APAP-overdosed datasets of human patients and mice ( $p < 0.05$ ), evaluation of genes containing 147 known APAP-associated polymorphisms, and evaluation of 48 genes involved in NAD metabolism. We additionally evaluate the therapeutic potential of 53 top candidate genes, both novel and known, identified by these approaches. This study has resulted in identification of numerous genes previously not linked to liver injury. Our translational analysis approach incorporates analysis of CRISPR/Cas9 screen data, gene expression data, and gene sets identified from the literature to build a more complete understanding of the genetics of APAP-induced ALF. We propose further evaluation of candidate genes for risk assessment, diagnostic, and therapeutic utility in clinical practice as well as continued functional studies to better characterize our findings. Collectively, this line of research highlights the power of genome-wide CRISPR/Cas9 screening technology to identify novel genes and pathways involved in APAP-induced hepatocyte toxicity and to provide potential targets to develop novel or repurpose existing therapeutics.

**Transcriptome meta-analysis reveals dysregulated molecular signatures in cystic fibrosis patients with normal lung function.** J.E. Ideozu<sup>1,2,3</sup>, X. Zhang<sup>1,2,3</sup>, V. Rangaraj<sup>1</sup>, M. Kandpal<sup>3</sup>, M. Kaldunski<sup>4</sup>, A. Pan<sup>4</sup>, R. Davuluri<sup>3</sup>, P. Simpson<sup>4</sup>, M. Hessner<sup>4</sup>, H. Levy<sup>1,2,3</sup>. 1) Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL; 2) Human Molecular Genetics Program, Stanley Manne Children's Research Institute; 3) Northwestern University, Chicago, IL; 4) Children's Hospital of Wisconsin, Medical College of Wisconsin, WI.

**Introduction:** In cystic fibrosis (CF), chronic lung infection with *Pseudomonas aeruginosa* (*Pa*) is the major cause of morbidity and mortality. Prior transcriptional profiling of peripheral blood mononuclear cells (PBMCs) suggested that impaired immune cell responses are a common feature in CF patients with lung disease. However, it remains unclear whether the immune system response is dysregulated at baseline, where there is normal lung function and no evidence of mucoid *Pa* lung infection. The identification of molecular targets dysregulated at baseline could hold therapeutic potential for treatment of CF. **Methods:** Gene expression dataset generated from PBMCs stimulated with plasma from CF and healthy control (HC) subjects were retrieved from the Gene Expression Omnibus repository (GSE71799). Sixteen CF subjects (mean age  $7.48 \pm 1.53$  years) and 5 age-matched healthy controls ( $8.71 \pm 1.78$  years) were selected and analyzed to identify differentially expressed signatures at baseline. All CF subjects were F508del homozygotes, had forced expiratory volume in 1s  $> 90\%$  predicted and were negative for mucoid *Pa* lung infection ( $\pm 6$  months). Array data were normalized with Robust Multi-array normalization (RMA) and differentially expressed genes were identified with Partek GSA tool. Biological pathway and gene ontology enrichment were assessed from top differentially expressed genes (FDR  $< 0.05$ ;  $\log_2$  foldchange  $> \pm 2$ ). Further in silico analysis using the gene expression data was performed to identify dysregulated immune cells. **Results:** We identified 1045 genes differentially expressed between CF and HC subjects (FDR  $< 0.05$ ;  $\log_2$  fold-change  $> \pm 2$ ). Top dysregulated immune pathways (adjusted  $p < 0.05$ ) include TREM1 signaling, agranulocyte adhesion and diapedesis, and communication between innate and adaptive immune cells. Upstream regulator analysis revealed downregulation of several cytokines ( $p < 0.001$ ) including CCL5, IL1B, IL17A, and IL1A. The top molecular and cellular functions impaired ( $P < 0.001$ ) were cell movement of myeloid cells, cell death and survival, cellular development, cellular growth and proliferation, and cell-to-cell signaling and interaction. Cell-type enrichment analysis highlighted dysregulation ( $P < 0.05$ ) of several immune cell types including lymphocytes, monocytes, and dendritic cells. **Conclusion:** Our results suggest that CF subjects with normal lung function and without airway infection have dysregulation of their immune responsiveness at baseline.

Battey<sup>2</sup>, N. Sierra<sup>2</sup>, R.M. Gadaleta<sup>2</sup>, A.P. Kiyasov<sup>1</sup>, J. Hoeng<sup>2</sup>, M.C. Peitsch<sup>2</sup>. 1) Kazan Federal University, Kazan 420008, Russian Federation; 2) PMI R&D, Philip Morris Products S.A., Neuchatel, Neuchatel, Switzerland.

Ulcerative colitis (UC) and Crohn's disease (CD) are the two major phenotypes of Inflammatory Bowel Disease (IBD). IBD is a chronic gastrointestinal disorder characterized by periods of relapse and remission. UC and CD are often difficult to distinguish during diagnosis due to a number of common phenotypic and pathogenic features. Reliable, non-invasive biomarkers to aid diagnosis and prognosis of flares are not currently available. To fill this gap, new molecular and microbiome-based biomarkers need to be identified. Toward this end, we collected stool and blood serum samples from 40 patients diagnosed with UC, 40 patients diagnosed with CD, and 40 healthy control subjects. We investigated the gut microbiome by 16S RNA and shotgun sequencing in the three subject groups, and we measured the serum levels of (i) perinuclear anti-neutrophil cytoplasmic antibodies (pANCA) and anti-*Saccharomyces cerevisiae* antibodies (pASCA), (ii) C-reactive protein (CRP), and (iii) lipopolysaccharide (LPS). We also quantified the stool levels of calprotectin, lactoferrin, neopterin and S100A12. Finally, we evaluated the inflammation status of each subject's serum using Luminex multiplex profiling of cytokines and chemokines. Preliminary results reveal differences in microbiome profile of UC and CD subjects and other known biomarkers, which may contribute to the identification of novel molecular and microbiome-based signatures and approaches for the clinical management of IBD. .

**Characterizing podocyte cell cultures and genetic markers of podocyte maturity.** T.W. Soare, W. Zhang, A.D. Westerling-Bui, H. Hoang, A. Tebbe, L. Walsh, P. Mundel, T. Tibbitts. Goldfinch Bio, Cambridge, MA.

**Background:** Podocytes are terminally differentiated kidney cells that are vital to blood filtration. Podocyte injury and loss leads to excess protein in the urine, kidney scarring, and ultimately renal failure. Conditionally-immortalized differentiated podocytes provide an in vitro model to test hypotheses regarding mechanisms of disease and responses to treatment. However, podocytes in culture lack slit diaphragms (a morphological marker of maturity) and may lack expression of certain podocyte-specific proteins, creating doubts as to cultured podocyte maturation. **Objective:** To assess maturity of cultured podocytes, we characterized transcriptomic changes of podocyte differentiation at the single-cell resolution. **Methods:** Undifferentiated and differentiated mouse podocyte cultures were disassociated, fixed, suspended, and sequenced (Illumina HiSeq 26x40). To assess transcriptomic changes associated with differentiation and passage number, cells were clustered with principal component analysis (PCA) and visualized with t-Distributed Stochastic Neighbor Embedding (tSNE). Cell clusters were labeled by visual inspection of expression of published cell-type specific markers. We leveraged publicly-available scRNAseq data of mouse kidney to identify differentially expressed genes associated with podocyte maturation and to infer the trajectory of differentiation along the podocyte lineage. **Results:** We analyzed 1.8e9 reads in 17467 cells, identifying marker genes expressed in differentiated mouse podocytes. Differentiated podocytes in culture expressed markers of S-shaped bodies and early podocytes (*Col4a1*, *Col4a2*, *Col4a5*, *Pax2*) as well as markers of mature podocytes (*Synpo*, *Podxl*, *Nupr1*, *Plce1*, *Foxd1*). Other markers of mature podocytes were not expressed in cultured podocytes (*Wt1*, *Nphs1*, *Nphs2*, *Col4a3*, *Col4a4*). We also assess the functional importance of genes associated with podocyte differentiation by leveraging summary statistics from recent GWAS of kidney function and disease. **Conclusion:** Though differentiated podocytes in culture share transcriptomic signatures with mature podocytes in vivo, important differences remain. Future work will continue to differentiate mature mouse podocytes in culture as well as mature human podocytes in kidney organoids. Because podocytes are critical to healthy kidney function, a robust in vitro model of mature podocytes is vital to assessing mechanisms of kidney disease and responses to treatment.

**1726T****Extracting expression-modulating genetic variants from Hidradenitis Suppurativa clinical trials using massively parallel reporter assays.**

Waring<sup>1</sup>, C. Lu. 1) Pharmacogenetics and Human Genetics, AbbVie Inc., North Chicago, IL; 2) Computational Genomics, Genomics Research Center, AbbVie Inc., North Chicago, IL; 3) Genomic Technologies, Genomics Research Center, AbbVie Inc., North Chicago, IL.

With the development of large genetic biobank data, genome-wide association studies (GWAS) and whole-genome sequencing have identified numerous loci linked to human diseases and response to drug therapy. However, the correlation between nearby polymorphisms within individual associations often leaves tons of hundreds of potential causal variants to be interrogated. Additionally, disease-associated variants in noncoding regions have been estimated to explain a greater portion of the heritability for some disorders than variants in coding regions. This implies that it is absolutely crucial to have an efficient and systematic approach for identifying clinically actionable disease-causing genetic variants and target genes for drug development. In order to identify potentially functional single-nucleotide variants (SNVs) from a large pool of highly linked SNPs, we performed and optimized a high-throughput Massively Parallel Reporter Assay (MPRA) against nearly 30,000 SNVs in strong linkage disequilibrium from a previously published hidradenitis suppurativa (HS) GWAS (2016 ASHG poster abstract 1340T), aiming to detect subtle differences in how each allele drives expression. Specifically, this library contains 507 non-coding variants from GWAS ( $p < 10^{-4}$ ) as well as more than 80 random sequences serving as negative controls to assess inter-experimental noise. We chose a primary human outer root sheath hair follicle cell line that is highly relevant to HS as a model cell line for pooled MPRA screening. Next-generation sequencing was performed using the Illumina NextSeq500. Out of 622 tested variants, MPRA analysis conservatively identified 17 potentially functional variants, which were then validated by individual luciferase reporter assays in a larger genomic context (~300 bp nucleotides with the SNP sequences, followed by the promoter of a nearby gene). Interestingly, of the top SNPs with allelic function identified by MPRA, none were the top SNPs (based on p-value) from the previously reported GWAS study. This result was confirmed by individual luciferase reporter assays. In summary, we were able to successfully employ MPRA to identify 17 potentially functional SNVs from a large number of candidate variants identified from previous GWAS results. Our study clearly highlights the limitation of relying on P values alone from GWAS studies and validates MPRA as a viable method to pinpoint causal variants in disease-relevant tissue.

**1727F****Somatic mutations in focal cortical dysplasia.** V.S. Almeida<sup>1,5</sup>, S.H. Avansini<sup>1,5</sup>, M. Borges<sup>1,5</sup>, F. Rogerio<sup>2,5</sup>, B.S. Carvalho<sup>3,5</sup>, A.M. Canto<sup>1,5</sup>, E. Ghizoni<sup>4,5</sup>, H. Tedeschi<sup>4,5</sup>, C.L. Yasuda<sup>4,5</sup>, F.R. Torres<sup>1,5</sup>, F. Cendes<sup>4,5</sup>, I. Lopes-Cendes<sup>1,5</sup>.

1) Department of Medical Genetics, School of Medical Sciences, University of Campinas (UNICAMP), Brazil; 2) Department of Anatomical Pathology, School of Medical Sciences, University of Campinas (UNICAMP), Brazil; 3) Department of Statistics, Institute of Mathematics, Statistics and Scientific Computing, University of Campinas (UNICAMP), Brazil; 4) Department of Neurology, School of Medical Sciences, University of Campinas (UNICAMP), Brazil; 5) Brazilian Institute of Neuroscience and Neurotechnology (BRAINN), Campinas, SP, Brazil.

**Introduction:** Focal cortical dysplasia (FCD) is often associated with the occurrence of refractory seizures. FCD is characterized by alterations in the brain cytoarchitecture. Recently, mosaic mutations in genes of the mTOR pathway were detected in FCD; however, it is still unclear the proportion of patients with FCD who present somatic mutations. **Methods:** Deep sequencing of the mTOR pathway genes was performed on genomic DNA extracted from brain tissue resected by surgery (BTRS) and blood samples of 12 patients with FCD type II. Samples were sequenced following a 150bp paired-end protocol in a Miseq (Illumina), to achieve at least 600x of average coverage. We aligned sequences using BWA-MEM and performed realignment around SNPs and indels, quality recalibration and variant calling using the Genome Analysis Toolkit (GATK). We evaluated mosaicism using Mutect2. Variants were classified as mosaic mutations when less than 10% of reads are not aligned to the reference genomes and are present only in BTRS. Variants were filtered prioritizing frameshift, missense, nonsense and splicing site mutations that were localized in coding regions or exon-intron boundaries. In addition, we also focused on variants not described previously or variants whose minor allele frequency (MAF) is  $\leq 0.01$ . Effect of variants was evaluated using Variant Effect Predictor (VEP). **Results:** We identified somatic mutations in 8/12 patients (65%), including a previously reported somatic mutation c.4379T>C/p.Leu1460Pro (rs1057519779, NM\_004958.3) with an allele frequency of 1.8% in the *MTOR* gene. In addition, we identified, in the same patient, a *TSC2* somatic mutation c.3781G>A/p.Ala1261Thr (not reported previously; NM\_000548.3) with an allele frequency of 1.7% and an *AKT1* somatic mutation c.349\_351del/ p.Glu117del (rs768025881, NM\_005163.2) with allele frequency of 2.2%. **Conclusion:** Somatic mutations in genes of the mTOR pathway seems to be relatively common in patients with FCD type II since we found potentially deleterious variants in 65% of our patients. One of the patients studied had two somatic mutations in genes of the mTOR pathway (*TSC2* and *AKT1*) supporting the two hits hypothesis in FCD.

**Cell type-specific responses in motor neuron disease: Analysis of the cell type-specific effects of C9orf72 repeat expansion in the motor cortex of mouse models of fALS at single cell resolution.** L.A. Goff<sup>1,2,3</sup>, K. Lee<sup>2</sup>, J. Anderson<sup>2</sup>, G. Stein-O'Brien<sup>1,2,4,5</sup>, B. Winer<sup>1</sup>, D. Heo<sup>2</sup>, D. Bergles<sup>2,3</sup>, S.P. Brown<sup>2,3</sup>.

1) Institute for Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Neuroscience, Johns Hopkins University, Baltimore, MD; 3) Kavli Neurodiscovery Institute, JHU, Baltimore, MD; 4) Institute for Data Intensive Engineering and Science, Johns Hopkins University, Baltimore, MD; 5) Department of Oncology, Johns Hopkins University, Baltimore, MD.

Neurodegenerative disorders (ND) are characterized by neuronal loss often diverging based on the selective vulnerability of different neuron types. Amyotrophic Lateral Sclerosis (ALS) is a progressive and selective loss of motor neurons in the motor cortex or spinal cord. Several pathological features of ALS, including neuronal hyperexcitability, are observed in many different cortical cell types in mouse models. While bulk gene expression studies across models have revealed both distinct and common features among NDs, suggesting commonalities in the underlying pathological processes, these studies do not describe the distinct pathological responses of discrete cell types; a hallmark of selective vulnerability. Here we use single-cell RNA-Seq (scRNA-Seq) to examine the cell-type-specific transcriptional responses in the motor cortex of two different mouse models of C9orf72 repeat expansion, a causal variant for familial ALS. We have developed a suite of tools for analysis of patterns of co-regulated gene expression in scRNA-Seq. Using these tools, we can identify distinct and shared molecular pathological features across discrete cell types in the motor cortex. These patterns represent both common cellular responses to the pathogenic C9orf72 repeat expansion as well as responses that are unique to subpopulations of cells, and can be used to enhance understanding of the selective vulnerability to this pathogenic repeat. Finally, we use these data to relate cell type-specific gene expression to genetic analysis of disease association. The most commonly used tool for studying complex disease is the genome-wide association study (GWAS). Although GWAS is agnostic to the context in which disease-risk variation acts, the biological impact of common functional variation has been shown to be cell context dependent. We have established a framework to prioritize candidate genes across GWAS loci using cell type-specific gene expression and use this approach to refine the genetic architecture of ALS. This analysis exploits the relationship between context-specific gene expression and genetic association to both identify affected cell types, and select candidate genes within GWAS loci for each cellular context. Collectively, these data demonstrate the importance of cellular context for understanding the molecular pathology of disease and selective vulnerability of upper motor neurons in fALS, and provide a template for single cell-resolution analysis of complex NDs.

**Generation and characterization of a conditional mouse model that uses SUMO1 to direct the BirA-mediated tagging of cell-type-specific nuclei *in vivo*.** M. Hudson<sup>1,2</sup>, X. Yuan<sup>1,2,3</sup>, M. Liang<sup>1,2</sup>, V. Gomes<sup>2</sup>, A. Tasneem<sup>4</sup>, J.L. Lefebvre<sup>1,4</sup>, M.D. Wilson<sup>1,2</sup>. 1) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Genetics and Genome Biology Program, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Developmental and Stem Cell Biology Program, Hospital for Sick Children, Toronto, Ontario, Canada; 4) Neuroscience and Mental Health Program, Hospital for Sick Children, Toronto, Ontario, Canada.

Knowing the roles each cell type plays within a given tissue at a given time is essential for understanding disease phenotypes. While genomic assays that capture gene expression, DNA methylation and open chromatin can now be deployed on single cells, there is a need for methods to rapidly isolate distinct cell populations from a tissue in a cost-effective manner. Recently, the powerful INTACT method (Isolation of Nuclei Tagged in specific Cell Types; Deal and Henikoff, 2011) was established for isolation of nuclei from genetically-labeled cell types and has now been applied to several model organisms including mice. Here we describe the generation and characterization of a new SUMO1-driven conditional INTACT mouse (CONTACT; CONditional Tagging of Cell-Type specific nuclei). This conditional mouse model expresses *SUMO1* fused to GFP and a biotin ligase recognition peptide that can be specifically biotinylated by the *E. coli* biotin ligase BirA. As SUMO1 is a cytoplasmic component of the nuclear pore complex, nuclei containing this construct can be rapidly purified from bulk populations using streptavidin-coated magnetic beads, similar to other INTACT methods. These nuclei can be used for genomic assays including ATAC-seq, ChIP-seq, or RNA-seq. A novel feature of our model is that it permits the detection of cell-type-specific SUMO1-modified proteins *in vivo*. Here I will present results using our SUMO1 CONTACT mouse to profile Purkinje cells, which are the sole output from the cerebellar cortex where motor signaling takes place. Purkinje cells have been implicated in motor neuron and neurodegenerative diseases and comprise ~0.03% of cells in the cerebellum. I will compare gene expression, open chromatin, and histone modifications of Purkinje cells (using the Purkinje-cell-specific *Pcp2-Cre*) to bulk cerebellar tissue at two postnatal ages. In summary, starting with Purkinje cells, this transgenic mouse tool will enable detailed investigations of cell-type-specific gene expression, epigenetic modifications, protein expression and post-translational modification.

### 1730F

**High efficiency neurological panel design using Twist Bioscience double-stranded custom targeted enrichment probes and capture optimization for aged dry blood spot samples.** . R. Pellegrino<sup>1</sup>, C. Kaminski Vaccaro<sup>1</sup>, J. Garifallou<sup>1</sup>, F. Mafra<sup>1</sup>, J. Smiler<sup>1</sup>, M. Gonzalez<sup>1</sup>, L. Tian<sup>1</sup>, F. Wang<sup>1</sup>, M. Consugar<sup>2</sup>, L. Kulikowski<sup>2</sup>, A. Dias<sup>3</sup>, H. Hakonarson<sup>1</sup>. 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Twist Biosciences; 3) FMUSP.

**Introduction:** Targeted gene sequencing panels are cost-effective and valuable tools for understanding the causative novel or inherited mutations in a specific disease. Custom targeted sequencing is ideal for exploring genes in specific pathways as for follow-up experiments larger studies such as from whole-exome and whole-genome sequencing. A critical component for successful sequencing analyses involves the design capability and the quality of the capture reaction, which drives the uniformity of the reads. A more uniform capture leads to more uniform sequencing (higher targets coverage, limiting wasted reads). Twist Bioscience's capture efficiency and coverage uniformity is the result of the probe design algorithm, dsDNA probes, and probe boosting based on GC composition. The oligo synthesis platform and amplification methodology yields highly uniform dsDNA capture probes that result in greater targeted enrichment capture and sequencing efficiencies. This innovation significantly permits the capture of both strands of the target, resulting in an increase in the number of unique molecules sequenced and allowing for detection of strand-specific mutations such as deamination events in ancient samples or FFPE specimens. **Methods:** CAG with the support of Twist, we created a curated design containing ~1120 probes covering 55 genes linked to Epilepsy. We generated gDNA libraries using the Kapa Hyper preparation kit and capture libraries using IDT universal adapters and Twist capture probes and hybridization reagents. Additionally we evaluated Twist's beta Custom Targeted Enrichment Core Kit in parallel for the same samples. Genomic DNA was obtained from 46 dry blood spots from very longstanding collections and presented very challenging QC for DNA concentration. **Results:** Capture libraries were successfully generated according to CAG's quality standards/metrics for all the samples in question. Libraries were sequenced to ~200X average depth of coverage on a HiSeq 2500. Capture data demonstrated good coverage, high uniformity and even distribution across the genes of interest. The predicted cost savings associated with Twist's greater dsDNA oligo probe's capture efficiency and resulting sequencing uniformity will markedly increase the attractiveness of future custom targeted enrichment projects at CAG.

### 1731W

**Clinical and genetic implications for long-read sequencing after testing the ONT MinION and PacBio Sequel across the C9orf72 'GGGGCC' repeat expansion in human carriers.** J. Fryer<sup>1</sup>, S. Farrugia<sup>1</sup>, J. Sens<sup>1</sup>, K. Jansen-West<sup>1</sup>, I. McLaughlin<sup>2</sup>, B. Bowman<sup>2</sup>, M. Seetin<sup>2</sup>, M. van Blitterswijk<sup>1</sup>, R. Rademakers<sup>1</sup>, L. Petrucelli<sup>1</sup>, M. Ebbert<sup>1</sup>. 1) Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Pacific Biosciences, Menlo Park, CA, USA.

**Background.** Structural variants, and repeat expansions specifically, are increasingly recognized for their role in human disease. Repeat expansions are a nucleotide sequence insertion (e.g., 'GGGGCC'; G<sub>n</sub>C<sub>2</sub>) that is repeated many more times than normal. They are known to cause many CNS diseases including Huntington's disease, spinocerebellar ataxias (SCA), frontotemporal dementia (FTD), and amyotrophic lateral sclerosis (ALS). A repeat expansion in ABCA7 associated with Alzheimer's disease was also recently reported. As researchers continue to investigate repeat expansions, it is important to know how well long-read sequencing technologies such as PacBio and Oxford Nanopore Technologies (ONT) perform when sequencing across repeats. Many repeat expansions are GC-rich, making them difficult to sequence. We previously presented data assessing how well PacBio and ONT sequencing platforms sequenced through repeat expansions cloned into plasmids for SCA36 (GGCCTG) and ALS/FTD (G<sub>n</sub>C<sub>2</sub>). We also presented preliminary data from whole-genome sequencing across the C9orf72 G<sub>n</sub>C<sub>2</sub> repeat expansion in a human carrier. Since then, we have refined our analyses for the whole-genome data, and we performed targeted sequencing across the C9orf72 repeat expansion using PacBio's new no-amplification (No-Amp) targeted sequencing method, based on CRISPR-Cas9. **Methods.** We identified two C9orf72 G<sub>n</sub>C<sub>2</sub> expansion carriers, extracted HMW DNA from cerebellar tissue, and performed whole-genome sequencing on the MinION (15 flowcells) and Sequel (5 SMRT-cells), and targeted sequencing on the Sequel. **Results.** Whole-genome data from the MinION and Sequel correctly estimated 8 repeats for the unexpanded allele. Throughput was a challenge for the MinION, but newer chemistries and hardware (e.g., PromethION) from ONT are likely to address this issue. The Sequel was able to sequence through the entire repeat at 1324 repeats (7941 bases). No-Amp sequencing on the Sequel generated 828 CCS reads across both the unexpanded and expanded alleles. We obtained a distribution of reads (mosaicism) that spanned the repeat and were able to accurately estimate the expansion size. We were also able to assess G<sub>n</sub>C<sub>2</sub> content in this individual. We cannot rule out repeat interruptions. **Conclusion.** Our results suggest ONT and PacBio long-read sequencing technologies are capable of traversing challenging repeat expansions. Both present exciting opportunities in clinical, genetic counseling, and genetic discovery efforts.

### 1732T

**Humanized STXBP1 animal model for detecting pathogenicity in clinical variants.** C. Hopkins, G. Hu, K. McCormick, T. Brock. Nemamatrix, Salt Lake City, UT.

There is growing demand for functional data on clinical variants. Genomic data reveals large numbers of clinically-observed gene variants remain not specified or designated as variants of uncertain significance (VUS). High quality functional assessments (PS3 and BS3) are needed. 20 genes ranked for highest submitters via ClinVar data (<https://clinvarminer.genetics.utah.edu>) were used in a dbSNP database query (<https://www.ncbi.nlm.nih.gov/variation/view>), which indicated average distribution between variant categories is 12.49% pathogenic, 2.94% likely pathogenic, 22.11% VUS, 7.54% likely benign, 0.69% benign, and 54.23% not provided/specified. Uncertainty increases as more genes are examined. Humanized (ClinPhen) animal models are created when a human cDNA is inserted as a replacement for the endogenous coding sequence and the cDNA sequence exhibits capacity to restore normal function. As example, cDNA sequence for early infantile epileptic encephalopathy 4 gene (STXBP1) was recoded for optimal expression in *C. elegans*. CRISPR-based editing inserted hSTXBP1 sequence as gene replacement of the coding sequence in the unc-18 locus. Rescue of activity observed at 100% by electrophysiology (up 4x from unc-18 KO) and 50% in a chemotaxis assay (up from 0% in the unc-18 KO). Two known pathological variants, R292H and R406H, inserted into the humanized hSTXBP1 backbone exhibit electrophysiology and chemotaxis deficiencies. Because all of the known pathogenic variants in STXBP1 are autosomal dominant, heterozygotes were examined for deficiencies in a modified chemotaxis assay. 5 known pathogenic variants all showed chemotaxis deficiencies as heterozygotes. One of the variants, p.R388X, creating a two-thirds truncation of STXBP1 protein, presented with a dominant negative phenotype in the haploinsufficiency assay - approx. 3 fold more severe than heterozygote with full gene KO. The hSTXBP1 ClinPhen platform is being extended to analyze all of the gene's known variants. Drug screening is planned for all variant systems exhibiting activity defects consistent with pathogenicity in hope of finding new or existing AEDs with likelihood to be therapeutic for the specific variant patient. ClinPhen is being expanded to address variant profiles in KCNQ2, ATP1A3, LMNA and MSH2 genes. Approximately 2000 Rare Disease genes are expected to be addressable when converted into a ClinPhen system.

### 1733F

**10x Genomics Chromium linked-reads for genotyping short tandem repeats in whole-genome sequence data.** I. Rajan-Babu<sup>1</sup>, R. Chiu<sup>2</sup>, I. Biro<sup>2</sup>, J.M. Friedman<sup>1</sup>. 1) Department of Medical Genetics, University of British Columbia, and Children's & Women's Hospital, Vancouver, British Columbia, Canada; 2) Michael Smith Genome Sciences Centre, BC Cancer Agency, Vancouver, British Columbia, Canada.

**Background:** 10x Genomics Chromium linked-read (LR) technology outperforms short-read sequencing in resolving complex structural variants; however, its utility in genotyping short tandem repeats (STRs) has not been examined. STRs are tandem arrays of repeat motifs composed of 1 to 6 base pairs (bp), and repeat expansions (increase in the number of copies of repeat units) at ~40 loci are associated with disease. We assessed the ability of 10x Genomics Chromium LR technology to characterize the *frataxin* (*FXN* [MIM 606829]) GAA and the *fragile X mental retardation 1* (*FMR1* [MIM 309550]) CGG repeat expansions that cause Friedreich ataxia (FRDA [MIM 229300]) and fragile X syndrome (FXS [MIM 300624]), respectively. **Methods:** Four FRDA and six FXS reference lymphoblastoid cell lines were obtained from the Coriell Cell Repository. High molecular weight genomic DNA specimens derived from the cell lines were used for Chromium library preparation. Paired-end whole-genome sequence (WGS) reads of 150-bp were generated on an Illumina HiSeq X instrument and processed using the Long Ranger™ pipeline. Seventeen disease-associated STRs, including the *FXN* GAA and *FMR1* CGG repeats, were genotyped in each sample using ExpansionHunter. **Results:** ExpansionHunter generated genotype calls for nearly all STRs, with repeat sizes that were accurate for the *FXN* normal alleles and in the normal range for most other STR loci tested. The heterozygous and homozygous expanded *FXN* alleles in the FRDA samples were clearly differentiated, but their repeat sizes, which actually ranged from ~650 to ~1030 GAA, were genotyped as 54 to 73 GAA. No genotype was obtained for the *FMR1* CGG repeat locus whether it was normal or expanded in eight of the 10 samples tested. Our inability to genotype the *FMR1* CGG repeats reflects very low or no sequence coverage of this region, in contrast to adequate coverage at the other STR loci genotyped in these Chromium LR WGS data. **Summary:** 10x Genomics Chromium LR WGS is a promising tool that has the potential to evolve into the "single test" for detecting all classes of genomic variants, but resolving issues related to poor coverage of GC-rich regions is critical to improve diagnostic sensitivity. Additional investigations of "difficult-to-genotype" STRs and of other analytical alternatives to ExpansionHunter for accurate repeat size estimation of full expansions in 10x Genomics Chromium LR WGS data are underway.

## 1734W

**Whole genome sequencing of amyotrophic lateral sclerosis discordant monozygotic twins identifies thousands of false positive somatic mutations.** K.L. Williams<sup>1</sup>, E.P. McCann<sup>1</sup>, N.A. Twine<sup>2</sup>, D.B. Rowe<sup>3</sup>, G.A. Nicholson<sup>4</sup>, D.C. Bauer<sup>2</sup>, I.P. Blair<sup>1</sup>. 1) Centre for Motor Neuron Disease Research, Faculty of Medicine and Health Sciences, Macquarie University, NSW, Australia; 2) Commonwealth Scientific and Industrial Research Organisation, Sydney, NSW, Australia; 3) Department of Clinical Medicine, Faculty of Medicine and Health Sciences, Macquarie University, NSW, Australia; 4) Molecular Medicine Laboratory, Concord Repatriation General Hospital, Sydney, NSW, Australia.

ALS is a fatal late-onset disease characterised by rapid progressive degeneration of upper and lower motor neurons. Sporadic and hereditary forms of ALS are clinically and pathologically indistinguishable, yet substantial variation is seen in age of onset and rate of disease progression, even among patients with identical causal mutations. This suggests a role for modifying factors influencing disease onset and progression. Disease-discordant identical twins provide a powerful study design to uncover modifiers of disease, as the unaffected co-twin is the best-matched control available for their affected co-twin, reducing known confounding factors (such as age, sex) and unknown confounding factors. This co-twin study investigated the genomes of n=3 monozygotic twin sets and n=1 MZ triplet set discordant for ALS. One MZ twin set both harbor a pathogenic C9orf72 hexanucleotide repeat expansion and the MZ triplet set all carry a pathogenic SOD1 mutation. Whole-genome sequencing of the 9 twins/triplets identified 20902, 23946, 35332 and 7380 discordant variants between the affected twin/triplet and their unaffected co-twin/triplets thus being putative modifier variants. This large number of discordant variants was unanticipated and reflects false positive variants. Validation 1 using any discordant variants present on a SNP microarray identified all selected variants as concordant homozygous within twin/triplet sets. Validation 2 involved variant filtering (private genotype, private location, quality scores, MAF, population controls) to reduce the number of discordant variants to 167, 269, 295 and 6 respectively. Sanger sequencing of selected filtered variants confirmed all as concordant between twin/triplet sets. Validation 3 repeated WGS of one twin set at a second sequencing service provider using the same library prep method and sequencing instrument as the original sequencing service provider. Original and new WGS data for this twin set were processed through the same bioinformatic pipeline to identify discordant variants. No discordant variants overlapped between the different service provider sequencing results, hence confirming WGS-identified discordant variants as false positive results. Therefore, somatic *de novo* mutations are not causing ALS. This study highlights the necessity to either improve alignment and variant calling algorithms to significantly reduce the number of false positives, or to perform all WGS experiments in duplicate or triplicate.

## 1735T

**Using Agilent SureSelect<sup>XT</sup> Human Methyl-Seq to further study gene regulation through methylation modifications.** C. Vaccaro<sup>1</sup>, J. Smiler<sup>1</sup>, L. Tian<sup>1</sup>, D. Li<sup>1</sup>, E. Bhoj<sup>1</sup>, S. Sheppard<sup>1</sup>, M. Filipek<sup>2</sup>, H. Hakonarson<sup>1</sup>, R. Pellegrino<sup>1</sup>. 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Agilent Technologies, Santa Clara, CA.

**Introduction:** In the era of next generation sequencing, it is not only important to examine mutations within genes, but to also focus on regulatory elements. DNA methylation is one form of epigenetic regulation. Some regions within DNA that are prone to methylation include CpGs, promoters, and differentially methylated regions (DMRs). Agilent has released an 84 Mb design that targets these methylated regions in their SureSelect<sup>XT</sup> Human Methyl-Seq protocol. The SureSelect<sup>XT</sup> Human Methyl-Seq protocol was constructed to capture both the design of SureSelect target enrichment and bisulfite treatment to target methylated regions. Its single base pair resolution and detection of individual CpGs make SureSelect<sup>XT</sup> Human Methyl-Seq an attractive alternative to microarrays (only target about 5-10%). More specifically, SureSelect<sup>XT</sup> Human Methyl-Seq covers 3.7 million CpGs (~91% of UCSC annotated CpGs) including CpG islands, shores, shelves, as well as detecting methylation in undermethylated regions, GENCODE promoters (~141,000), DNaseI hypersensitive sites, and cancer tissue-specific DMRs (~23,000). Additional improvements of the SureSelect<sup>XT</sup> Human Methyl-Seq in comparison to microarrays are increased throughput, reducing sequencing costs, an increase in library complexity, and a reduction in bias. **Materials/Methods:** Our study consists of nine samples processed with the SureSelect<sup>XT</sup> Human Methyl-Seq. Amongst this cohort, there were patients with *de novo* heterozygous mutations in *KMT5B*, a histone methyltransferase that is associated with a neurodevelopmental disorder, and age/sex matched controls. The SureSelect<sup>XT</sup> Human Methyl-Seq required DNA shearing via sonication on the Covaris LE220, library preparation (end repair, a-tailing, and ligation), hybridization with the 84 Mb Human Methyl-Seq, bisulfite treatment, PCR, and sequencing on the Illumina HiSeq2500. **Results:** All samples passed sequencing QC. On average, 158 million reads were produced per sample. All samples exhibited a Q30 score of 88% and cluster density of 1041K/mm<sup>2</sup>. **Conclusion:** The SureSelect<sup>XT</sup> Human Methyl-Seq protocol offers a new alternative to studying gene regulation in areas that are modified by methylation. This protocol from Agilent will give a more cost-effective method for labs and increase their data at the single base pair resolution.

**Exome analyses in subfamily trios from large family tree in the South-Eastern Moravia (Czech Republic) population with high incidence of parkinsonism.** R. Vodicka<sup>1</sup>, R. Vrtel<sup>1</sup>, K. Kolarikova<sup>1</sup>, M. Prochazka<sup>1</sup>, K. Mensikova<sup>2</sup>, P. Kanovsky<sup>2</sup>. 1) Institute of Medical Genetics, University Hospital and Palacky University Olomouc, Olomouc, Czech Republic; 2) Department of Neurology Faculty of Medicine and Dentistry, Palacky University, University Hospital, Olomouc, Czech Republic.

There has been previously described higher prevalence of parkinsonism in small isolated region with well assembled 11 generation large pedigree from the South-Eastern Moravia. Aim of the study was to analyze whole exomes in selected subfamily trios from the pedigree. We used NGS Ion AmpliSeq Exome method (IonTorrent) for two (A and B) subfamily trios. Each trio comprised of two affected and one healthy person. DNA exome libraries were sequenced on IonPI chips. Variants were predicted using Torrent Suite and IonReporter softwares. Aligned reads (BAM files) were then analyzed using IonReporter Whole Exome Trio workflow. Final filtering was done with respect to population frequency, variant effects and with respect to the presence of variants in Parkinsonism disease responsible genes. Last filter was done with respect to the segregation of the disease. Almost whole exome was sequenced with coverage 1-20 and 90 % of exome was covered more than 20x in all the samples. Together more than 70.000 variants with average base coverage depth 75 were analyzable in both trios before filtering. After filtering there were found 99 and 96 variants in trio A and B respective. The most potentially associating variants with Parkinsonism are following: Trio A: SLC18A2:p.Gly195Ser;c.583G>A DRD1:p.Ala353Val;c.1058C>T AP2A2:p.Asn401Ser;c.1202A>G CCDC88C:p.Leu1696Pro;c.5087T>C ZFH3:p.Met2102Thr;c.6305T>C ARAP2:p.Pro159Ser;c.475C>T CYP4F11:p.Trp29Ser;c.86G>C MRPS15:p.Thr252Ile;c.755C>T MRPS28:p.Arg48Pro;c.143G>C PRELID2:p.Val62Met;c.184G>A FAM171A1:p.Ser844Leu;c.2531C>T CAPRIN2:p.Arg373His;c.1118G>A FAM186B:p.Ala727Val;c.2180C>T CROT:p.Glu118Asp;c.354A>C MPDZ:p.Cys119Ser;c.356G>C Trio B: TENM4:p.Asn965Ser;c.2894A>G MON2:p.Gln531Arg;c.1592A>G MTCL1:p.Ala482Val;c.1445C>T NEPRO:p.Val297Ile;c.889G>A FAM131A:p.Leu280Val;c.838C>G ADH1C:p.Arg48His;c.143G>A SYNE1:p.Lys3729Asn;c.11187G>T RXFP2:p.Thr222Pro;c.664A>C AKAP11:p.Ile183Met;c.549A>G ZNF19:p.Pro216Ser;c.646C>T LRRK2:p.Arg1514Gln;c.4541G>A OSBPL1A:c.115\_116insAATT SACS:p.Met1359Thr;c.4076T>C ZFH3:p.Met2102Thr;c.6305T>C COL18A1:p.Ala1381Thr;c.4141G>A Detailed whole exome analyses in genetic isolated parkinsonism patients could contribute to further understanding of molecular-genetic mechanism and background of the disease. **Single-cell RNA-sequencing identifies multiple human microglial subtypes associated with neurodegenerative disease.** V. Menon<sup>1</sup>, M. Olah<sup>1</sup>, M. Taga<sup>1</sup>, C. Yung<sup>1</sup>, R. Sarkis<sup>1</sup>, J. Schneider<sup>1</sup>, D. Bennett<sup>1</sup>, W. Elyaman<sup>1</sup>, E. Bradshaw<sup>1</sup>, P. De Jager<sup>1</sup>. 1) Neurology, Columbia University Medical Center, New York, NY; 2) Alzheimer's Disease Center, Rush University, Chicago, IL.

Our understanding of the biology of human microglia is advancing rapidly as modern transcriptome-wide assessments – along with proteomic and epigenomic studies of bulk microglia – have provided new insights into the role of this cell type in brain development, central nervous system tissue homeostasis and neurodegenerative diseases. However, our understanding of the diversity of cell states that microglia can adopt in the human brain remains limited; microglia are highly plastic and have multiple different roles, making the extent of intra-individual heterogeneity a central question as we begin to consider the development of therapies targeting this cell type. Here, we investigated the population structure of human microglia by single cell RNA-sequencing. Using surgical and autopsy-derived cortical samples, we isolated >15,000 cells and identified 14 distinct human microglial populations. We note substantial intra- and inter-individual heterogeneity, suggesting that microglial diversity in humans may be affected by both genetic background and disease state. The overall heterogeneity comprises both graded variation in a large, putatively homeostatic population as well as discrete subtypes that are associated with proliferative and neurological disease states. These microglial subclasses are distinguished by distinct transcription factor and cell surface combinations and display divergent associations with Alzheimer's pathology, dementia and multiple sclerosis. Upon comparison with previous studies, we find similarities with disease-associated microglial states reported in mouse, but the greater diversity of states in human suggests a more varied role of microglia in the brain.

**Single-cell RNA-sequencing in facioscapulohumeral muscular dystrophy disease etiology and development.** A. van den Heuvel<sup>1</sup>, A. Mahfouz<sup>2,6</sup>, S.L. Kloet<sup>1</sup>, J. Balog<sup>1</sup>, B.G.M van Engelen<sup>3</sup>, R. Tawil<sup>4</sup>, S.J. Tapscott<sup>5</sup>, S.M. van der Maarel<sup>1</sup>. 1) Human Genetics, Leiden University Medical Center, Leiden, Zuid-Holland, Netherlands; 2) Leiden Computational Biology Center, Leiden University Medical Center, Leiden, Zuid Holland, Netherlands; 3) Department of Neurology, Donders Institute for Brain Cognition and Behaviour, Radboud University Medical Center, Nijmegen, Gelderland, the Netherlands; 4) Department of Neurology, University of Rochester, Rochester, NY 14642 USA; 5) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA 98109 USA; 6) Bioinformatics Lab, Delft University of Technology, Delft, Zuid-Holland, Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is one of the most common inherited muscle diseases worldwide, with patients suffering from progressive wasting and weakness of the muscles in the face and upper extremities. FSHD has a unique etiology being caused by the de-repression of the cleavage-stage transcription factor DUX4 in only a small number of myonuclei of the affected muscle. This activates a cascade of muscle disrupting events ultimately leading to muscle atrophy and apoptosis. Yet, with approximately 1:500 nuclei expressing DUX4 in primary myotube cultures, how such sporadic expression leads to the severe muscle wasting observed in FSHD patients remains unclear. With this, essential insights in the order of- and interaction between the cascade of events implicated in FSHD are currently limited. Transcriptome analyses in FSHD muscle cell cultures or biopsies have systematically been challenged by the sporadic nature of DUX4 expression, with the majority of non-affected cells masking the FSHD transcriptome signature. Consequently, the analysis of the FSHD-transcriptome has thus far largely been facilitated by DUX4-expression or DUX4-reporter systems, limiting the analyses to DUX4-associated effects, and leaving non-cell-autonomous effects underrepresented in the FSHD transcriptome. We used single-cell RNA-sequencing, combined with pseudotime trajectory modeling, to study FSHD etiology and cellular progression. We show that we can identify a small FSHD-specific cell population in all tested patient-derived cultures, and we detect new expression signatures that are likely related to both direct and indirect effects of DUX4. Furthermore, capitalizing on the cellular heterogeneity in FSHD cell cultures, we performed pseudotime trajectory modeling to generate a detailed FSHD cellular progression model. We show that our model faithfully reflects both the early burst-like DUX4 expression, as well as the programmed downstream activation of various pathways previously implicated in FSHD. Altogether, our data highlights the potential for single-cell transcriptomics in studying disease etiology and cellular progression of genetic diseases, even when hallmarked by cellular heterogeneity as strong as in FSHD. We expect that pseudotime trajectories like our FSHD pseudotime model holds valuable information not only for further unraveling the disease etiology and progression, but also for biomarker and target selection guiding future therapy development.

**Amplification-free targeted SMRT sequencing using CRISPR/Cas9 for studying repeat expansions in Huntington's disease.** I. Höjjer<sup>1</sup>, Y. Tsai<sup>2</sup>, I. Jonasson<sup>1</sup>, E-L. Stattin<sup>1</sup>, M-L. Bondeson<sup>1</sup>, T.A. Clark<sup>2</sup>, U. Gyllenstein<sup>1</sup>, A. Ameer<sup>1</sup>. 1) SciLifeLab, Dept. of immunology, genetics and pathology, Uppsala University, Uppsala, Uppsala, Sweden; 2) Pacific Biosciences, Menlo Park, CA, USA.

Amplification of DNA is required as a mandatory step during library preparation in most targeted sequencing protocols. This can be a critical limitation when targeting regions that are highly repetitive or with extreme guanine-cytosine (GC) content, including repeat expansions associated with human disease. Here we used an amplification-free protocol for targeted enrichment utilizing the CRISPR/Cas9 system (No-Amp Targeted sequencing) in combination with Single Molecule, Real-Time (SMRT) sequencing for studying repeat elements in the huntingtin (*HTT*) gene, where an expanded CAG repeat is causative for Huntington's disease (HD). A guide RNA was designed in proximity to the *HTT* CAG repeat and was used to target and digest whole genome PacBio libraries (SMRTbells). Capture adapters were subsequently ligated to the digestion site and magnetic beads used to enrich for SMRTbells containing the targeted sequence. We applied the No-Amp method to eleven HD patient samples and found that the CAG repeat count from our method agreed with previous results based on fragment analysis for all 22 alleles. Furthermore, polymorphic CCG repeats in the flanking regions of the CAG repeats could be analyzed in detail. We also observed somatic variability of the CAG repeats, with greater variability seen in the expanded alleles. This is a known phenomenon but has been difficult to investigate using PCR-based protocols. In addition to on-target reads, off-target effects by the CRISPR/Cas9 could be identified in sequences with high homology to the guide RNA. The No-Amp protocol allows multiplexing of targets and barcoding of samples. It also enables detection of epigenetic modifications in the data. In conclusion, with the No-Amp Targeted sequencing method, we are able to accurately sequence through repeat expansions that are difficult or even impossible to investigate using PCR-based targeted sequencing protocols. .

## 1740W

**Investigating changes to the gut microbiome before and during symptom progression in the MeCP2-e1 mouse model of Rett syndrome.** T.E. Grant<sup>1</sup>, T.S. Totah<sup>1</sup>, A. Vogel Ciernia<sup>4</sup>, B.P. Durbin-Johnson<sup>2</sup>, D.H. Yasui<sup>1</sup>, M.R. Rolston<sup>1</sup>, M. Settles<sup>5</sup>, J.M. LaSalle<sup>2</sup>. 1) Medical Microbiology and Immunology, University of California, Davis, Davis, CA; 2) Department of Medical Microbiology and Immunology, Genome Center, MIND Institute, UC Davis School of Medicine, CA, 95616, USA; 3) Division of Biostatistics, Department of Public Health Sciences, UC Davis School of Medicine, Sacramento, CA, 95817, USA; 4) Department of Medical Microbiology and Immunology, MIND Institute, UC Davis, CA School of Medicine, 95616, USA; 5) Genome Center, University of California, Davis, CA, 95616, USA.

Rett syndrome (RTT) is an X-linked dominant neurodevelopmental disorder caused by mutations in the MECP2 gene encoding methyl CpG binding protein 2 (MeCP2), an abundant neuronal chromatin factor. Girls with RTT have typical early development, followed by regression in developmental milestones and the progression of gastrointestinal symptoms and oxidative stress. While most RTT research has focused on the role of MeCP2 in the central nervous system, MeCP2 is expressed in all cell; including microglia implicated in neuroimmune interactions in RTT. Microglial maturation is influenced by the gut microbiome, and the gastrointestinal RTT symptoms such as constipation suggest that MeCP2 mutation may interact with the gut microbiome and enteric nervous system during symptom progression. To examine this relationship, we utilized a mouse model with an RTT targeted mutation of *Mecp2* exon 1 (*Mecp2<sup>e1</sup>*). MeCP2-e1 deficient male and female mice develop progressive motor impairments, behavioral changes, and metabolic symptoms similar to those observed in RTT patients. Therefore, we hypothesized that MeCP2-e1 mutation may contribute to a perturbed gut microbiome, potentially exacerbating the severity and progression of the neurological symptoms observed in RTT. To test this hypothesis, we performed weekly timed collections of fecal pellets, disease progression scoring, and body weights from 4 to 20 weeks in MeCP2-e1 deficient and control littermate mice of both sexes. DNA was isolated from fecal pellets and amplified using 16S ribosomal primers to make sequencing libraries for the Illumina MiSeq. Bioinformatic and statistical analyses (FDR<0.05) demonstrated several microbial genera significantly altered by time and genotype, with mutant males showing more significant differences than females. Interestingly, significant microbial differences were also observed before the progression of hindlimb clasping or weight gain. Bifidobacteria were consistently lower in MeCP2-e1 mutant males and females across time. Furthermore, several butyrate producing Clostridia class members were significantly elevated at early time points in MeCP2-e1 mutant males, suggesting a potential interaction of the histone deacetylase inhibiting the action of butyrate with increased histone acetylation levels observed in RTT brain. Future work will examine the effects of probiotic therapy using Bifidobacteria.

## 1741T

**An integrated deep mutational scanning approach to defining the PTEN genotype-phenotype map.** T.L. Mighell<sup>1,2</sup>, J.L. Mester<sup>6</sup>, K.S. Hruska<sup>3</sup>, K.A. Matreyek<sup>4</sup>, D.M. Fowler<sup>4,5,6</sup>, B.J. O'Roak<sup>2</sup>. 1) Neuroscience Graduate Program, Oregon Health & Science University, Portland, OR; 2) Department of Molecular & Medical Genetics, Oregon Health & Science University, Portland, OR; 3) GeneDx, Gaithersburg, MD; 4) Department of Genome Sciences, University of Washington, Seattle, WA; 5) Department of Bioengineering, University of Washington, Seattle, WA, USA; 6) Genetic Networks Program, Canadian Institute for Advanced Research, Toronto, Ontario, Canada.

Empirically testing genetic variants is the gold standard for predicting pathogenicity, but for most variants these data are lacking. PTEN Hamartoma Tumor Syndrome (PHTS) includes a set of clinical presentations sharing benign overgrowths and cancer susceptibility caused by germline mutations. PTEN mutation carriers may also display macrocephaly with autism spectrum disorder (ASD) or developmental delay with or without symptoms of PHTS. Limited availability of clinical data and the scale of experimental data on specific mutations has hampered our understanding of PTEN genotype-phenotype relationships and over half of ClinVar missense variants are still characterized as variants of uncertain significance (VUS). Deep mutational scanning (DMS) datasets that test the effects of thousands of variants in parallel have been generated for a few human genes. For PTEN, DMS data describe effects of variants on lipid phosphatase activity (LPA) (7,244/8,463 variants, 86%, Mighell *et al.*, 2018) as well as cellular stability (CS, 4,112 variants, 49%, Matreyek *et al.*, 2018). LPA alone can predict pathogenicity with high positive predictive value (PPV, 93%), but modest sensitivity (SEN, 83%). ASD-associated variants retain hypomorphic LPA, while PHTS-associated variants are generally loss-of-function. We hypothesized that integrating multiple PTEN DMS datasets would improve pathogenicity prediction and form a more complete genotype-phenotype map. Using random forest models trained on 12-15 biochemical and evolutionary features, we first imputed missing LPA and CS scores with high accuracy (r=0.80 and 0.76, respectively, 10x cross validation). We then developed a two-step integrated pathogenicity model, which was evaluated on 79 pathogenic (ClinVar) and 74 putatively benign (gnomAD) missense variants. This model increased SEN (90%) and maintained high PPV (87%) relative to LPA alone. Applying this model to VUS supports reclassification of 49 (37%) as pathogenic. We also found 617/1,941 (32%) of variants with low LPA had high CS, which may indicate a dominant negative effect. Finally, integrating published missense variants with a new set of 80 recurrent clinical variants revealed that variants found in both PHTS and ASD trend toward intermediate LPA scores that fall between PHTS or ASD alone. These data support the use of integrated DMS datasets for dissecting complex disorders and lay the groundwork for personalized care for PTEN mutation carriers.

## 1742F

**A copy number variation map of pediatric neuropsychiatric traits.** M. Zarre<sup>1,2</sup>, C. Burton<sup>3</sup>, W. Engchuan<sup>1,2</sup>, D. Merico<sup>1,4</sup>, E. Chan<sup>1,2</sup>, G. Pellecchia<sup>1</sup>, T. Nalpathamkalam<sup>1</sup>, R. Davies<sup>1,2</sup>, M. Faheem<sup>1,2</sup>, R. Manshaei<sup>6</sup>, S. Lamoureux<sup>1</sup>, S. Walker<sup>1</sup>, L. Strug<sup>1,2,7</sup>, R. Yuen<sup>1,2</sup>, C. Marshall<sup>1</sup>, R. Wintle<sup>1</sup>, P. Arnold<sup>8,9</sup>, J. Crosbie<sup>3</sup>, R. Schachar<sup>3</sup>, S. Scherer<sup>1,2,10</sup>. 1) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Program in Genetics and Genome Biology, the Hospital for Sick Children, Toronto, Canada; 3) Neurosciences and Mental Health, Psychiatry, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Deep Genomics Inc., Toronto, Ontario, Canada; 5) Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, UK; 6) Ted Rogers Centre for Heart Research, Cardiac Genome Clinic, The Hospital for Sick Children, Toronto, Ontario, Canada; 7) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 8) Mathison Centre for Mental Health Research and Education, Hotchkiss Brain Institute, University of Calgary, Alberta, Canada; 9) Departments of Psychiatry and Medical Genetics, Cumming school of Medicine, University of Calgary, Alberta, Canada; 10) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada.

'Spit for Science' is a cohort of over 17,000 youth (6-17 years of age) with associated psychiatric phenotype measurements and saliva DNA collection. Quantitative phenotype data were collected for attention deficit hyperactivity disorder (ADHD), obsessive compulsive disorder (OCD), and response inhibition using Stop-Signal Reaction Time (SSRT). We genotyped unrelated Caucasians (n=4,817) using Illumina HumanCoreExome beadchips. Participants with self-reported diagnosis of neurodevelopmental disorders (NDD; e.g. autism, OCD, ADHD), comprised 1,100 (23%) individuals. A total of 1,907 (40%) of participants had either a diagnosis of NDD or having neuropsychiatric trait(s). We performed global and functional gene-set burden analyses, and locus association test on rare CNVs and SNV/indels using linear regression against different traits. We identified CNVs linked with neuropsychiatric disorders in 191 (4.0%) participants with elevated standardized z-scores, for all traits. These variants were enriched in participants with a diagnosis of NDD ( $p=0.002$ ), but not in those only on a trait spectrum ( $p=0.617$ ). These CNVs included i) sex-chromosome and autosomal aneuploidies (e.g. 45,XO, 47,XXY, 47,XXX, 47,XXY, 48,XXXY, and 47,XX,+21) in 12 (0.25%) individuals, ii) 13 unique genomic loci previously implicated in NDD (e.g. 1q21.1, 15q11.2, 16p12.1, 17p12, 22q11.2) in 52 (1.1%) different participants, and iii) large CNVs affecting genes with known functions in the human brain such as *ASTN2*, *CNTN4*, *DLGAP2*, *MACROD2*, *NRXN1*, and others. ADHD traits were associated with increased deletion burden ( $p=0.014$ ), whereas there was an increased burden of duplication for SSRT ( $p=0.034$ ). We found no global CNV burden for OCD traits. ADHD traits showed significant enrichment for deletions in genes associated with mouse neurophenotypes ( $p=0.009$ ) and with human brain gene expression ( $p=0.04$ ). OCD and SSRT traits showed enrichment for duplications in genes expressed in human brain ( $p=0.004$  and 0.016, respectively). Adding the effect of SNVs/indels increases the significance level in many neurofunction and brain expression gene sets for ADHD traits. The following genes were driving signals: ADHD: *TUBGCP5*, *GALC*, *GJB6*, *TERT*, *BTN3A3*, *GCNT2*, *GPC5*, *RBFOX1*, *PLEC*, *MACROD2*, *PRKN*; OCD: *PRKCE*, *SRBD1*, *TNR*, *DISC1*; SSRT: *KIF1A*, *LDOC1*, *RB1CC1*. SSRT traits showed enrichment for duplications in eight loci: 1q21.1, 1q42.3, 2q37.3, 9q22.2, 12q13.13, 18p11.21, and 22q11.21.

## 1743W

**Phased SLC6A4 promoter haplotype determination using long-read single molecule real-time (SMRT) sequencing.** Y. Yang<sup>1,2</sup>, M.R. Botton<sup>1,2</sup>, A. Salomatov<sup>2</sup>, E.R. Scott<sup>1,2</sup>, R. Sebra<sup>1,2</sup>, R.J. Desnick<sup>1</sup>, L. Edelman<sup>1,2</sup>, E.E. Schadt<sup>1,2</sup>, S.A. Scott<sup>1,2</sup>. 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 2) Sema4, a Mount Sinai venture, Stamford, CT 06902.

The *SLC6A4* gene at chromosome 17q11.2 encodes the serotonin (5-HT) transporter (5-HTT), which mediates 5-HT reuptake and is the target of many tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRI). 5-HTT expression influences 5-HT transporter function, which has been implicated in psychiatric disorder risk and interindividual SSRI response variability. The polymorphic *SLC6A4* promoter is composed of a variable number of homologous 20-24 bp repeats (5-HTTLPR), which is strongly correlated with 5-HTT expression. The long (16 repeats) and short (14 repeats) alleles of the insertion/deletion variant (rs4795541) are associated with higher and lower expression, respectively. However, two additional *SLC6A4* promoter variants (rs25531, rs25532) also influence expression but are most informative when considered with the insertion/deletion as a promoter haplotype. Given the clinical relevance and polymorphic nature of the *SLC6A4* promoter, we developed a novel long-read single molecule real-time (SMRT) sequencing method using the Pacific Biosciences (PacBio) platform. Overlapping *SLC6A4* promoter amplicons up to 2 kb had complete concordance between all identified variants across six control samples. Importantly, whole genome sequencing (WGS) data from 70 GeT-RM Coriell controls (~45X) indicated that short-read sequencing does not detect the short *SLC6A4* promoter allele due to the homologous tandem repeats; however, SMRT sequencing of 1.0 kb amplicons unambiguously identified the long and short alleles and clearly phased the polymorphic promoter in all 70 samples, including complex compound heterozygous haplotypes. Moreover, six additional promoter variants were detected by SMRT sequencing, including two samples with expanded 5-HTTLPR haplotypes that were also not detected by short-read sequencing. Targeted enrichment and high-depth (~330X) short-read sequencing also could not resolve the *SLC6A4* promoter architecture in an additional 96 control samples. A final cohort of 52 samples were subjected to *SLC6A4* SMRT sequencing, which clearly detected phased promoter haplotypes that were confirmed by orthogonal genotyping and Sanger sequencing in a subset of samples. These data indicate that long-read *SLC6A4* promoter SMRT sequencing is an innovative and validated method for phased resolution across complex repetitive regions, which will likely improve *SLC6A4* interrogation for both candidate gene research studies and clinical pharmacogenetic testing.

## 1744T

**Cell-type specific differential gene expression in post-mortem snRNA-seq of the depressed brain.** M. Maitra<sup>1</sup>, C. Nagy<sup>1</sup>, M. Suderman<sup>2</sup>, J.F. Thérault<sup>3</sup>, I. Ragoussis<sup>3</sup>, G. Turecki<sup>1</sup>. 1) McGill Group for Suicide Studies, Douglas Institute, Verdun, QC, Canada; 2) Bristol Medical School - Population Health Sciences, Bristol, UK; 3) McGill University Centre for Molecular and Computational Genomics, Montreal, QC, Canada.

**Background:** Measurement of gene expression changes in homogenized tissues with very heterogeneous cell-type composition, as seen in the brain, can mask subtle cell-type specific effects. Multiple high-throughput protocols for single-nucleus RNA-sequencing (snRNA-seq) have been established in archived post mortem human brain tissue. Here we exploit the enhanced ability for genetically defining cellular subgroups on a large scale to identify cell-type specific differentially expressed genes in major depressive disorder. **Methods:** We used 10X Genomics' droplet based snRNA-seq technology and a custom, optimized wet-lab protocol, to characterize single-nucleus transcriptomic profiles of > 70,000 cells from the prefrontal cortex (Brodmann areas 8 and 9) of 34 individuals - including 17 depressed patients who died by suicide and 17 psychiatrically healthy subjects. A customized bioinformatic approach using the Seurat and lme4 R packages was used for data analysis. **Results:** Graph-based clustering within Seurat was followed by automatic and manual quality control of clusters. Annotation of cell-types based on previously established markers, allowed us to identify 10 excitatory neuronal clusters, 7 inhibitory neuronal clusters, and 9 non-neuronal clusters. Major glial cell-types including astrocytes, oligodendrocyte lineage cells, and microglial cells were readily identified. Cortical layer specific markers and interneuron subtypes markers also demarcated sub-groups of cells as expected. Expression profiles were in good agreement with previously published human brain snRNA-seq datasets. Within each cluster, further selection of high-quality cells followed by differential expression analysis with lme4 revealed 16 significantly upregulated and 80 significantly downregulated genes across 16 out of the 26 clusters (FDR < 0.1). **Conclusion:** Our sample preparation and custom analysis protocols allowed us to identify specific cell-types which are dysregulated in the prefrontal cortex in depressed individuals who died by suicide and genes with altered expression in those cell-types. Further analysis of the interconnections between the dysregulated cell-types and between the identified genes should yield insights into the cellular and molecular pathways that contribute to depression.

## 1745F

**Neural stem cells from MAND patients reveal a significant role for MBD5 in neurodevelopment, circadian rhythm, Wnt and leptin signaling, and autism.** S.V. Mullegama<sup>1</sup>, S.R. Williams<sup>2</sup>, S. Klein<sup>3</sup>, J.W. Innis<sup>4</sup>, F.J. Probst<sup>5</sup>, C. Haldeman-Englert<sup>6</sup>, J.A. Martinez-Agosto<sup>2</sup>, T. Ezashi<sup>6</sup>, S.H. Elsea<sup>2</sup>. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, TX, 77030, USA; 2) University of Virginia, VA; 3) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, California, USA; 4) Departments of Human Genetics and Pediatrics and Communicable Diseases, University of Michigan, Ann Arbor, MI 48109, USA; 5) Department of Pediatrics, Section on Medical Genetics, Wake Forest University Health Sciences, Winston-Salem, NC, 27157, USA; 6) Division of Animal Sciences, University of Missouri, Columbia, Missouri 65211, USA.

**MBD5-Associated Neurodevelopmental Disorder (MAND)** is an autism spectrum disorder (ASD) characterized by intellectual disability, motor delay, severe speech impairment and autism behavioral problems. MAND serves as an umbrella term that encompasses 2q23.1 deletion syndrome, *MBD5* variant cases and 2q23.1 duplications. The importance of *MBD5* in neurodevelopmental function and autism remains largely undefined. Thus, to understand the role of *MBD5* in neurodevelopmental function and autism, we created neural progenitor stem cells derived from patients with *MBD5* deletions and conducted RNA-seq to identify the contributory altered gene pathways. We identified 499 genome-wide significant differentially expressed annotated genes. To understand the neurodevelopmental functions affected when *MBD5* is deleted, we used DAVID to perform GO analysis of significantly differentially expressed genes from each analysis. Most of the GO clusters were related to three groups: neuron development, brain development and cellular processes. We utilized the Reactome FIViz application in Cytoscape to identify the top signaling pathways enriched in our genome-wide significantly differentially expressed genes. We found significant enrichment for Hippo, CREB, leptin, MAPK, circadian rhythm, and Wnt signaling pathways. The transcriptional impact of *MBD5* deletions on expression of known autism-associated genes was significant. We show that 60 genes which are differentially expressed in MAND neural progenitor stem cells are known ASD associated genes according to SFARI. Utilizing ToppCluster, we compared differentially expressed genes in MAND to the publically available SFARI syndromic autism genes to identify common biological processes. This analysis revealed a striking significant overlap between the two gene lists in biological processes which are in keeping with the neurological phenotype and ASD, such as neuronal differentiation, brain development, and regulation of neurogenesis. Overall, our study reveals that deletion of *MBD5* disrupts important processes involved in neurodevelopment and ASD, identifying specific pathways that may be targets for therapeutic intervention. .

**1746W**

**A splice-site mutation and overexpression of *CCNT2* in autosomal recessive intellectual disability patients.** K. InanlooRahatloo<sup>1,2</sup>, F. Peyman<sup>2</sup>, K. Kahrizi<sup>2</sup>, H. Najmabadi<sup>2</sup>. 1) School of Biology, College of Science, University of Tehran, Tehran, Iran; 2) Genetic Research Center, University of social welfare and Rehabilitation Sciences, Tehran, Iran.

Intellectual disability (ID) is a most prevalent neurodevelopmental disorder. Although ID is a clinically important disorder, the etiology and pathogenesis are poorly understood. Transcriptome profiling is a very important tool for understanding how genetic variants alter cell expression. Exome sequencing revealed a homozygous splice site mutation (chr2: 135677463, T>G) in the *CCNT2* gene in one ID family. *CCNT2* gene belongs to the cyclin family and gene ontology annotation related to this gene includes protein kinase binding. RNA-Seq results indicated overexpression of normal isoform and non-protein coding isoform of *CCNT2* gene in *CCNT2* mutant patients. Furthermore, *CCNT2* mutation was found to disrupt the transcriptional regulatory function of *CCNT2* in both patients. In silico sequence analysis using PROMO 2.0 web based tool predicted the creation of two binding sites for transcription factor YY1 in the mutant G allele. TRAP also predicted the creation of binding sites for several transcription factors in the mutant sequence such as YY1, SRF and, ELK. MISO (Mixture of Isoforms) results indicated the retention of intron 2 in *CCNT2* gene in patients. Allele-specific expression study of the *CCNT2* gene showed that the expression of mutant allele was higher than wild-type allele in heterozygote control. It seems likely that the mutation leading to an increased expression in mutant cases. To obtain insights into the biological pathways influenced by overexpression of *CCNT2*, we applied our RNA-Seq data to several gene ontology programs. The most significantly dysregulated pathways were relevant to neural development and function, such as "Tyrosine protein Kinase SRC", "Nervous system disease", "Gene expression", and "actin cytoskeletal organization". Pathway enrichment analysis using Genomatix revealed a down-regulation of genes linked with nervous system development, regulation of axonogenesis, actin cytoskeleton pathways and over-representation of gene expression pathway in *CCNT2* mutant patients. The findings reported here provide new insights into the molecular pathways underlying intellectual disability and highlight the importance of this transcription factor in neuronal functions.

**1747T**

**Single cell sequencing of iPSC neural cells from Down syndrome patients uncovers perturbed cell differentiation.** J. Klar, J. Schuster, M. Sobol, L. Laan, A. Fatima, N. Dahl. Department of Immunology, Genetics and Pathology, Science for Life Laboratory, Uppsala, Sweden.

**Background:** Down syndrome (DS) is a leading genetic cause of intellectual disability. Approximately 95% of patients with DS have a full trisomy 21 (T21) resulting in a global transcriptional dysregulation. Furthermore, studies suggest that the distribution of neuronal and glial cells is altered in DS. **Aim:** To investigate transcriptional profiles of single neural cells with T21 to uncover alterations in cell fate specification, commitment and differentiation relevant for DS brain development. **Methods:** We established induced pluripotent stem (iPS) cells from a patient with DS (full T21) and a healthy control individual. The iPS cells were further differentiated into neural cells for 30 days using an undirected protocol followed by immunostaining for neural markers and RNA extraction. Sequencing libraries for single cell sequencing was prepared using the Chromium Single Cell 3' Reagent Kits v2 (10X Genomics). Sequencing was performed on a HiSeq 2500 PE (Illumina) and the data was analyzed using Cell Ranger V2.0 (10X Genomics) and Monocle 2 (Trapnell Lab). **Results:** Cluster analysis of transcriptomes from 3734 euploid single neural cells shows that 63% correspond to radial glia, 6% to intermediate progenitor cells, 20% to neurons and 5% to a cluster of glia cells expressing *PDGFRA*. A pseudo-time analysis of euploid cells confirms an early formation of radial glia followed by mature glia and neuronal cells. In contrast, the cluster analysis of 4169 T21 cells shows that 24% correspond to radial glia, 5% to intermediate progenitor cells and only 4% neuron-like cells. Importantly, 56% of trisomic cells express the glia cell marker *PDGFRA*, making this cell type predominant in trisomic cells. Furthermore, pseudo-time analysis of T21 cells reveals a continuous formation of glial cells along differentiation as well as a relative reduction in the formation of neuronal-like cells. **Conclusion:** In our iPSC model of T21 neurogenesis we observe a reduced proportion of neuronal cells and an increased proportion of glia cell population when compared to euploid control cells. In T21 cells, the formation of glia cell populations appear to be continuous and with a differentiation trajectory distinct from that of euploid cells.

**Scaling up genome engineering for modeling reciprocal genomic disorders.** X. Nuttle<sup>1,2,3</sup>, D.J.C. Tai<sup>1,2,3</sup>, C.E. de Esch<sup>1,2,3</sup>, K. Mohajer<sup>1,2,3</sup>, J.F. Gusella<sup>1,4</sup>, M.E. Talkowski<sup>1,2,3,5</sup>. 1) Center for Genomic Medicine and Department of Neurology, Massachusetts General Hospital, Boston, MA, USA; 2) Department of Neurology, Harvard Medical School, Boston, MA, USA; 3) Program in Medical and Population Genetics and Stanley Center for Psychiatric Research, Broad Institute, Cambridge, MA, USA; 4) Department of Genetics, Harvard Medical School, Boston, MA, USA; 5) Departments of Pathology and Psychiatry, Massachusetts General Hospital, Boston, MA, USA.

Reciprocal genomic disorders (RGDs) arise from recurrent deletions and duplications of specific chromosomal segments and account for 5-10% of autism spectrum disorder, schizophrenia, and intellectual disability. Performing genome engineering in induced pluripotent stem cells (iPSCs), we previously recapitulated microdeletions and microduplications at 16p11.2 and 15q13.3, some of the most common pathogenic rearrangements associated with abnormal neurodevelopment. Extending this approach, we generated cellular models of Prader-Willi syndrome and Angelman syndrome in two iPSC lines, including ~6 Mbp type I deletions and ~5.3 Mbp type II deletions on both parental homologs. To streamline the expensive, time-consuming process of creating and validating RGD cellular models, we developed a parallelized genome engineering approach incorporating libraries of CRISPR/Cas9 guide RNAs (gRNAs) into a piggyBac (PB) transposon system. We designed 59 gRNAs for producing deletions and reciprocal duplications at 19 RGD loci and cloned them into a plasmid-encoded PB transposon harboring doxycycline-inducible Cas9 and a positive/negative selection marker. We co-transfected iPSCs with this library and a plasmid encoding PB transposase, evaluating 12 different combinations of library and transposase DNA input. Leveraging cell-population and single-cell amplicon sequencing, we are currently identifying conditions yielding 0-1 genomic PB integrations per cell with complete library representation. After optimizing transfection parameters to ensure each puromycin-resistant cell expresses one gRNA and each gRNA gets expressed in several cells, we will induce Cas9 expression to perform efficient, temporally controlled genome editing. Using fluorescence-activated cell sorting, we will then isolate single cells, expand resultant colonies, and screen for deletions and duplications of interest using molecular inversion probes. To remove our PB construct from genomes of successfully edited colonies, we will transfect them with a plasmid encoding excision-only PB transposase. Because this transposase achieves >99.7% scarless excision, the resulting cellular models will be near-isogenic, genetically differing only by targeted modifications. The ability to rapidly establish high-quality cellular models at scale will position us well to investigate functional consequences of RGD rearrangements and disrupt specific genes within RGD regions to elucidate their roles in pathogenesis.

**Integrated functional characterization of a non-coding GPC3 allele in a family with recurrent cases of suspected Simpson-Golabi-Behmel syndrome.** A. Vitobello<sup>1</sup>, J. Thevenon<sup>2</sup>, P. Callier<sup>1,3</sup>, T. Jouan<sup>1</sup>, L. Duplomb<sup>1</sup>, M. Bordesoules<sup>1</sup>, Y. Duffourd<sup>1,3</sup>, E. Tisserand<sup>1</sup>, A. Boland<sup>4</sup>, R. Olasso<sup>4</sup>, J.F. Deleuze<sup>4</sup>, D. Sanlaville<sup>5</sup>, C. Thauvin-Robinet<sup>1,3,6</sup>, L. Faivre<sup>1,3,6</sup>. 1) Université Bourgogne Franche-Comté, Inserm UMR 1231 GAD team, Genetics of Developmental disorders, Dijon, Burgundy, France; 2) Service de Génétique, CHU de Grenoble, Grenoble, France; 3) CHU Dijon, FHU TRANSLAD, Dijon, France; 4) Centre National de Recherche en Génétique Humaine (CNRGH), CEA, Evry Cedex, France; 5) Service de Génétique, Laboratoire de Cytogénétique, CHU de Lyon, HCL, France; 6) CHU Dijon, Centre de référence Anomalies du Développement et Syndromes Malformatifs, Centre de Génétique, F-21000 Dijon, France.

Simpson-Golabi-Behmel syndrome (SGBS) is an X-linked condition occurring primarily in males, characterized by pre- and postnatal overgrowth, coarse facial features, variable intellectual disability, congenital heart defects, supernumerary nipples, hepatomegaly and increased risk to develop neoplasia such as Wilms tumors. The major cause of SGBS is mutation/deletion in the gene *GPC3* encoding glypican-3, an outer membrane glycoprotein implicated in WNTs, Hedgehogs (Hh), fibroblast growth factors (FGF), and bone morphogenetic proteins (BMP) signaling modulation. Yet, a variable fraction of convincing SGBS are negative to routine *GPC3* testing, indicating either genetic heterogeneity or clinical overlapping with different overgrowth conditions. Targeted approaches as well as whole exome sequencing (WES) analysis of single-nucleotide variants (SNVs) and copy-number variants (CNVs) failed to detect the molecular cause responsible for recurrent incidence of suspected Simpson-Golabi-Behmel syndrome within a family referred to our center. An integrated analysis deploying whole genome sequencing (WGS) and total RNA sequencing (RNA-seq) was performed in patient-derived samples, in order to interrogate non-coding mechanisms potentially accounting for dysregulation of known and novel candidate genes implicated in overgrowth syndromes. WGS allowed us to identify the presence of a complex intrachromosomal rearrangement resulting in the insertion of a 150 Kb region within the second intron of *GPC3*. Furthermore, RNA-seq analysis allowed the identification of SGBS-specific transcriptional pathways compatible with glypican-3 knockout. We provide evidence of the utility of genome-wide genetic and expression analyses as complementary approaches to interrogate the transcriptional readout of non-coding variants in an ultra-rare genetic condition with negative or inconclusive routine laboratory results in undiagnosed overgrowth syndromes.

**A next-generation mapping approach for the assembly and detection of structural variation within genomic regions containing complex segmental duplications.** F. Yilmaz<sup>1,2</sup>, Y. Mostovoy<sup>2</sup>, E.A. Geiger<sup>2</sup>, N.J.L. Meeks<sup>2</sup>, K.C. Chatfield<sup>2</sup>, C.R. Coughlin II<sup>2</sup>, P.Y. Kwok<sup>3,4,5</sup>, T.H. Shaikh<sup>2</sup>. 1) Integrative and Systems Biology Program, University of Colorado Denver, Denver, CO; 2) Department of Pediatrics, University of Colorado Denver, School of Medicine, Aurora, CO; 3) Cardiovascular Research Institute, University of California, San Francisco, San Francisco, CA; 4) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 5) Department of Dermatology, University of California, San Francisco, San Francisco, CA.

Segmental duplications (SDs) are a class of low copy repeats, which promote genomic rearrangements associated with numerous genomic disorders via nonallelic homologous recombination (NAHR). In addition, SD-mediated structural variations (SVs) also play a role in genomic variation within the general population. However, the true extent of SD-mediated variation in the genome remains to be fully elucidated, due to the limitations in accurate mapping and sequencing of these complex regions using conventional techniques, being especially recalcitrant to short-read sequencing technologies. We used next-generation mapping with Bionano Genomics' Irys and Saphyr systems to analyze SD-containing regions within the human genome. We focused on three genomic regions, 7q11.23, 15q13.3 and 16p12.2, containing large (>300 Kb), paralogous SDs associated with known genomic disorders. We first analyzed optical mapping data from 154 control individuals from five super populations within the 1000 Genomes Project: African, American, European, East Asian and South Asian. Using a combination of single molecules and *de novo* assembled contigs from multiple overlapping molecules, we were able to accurately map the SD-containing regions on 7q11.23, 15q13.3 and 16p12.2. We confirmed previously known large inversions of these regions, which were observed in all populations. Notably, we observed several novel SVs within specific paralogs of SDs. These included copy number variations of a ~16 kb duplicated module within 7q11.23 SDs, ranging between one copy, which was the most common, and six copies, which was the rarest. In addition, we also observed several novel inversions within 7q11.23 SDs. In 15q13.3, a large (~500kb) novel deletion was observed within one of the SDs in all populations, along with multiple inversions, both previously known and novel. Thus, we present a more refined map of SD-mediated variation in these three genomic regions. We were also able to accurately identify the hybrid junction fragments resulting from NAHR-mediated microdeletions in multiple patient samples, allowing an unprecedented level of breakpoint localization within highly paralogous SDs. The high level of variation observed within SDs may contribute to variation in the degree of their instability and their subsequent predisposition to rearrangements associated with genomic disorders. Overall, we demonstrate the power of NGM for better mapping and characterization of SD-containing genomic regions.

**Longitudinal aging-associated gene expression profiling in African green monkey (*Chlorocebus aethiops*).** J. Huh<sup>1,2</sup>, J. Lee<sup>1</sup>, S. Choe<sup>1,2</sup>, H. Cho<sup>1,2</sup>, S. Park<sup>1</sup>, Y. Kim<sup>1,2</sup>. 1) National Primate Research Center, Korea Research Institute of Bioscience and Biotechnology(KRIBB), 30 Yeongudanji-ro, Ochang-eup, Cheongwon-gu, Cheongju-si, Chungcheongbuk-do, Korea; 2) Department of Functional Genomics, KRIBB School of Bioscience, Korea University of Science & Technology(UST), 217 Gajeong-ro, Yuseong-gu, Daejeon, Korea.

*Chlorocebus aethiops* is an old world monkey, has been traditionally used as an experimental model for biomedical research. In addition, recent technological advances of next generation sequencing is useful for unravel the genetic mechanisms of senescence, aging and age-related diseases. The blood transcriptome of healthy aged *C. aethiops* from nine individuals ranging in age from 17 to 25 years old, were analyzed in each of the last three years by the Illumina sequencing platform. We identified 910 to 1399 accumulated differentially expressed genes (DEGs) in each nine individuals, tend to increase with age. Aging-related DEGs were sorted in total three time points of each nine individuals. A major proportion of the aging-related DEGs were belonged to gene ontology (GO) categories involved in translation, rRNA metabolic process. Next, we sorted aging-related common DEGs in total three time points of all nine individuals. Aging-related common DEGs mainly were belonged to GO categories involved in translation, cellular component biogenesis, rRNA metabolic process, cellular component organization or biogenesis, and RNA metabolic process. Furthermore, we identified 29 aging gene which upregulated through the time, by time-series analysis. These aging genes were linked to protein synthesis and mitochondrial dysfunction. This study reported the gene expression changes during aging in *C. aethiops* longitudinal transcriptome, and aging genes identified have the potential as the particular target of aging.

**Simons Foundation data through the GPF (Genotypes and Phenotypes in Families) system.** *I. Iossifov<sup>1,2</sup>, L. Chorbadjiev<sup>2</sup>, N. Dimitrov<sup>3</sup>, A. Chernae<sup>3</sup>, E. Gotsev<sup>3</sup>, N. Volfovsky<sup>4</sup>.* 1) CSHL, Cold Spring Harbor, NY; 2) NYGC, New York, NY; 3) Seqpipe Ltd, Sofia, Bulgaria; 4) Simons Foundation, New York, NY.

In recent years, we witnessed the impressive success in the genetics of autism and other disorders through the analysis of sequence datasets generated from deeply phenotyped large family collection like the Simons Simplex Collection (SSC). There is an enormous amount of work that needs to follow the early success in order to develop effective treatment and early diagnostic strategies. A variety of future research projects will study in detail the effects of hundreds genetic variants and genes at molecular, cellular and organismic levels. Such projects will greatly benefit from the accumulated datasets but their large size and complex structure create a major obstacle for their efficient use. We addressed such difficulties by building a system called Genotype and Phenotype in Families (GPF) that enabled simple and intuitive interaction with the data that was generated by us and data generated independently by other groups. The system allows the integration and the joint analyzes of diverse phenotypic and genotypic data and the efficient distribution of the valuable resources to the wider scientific community through the GPF's intuitive web interface. An instance of the GPF system was deployed at SFARI (<http://gpf.sfari.org>) where it manages a number of large genotypic and phenotypic datasets built through SAFARI's support. These datasets include the phenotypic data gathered from SSC, Simons Variation in Individuals Project (SVIP), and Simons Foundation Powering Autism Research for Knowledge (SPARK) collections and the genotypic data from these collections generated through whole-exome and whole-genome sequencing. .

**Platform for single-cell transcriptomics data analysis and management.** *S. Ramachandrala, A. Pal, H. Adil, D. Chohan, S. Cherukuri, M. Nagarajan.* Strand Life Sciences Private Limited, Bengaluru, India.

StrandNGS is a next-generation sequencing data analysis software designed for the biologists. By following the well-established computational best practices, StrandNGS doubles up as flexible data management system as well. While there are innumerable open source pipelines that help in the analysis of single-cell transcriptomics sequencing studies, data management and results verification remains a challenge. Also, given that most of these are standalone approaches, results from various approaches cannot be easily compared against each other. By allowing the use of R-scripts and Jython-scripts well within the framework of the software, StrandNGS provides a platform to not only organize all the data, analysis, and results but also provides immaculate visualization options that help in comparing and understanding the results from various approaches. Using data from a mouse pancreatic single-cell study (GSE87375), we illustrate these capabilities of StrandNGS. The raw data was imported and aligned against known RefSeq transcripts. Differential expression analysis across the various cell types and developmental stages was performed using the statistical tests that are packaged in the software, and the tests executed through R-scripts. Also, resultant gene lists from externally run tests were imported into the software. The confounding effects in the data set due to varied cell collection methods were identified and corrected for using the in-built surrogate variable analysis; the corrected data matrix was used for all subsequent analysis. Expression profile clustering with sample metadata framework and t-SNE visualization options were extensively used for pattern identification and refinement of results. Moreover, using NLP framework available in StrandNGS, developmental models from peer-reviewed publications were mined and converted into networks. Data from the current study was overlaid on those networks as quilt plots to assess conformity with previous studies. .

**Omic-analysis to discovery genetic biomarker of severe forms of incontinentia pigmenti by using IPGB biobank samples.** *F. Fusco<sup>1</sup>, V. Valente<sup>1</sup>, D. Fergola<sup>1</sup>, A. Pescatore<sup>1</sup>, MB. Lio<sup>2</sup>, MV. Ursini<sup>1</sup>.* 1) Institute of Genetics and Biophysics "A. Buzzati-Traverso" CNR, Italy; 2) University of Basilicata, Potenza 85100, Italy.

The phenotypic heterogeneity of Incontinentia Pigmenti (IP, MIM308300), a rare X-linked dominant disorder affecting neuroectoderm, suggests to search for molecular genetic markers to aim personalized therapeutic strategies. Although significant progress has been made over the last few years in the diagnosis of this rare condition, the genetic defect and underlying pathological abnormality remain unknown. Moreover, to date no definitive cure is available for IP, nor are there sufficiently reliable and specific biomarkers to predict the disease severity. This is in part due to the rarity and genetic and phenotypic heterogeneity of IP disease and the lack of access to patient samples. The availability of the genetic Biobank for IP has addressed this bottleneck and supported IP research. The Incontinentia Pigmenti Genetic BioBank Project (IPGB, <http://www.igb.cnr.it/ipgb>) was launched in 2015 with the aim of providing evidence for the implementation of personalized medicine by constructing a large, patient-based biobank and to enhance research on IP, related to pathophysiology, biomarkers and therapeutic approaches. The cohort includes 0–60 years old, encompassing 436 clinically-confirmed IP cases (IP females and IP males) from 200 cooperative medical institutes worldwide including USA. The Biobank contains blood samples, peripheral blood mononuclear cells (PBMC), red blood cells/granulocyte pellet (totaling 1370 samples). We will describe the IPGB infrastructure and we will present preliminary results of the project to identify what variations/genes/pathways may affect the severity of IP; we used an OMIC-strategy: Target Exome Sequencing of Metabolic Pathway in 80 IP cases (40 IP-severe, 40IP-mild); Whole Exome and Transcriptome Sequencing in 3 IP-severe. More than 30,000 high quality variants were found across the haloplex samples, with an average of 430 variants/sample, and more than 300,000 across the exome samples, with an average of 40,900 variants/sample. Statistical analysis and gene validation are in progress. All IP samples belonged to our historical collection and to IPGB biobank. This research was supported by grant from the CNR-DSB Progetto-Bandiera "InterOmics". .

**Cell-free DNA analysis by automated electrophoresis.** *M. Liu, S. Borg.* Agilent Technologies, La Jolla, CA.

Sequencing of cell-free DNA (cfDNA) extracted from blood specimens or other body fluids is possible due to the establishment of low input library protocols for next-generation sequencing workflows. Accurate quantification of cfDNA samples is essential to determine suitable input amounts for cfDNA library preparation prior to sequencing. The main component of cfDNA samples is the mononucleosome with a size around 170 bp, sometimes with additional species representing nucleosome multimers. Further, cfDNA samples may contain larger DNA fragments dependent on the donor's health status, preanalytical sample treatment, or extraction method. High molecular weight material can negatively influence library preparation and subsequently result in lower sequencing depth. Therefore, reliable quantification of cfDNA requires a method that separates DNA fragments by size, such as electrophoresis. This poster shows the use of a new cell-free DNA assay for an automated electrophoresis system. The cell-free DNA assay enables automated cfDNA quantification with pre-defined regions. Moreover, the results include sample purity as a score to qualify cfDNA samples according to their contamination level with high molecular weight material. The features of the cfDNA assay are described with examples of typical sample patterns.

**BGI employee multi-scale and multi-omics cohort and analysis.** *R. Li<sup>1,2</sup>, P. Li<sup>1</sup>, R. Guo<sup>1</sup>, L. Chen<sup>1</sup>, X. Liu<sup>1</sup>, C. Nie<sup>1</sup>.* 1) BGI-Research, Shenzhen, China; 2) Harbin Institute of Technology Shenzhen Graduate School, Xili University Town, Shenzhen, China.

Body check data of BGI employee were collected annually in BGI to get multi-omics data of health people since 2015. In 2017, multi-scale and multi-omics data of ~4000 employee were collected, including whole genome sequences, immune repertoire and gut metagenome sequences; blood biochemistry and routine test, hormones, amino acids and vitamins and micro-elements concentrations in blood; facial skin image test, body composition, physiological and psychological test and life-style survey. Using 2017 data, we built baselines and setup an aging (biological ages) and healthy assessment system of different aspects of health, like skin, immune, body composition, metabolism, Gut microbiota etc. We constructed a correlation network of different data and communities within reveal groups of closely correlated biomarkers. We found Body composition data were the most correlated data type, indicating that body composition can be general marks in health improvement practices. Personal network relative to the whole cohort gives candidates of abnormal biomarkers pairs, which were in accordance with our health and aging assessment results. For the first time, we did GWAS analysis so many phenotype, most are new, like skin and immune. GWAS-PheWAS together with lifestyle analysis separated genetic and environmental risk of specific health problem, which gave clues to guide health intervenes, for example we found smoking is the key factor determined Cadmium concentration in blood. Gender differences of phenotypes changes with age were also analyzed, simultaneously we found several biomarkers changes with age at different pace for different genders, including physiological and nutritional biomarkers. Our results show measurement of multi-scale and multi-omics data can increase our knowledge of health and help to improve effect of health intervenes.

**1757F**

**A rapid library prep with enzymatic shearing for an improved next generation sequencing workflow for WGS and target enrichment.** *J. Lenhart, B. Lahann, R. Stedtfeld, S. Sandhu, L. Kurihara, V. Makarov.* SwiftBiosciences, Ann Arbor, MI.

Cost efficient and rapid NGS library preparation protocols will further enable high-throughput next generation sequencing for inherited and somatic variant detection. To this end, a rapid library preparation method was developed that employs a combination of enzymatic fragmentation, unique DNA repair mechanisms, and an exceptionally efficient adapter ligation strategy to generate highly complex libraries for Illumina sequencing. Geared to increase NGS library complexity and optimize sequencing output, a sub two-hour workflow (not including PCR) provided libraries for WGS and targeted sequencing. Libraries were prepared from a range of DNA inputs including FFPE and sequenced on MiSeq and NovaSeq. Validated using genomic DNA from human samples, the workflow provided unbiased coverage and consistent fragmentation across multiple input quantities. Libraries prepared for target enrichment were further validated with the IDT xGen Lockdown Exome and Pan Cancer hybridization capture panels. The rapid library preparation workflow provided unbiased target coverage, high complexity, high percent bases on target, and maintained uniform coverage. In conclusion, Swift's new library preparation workflow enables a rapid workflow for whole genome and targeted sequencing of samples.

**Towards precision medicine: Accelerating diagnostics for infectious and inflammatory diseases using blood gene expression biomarkers.** M. Kaforou, D. Habgood-Coote, J.A. Herberg, A. Cunningham, M. Levin. Imperial College London, Medical School Building, Norfolk Place, London, W2 1PG, UK.

Infectious diseases continue to be amongst the most important causes of illness and mortality accounting for 17% of deaths worldwide and are responsible for a major component of the workload and cost of medical care. Available pathogen-based microbiological and laboratory tests are not sufficiently rapid or accurate to allow antibiotics to be safely withheld. Instead of trying to detect the pathogen, an alternative approach measuring gene expression patterns in the patient's blood is being introduced. However, until now, diagnostic signatures attempt to address the patient classification problem in a simplistic dichotomous way limiting the opportunities for clinical use (bacterial vs. viral, malaria vs. other diseases etc.). Here, we address gene expression based disease assignment, as a hierarchical multi-label classification problem mimicking the actual clinical decision-making processes. Using a cohort of well-phenotyped patient transcriptomic data (n~1350) with a range of infectious and inflammatory diseases, including bacterial and viral infections, as well as healthy controls we implemented a hierarchical multi-label classifier while rebalancing the classes according to cost of misclassification. We employed variable selection methods to identify the best set of biomarkers, which can, in different combinations, optimally discriminate between diseases. The biomarker set was discovered for all conditions jointly to maximize usage of the information captured by individual genes. Multi-label classification assigns each patient to a set of diagnostic labels, which are not mutually exclusive, and allows for the assignment of non-infectious diseases, co-infections and severity. Hierarchical multi-label classification methods applied on patient transcriptomic data can provide greater diagnostic information than simplistic binary classifiers or conventional clinical classification. An accurate and robust classifier based on a parsimonious set of genes has the potential to be measured using a single blood test and could enhance disease diagnosis and treatment decision-making, enabling the transition to the precision medicine era. [1] Herberg, J.A. et al. *JAMA*, 316 (8): p. 835-45 (2016) [2] Zaas, A.K. et al., *Cell Host Microbe*, 6 (3): p. 207-17. **Development and validation of the CESeq and WESeq test systems.** S. Burns, M. Soucy, J. Uvalic, D. Bergeron, M. Peracchio, M. Preggo, G. Ananda, A. Hesse, P. Panneer Selvam, J. Davey, K. Kelly, H. Reddi. The Jackson Laboratory, Farmington, CT.

**Introduction** The Jackson Laboratory has introduced a new reflex testing algorithm for inherited disorders designed to efficiently address clinical utility from a diagnostic perspective while maintaining a short turn-around time. CESeq is a targeted panel allowing genotypic identification of causal variants in clinically significant coding exons spanning about 4,800 genes. If CESeq turns up no disease causing variants, the sample is reflexed to WESeq, which provides 45 Mb of exome coverage. **Methods** Both CESeq and WESeq were developed and validated using Illumina library preparation kits. Both assays were optimized for DNA input, batch size, PCR conditions, and loading concentration. For the validation of CESeq, 24 gDNA samples were blinded and prepared in 3 batches. WESeq validation included the evaluation of 21 blinded gDNA samples prepared in 3 batches. Both assays were assessed for accuracy, sensitivity, specificity, precision, limit of detection, and reportable range. Variants were called by the Genome Analysis Toolkit (GATK) HaplotypeCaller, annotated using Alamut Batch against the reference genome build HG19/GRCh37 and further computationally annotated by the gene/variant prioritizer software Exomiser using best-matched controlled Human Phenotype Ontology (HPO) terms. **Results** Table 1 demonstrates the results for each performance characteristic.

Performance Characteristic	CESeq (%)	WESeq (%)
Accuracy	99.88	99.97
Sensitivity	96.5	99.76
Specificity	99.98	99.97
Precision (Repeatability)	97.98	95.92
Precision (Reproducibility)	96.12	95.9
Limit of Detection SNVs	minDP 15, AF width 25%	minDP 15, AF width 20%
Limit of Detection Indels	minDP 10, AF width 25%	minDP 10, AF width 20%
Reportable Range	Variants detected/not detected above the LOD within the region of interest.	Variants detected/not detected above the LOD within the region of interest.

Performance characteristics for the validation of CESeq and WESeq are all greater than 95%. **Conclusion** Based on performance characteristics for the validation of CESeq and WESeq, the assays were incorporated into the clinical menu at The Jackson Laboratory. If CESeq fails to uncover a disease causing variants, the sample is reflexed to WESeq without any additional requirements from the physician. JAX's reflex exome algorithm provides an efficient solution for clinicians and their patients. .

**Genome manipulation of induced pluripotent stem cells using CRISPR/Cas9.** *A.M. Resch<sup>1</sup>, J.S. Hsiao<sup>2</sup>, N. Turan<sup>1</sup>.* 1) Coriell Institute for Medical Research, Camden, NJ; 2) Novartis Institutes for BioMedical Research, Cambridge, MA.

Induced pluripotent stem cells (iPSCs) are unique tools that have been used to model genetic disorders and unravel underlying disease mechanisms. Clustered regularly interspaced short tandem repeats (CRISPR) and CRISPR associated protein 9 (Cas9) have made genome engineering in mammalian cells possible for laboratories with basic molecular biology capabilities. Many cell types are relatively easy to manipulate. However, engineering pluripotent stem cells (PSCs) is still insufficient and difficult to achieve. Here, we provide a method to efficiently obtain genome-edited human PSC lines, minimizing the number of clones to be screened. Many types of genome engineering including knock-in, knock-out, and point mutations can be achieved with this method. Genomic knock-out can be achieved with two CRISPR guide RNAs flanking the target region, while genomic knock-in can be achieved using a plasmid donor with 800-1000 bp homologous arms flanking the knock-in sequence. Point mutations can be achieved using a single-stranded oligonucleotide (ssODN) as a donor template. Temporary antibiotic selection greatly increases the success rate of editing events by eliminating cells without the CRISPR/Cas9 plasmid. We demonstrate that this method is suitable for most laboratories to perform gene-editing in human PSCs to sufficiently obtain modified PSC clones. This technology is being used to create isogenic control lines for disease research. In the past, comparisons between disease and healthy controls were performed using cell lines from separate individuals. This approach is constrained because of differing genetic backgrounds between individuals. The creation of gene-edited isogenic lines that control for differences in genetic background between individuals will provide new tools for disease research.

**Variant identification from whole genome sequencing at the UPMC Genome Center.** *A. Berndt<sup>1</sup>, S. Mentch<sup>1</sup>, M. Zhuo<sup>1</sup>, L. Luo<sup>1</sup>, C. Sims<sup>1</sup>, J.M. Xavier<sup>2</sup>, P. Empey<sup>2</sup>, A.V. Lee<sup>2</sup>.* 1) UPMC Genome Center, Pittsburgh, PA; 2) Institute for Precision Medicine, University of Pittsburgh, Pittsburgh, PA.

Falling costs for high-throughput genome sequencing have shifted our attention from using whole genome sequencing solely in research settings to embedding the services into clinical care. In parallel, cloud and software vendors provide secure and compliant environments to protect personal health information, therefore providing an infrastructure platform that can scale with the demands of high-throughput, whole genome data volumes (storage) and throughput (compute). We will show how UPMC has stood up its own in-house, industrial scale, and clinical-grade genome center over the last 12 months. The UPMC Genome Center integrates with a cloud-only data infrastructure that allows for processing and securing genomic data for clinical processing. We will present data from our extensive validation set for whole genome germline sequencing. We will also present results from two clinical use cases: i) comparing whole genome sequencing and genotyping data for pharmacogenomics variants and ii) rare variant identification from patients in the Neonatal Intensive Care Unit (NICU).

Maestri<sup>1</sup>, E. Fortunati<sup>1</sup>, M. Rossato<sup>1</sup>, L. Xumerle<sup>2</sup>.*

1) University of Verona, Verona, Italy; 2) Personal Genomics srl, Verona, Italy.

Whole exome sequencing (WES) is a mature, quite standardized methodology where the most important parameter for WES quality is the coverage (read depth) in order to properly call variants. WES data are typically stored as variant call format (VCF) files, which was developed primarily to represent human genetic variation and not to make causal links between variants and human disease. Standard variant calling pipelines based on VCF are in fact limited in their ability to call the patient genotype in loci homozygous or hemizygous for the reference allele. Absence of a variant in a certain position may be due to the absence of the variant but it may also be due to the failure to detect it because of poor read depth in that region or because of poor mapping quality of the reads due to multiple alignment of those reads on the genome. By taking advantage of the gVCF file format, an extension to the standard VCF format that stores genotypes of variant sites and invariant genomic regions with associated calling scores, we compared coverage and base calling (genotypability) of different whole exome enrichment technologies and found that in many cases there is not a direct relationship with the coverage. Apart from repetitive regions, so far rarely object of investigation in a clinical setting, the lack of a direct relationship is particularly evident - as expected - for genes having pseudogenes, for duplicated genes and for gene families, because of the uncertain read alignment on the genome that determine a low mapping quality of the reads. We observed that increasing the average length of the DNA fragments increases the mapping quality of some regions and improves the base calling for a significant number of genes. The reads mapping near the target (padded regions) expand with longer DNA fragments, but the increased sequencing depth necessary to maintain a good coverage of the targets is negligible for gene panels and, for WES, it is compensated by the high uniformity of some enrichment platforms, which reach base calling saturation at low coverage.

**POP 1: A new sieving matrix for capillary electrophoresis that supports a wide range of applications with a single instrument set-up and with extended stability at ambient temperature.** *J. Romero.* Thermo Fisher Scientific, South San Francisco, CA.

The sieving polymer formulations (POP-4™, POP-6™, and POP-7™) that Thermo Fisher Scientific manufactures for capillary electrophoresis (CE) are designed to provide optimal performance when installed on a CE instrument for up to one-week at ambient temperature (15-30 °C). To assure optimum electrophoretic performance, these formulations must be shipped to customers under refrigerated conditions to prevent the breakdown of urea, which causes an increase in electric current and joule heating and eventually a loss in resolution performance. In an investigation to develop a new universal formulation that could replace POP-4™, POP-6™, and POP-7™ we have explored methods to stabilize performance for an extended period at ambient temperature. There is not an electrophoretically compatible substitute for urea, and urea breakdown cannot be prevented at elevated temperatures. The new POP formulation, POP 1, has been designed to compensate for urea breakdown, allowing a longer lifetime for the reagent on the instrument. POP 1 has also been designed to capture most the electrophoretic properties of POP-4™, POP-6™, and POP-7™ so that a single POP formulation can now be used for multiple applications. For example, POP 1 provides better resolution for fragment analysis applications than POP-4™, with slightly faster run times. Sequencing run times are substantially faster with POP One than with POP-6™, but resolution of short sequencing fragments is significantly better for POP One than for POP-7™. For sequencing applications, with either a 36 cm or 50 cm capillary array, a set of three run modules were developed that provide (1) the longest possible basecalling read-length without consideration of run time, or (2) the best compromise between basecalling read-length and run time, or (3) the fastest run time but with a shorter read-length (> 500 bases). For fragment analysis applications, run modules have been developed to support a range of applications from very fast analysis of short fragments (e.g. single-base extension genotyping) to high-resolution analysis of long fragments up to 1kb long. We will compare the resolution performance of POP 1 to previous POP formulations, provide examples of sequencing and fragment separations with the different run modules. We will also compare the electrophoretic performance of freshly installed POP 1 versus polymer that has resided on the CE instrument for multiple weeks.

**1764W**

**The design of Taiwanese-specific SNP array by Taiwan Biobank.** *P.E. Wu<sup>1,2</sup>, C.Y. Shen<sup>1,2</sup>*. 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Taiwan Biobank, Academia Sinica, Taipei, Taiwan.

To understand the relationship between genetics, environmental exposure, diet, and the etiology/progression of chronic disease, the Taiwan Biobank is establishing a scientific infrastructure accessible to biomedical researchers. Through the recruitment and follow-up of a cohort of 200,000 individuals from the general population and another of 100,000 patients with chronic diseases of public health importance from medical centers, the Taiwan Biobank aims to improve the health of future generations and facilitate genomic research in the post-genomic era in Taiwan. Currently, more than 100,000 participants of general population have been recruited, and more than 1,500 participants with chronic diseases have been recruited. Whole-genome genotyping information of more than 24,000 individuals using TWBv1.0 chip (653,291 SNPs, specifically for the Han Chinese in Taiwan) were obtained. The work of whole genome sequencing of 1,500 individuals has been completed. Based on this, Taiwan Biobank has designed a Taiwanese-specific SNP array, which is called TWB v2.0 chip to differentiate the SNP chip (i.e. TWBv1.0) we currently use. There are 717,510 variants included in this chip. In this chip, we use the whole genome sequencing data to select representative 415,000 variants among Taiwanese population, serving as the backbone of this chip. The SNPs used in backbone are the markers showing minor allele frequency (MAF)>5% and covering 0.968 of our genome. Additionally, the coverage rate is 0.702 for the markers showing MAF between 1% and 5%. In TWB v2.0, we also include 105,000 variants with clinical relevance, 81,000 functional variants, 31,000 cancer-associated variants, 50,000 pathogenic variants, the variants showing GWAS significant and the variants of copy number variation. We aim at making the chip both representative to Taiwanese population, and valuable for clinical usage. This chip will be used in the participants of Taiwan Biobank, and summary genetic information will be released in our website (i.e. Taiwan View website) for the public. Taiwan Biobank creates one of the largest publicly accessible databases that is combine genetics, environmental exposure, diet, and clinical information. Based on these data, human geneticists can make use of this valuable and ample information for further research.

**1765T**

**Covaris and Twist fully validated NGS target enrichment library preparation with LE220-plus and oneTUBE.** *P. Kocjan<sup>1</sup>, J. Simon<sup>1</sup>, H. Khoja<sup>1</sup>, J. Laugharn<sup>1</sup>, M. Consugar<sup>2</sup>, C. Thompson<sup>2</sup>, R. Gantt<sup>2</sup>*. 1) Covaris, Woburn, MA; 2) Twist, San Francisco, CA.

Covaris, known as the Gold Standard for DNA shearing in NGS, partnered with Twist Bioscience for an exome enrichment library prep workflow. For NGS applications such as WGS and WES, accurate DNA fragmentation is key to achieve high quality libraries ready for sequencing. Covaris produces Focused-ultrasonicators such as the ME220 and LE220-plus which utilize Adaptive Focused Acoustics® (AFA)® technology to mechanically shear nucleic acids and aid in extraction of other biological sample types. Pairing AFA technology with Twist's uniquely designed double-stranded DNA probes offers a solution for a targeted exome enrichment library prep. The LE220-plus, which has high-throughput processing capabilities for up to 96 samples is compatible with the newly developed 96 oneTUBE-10 AFA Plate. This specially engineered polymer allows for low impedance and better transmission of acoustic energy producing tight size distributions necessary for NGS. Designed for use as typical labware, the 96 oneTUBE-10 AFA plate can simplify library prep workflows improving turnaround time and throughput. Utilizing this new consumable, we sheared human genomic DNA evaluating various size distributions to determine the optimal AFA conditions for Twist library construction. For lower throughput applications, the ME220 is the ideal solution processing up to 8 samples in one batch. The 8 strip formats of the oneTUBE-10 or microTUBE-50 allow the flexibility necessary for Twist workflows. Covaris and Twist in combination offer a fully validated library prep solution for targeted exome sequencing. Producing highly accurate and reproducible results for DNA fragmentation with AFA®, Covaris offers a wide variety of Focused-ultrasonicators such as the LE220-plus and ME220. Paired with Twist's superior enrichment efficiency, Covaris and Twist produce the highest quality results for targeted exome library preparation. .

**1766F**

**NEBNext Ultra II FS DNA: A robust, enzyme-based DNA library preparation method.** *K. McKay, L. Apone, V. Panchapakesa, B. Langhorst, T. Shtatland, C. Song, P. Liu, C. Sumner, C. Rozzi, M. Arn, D. Munafo, F. Stewart, E. Dimalanta, T. Davis.* New England Biolabs, Inc, Ipswich, MA.

Next Generation Sequencing technology has advanced our knowledge of the molecular mechanisms involved in disease development and progression. This understanding has led to advancements in target identification and drug discovery in therapeutic medicine. The extremely high data output of current sequencing instruments has shifted the bottleneck from sequencing to optimal, high-throughput sample preparation in NGS workflows. To meet this challenge, we have developed a robust library construction method that integrates enzyme-based DNA fragmentation with end repair and dA-tailing in a single tube. This method eliminates the need for expensive equipment to fragment DNA; moreover, the optimized workflow reduces the numerous cleanup and liquid transfer steps, reducing time, cost and errors associated with library construction. Genomic DNA with various GC contents was used to construct Illumina libraries. DNA (100pg - 500ng) was fragmented, end repaired and dA-tailed in a single step followed by adaptor ligation in the same tube. PCR amplified and PCR-free libraries were sequenced, reads aligned to the appropriate reference genome, and quality metrics generated using Picard tools. The high library yields obtained with enzyme-based shearing enable PCR-free workflows from as little as 50ng starting material. Sequencing quality of these libraries generated show similar coverage uniformity and fragment size distribution, with minimal GC bias. To demonstrate that genome integrity is maintained with the Ultra II FS, libraries were constructed from human genomic DNA spiked with DNA reference standards containing multiple common cancer mutations (Horizon Discovery, Inc.) at defined frequencies. Target enrichment and deep sequencing of a panel of cancer genes were performed, and variant frequency of input DNA and enriched FS libraries were quantified using digital droplet PCR. Our data showed that Ultra II FS maintains mutation abundance in samples without introducing bias. In addition, Ultra II FS enables high-quality library construction from a broad range of DNA quantities and qualities. Sequencing metrics of FS libraries are similar or superior, to those produced with mechanically sheared DNA. These advances will allow greater use and adoption of NGS technologies in clinical and diagnostic settings.

**1767W**

**Rapid isolation (<2 h) of ultra-high molecular weight genomic DNA from fresh/frozen human blood and cultured cells/frozen cell pellets without the use of agarose plugs.** *H. Sadowski, C. Proskow, A. Files, K. Pham, G. Pljevaljcic, M. Borodkin.* Bionano Genomics, San Diego, CA.

Successful optical mapping of genomic DNA on the Bionano Genomics Saphyr® system for genome assembly or structural variation detection relies on starting with ultra-high molecular weight (UHMW) DNA. To achieve this, we have established methods for the isolation of genomic DNA from various sources that involves the embedding of material in agarose plugs and overnight lysis *in situ* with detergent and proteinase K. After extensive washing on day 2, the agarose plug is melted, treated with beta agarase to digest agarose polymers to monomers and the liberated DNA is finally subjected to drop dialysis. The UHMW DNA is ready for quantification and labeling on day 3. This "plug lysis" method is extremely robust, but it is also labor intensive, difficult to automate, lengthy and expensive. To address these shortcomings, we have developed a solution based lysis method which we have coupled with a purification step that leverages a novel process to bind, wash and elute UHMW genomic DNA. This entire protocol can be conducted in less than two hours on a batch of samples. The eluted material contains high quality DNA that is clean enough for enzymatic labeling using nick-label-repair-stain (NLRS) or direct labeling and staining (DLS). The resulting metrics of this labeled DNA on a Saphyr Chip® are comparable to labeled DNA isolated by the traditional "plug lysis" protocol. We have validated protocols for fresh and frozen blood as well fresh cultured cells and frozen cell pellets and are developing protocols for plant and animal tissue. This protocol is automatable providing the needed solution for researchers needing to purify DNA from hundreds to thousands of individuals per year.

**1768T**

**Single-cell protein and gene expression profiling of stem memory T cells by Ab-seq.** M. Nakamoto<sup>1</sup>, C. Chang<sup>1</sup>, E. Shum<sup>1</sup>, J. Martin<sup>1</sup>, J. Ghadiali<sup>1</sup>, M. Corselli<sup>2</sup>, D. Jensen<sup>1</sup>, J. Hu<sup>1</sup>, D. Rosenfeld<sup>1</sup>, C. Fan<sup>1</sup>. 1) BD Biosciences; 2) BDTI.

High-throughput single-cell RNA sequencing recently emerged as a powerful tool to profile complex and heterogeneous cell populations and dynamics. However, the lack of information on protein expression can make identifying cell types that have conventionally been defined by cell-surface markers challenging, as mRNA and protein expression are often not tightly correlated. T cells in particular contain relatively low abundance of transcripts, and different T-cell subsets often exhibit highly similar transcriptional profiles. Here we utilized BD Ab-seq, a novel protein sequencing technology enabled by oligo-conjugated antibodies, to study stem memory T cells (Tscm), a rare long-lasting memory T-cell population with stem cell-like properties. An oligo-conjugated antibody panel against immune-relevant cell-surface markers was created and used for protein profiling alongside gene expression profiling in single cells. From human PBMCs, we enriched for Tscms, naïve T cells, central memory T cells and effector memory T cells by FACS. The sorted samples were labeled with antibodies barcoded with unique sample IDs, which allowed us to pool multiple samples into one single-cell experiment, and de-multiplex the samples after sequencing. The antibody-specific oligos and sample ID-specific oligos were captured, amplified and sequenced alongside mRNAs in a single workflow on BD Rhapsody™, a massively-parallel single-cell analysis system. The resulting sequencing data provided a combined output of gene expression, protein expression and sample identity. The detection of protein expression by BD Ab-seq was highly sensitive and specific, and we observed consistent protein expression patterns when comparing BD Ab-seq data to FACS data of the same samples. The addition of protein marker expression provided more distinct and robust clustering of single-cell data compared to clustering by gene expression alone. We were also able to correlate gene expression differences between the four T-cell subsets with protein marker expression at the single-cell level to examine heterogeneity within the Tscm subset. Our study demonstrates the power of combining BD Ab-seq with RNA-seq to gain a more comprehensive understanding of cell lineage and function at the single-cell level.

**Deep mutational scanning of the  $\beta_2$ -adrenergic receptor.** E.M. Jones, N.B. Lubock, D. Cancilla, M. Satyadi, J. Davis, R. Jajoo, S. Kosuri. Dept. of Chemistry and Biochemistry, Molecular Biology Institute, University of California Los Angeles.

G protein-coupled receptors (GPCRs) are principal mediators of cell signaling in humans. GPCRs are widely implicated in disease and targeted by roughly 30% of all FDA approved drugs. How their genetic variation affects drug/ligand binding and signaling remains unknown on a comprehensive scale. The difficulty to interrogate GPCR structure through traditional methods further obfuscates this relationship. Deep mutational scanning presents a way to probe the fitness effect of every missense mutation possible for a protein and understand the contribution of each individual residue to function. We have leveraged advances in DNA synthesis, gene editing, and next-generation sequencing to create a platform able to measure the difference in drug-induced G-protein signaling of all beta-2 adrenergic receptor missense variants (~8000) in multiplex. Our assay enables us to understand broad structural rules for regions of the protein, comprehensively understand the fitness of previously known and novel motifs, and relate this data to genetic variation in humans. Additionally, we found simple algorithms such as k-means clustering groups our mutations into distinct classes that map onto the structure in a functionally relevant manner.

**1770W**

**CleanPlex® UMI with unique dual index increases the overall usable reads available for ultralow-frequency variant calling.** *L. Lee, Z. Liu, L.Y. Liu, G. Liu, J. Liu, L.J. Zhang, L. Lin.* Paragon Genomics, Hayward, CA.

With recent advances in next generation sequencing, larger capacity sequencers are pushing for higher multiplexing of samples per sequencing run. With this increase in paralleling power, there is a growing need for not only additional indices, but also robust and high performing indices that minimizes errors associated with certain sequencing chemistries. It was recently discovered that high capacity sequencers are susceptible to "index hopping" that can increase mis-assignment and also lead to an increase in false positives. With increasing interest in ultra-low allele frequency detection, such as in liquid biopsy, it is crucial that the index itself does not contribute to errors that will interfere with accurate calling. To mitigate these issues, Paragon Genomics created unique dual indices (UDI) or distinct pairs such that show a significant improvement in usable double-stranded barcoding reads compared to libraries with the traditional overlapping i5 and i7 combination indexing method. The CleanPlex® UMI technology's fast and simple libraries made with Paragon Genomics's UDI allows allele frequency detection down to 0.1%, utilizing less read depth.

**Taiwan biobank surveys of gut microbiota.** *M. Su, H. Chu, T. Yu, C. Chang, C. Chang, C. Lin, C. Hsiung, C. Shen.* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

The gut microbiota is a hidden organ because it serves many biological functions are equivalent or more important than other organs. It can affect human behavior and complex diseases such as inflammatory bowel diseases, type 2 diabetes, and colorectal cancer. Various clinical studies have demonstrated that fecal microbiota transplantation (FMT) could become a viable therapeutic option. Biobanking gut microbes along with their genetic and metabolic profiles will become important to a wide range of diseases. We have observed many confounding issues through sample collection to data analysis in biobanking microbes. In this study, we evaluate the effect of sample storage condition, sample collecting time, sample collecting kit, sequence target region and data analysis pipelines. Results show that sample storage condition is the most important confounding factor of a microbiota study. If fecal samples cannot be frozen at -80 degree centigrade immediately, store the samples in a stabilization reagent is optimized for sample collection. The standard approach of 16S data analysis is clustering reads by sequence similarity into operational taxonomic units (OTUs). Denoising approaches have been proposed to improve the resolution of the 16S analysis. A comparative analysis of clustering and denoising methods showed that clustering method impacts on the number of OTUs and denoising algorithm influence more on taxonomic affiliations. The discrepancy in the number of OTUs between partial 16S rRNA and full-length 16S rRNA need further validations to determine whether the full-length bacterial 16S rRNA will provide a better bacterial classification.

**1772F**

**Evaluation of methods for the extraction of microbial DNA from vaginal swabs used for microbiome studies.** S. Tomei, V. Mattei, S. Murugesan, M. Al Hashmi, P. Singh, R. Mathew, N. James, A. Lakshmanan, A. Terranegra, S. Al Khodor. Sidra Medical and Research Center, Doha, Qatar.

**Background.** The composition of the microbiome in various human body sites plays an important role in health and disease. The advancement of sequencing technologies has made the assessment of the composition of the microbiota possible through microbial DNA extraction and sequencing. Therefore, it is of a paramount importance to select a sensitive and reproducible DNA extraction method, that facilitates isolation of microbial DNA with a sufficient quantity and purity, from microbial species living in the vaginal environment. In this study, we have evaluated four different DNA extraction protocols from self-collected vaginal swabs. **Methods.** Five healthy female volunteers were enrolled in the study. Each donor was asked to self-collect 4 samples using Copan ESwab. DNA was extracted using Qiagen DNeasy kit and three modified protocols of the MoBio PowerSoil kit. DNA quantity and integrity was checked through Nanodrop and LabChip GX. DNA was further tested through quantitative real-time PCR (qPCR) and 16S sequencing. Vaginal microbiota diversities were determined using MiSeq-Illumina high-throughput sequencing of bacterial 16S rDNA V1-V3 fingerprint. Sequencing data were analyzed using QIIME pipeline. **Results.** Qiagen DNeasy protocol resulted in the highest DNA yield as compared to the modified protocols of MoBio Powersoil kit. The size of the DNA extracted using each protocol was ~40kb. Qiagen DNeasy protocol gave the highest Genomic Quality Score (average  $\pm$  standard deviation:  $4.24 \pm 0.36$ ), followed by the different MoBio Powersoil protocols. A substantial variability in microbial DNA abundance was found across the different protocols tested. As expected, the vaginal microbiota of the healthy volunteers was dominated by *Lactobacillus species*. MoBio Powersoil kit provided a significantly higher alpha diversity as compared to the Qiagen DNeasy kit. On the other hand, beta diversity measures did not reveal any significant cluster changes among the four protocols tested. **Conclusion.** Using all four DNA extraction protocols described in this study, we were able to isolate microbial DNA from the vaginal swabs. However, the results vary based on the downstream application needs. We show that, the Qiagen DNeasy is the best extraction protocol to use in terms of DNA yield and quality. However, the modified MoBio PowerSoil protocols showed higher microbial diversities as compared to the standard protocol.

**Streamlining single-cell next-generation sequencing of small non-coding RNA.** J.M. Henderson<sup>1</sup>, D. Keys<sup>1</sup>, S. Shore<sup>2</sup>, R. Khnouf<sup>3,4</sup>, C.M. Han<sup>3,5</sup>, R.I. Hogrefe<sup>1</sup>, A.P. McCaffrey<sup>1</sup>, S.A. Munro<sup>3,6</sup>, H. Shintaku<sup>7</sup>, J.G. Santiago<sup>3</sup>. 1) Research and Development, TriLink BioTechnologies, San Diego, CA; 2) Singular Genomics, San Diego, CA; 3) Department of Mechanical Engineering, Stanford University, Stanford, CA; 4) Department of Biomedical Engineering, Jordan University of Science and Technology. Irbid, Jordan; 5) National Institute of Standards and Technology (NIST), Gaithersburg, MD; 6) Department of Bioengineering, Stanford University, Stanford, CA; 7) RIKEN Cluster for Pioneering Research, Saitama Japan.

Differential expression of small RNA (sRNA) is crucial for many cellular processes such as development and regulation, however current techniques to study such events via massively parallel sequencing are limited by difficulties associated with tagging low amounts of short sequences and often rely on bulk cell analysis. It is becoming more apparent that variations in gene expression within a single cell can go undetected within a pooled population and may lead to false negative results, especially if assaying for rarities such as circulating tumor cells. Therefore, the need for improved small RNA next generation sequencing (sRNA-Seq) of single cells is imperative. One of the main challenges in sRNA-Seq occurs during library preparation when fixed-sequence adapters ligate directly to each other instead of to the small RNA within the sample. Because the adapters are complementary to primers used for reverse transcription and PCR, empty libraries known as "adapter dimer" will also amplify. Adapter dimer may be only 20 nucleotides shorter than the tagged small RNA, making it difficult to separate away from the library of interest. This formation of adapter dimer becomes more prevalent when lower amounts of sRNA are available in the reaction. If this contaminant is not efficiently removed then adapter sequences will monopolize NGS reads. We reasoned that reducing adapter dimer would lead to improved sensitivity at low RNA input levels, allowing for sRNA-Seq of single cells. In this work we present a combination of novel technologies; chemically modified CleanTag adapters for dimer suppression and single-cell microfluidic on-chip isotachopheresis (ITP) for separation of nucleus and cytoplasm. We compared CleanTag sRNA libraries prepared from bulk K562 cells, single K562 cells lysed in Triton X-100, and ITP separated cytoplasmic RNA from single K562 cells. Our results indicate that combining the streamlined methods of microfluidic chip-based single cell isolation with CleanTag library preparation will be invaluable in automating high throughput research and diagnostics in the small RNA field. .

**Returning unanticipated genomic results in a hospital-based research biobank.** R.C. Green<sup>1,2,3,4</sup>, C.L. Blout<sup>1</sup>, M.S. Lebo<sup>2,3,4,5</sup>, J.B. Krier<sup>1,2,3</sup>, J. Smoller<sup>5,6</sup>, E.W. Karlson<sup>1,3</sup>, L. Mahanta<sup>2</sup>, K. O'Brien<sup>2</sup>, K.D. Christensen<sup>1,3</sup>, N. Boutin<sup>2</sup>, S.T. Weiss<sup>2,3</sup>. 1) Department of Medicine, Brigham and Women's Hospital, Boston, MA; 2) Partners HealthCare Personalized Medicine, Cambridge, MA; 3) Harvard Medical School, Boston, MA; 4) Broad Institute, Cambridge, MA; 5) Department of Pathology, Brigham and Women's Hospital, Boston, MA; 6) Department of Psychiatry, Massachusetts General Hospital, Boston, MA.

**Introduction:** Many healthcare systems are analyzing genetic data from biobanks along with patients' electronic health records (EHRs). We present early results from Partners Biobank on return of genomic results (gRoR). **Methods:** We elected to return pathogenic/likely pathogenic (P/LP) variants in ACMG59 genes from genotyping (GT) on the Illumina MEGA (N=15,000 to date) or by next-generation gene sequencing (GS) (N=2500 to date). Participants with P/LP variants first received orientation to the non-CLIA finding from a study GC and were offered CLIA confirmation paid by the study. Those electing to confirm were transitioned to a clinical work stream to learn the exact variant from a clinician trained in genetics and the result entered into the EHR and communicated to their provider. **Results:** GT quality control yielded a false positive rate of 37%, 2/3 of which were caused by multi-allelic sites. Of 15,000, GT yielded reportable results in 108 participants (0.72%), while GS of 2,500 samples yielded reportable results in 58 subjects (2.3%), the difference reflecting probes in GT limited to previously known variation and difficulties genotyping rare variation. Together 166 individuals were identified, with results related to cancer (88), cardiology (44), cholesterol (27) or other phenotypes (7). Of these, 42 already had EHR documentation of the result, 9 were deceased, 11 were lost to follow-up and 34 are in process. Of 59 participants so far reached and offered confirmation, 11 (18.6%) declined to proceed. For an additional 6 subjects, P/LP variants in the ACMG59 genes were determined to be somatic due to previously diagnosed cancer (1) or clonal hematopoiesis (5). **Conclusions:** GT is less expensive but less sensitive or specific than GS. A substantial number of biobank participants already had the detected variant in their EHR or were unreachable, and among those contacted nearly one-fifth declined confirmation. Some variants classified as P/LP required deep sequencing and clinical correlation to recognize they were somatic rather than germline. Transition to a specialized clinical workstream as a requirement for confirmatory disclosure may help avoid misunderstanding or mismanagement around results delivered directly to the participant or their provider. Additional data on technical considerations and participant outcomes will be presented. Lessons learned from these experiences may help inform gRoR for other biobanks including the All of Us Research Program.

**1775F**

**Genetic profiling of ADME markers using PharmacoScan™ solution across blood, saliva, and buccal cell-derived genomic DNA.** D. Lizarraga<sup>1</sup>, J. Law<sup>1</sup>, K. Tsai<sup>1</sup>, L. He<sup>2</sup>, S. Larocca<sup>2</sup>, X. Fang<sup>2</sup>, R. Setterquist<sup>2</sup>, C. Bruckner<sup>1</sup>, R. Varma<sup>1</sup>, J. Gollub<sup>1</sup>, D. Black<sup>1</sup>, M. Shapero<sup>1</sup>. 1) Thermo Fisher Scientific, 3450 Central Expressway; Santa Clara, CA 95051; 2) Thermo Fisher Scientific, 2130 Woodward Street; Austin, TX 78744.

Genetic variation in drug absorption, distribution, metabolism, and excretion (ADME) genes forms the basis for each individual's clinical response to xenobiotics. The Applied Biosystems™ PharmacoScan™ Solution enables comprehensive, accurate genotyping on a DNA microarray of ~4,600 markers in over 1,000 genes involved in drug-metabolizing enzymes and transporters research. As personalized medicine becomes increasingly important in patient care, this study set out to expand the application of this platform to various DNA sample types and extraction methodologies. To this end, the characterization and verification of genotyping performance of saliva and buccal cell sample types with PharmacoScan™ Assay 96-Array Format and PharmacoScan™ Assay 24-Array Format plates was carried out. The study verified the use of both magnetic, bead-based high-throughput DNA isolation and manual, precipitation-based DNA extraction methods. Both extraction methods provided high-quality genomic DNA (gDNA) that is compatible with PharmacoScan Assay. This study demonstrated similar genotyping performance between DNA from oral samples versus whole blood. All sample types analyzed passed the PharmacoScan Assay in-process quality control (QC) checks and met the genotyping and copy number performance metrics. Results showed that saliva and buccal-derived DNA perform as well as whole blood in both the PharmacoScan™ Assay 96-Array Format using the Beckman Biomek FXP automated target preparation workflow and the PharmacoScan™ Assay 24-Array Format using manually prepared DNA target. This study supports the use of gDNA derived from oral samples, such as saliva and buccal cells, in the PharmacoScan™ Assay. For Research Use Only. Not for use in diagnostic procedures.

**1776W**

**Longitudinal individualized saliva omics profiling.** *G.I. Mias<sup>1,2</sup>*. 1) Biochemistry and Molecular Biology, Michigan State University, East Lansing, MI; 2) Institute for Quantitative Health Science and Engineering, East Lansing, MI.

Precision individualized wellness can now utilize state-of-the-art sequencing technology and computational capabilities to monitor hundreds of thousands of molecular components. As we move closer to clinical implementations, a realistic medical approach must supplement static genomic data (the current focus of most investigations) with the dynamics of disease, as reflected by longitudinal monitoring of patients. Integrating multi-omics dynamics (previously transcriptomes, proteomes, and now including extracellular vesicles and microbiomes) can reveal individualized deviations from a healthy baseline as these occur. We will present updates from our individualized pneumococcal vaccination response project, where we integrated longitudinal profiling in saliva and peripheral blood mononuclear cells (PBMCs), including extracellular vesicle-like (EV) composition in saliva. We focus on detecting adverse events or gradual changes, that may lead to early treatment or prevention, and additionally on the utility of saliva for continuous non-invasive diagnostic monitoring. We have expanded our saliva-based dataset on an individual to include 104 timepoint evaluation of EV RNA, and 12 timepoints on other individuals undergoing the same immunization (pneumococcal vaccine, PPSV23). The small RNA-seq from saliva EVs supplements our proteomics (mass spectrometry) and mRNA-sequencing in saliva and PBMCs at various timepoints (100+ for saliva, 30 for PBMCs). The EVs provided information on miRNAs, and endogenous or exogenous genome contributions (microbiome components), as these vary with vaccination response, indicative of both innate and adaptive responses: from 104 timepoints we detected on average (in reads per timepoint)  $2 \times 10^5$  miRNA,  $25 \times 10^5$  miRNA precursors,  $26 \times 10^5$  piRNA,  $64 \times 10^5$  exogenous (non-human) miRNA, and  $4 \times 10^6$  exogenous genome reads. All omics were integrated using MathIOmica to identify corresponding longitudinal behavior across the different modalities in time-frames that match the phenotype (including fever within hours of vaccination, and innate/adaptive responses over multiple days). The full dataset is being made publicly available and can be used to model longitudinal personalized omics with saliva. This research continues to be to our knowledge the only systematic implementation of personalized wellness monitoring that employs the same controlled immune activation, pneumococcal vaccination, across all subjects with non-invasive saliva monitoring.

**1777T**

**Combined mRNA and microRNA NGS library prep enables a more complete characterization of cell-free RNA.** *K.D. Allen, A.R. Morris, S.N. Piehl, K. Kushiro, A. Kothandaraman*. Applied Genomics, PerkinElmer, Austin, TX.

Historically, most RNA-seq experiments have been performed with the goal of studying mRNAs. Recently, deep sequencing of small RNAs, in particular miRNAs, has gained in popularity as researchers have begun to appreciate that miRNA expression can also be used to create gene signatures and that miRNAs have significant impact on regulation of gene expression. Researchers are increasingly interested in profiling both mRNA and miRNA content of a sample, but no simple method currently exists for a combined library preparation. The methods currently in existence typically require splitting a sample into two fractions, isolating mRNA in one fraction, fragmenting the mRNA, treating the fragmented mRNA with T4 PNK, then recombining the fractions and using a small RNA library preparation protocol with direct ligation of adapters to RNA molecules. Here, a combined mRNA/miRNA library preparation protocol is described that is streamlined, does not require rRNA depletion or poly(A) selection, and does not require splitting the sample into separate fractions. It relies upon a novel technique in which poly(A)-tailed RNA species are selectively reverse transcribed, then sheared by RNase H into fragments of useful length. Sequencing results show high concordance of RNA abundance between this method and traditional mRNA-Seq protocols, as well as high replicability. This method will be especially valuable to researchers studying cell-free, or circulating, RNA. Both mRNA and miRNA biomarkers are known to be present in biofluids, however due to their low concentration, no practical method yet exists for sequencing both RNA species simultaneously. As a proof of principle, we show that this previously presented method can also be employed to generate combined mRNA/miRNA libraries from human serum and plasma. We expect that this method will become a powerful new tool for researchers interested in biomarker discovery in this first report on data generated using this method.

**1778F****Encapsulating single cells with barcoded beads on the Nadia Instrument.**

*M. Breteau, J. Fischer, N. Shakir.* Dolomite Bio, Royston, England, United Kingdom.

Single-cell RNA-sequencing (scRNA-seq) is a cutting edge innovative technique that provides unprecedented insight into the expression patterns of thousands of single cells. Using droplet microfluidic technology, thousands of single cells can now be individually analyzed enabling the discovery of previously unidentified or cryptic cell types in a tissue of interest and the characterization of individual cells within biologically important processes. Using cutting edge microfluidic technology this abstract reports the results obtained by encapsulating single cells with barcoded mRNA beads. Using the Drop-Seq protocol developed by Macosko et al., single cells are encapsulated alongside a single bead within a droplet. These beads have surfaces coated with DNA-oligos containing a (dT)30 stretch allowing for the capture of polyadenylated mRNA which is subsequently reverse transcribed into cDNA. Each bead also carries a unique DNA barcode that identifies not only individual cells but also individual mRNA transcripts derived from any given cell. It is desirable that a single cell be encapsulated alongside a single bead within a droplet. This can be achieved through the dilution of cell and bead suspensions, but there is a fine balance to be struck between quality (fewer cells but data of higher quality) and quantity (higher throughput but data of lower quality). In this protocol, cell and bead suspensions are adjusted to achieve encapsulation in which 10% of droplets will contain a bead (i.e. 1 in 10 droplets) and 5% of droplets will contain a cell (i.e. 1 in 20 droplets). This translates to 10% of cells being encapsulated with a bead and very low cell doublet rates. A 15-minute run on the Nadia instrument, with 250  $\mu$ l of bead suspension and 250  $\mu$ l of cell suspension will result in the production of 6,000 individual cellular transcriptomes. Cell encapsulation is fast becoming a mature technology having transitioned from early prototypes into robust instruments suitable for use in biological research that is at the cutting-edge. The results indicate that using the drop-seq protocol on this single cell microfluidic platform high quality single cell libraries were produced in a high throughput manner. This reports results obtained from the encapsulation of cells with barcoded beads for single-cell RNA sequencing using the Dolomite Bio Nadia Instrument.

**1779W****Analysis of single cell transcriptome from PBMCs using ddSeq with different sequencing conditions.**

*H. Kim<sup>1</sup>, E. Cho<sup>1</sup>, H. Lee<sup>2</sup>, S. Yun<sup>3</sup>, A.K. Cashion<sup>1</sup>, J. Gill<sup>1</sup>.* 1) National Institute of Nursing Research, Bethesda, MD; 2) College of Nursing, Yonsei University, Seoul, Korea; 3) Yotta Biomed, Bethesda, MD.

Use of well characterized and reproducible biomarkers can help monitor and improve clinical outcomes across a variety of treatments and populations. However, the validity of biomarkers cannot be easily evaluated, especially when subtle changes in small populations of cells are masked. Single cell assays can provide critical information for the development of biomarker assays for clinical applications. However, reliable methodologies need to be developed and validated to use this novel technique. In this study, we demonstrate how to prepare single cell libraries of PBMCs by using the ddSEQ, a single cell isolator based on droplet technology followed by sequencing with different conditions, and we analyze the data with BaseSpace and Seurat. We used cryopreserved human PBMCs from a clinical patient at 3 different time points with ~75% of cell viability. Concentration of cells was adjusted to 3,000 cells/ $\mu$ l for PBMCs. One same sample was loaded on all 4 wells of a ddSeq cartridge. They were merged before tagmentation considering relatively low quantity of transcriptome of PBMCs. Based on QC, final concentration of the sample was 0.43 nM to 0.89 nM. Libraries of the sample were sequenced on both Illumina HiSeq 2500 and NovaSeq. FASTQ files were uploaded and processed on Illumina's BaseSpace to get UMI count table using SureCell RNA Single-Cell (version 1.2.0). Background cells were removed by filtering with a knee plot. We obtained 1,446 to 5,425 cells with 16 to 170 million reads, which is ~11,000 reads to ~42,000 reads per cell. Detected variable genes expressed in PBMCs ranged from 285 to 568. Seurat was used to perform further quality control and clustering analysis. Seven to 8 different cell types were clustered per sample by tSNE, which is comparable to another study with 1-2 million reads per cell. Our results suggest that 1) library preparation of ddSeq single cell assay using PBMCs needs to be modified from other types of cells, 2) a relatively low read number per cell along with a small number of detected genes are enough for classification of PBMCs based on their transcriptome profile, and 3) increasing read number per cell detects more genes, which may be critical in biomarker findings.

**High-throughput single nuclei RNA-seq from limited amounts of frozen human and mouse tissues.** *A.M. Raman<sup>1</sup>, S. Preiss<sup>1</sup>, Z. Cheng<sup>2</sup>, S. Chen<sup>3</sup>, Z. Ye<sup>4</sup>, S. Kuan<sup>1</sup>, K. Zhang<sup>5</sup>, C. Barr<sup>1</sup>, C. Chen<sup>5</sup>, B. Ren<sup>1,2,6</sup>.* 1) Ludwig Institute for Cancer Research, 9500 Gilman Drive, La Jolla, CA 92093, USA; 2) Center for Epigenomics, University of California, San Diego, 9500 Gilman Drive, MC 0653, La Jolla, California 92093-0653; 3) Department of Bioengineering, University of California San Diego, 9500 Gilman Drive, La Jolla, CA 92093, USA; 4) Krembil Research Institute University Health Network, The Hospital for Sick Children, The University of Toronto, Krembil Discovery Tower, 60 Leonard Ave. 8KD-412, Toronto, ON M5T 2S8, Canada; 5) Department of Neurosurgery, University of Minnesota, Minneapolis, D429 Mayo Memorial Building, 420 Delaware Street S.E., MMC 96MN 55455, United States; 6) Department of Cellular and Molecular Medicine, University of California, San Diego, School of Medicine, 9500 Gilman Drive, La Jolla, CA 92093, USA.

While single cell RNA-seq is a powerful tool to dissect tissue heterogeneity, it is difficult, and sometimes even impossible, to isolate intact cells from frozen tissue samples. Additionally, current approaches to analyze such samples are limited by throughput or requirement of high input material. To overcome these hurdles, we have optimized nuclei preparation from frozen tissues, and combined it with the droplet-based single cell RNA-seq platform from 10x Genomics. Nuclei contain only 10% of a cell's mRNA; therefore, single nuclei RNA-seq (snRNA-seq) data are exceptionally sparse with a median number of 260-770 detected genes per nucleus. To overcome this, we optimized a computational analysis workflow to enable robust analysis and clustering of snRNA-seq profiles. In total, we profiled 33,252 single nuclei from a wide variety of tissue types, including mouse forebrain, human frontal cortex and hippocampus, human cardiac left and right ventricles, and glioblastoma sections from a human brain. Using our analytical framework we digitally dissected cellular composition and identified: differences between ventricle specific cardiomyocytes in human ventricles, a neural stem-cell like population in the mouse forebrain; and grey and white matter specific astrocyte populations, as well as hippocampal and frontal cortex specific OPCs (oligodendrocyte progenitor cells) in the human brain. Coupling our analysis of these normal human frontal cortex and hippocampus samples with inferred CNV calls from our snRNA-seq data, we were then able to differentiate tumor from normal cells in our glioblastoma sections, and characterize intratumoral heterogeneity. The presented strategy enables the characterization of cellular heterogeneity from limited amounts of archived snap frozen tissue samples.

**Single cell profiling of the developing mouse brain and spinal cord with split-pool barcoding.** *C. Roco<sup>1</sup>, A. Rosenberg<sup>1</sup>, R. Muscat<sup>1</sup>, A. Kuchina<sup>1</sup>, P. Sample<sup>1</sup>, Z. Yao<sup>2</sup>, L. Gray<sup>2</sup>, D. Peeler<sup>1</sup>, S. Mukherjee<sup>1</sup>, W. Chen<sup>1</sup>, S. Pun<sup>1</sup>, D. Sellers<sup>1</sup>, B. Tasic<sup>2</sup>, G. Seelig<sup>1</sup>.* 1) University of Washington, Seattle, WA; 2) Allen Institute for Brain Science, Seattle, WA.

To facilitate scalable profiling of single cells, we developed Split Pool Ligation-based Transcriptome sequencing (SPLIT-seq), a single-cell RNA-seq (scRNA-seq) method that labels the cellular origin of RNA through combinatorial barcoding. SPLIT-seq is compatible with fixed cells or nuclei, allows efficient sample multiplexing and requires no customized equipment. We used SPLIT-seq to analyze 156,049 single-nucleus transcriptomes from postnatal day 2 and 11 mouse brains and spinal cords. Over 100 cell types were identified, with gene expression patterns corresponding to cellular function, regional specificity, and stage of differentiation. Pseudotime analysis revealed transcriptional programs driving four developmental lineages, providing a snapshot of early postnatal development in the murine central nervous system. SPLIT-seq provides a path towards comprehensive single-cell transcriptomic analysis of other similarly complex multicellular systems. We will present on new developments to SPLIT-seq, including significant increases to sample multiplexing and gene detection as well as new applications where we have applied the technology in fields including oncology, cardiology, and immunology.

**1782W**

**Improving transcriptome profiling for single cell and low input RNA.** *J.C. Sanford<sup>1</sup>, K. Krishnan<sup>1</sup>, Y. Bei<sup>1</sup>, J.G. Borgaro<sup>1</sup>, S. Guan<sup>1</sup>, V. Panchapakesa<sup>1</sup>, K. McKay<sup>1</sup>, L. Apone<sup>1</sup>, T. Shtatland<sup>1</sup>, B.W. Langhorst<sup>1</sup>, M. Arn<sup>1</sup>, C. Sumner<sup>1</sup>, D.R. Pattabiraman<sup>2</sup>, T.C. Evans, Jr.<sup>1</sup>, E. Dimalanta<sup>1</sup>, N.M. Nichols<sup>1</sup>, T. Davis<sup>1</sup>.* 1) New England Biolabs, Ipswich, MA 01938; 2) Geisel School of Medicine at Dartmouth, Hanover, NH 03755.

RNA sequencing –determining gene expression profiles of diverse tissues, cell types, developmental stages and diseases –is a widely used method with utility in basic and clinical sciences. However, RNA sequencing studies often use heterogeneous populations of thousands of cells in order to adequately profile gene transcripts. As such, significant biological variations among individual cells are obscured by the overall RNA pool. To overcome this limitation, single-cell RNA-seq is emerging as a powerful approach to characterize gene expression heterogeneity within phenotypically identical or complex cell populations and in rare cell types. Here, we have developed a simple and robust single-cell, low input RNA-seq workflow to generate full-length cDNAs that can be easily prepared for Illumina sequencing when combined with the NEBNext Ultra II FS DNA Library Preparation Kit with enzymatic fragmentation. Using this approach, we generated libraries from a variety of input material including Universal Human Reference RNA (2.5pg – 200ng), as well as single cells from cultured cell lines and mouse primary cells, and sequenced on the Illumina Nextseq 500. High quality sequencing data was obtained from all samples, with excellent gene body coverage observed. The workflow is highly sensitivity as demonstrated by detection of a high number of transcripts and single copy of RNA spike-ins (ERCC). The data showed strong gene expression correlation (Pearson  $r > 0.9$ ) between RNA inputs that span over five orders of magnitude and in cultured cells (single vs hundreds). Analysis of primary cells could successfully distinguish two developmental lineages from 8-week old mouse mammary glands, tracing them to the basal and luminal developmental lineages, highlighting the high sensitivity of the protocol. We have developed a highly robust and sensitive method that consistently generates high quality sequencing data from single cells or low input RNA. This workflow is streamlined, amenable to automation, and is accessible to high throughput studies. We envision this method facilitating novel discoveries in the area of low-input transcriptome applications across various platforms.

**Supporting single-cell RNA-seq at scale in the genomics platform at the Broad Institute.** *C. Walsh, B. Granger, A. Hollinger, T. Desmet, T. Bowers, N. Lennon.* Broad Institute, Cambridge, MA., USA.

Single-cell RNA-sequencing (scRNA-seq) is a powerful technique to study gene expression, cellular heterogeneity, and delineation of cell states. Interest in single-cell research has risen to an all-time high, as illustrated by the launch of the Human Cell Atlas project. Traditionally, single-cell sample preparation and sequencing is conducted by individual research labs, at relatively low scale, with little support for end-to-end processing and analysis. As projects become larger and more collaborative, the need for reproducibility and quality at scale becomes increasingly important. In response, we have developed a portfolio of single-cell services that utilize automated workflows, and integrated sample tracking to support 10X Genomics Chromium Single-Cell 3' single-cell, and a modified SMART-Seq2 mRNA library construction, sequencing, and analysis at scale. Major design challenges we encountered scaling SMART-Seq2 included managing the minimal input concentrations, high viscosity master mixes, low volumes and necessary dead volumes for full-scale automation. This was achieved using a variety of in-house created liquid classes, labware, and protocol design. Data delivery and analyses from single cell sequencing is made available through our cloud based platform, Firecloud. For each cell, we run a best practices QC and analysis workflow that mirrors the methods being made publically available via the Human Cell Atlas consortium, consisting of alignment with HISAT2, sequencing quality assessment with Picard tools, and determination of expression with RSEM. The outputs from these QC tools is aggregated and run through a second workflow to visualize the results at the level of the plate allowing for troubleshooting of lab processes and the identification of systematic biases.

**1784F****Discovery of phylogenetically informative Y-chromosomal variants in Argentine Amerindians Q haplogroup using next-generation sequencing data.**

*P.B. Paz Sepúlveda<sup>1</sup>, P. Hallast<sup>2</sup>, J.J. Zaiat<sup>3</sup>, E.L. Alfaro<sup>4</sup>, J.E. Dipierri<sup>5</sup>, C.M. Bravi<sup>1,5</sup>, M. Muzzio<sup>1,5</sup>, G. Bailliet<sup>1</sup>.* 1) Instituto Multidisciplinario de Biología Celular, La Plata, Buenos Aires, Argentina; 2) University of Tartu, Institute of Biomedicine and Translational Medicine, Faculty of Medicine, Tartu, Estonia. Wellcome Trust Sanger Institute, Wellcome Genome Campus, Hinxton, UK; 3) Instituto de Química Biológica de la Facultad de Ciencias Exactas y Naturales (QUIBICEN), Plataforma Bioinformática Argentina (BIA), CONICET, Universidad de Buenos Aires. Ciudad Autónoma de Buenos Aires, Argentina; 4) Instituto de Ecorregiones Andinas (INECOA), UNJu-CONICET, Instituto de Biología de la Altura, Universidad Nacional de Jujuy, San Salvador de Jujuy, Jujuy, Argentina; 5) Facultad de Ciencias Naturales y Museo, Universidad Nacional de La Plata, La Plata, Buenos Aires, Argentina.

The human Y-chromosomal Haplogroup Q is the most frequent haplogroup in Amerindian people of South America. Haplogroup Q-M3 and Q-Z780 are subclades of Haplogroup Q-L54. Haplogroup Q-M3 (Q1b1a1a) is defined by the presence of M3 Single Nucleotide Polymorphism (SNP) and Haplogroup Q-Z780 (Q1b1a2) by SNP Z780. The sub-haplogroups of Q-M3 and Q-Z780 have the highest frequency within the autochthonous lineages in Argentina. Currently the research of both sub-haplogroups is limited due to poor resolution of Y-chromosomal phylogenetic tree constructed from the classical SNP markers. Here, we analysed four amerindian whole Y chromosomes from Gran Chaco, Patagonia and Northwest Argentina generated using next-generation sequencing (NGS). We compare these with previously published Q-M3 and Q-Z780 sequences with the aim to discover new phylogenetically informative variants and increase the resolution of this branch of the Y Phylogenetic tree. Those new variants will improve our understanding of the geographic structuring of the genetic diversity of the Y chromosome in South America.

**1785W****Genomic characterization of fluorescently tagged human induced pluripotent stem cells.** *T.S. Grancharova, R.N. Gunawardane, Allen Institute for Cell Science. Allen Institute for Cell Science, Seattle, WA.*

The Allen Institute for Cell Science is using CRISPR/Cas9 to create a collection of fluorescently tagged clonal hiPSC lines targeting organelles and other major cellular structures in stem cells and cardiomyocytes. After extensive quality control, cell lines expressing endogenously tagged proteins are live imaged, and segmented images are used to create integrated models of cellular organization and behavior. As part of the quality control workflow, we used transcriptome and exome sequencing to assess the effects of gene editing, cloning, and extended culturing on the hiPSCs. We found that a set of ~50 genes enriched for developmental process gene ontology categories were down regulated in the edited lines relative to the unedited parental line (WTC). However, serially passaged parental cells (~15 passages after thaw) and mock edited cell lines (mock transfected, cloned, and subjected to same quality control as edited lines) displayed similar shifts in their transcriptional profiles suggesting that these changes are due to extended culturing and not to gene editing itself. A pilot single cell RNA-Seq experiment with the parental line and one edited cell line revealed more heterogeneity (multiple clusters with distinct profiles) in the parental population relative to the edited. The parental unedited line was whole genome sequenced, and exome sequencing was used to look for novel variants (absent from the parental line) in the edited clonal lines with a focus on mutations in genes involved in cancer susceptibility and cell proliferation. We found that most of the edited lines had a truncating mutation (NC\_000017.11:g.60663160G>T; NP\_003611.1:p.Glu476\*) in the sixth exon of *PPM1D*, a known oncogene and regulator of *TP53* and *CHK2*. Although this mutation was not detected in the whole genome sequence of the early passage parental line, RNA-Seq data and a ddPCR SNP assay revealed that it was present at a low frequency in the parental population indicating that it arose sometime during the culturing of the parental line before it was used for editing. Preliminary ddPCR data also suggests that the allele frequency of the mutation increases in the parental population as it is serially passaged. The edited hiPSC lines are available to the non-profit scientific community, and their associated image and sequencing data will be openly available through the Allen Cell Explorer ([allencell.org](http://allencell.org)).

**1786T****Improved sequencing depth metrics for variant calling error rate.** *K.**Dunaway, S. White, W. Lee.* Helix, San Carlos, CA.

Sequencing depth (DP) is one major metric often used to determine validity of germline genotype calls. However, there are conflicting opinions about what the minimum DP should be. While a common held opinion is that 20x DP is the minimum acceptable DP for a confident call, many papers have cited differing opinions on the matter. Some of the confounding factors include type of experiment, sample preparation, and sequencing chemistry. This issue is further confused by conflating DP of a call with average coverage across the entire sample. Here we present the results of over 2000 replicates of control samples with known genomic sequence (NA12877 and NA12878). These were Exome+ sequenced in a CLIA/CAP controlled sequencing environment and analyzed using a proprietary pipeline that primarily follows GATK best practices. We have found that error rate does not decrease as DP increases above 20x. In fact, the DP threshold can move down even lower than 20x without significant increase in error rate. Moreover, adding additional thresholds to other metrics can yield more significant decreases in error rate. For instance, heterozygous calls with extremely low alternate or reference allele depth (AAD, RAD) will have higher error rate. We spell out these additional metrics to aid returning as much information as possible while still minimizing error rate.

**1787F**

**Theoretical and practical considerations for validation of functional assays in clinical variant interpretation applications.** *S.E. Brnich<sup>1,2</sup>, J.J. Seleksky<sup>1</sup>, J.S. Berg<sup>1</sup>.* 1) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Curriculum in Genetics and Molecular Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC.

The increasing number of clinically identified genetic variants poses challenges to clinical variant interpretation, which considers patient phenotype, population data, and an appraisal of the literature for each variant in a disease-associated gene. Professional organizations such as the American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP) have developed standards and guidelines that weigh the strength of each piece of evidence for an overall classification along a spectrum from benign to pathogenic. The classification of "variant of uncertain significance" (VUS) applies in the case of conflicting or insufficient available evidence, as is common for rare, missense variants. VUS are numerous and cannot be used for diagnosis or clinical decision-making, thereby complicating patient counseling and management. The rarity of most individual VUS limits the collection of patient and family data, thus efforts to resolve VUS classifications have touted the potential of high-throughput functional approaches to pathogenicity assessment. We developed an algorithmic approach to examine evidence combinations within the ACMG/AMP classification framework and the effect of strong, functional evidence on overall variant interpretation. This method can be used to prioritize genes and variants for functional assay development based on the number of missense VUS that could be reclassified. Our initial analysis of two ClinGen variant curation expert panels indicates that 10/17 non-conflicting missense VUS would reclassify with strong functional evidence. Although there is great theoretical potential for functional assays to reclassify missense VUS, there are practical considerations related to how any given assay can qualify as "well validated" for application in the ACMG/AMP framework. First, it should consider the appropriateness to disease mechanism. The second consideration is validating with an adequate number of pathogenic and benign controls. Third is the ability to apply statistical rigor in estimating the sensitivity and specificity of the assay. Finally, the cost and throughput merit consideration, as they are rate-limiting steps in evaluating the growing number of VUS. In an ongoing process of establishing a homologous recombination assay for *PALB2* (MIM: 610355) missense variants, we developed real-world experience with each of these considerations, which will be presented here to help inform guideline development.

**1788W**

**Long-read single-molecule maps of the hydroxymethylome.** *Y. Ebstein<sup>1</sup>, T. Gabrieli<sup>1</sup>, H. Sharim<sup>1</sup>, G. Nifker<sup>1</sup>, J. Jeffet<sup>1</sup>, T. Shahal<sup>1</sup>, R. Arielly<sup>1</sup>, M. Levi-Sakin<sup>1</sup>, N. Arbib<sup>2</sup>, Y. Michaeli<sup>1</sup>.* 1) School of Chemistry, Tel Aviv University, Tel Aviv, Israel; 2) Meir Hospital, Kfar Saba, Israel & Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

We report on the development of a genome-wide analysis workflow for optical detection of fluorescent 5-hydroxymethylcytosine profiles along chromosomal DNA molecules. The epigenetic mark 5-hydroxymethylcytosine (5-hmC) is a distinct product of active DNA demethylation that is linked to gene regulation, development, and disease. In particular, 5-hmC levels dramatically decline in many cancers, potentially serving as an epigenetic biomarker. The noise associated with next-generation 5-hmC sequencing hinders reliable analysis of low 5-hmC containing tissues such as blood and malignant tumors. Additionally, genome-wide 5-hmC profiles generated by short-read sequencing are limited in providing long-range epigenetic information relevant to highly variable genomic regions, such as the 3.7 Mbp disease-related Human Leukocyte Antigen (HLA) region. We present a long-read, highly sensitive single-molecule mapping technology that generates hybrid genetic/epigenetic profiles of native chromosomal DNA. The genome-wide distribution of 5-hmC in human peripheral blood cells correlates well with 5-hmC DNA immunoprecipitation (hMeDIP) sequencing. However, the long single-molecule read-length of 100 kbp-1 Mbp produces 5-hmC profiles across variable genomic regions that failed to show up in the sequencing data. In addition, optical 5-hmC mapping shows a strong correlation between the 5-hmC density in gene bodies and the corresponding level of gene expression. The single-molecule concept provides information on the distribution and coexistence of 5-hmC signals at multiple genomic loci on the same genomic DNA molecule, revealing long-range correlations and cell-to-cell epigenetic variation.

**1789T**

**A simple segue from Sanger to high-throughput SMRT Sequencing with an M13 barcoding system.** *C. Heiner, A. Larea, J. Gu, J. Harting, L. Aro, S. Ranade, J. Korlach.* Pacific BioSciences, Menlo Park, CA.

High throughput NGS methods are increasingly utilized in the clinical genomics market. However, short-read sequencing data continues to remain challenged by mapping inaccuracies in low complexity regions or regions of high homology and may not provide adequate coverage within GC-rich regions of the genome. Thus, the use of Sanger sequencing remains popular in many clinical sequencing labs as the gold standard approach for orthogonal validation of variants and to interrogate missed regions poorly covered by second-generation sequencing. The use of Sanger sequencing can be less than ideal, as it can be costly for high volume assays and projects. Additionally, Sanger sequencing generates read lengths shorter than the region of interest, which limits its ability to phase allelic variants accurately. High throughput SMRT Sequencing overcomes the challenges of both the first and second generation sequencing methods. PacBio's long read capability allows sequencing of full-length amplicons with multiple passes per molecule for accurate genotyping with the phasing of allelic variants. In the present work, we have developed a universal M13 barcoding system for SMRT Sequencing that utilizes the M13 sequences commonly used to tail PCR amplicons for Sanger sequencing. We demonstrate both workflow efficiency and cost-efficiency of SMRT Sequencing for a broad range of clinically relevant targets >500 bp up to 5 kb. Our method provides a simple, cost-effective and highly accurate segue from Sanger to SMRT Sequencing for existing or new clinical sequencing assays to interrogate a spectrum of polymorphisms across a wider span of amplicon size, regardless of the genomic sequence context. .

**1790F**

**SMRT Sequencing of clinically relevant targets using an amplification-free target enrichment approach.** *S. Ranade<sup>1</sup>, P. Baybayan<sup>1</sup>, S. Chakraborty<sup>1</sup>, R. Hall<sup>1</sup>, L. Aro<sup>1</sup>, K. Varley<sup>2</sup>, I. Vasenkova<sup>2</sup>, T. Moore<sup>2</sup>.* 1) Pacific Biosciences, Menlo Park, CA, USA; 2) Kailos Genetics, Huntsville, AL, USA.

Simultaneous interrogation of genetic and epigenetic signatures in genomic DNA provide unique insights into clinically actionable variants of genes. However, isolation of genomic regions of interest without PCR amplification or complex bisulfite treatment for obtaining such information are still under-developed. In the present work, we have paired an amplification-free target enrichment method developed by Kailos Genetics with long-read SMRT<sup>®</sup> Sequencing technology. The circular consensus sequences (CCS) generated from contiguous long reads (average read-length >15-20 kb) for the control and methylated BRCA genes not only produced accurate genetic information but also detected all the expected epigenetic markers.

**1791W**

**A new thermostable reverse transcriptase improves sensitivity, specificity and time to result for multiplex RT-PCR-based detection and quantification of RNA.** *T.W. Schoenfeld, R.C. Heller, S. Chung, K. Dumas, K. Crissy, P.R. Barchard, D.M. Schuster.* Research and Development, Quantabio, Beverly, MA.

Reverse transcriptase quantitative PCR (RT-qPCR) is often used to confirm, quantify and monitor transcripts, noncoding RNAs and viral targets that were initially identified by RNA-Seq projects. Despite their importance, the limited options among available reverse transcriptase enzymes can compromise performance in certain application. Most one step RT-PCR kits contain a mixture of two enzymes: a retroviral RT, usually an M-MLV derivative, and a thermostable DNA polymerase, usually derived from Taq polymerase. This reliance on two enzymes limits the temperature of cDNA synthesis and necessitates compromises in reaction conditions between those favorable for each respective component, which can reduce performance, especially on low-abundance and structured targets, and can limit storage stability. A molecular screening and directed evolution program has generated a new thermostable RT, active at up to 85°C and stable up to 95°C, that allows single-enzyme hot-start RT-PCR. Higher temperature cDNA synthesis and detection improves specificity and sensitivity and allows direct detection of RNA targets at near-single-copy sensitivity, notably on rare or highly structured targets. This new chemistry is compatible with singleplex and multiplex formats using most dye and probe-based detection chemistries. Detection facilitated by this enzyme is equally effective on RNA and DNA targets and can allow simultaneous detection of both targets without modification of the detection protocol. Because cDNA synthesis occurs rapidly during the initial stage of PCR, the elimination of a distinct RT step and inherently faster kinetics reduces detection times to less than 40 minutes. The inherent stability of the enzyme provides simplified formulation and improved liquid and dry storage. These improvements promise to simplify, accelerate and improve the reliability and flexibility of detection and analysis of mRNA, noncoding RNA and viral targets.

**1792T****Harmonized sequencing based genetic testing in the eMERGE III**

**Network.** *D.M. Muzny<sup>1</sup>, N. Lennon<sup>2</sup>, H. Zouk<sup>3</sup>, E. Venner<sup>1</sup>, R.A. Gibbs<sup>1</sup>, H.L. Rehm<sup>2,3,4</sup>, The eMERGE III Consortium.* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Broad Institute of MIT and Harvard, Cambridge, MA 02141; 3) Laboratory for Molecular Medicine, Partners Healthcare, Cambridge, MA 02139; 4) Center for Genomic Medicine, Massachusetts General Hospital, Boston, MA 02114.

**Background:** In eMERGE III, the network is for the first time conducting genetic testing via massively parallel sequencing. This necessitated coordination and harmonization of pre-analytical and analytical processes across two Genome Sequencing Centers (GSCs) and eleven clinical sites. **Methods:** Targeted capture panels of ~500 kb (including 56 'ACMG genes', 54 additional genes for discovery, and ~1400 individual single nucleotide variant sites (SNVs)) were designed on two different capture platforms (one per each GSC). These panels were applied for the analysis of 25,000 participant DNA samples. All steps, from collection of samples, panel clinical validation, sequencing, interpretation, reporting, and data distribution were harmonized. **Results:** We addressed issues at collection sites, in assay development, validation, primary analysis, variant classification, defining report content, data delivery, network access to interpreted variants and for progress reporting to build a complete and compliant network. For example, through data comparison and probe optimization, both sequencing centers achieved greater than 99.7% coverage of all bases targeted on the panels. In addition, through ongoing comparison of reportable variants between the two sequencing centers, we identified 51 variants with discordant interpretations. These were able to be resolved and enabled consistency in the interpretive process. Analysis of an interim data freeze representing 15,574 sequenced subjects, demonstrated the high quality of assay performance and showed that the rate of return of Likely Pathogenic and Pathogenic results was approximately 1.5%, but varied according to the collection criteria. **Conclusions:** We developed methods to coordinate genetic testing from multiple clinical sites and showed that two sequencing centers can harmonize both the technical and interpretive aspects of clinical sequencing tests, a critical achievement for the standardization of genomic testing.

**1793F**

**Deciphering the methylome: Enzymatic Methyl-seq.** *L. Williams, C.V.K. Ponnaluri, B. Sexton, L. Saleh, K. Marks, M. Samaranayake, L. Ettwiller, S. Guan, H.E. Church, N. Dai, E. Tamana, E. Yigit, B. Langhorst, Z. Sun, T.C. Evans, R. Vaisvila, E. Dimalanta, T.B. Davis.* New England Biolabs, Ipswich, MA.

Cytosine (C) methylation is an important regulatory mechanism and identifying 5-methylcytosine (5mC) and 5-hydroxymethylcytosine (5hmC) is essential in understanding gene regulation. Bisulfite sequencing (BS) is the gold standard for detecting methylated C's; however, DNA is commonly damaged and degraded by the chemical bisulfite reaction. Whole genome bisulfite sequencing (WGBS) demonstrates high GC-bias and enriched methylated regions. Here we describe an enzymatic approach to detect methylated C's: NEBNext Enzymatic Methyl-seq (EM-seq). EM-seq overcomes many of BS disadvantages as the DNA remains intact, thereby enabling longer sequencing reads. Additionally, libraries have reduced GC bias. EM-seq and WGBS libraries were prepared using 10 ng, 50 ng or 200 ng NA12878 genomic DNA. All libraries were sequenced using Illumina's NovaSeq 6000 and data were analyzed using a standard Bismark workflow. GC bias and insert size distribution were determined using Picard 2.17.2. MethylKit was used for correlation analysis. EM-seq libraries have longer inserts, lower duplication rates, a higher percentage of mapped reads and less GC bias compared to WGBS libraries. Global methylation levels are similar between EM-seq and WGBS libraries while CpG correlation plots demonstrate that EM-seq libraries are superior. EM-seq libraries identify ~2 million more CpG's than WGBS libraries and have a higher percentage of CpG's covered for all minimum coverage depths examined (up to 20X). Methylation profiles across genomic features (TSS, CpG island, etc.) were similar, however, normalized coverage was much higher for EM-seq compared to WGBS. Dinucleotide analysis showed EM-seq did not suffer from depletion of C containing dinucleotides nor enrichment of A/T containing dinucleotides as seen in WGBS. EM-seq is superior to WGBS: it is robust and works over a wide range of DNA inputs, has better sequencing metrics and detects more CpG's over a wide range of genomic features. .

**Systematic comparison between different library preparation kits and sequencing machines for high-throughput whole genome bisulfite sequencing.** L. Zhou<sup>1</sup>, H.K. Ng<sup>1</sup>, B. Lehne<sup>2</sup>, D. Moses<sup>3</sup>, S. Schuster<sup>4</sup>, C.H. Kim<sup>4</sup>, J.C. Chambers<sup>1,2,5,6</sup>, M. Loh<sup>1,2,7,8</sup>. 1) Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore; 2) Department of Epidemiology and Biostatistics, Imperial College London, London W2 1PG, UK; 3) Singapore Centre for Environmental Life Sciences Engineering, Nanyang Technological University, Singapore 637551; 4) MACROGEN, Inc., Seoul, Republic of Korea; 5) Department of Cardiology, Ealing Hospital, London North West Healthcare NHS Trust, Southall UB1 3HW, UK; 6) Imperial College Healthcare NHS Trust, London W12 0HS, UK; 7) Translational Laboratory in Genetic Medicine, Agency for Science, Technology and Research, Singapore (A\*STAR), 8A Biomedical Grove, Immunos, Level 5, Singapore 138648; 8) Yong Loo Lin School of Medicine, National University of Singapore, Singapore 117596.

Whole genome bisulfite sequencing (WGBS) is an emerging high-throughput technique for profiling DNA methylation at single nucleotide resolution across the entire genome in both fundamental and clinical research. Although there are extensive choices of WGBS library preparation kits and sequencing platforms available, their output and performance have not been systematically evaluated yet. We perform a comprehensive analysis on two leading library preparation kits (TruSeq and Swift Accel-NGS) that require low DNA input and two highest-throughput Illumina sequencing machines (X10 and NovaSeq) for their data quality and performance. We find that the average Q30 fraction and mapping rate in TruSeq sample is similar to Swift sample (95.7% vs 95.9%;  $p=0.81$  and 79.4% vs 79.8%;  $p=0.66$  respectively). However, the average median insert size of TruSeq sample is significantly shorter than that of Swift sample (142bp vs 276bp;  $p<0.001$ ), with PCR duplication rate of TruSeq sample significantly higher than that of Swift sample (42.1% vs 23.4%;  $p<0.001$ ). The percentage of methylated cytosine in CpG context of TruSeq sample is also significantly lower than that of Swift sample (76.8% vs 80.8%;  $p<0.001$ ). Most importantly, the effective genome coverage (coverage normalized by raw reads) of TruSeq sample is significantly lower than that of Swift sample (9.6x vs 24.6x;  $p<0.001$ ). When comparing the sequencing platforms, we find that although NovaSeq sample provides better sequencing quality than that of HiSeq X10 (Q30 fraction 96.9% vs 95.3%;  $p<0.05$ ), neither the PCR duplication rate nor the effective genome coverage is significantly different from that of HiSeq X10 sample (35.5% vs 29.7%;  $p=0.13$  and 18.2x vs 17.9x;  $p=0.91$  respectively). In addition, we also compare our WGBS data with available array results and find that WGBS data show systematic bias. For beta values between 0 and 0.5, the WGBS sample methylation level is lower than the array beta value by 5.1% on average (SD: 1.5%), whereas for beta value between 0.5 and 1, the WGBS sample methylation level is higher than that from the array by 4.6% on average (SD: 2.3%). The bias is consistent across library preparation kits as well as sequencing platforms ( $p>0.05$ ). In summary, our results demonstrate that Swift library kit outperforms the currently widely used TruSeq kit in various aspects and provide a potential solution for preparing WGBS library with better quality.

**Comparison of whole exome capture products: Coverage & quality vs cost.** B. Marosy, J. Gearhart, B. Craig, K.F. Doherty. Johns Hopkins School of Medicine, Baltimore, MD.

Next Generation Sequencing technology has been a driving force for reducing sequencing costs and enhancing genome technology; allowing investigators and clinicians the opportunity to better delineate an individuals' genetic makeup. For facilities providing genetic services, maintaining the balance of providing high quality data at the lowest cost is a continuous effort requiring recurrent evaluation and optimization of protocols. Here we have compared the performance between four different exome capture products: SureSelect Human All Exon v7 (Agilent Technologies), xGEN@Exome Research Panel v1.0 (Integrated DNA Technologies), SeqCap EZ Exome V3.0 (Roche) and Twist Human Core Exome (Twist Bioscience) to determine cost effectiveness and coverage improvements between products. Libraries were prepared from 50ng of HapMap DNA using the Kapa Hyper Prep kit (KAPABiosystems). Libraries were captured using either the Agilent, IDT, Roche or Twist exome capture product according to each manufactures protocol. Captured libraries were clustered and sequencing was performed on the Illumina HiSeq2500 platform. Sequencing data was down-sampled and the UCSC Exonic coding regions (35.2Mb) were used to ensure equal comparison between methods. Preliminary sequencing data analysis yielded 81.86%, 90.54%, 88.95% and 92.21% of targeted bases captured at  $\geq 20x$ , respectively, when down-sampled to 4 Gb of raw sequencing data. Additional analysis of quality versus cost will be presented.

**1796F**

**A re-designed and unified workflow for exome and custom targeted panels developed to support a high throughput clinical research environment.** E. Roth, J. Abreu, B. Blumenstiel, M. Cipicchio, M. DeFelice, M. Fleharty, J. Grimsby, A. Hollinger, S. Low, H. Lyon, A. Macbeth, G. Vicente, M. Costello, T. Desmet, N. Lennon, S. Gabriel. Broad Institute, Cambridge, MA.

The Broad Institute Genomics Platform has developed a novel, unified workflow for whole exome and custom targeted gene panels. Our method utilizes Integrated DNA Technologies universal blocking reagents and capture method, resulting in exceptionally high specificity and even coverage, and compatibility with any DNA probe based panel design. By using this method in conjunction with panels synthesized by Twist Bioscience, we have demonstrated the ability to reach 97% of target bases at 20X coverage with only 5 gigabases of sequencing and a Fold 80 base penalty evenness calculation of 1.5 for a 12-plex exome pool, significantly decreasing the amount of sequencing lanes needed to reach product deliverables. In addition to developing a unified capture process, we have further optimized the workflow to be compatible with a wide range of sample input types and a variety of different DNA probe sets which can be selected on the same 96 well plate. This streamlining reduces turnaround time for custom panels and whole exomes in both research and clinical environments. Our Lab Information Management System (LIMS) provides tracking of individual libraries and allows for complex automated procedures and pooling techniques without loss of sample integrity. This novel workflow enables the optional use of unique molecular index (UMI) duplex adapters, allowing for highly efficient library construction that allows for consensus-based somatic variant calling for detection of low variant allele fraction events in deep coverage sequencing projects. For germline focused exome or custom projects, we have also developed a cost effective longer insert process to achieve more Gb per lane and minimize the amount of sequencing lanes needed to reach desired coverage. By combining highly efficient library construction techniques tailored to project needs with a novel capture method, we have achieved exceptionally even coverage for exome and custom panels with a minimal amount of sequencing.

**Beyond the exome report: Approaches to additional analysis for undiagnosed genetic disease.** D.B. Zastrow<sup>1,2</sup>, D.E. Bonner<sup>1,2</sup>, L. Fernandez<sup>1,2</sup>, J.N. Kohler<sup>1,2</sup>, C. Reuter<sup>1,2</sup>, M. Majcherska<sup>1,2</sup>, C. McCormack<sup>1,2</sup>, S. Marwaha<sup>1,2</sup>, C. Curnin<sup>1,2</sup>, C.M. Eng<sup>3</sup>, Y. Yang<sup>3</sup>, P. Ward<sup>3</sup>, D. Bick<sup>4</sup>, B. Korf<sup>5</sup>, E. Worthey<sup>6</sup>, E.A. Ashley<sup>1,2,5</sup>, P.G. Fisher<sup>1,6</sup>, J.A. Bernstein<sup>1,7,8</sup>, M.T. Wheeler<sup>1,2</sup>, U.D.N. Undiagnosed Diseases Network<sup>9</sup>. 1) Stanford Center for Undiagnosed Diseases, Stanford University, Stanford, CA; 2) Division of Cardiovascular Medicine, Stanford University, Stanford, CA; 3) Baylor College of Medicine, Houston, TX; 4) HudsonAlpha Clinical Services Lab, Huntsville, AL; 5) Department of Genetics, Stanford School of Medicine, Stanford, CA; 6) Department of Neurology, Stanford School of Medicine, Stanford, CA; 7) Department of Pediatrics, Stanford School of Medicine, Stanford, CA; 8) Lucille Packard Children's Hospital Stanford, Palo Alto, CA; 9) NIH Undiagnosed Diseases Network, Common Fund, Office of the Director and the National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Exome sequencing (ES) is often performed when a patient presents with a suspected genetic disorder that is genetically heterogeneous or when phenotype-directed genetic testing has not been diagnostic. Estimated yield of clinical ES is around 25% to 28% (Lee, 2014; Yang 2013, 2014; Retterer, 2016), still leaving a majority of patients undiagnosed. The Stanford Center for Undiagnosed Diseases has completed sequencing or ES reanalysis on 79 probands between Sep 2015 and May 2018: exome (n=51) or genome (n=21, 5 after ES reanalysis), ES reanalysis (n=12). Available family members were included to enhance sequencing analysis. The probands ranged in age from 4 months to 74 years and had disease suspicious for a genetic etiology in a broad range of systems (most common: neurologic, n=40; immune, n=11; and musculoskeletal, n=9). A genetic diagnosis was obtained from the initial ES report for 13/51 probands (25.5%), and further approaches were attempted to uncover a diagnosis for the remaining probands. Our ES reanalysis cohort had 3 diagnoses, and genome sequencing (after negative ES) identified 3 diagnoses. We present additional approaches for reaching a genetic diagnosis after an inconclusive clinical ES report, along with case examples. Additional analyses includes: multi-omics/RNA sequencing; clinical correlation with candidate variants (VUS, or autosomal recessive conditions with only 1 pathogenic variant identified); "research" variants identified by the clinical laboratory; data reanalysis; data sharing and collaboration (e.g. GeneMatcher); segregation analysis; additional data from patient/family (e.g. phenotype or family history); and assessment of mosaicism. These methods have resulted in 9 additional diagnoses in our cohort (9/79, 11.4%), and 10 probands with a candidate diagnosis where confirmation is ongoing (10/79, 12.6%), increasing our overall diagnosis rate from 16.5% after WES (13/79) to 44.3% (35/79). For patients receiving inconclusive exome sequencing results, these approaches may be utilized by the clinician to increase the chance of a genetic diagnosis.

Sequencing Diagnoses				
Sequencing	Probands	Diagnosis from initial report	Diagnosis after internal analysis	Candidate Diagnosis
Exome	51	13	3	5

**Nextera Flex enrichment with automation provides a rapid and panel agnostic NGS workflow.** *J. Zhao<sup>1</sup>, S. Gross<sup>1</sup>, R. Tim<sup>1</sup>, S. Andrew<sup>2</sup>, G. Schroth<sup>1</sup>, S. Youting<sup>1</sup>, E. Allen<sup>1</sup>, Y. Martin<sup>1</sup>, J. Rodriguez<sup>1</sup>, S. Kevin<sup>1</sup>, S. Deshmukh<sup>1</sup>, A. Barr<sup>1</sup>, M. Anthony<sup>1</sup>, G. DeSantis<sup>1</sup>.* 1) Core Application Group, Illumina, Inc, San Diego, CA; 2) Biochemistry System, Illumina, Inc, The Watson Building 11 Granta Park Great Abington Cambridgeshire CB21 6GP United Kingdom.

The advance of Next Generation Sequencing (NGS) has greatly accelerated genomic studies, clinical diagnostics, microbiology and forensic science fields. Recent NGS technology advancements and cost reductions have democratized whole genome sequencing. However, in some cases, targeted sequencing assays are appropriate to achieve very high depth coverage of interesting regions. In such cases, highly multiplexed processes and simple workflows are necessary to reduce time and cost. Both amplicon and hybrid capture enrichment assays offer viable workflows. We have developed an innovative and simple fast hybridization reagent which, when paired with the advanced technology of Nextera Flex, can provide a sample to sequencer workflow to be completed in less than one day. Our assay was optimized to be panel agnostic and accept probe panels as small as 500 oligos or as large as 500,000 oligos, or greater. In addition, equivalent performance was demonstrated with both 120-bp and 80-bp capture oligos, achieving high padded read enrichment, high uniformity, low duplicate reads and sensitive minor allele frequency detection. The simple 6 hour workflow is compatible with direct blood or saliva input, and compatible with extracted FFPE. We have automated the workflow on common liquid handling systems to achieve hands-free preparations with minimal intervention. Data for several fixed and custom panels are presented that demonstrate padded read enrichment up to 90%, uniformity of coverage up to 97%.

**1799F**

**Rapid and accurate quantification of Illumina NGS libraries using the Q real-time qPCR instrument.** *P. Bartholomew, H. Liu, E. Kolossovski, B. Komorous, D. Schuster.* Quantabio, Beverly, MA.

Accurate quantification of the number of amplifiable library molecules is a critical factor for obtaining high quality read data with next-generation sequencing technologies. The high sensitivity, broad dynamic range, and specificity of qPCR to quantify library molecules that are suitable for the bridge PCR provide significant advantages over methods for total DNA quantification. However, these advantages are often offset by the time to result, requirement for inclusion of absolute DNA standards in every qPCR run and errors associated with dilution of libraries so that reportable results are within the linear dynamic range of the technology. Here we describe application of a new real-time quantitative PCR instrument, the Q from Quantabio, to simplify reliable library quantification with faster run times. The Q real-time PCR instrument exploits a novel magnetic induction technology to rapidly heat reactions held in a unique spinning aluminum rotor. This provides superior temperature uniformity of  $\pm 0.05^{\circ}\text{C}$  that eliminates well position effects and cross-instrument variability associated with traditional peltier block-based real time cyclers. Robust optics with rapid data acquisition times are coupled to an intuitive data analysis interface driven by industry leading algorithms to provide highly accurate and reproducible qPCR results. To test the efficacy of this new qPCR instrument for quantification of NGS libraries, we measured libraries of various fragment sizes and GC contents over multiple trials using qPCR chemistries with the P5 and P7 primers, specific for Illumina adapter libraries under varying cycling conditions. The collective results clearly establish the suitability of the Q real-time PCR instrument for accurate quantification of NGS libraries. The clear benefits provided by the Q include: highly precise measurements across multiple trials; high efficiency amplifications under varied cycling conditions; exceptional quantitative sensitivity for distinguishing down to 1.2-fold differences; reliable results and performance from run times shorter than typical cycling protocols.

## 1800W

**A quarter century of sequencing: Lessons learned and best practices for high quality genome sequencing at any scale.** *M. Costello, Y. Farjoun, M. Fleharty, A. Hollinger, T. Desmet, J. Meldrim, S. Dodge, N. Lennon, S. Gabriel.* Broad Genomics, Broad Institute, Cambridge, MA.

In the mid 1990s, the Whitehead Institute for Genomic Research moved into an unassuming two-story building in Cambridge, MA that once housed a beer and popcorn distribution warehouse for nearby Fenway Park. This group would soon embark on an exciting new endeavour: the Human Genome Project. In November of 2003, the Whitehead Institute for Genome Research became the first cornerstone facility of the Broad Institute, and since that time we have sequenced hundreds of thousands of samples utilizing ever evolving technologies. Here, we provide our best practices and lessons learned from a quarter century of genome sequencing and analysis experience, with an emphasis on data quality, reduction in errors and variation, and sample integrity. Maintaining data quality at any scale can be taxing, particularly as samples from some biological sources and preservation methods may be inherently challenging. Here we highlight our experiences with both saliva and FFPE samples, two sample types with properties that can lead to decreased data quality. While saliva samples on average contain just 8-9% non-human DNA, this can range to greater than 50%, which we show in extreme cases could lead to low allele fraction false positives due to misalignment and describe a pre-sequencing assay we've developed to flag outlier samples. FFPE is notoriously hard to work with, and we describe our additional quality control steps to screen for and filter data containing FFPE-specific artifacts. Additionally, common genomics lab and analysis processes themselves can introduce errors and variation in downstream data, and we describe error profiles and suggest solutions for: (1) oxidation artifacts introduced during DNA shearing, (2) "index hopping" due to issues with Illumina patterned flow cell/exclusion amplification chemistry, and (3) false positives due to improper binning of quality scores for sequencer artifacts. Finally, knowing that the sequencing data we are generating is from the correct patient is extremely important, and we rely on a set of best practices to maintain sample chain of custody. This includes an orthogonal non-sequencing genotyping assay performed as samples enter the Broad to generate a "fingerprint" over carefully selected SNPs, as well as monitoring contamination in all samples using a metric sensitive to fractions of a percent of contamination.

## 1801T

**CLIA whole genome sequencing and genotyping data at scale.** *T. Howd, N. Fitzgerald, F. Kelley, M. DaSilva, T. Desmet, S. Ferreira, J. Meldrim, M. Harden, A. Macbeth, B. Woolf, K. Tibbetts, E. Banks, L. Gauthier, S. Friedman, L. Lichtenstein, W. Brodeur, M. Lebo, H. Rehm, N. Lennon, S. Gabriel.* The Broad Institute, Cambridge, MA.

As precision medicine continues to move from the realm of clinical utility studies towards standard of care, there is increasing demand for high-throughput and widely accessible molecular profiling delivered rapidly and securely. To meet this demand we have validated our germline whole genome sequencing (WGS) and genotyping processes for clinical use. We present here the major improvements made to our workflow to accomplish this goal, which include: Leveraging our existing research WGS and arrays workflows to produce CLIA validated data for diagnostic and clinical research use at scale; Optimizing laboratory processing and quality management to meet a deliverable of 95% of the genome at  $\geq 20\times$  coverage or  $>98\%$  call rates; Implementing and validating the Illumina Novaseq 6000, as well as upgrading our cloud analysis pipeline to maximize available capacity for both primary and secondary analysis of large WGS datasets. Broad has generated  $>100,000$  WGS and  $>1,000,000$  genotyping datasets in a research setting. By implementing and rigorously validating new technologies, streamlining user training and quality management, and integrating dynamic work design, we have created an environment that can be used to rapidly develop and implement new CLIA tests. We are continuing to learn from and improve upon the methodology used in the creation of our clinical WGS product to develop and launch a CLIA validated genotyping array workflow. Additionally, we are committed to providing the best analysis tools to serve the clinical community - we have integrated GATK SNV and InDel and calling with advanced single sample filtering to provide high quality variants that can be further annotated for pathogenicity. Our ability to generate high-quality, CLIA validated WGS and array data at scale serves the Broad's goals to improve human health by using genomics to advance our understanding of the biology and treatment of human disease, and to help lay the groundwork for a new generation of therapies.

**1802F**

**Adapting long-read sequencing technologies for targeted and single cell applications.** S. Iyer<sup>1,2</sup>, S. Goodwin<sup>1</sup>, W.R. McCombie<sup>1</sup>. 1) Genome Center, Cold Spring Harbor Laboratory, Woodbury, NY; 2) Genetics Program, Stony Brook University, Stony Brook, NY.

Understanding the basis of complex diseases relies heavily on the ability to effectively study the genomic loci associated with these conditions. In the past, large-scale genomic studies have helped identify several disrupted genes and pathways associated with complex diseases, suggesting many risk loci. These risk variants - often copy number variants (CNVs), repeats, and structural variants (SV) - contribute to the highly complex regions of the genome that have not been successfully resolved yet. Long-read sequencing using the Oxford Nanopore Technology (ONT) allows for resolution of these complex genomic features by generating reads that are several (>10) kb long. Such reads have the potential to span difficult SV or repetitive regions with a single continuous read, giving a clearer idea of the variation and eliminating ambiguity in position or size. Currently, long-read sequencing methods are greatly limited by the DNA preparation step, with fragment lengths and yield often compromised by standard extraction methods. Moreover, the potential to generate reads at the megabase level relies greatly on library preps using large amounts (several µg) of DNA input. Our overarching goal is to be able to develop an approach that generates large contiguous reads from moderate to low input DNA masses (1-100 cell level). To this end, we use different extraction, amplification, fragmentation, and capture strategies to efficiently target and resolve complex regions of the genome that are often associated with disease conditions. We are currently employing and adapting CRISPR-based targeting techniques to enrich for specific regions of the genome directly from intact cells. Development of a targeted long-read sequencing strategy using low DNA input gives us the potential to study heterogeneous cell populations and work with rare samples. This approach would therefore give us the opportunity to characterize the landscape of genomic and transcriptomic variants in cancers, neuropsychiatric disorders, and other complex conditions across large populations of individuals suffering from these conditions.

**1803W**

**Generating high-quality reference human genomes using PromethION nanopore sequencing.** M. Jain<sup>1</sup>, H. E. Olsen<sup>1</sup>, K. H. Miga<sup>1</sup>, J. Zook<sup>2</sup>, R. E. Green<sup>1</sup>, D. Haussler<sup>1</sup>, M. Akeson<sup>1</sup>, B. Paten<sup>1</sup>. 1) Department of Biomolecular Engineering, University of California Santa Cruz, Santa Cruz, CA; 2) National Institute of Standards and Technology, Gaithersburg, MD.

The human reference genome assembly (currently GRCh38) is the bedrock of human genomics, however it represents the sequence of just one haplotype across much of its span. The modernization of the human reference to include a collection of diverse and highly accurate, haplotype-phased genome assemblies is now critical to future studies aimed at more comprehensively understanding the genetic and genomic basis of human health and disease. A comprehensive representation of common variants with higher than 1 percent allele frequency will require sequencing hundreds of such diploid genomes. This will require a consistent, maximally cost-effective and rapid protocol to dramatically increase the production of high accuracy, haplotype-phased assemblies. Current efforts for producing high-quality assemblies of a small number of individuals have mostly focused on expensive high-coverage, long-read sequencing and assembly protocols. While this work has been successful in delivering the necessary standards of quality, the overall cost and production time prohibit scaling to hundreds of individuals in a timely manner. However, new technologies and assembly methods allow for potentially substantial improvements in both cost and time without compromises in assembly quality. We will present our work on evaluating the PromethION sequencing platform from Oxford Nanopore Technologies. We are testing the platform's ability to produce long read, high-quality and high-coverage data in a fraction of time and cost necessary for contemporary long read sequencing methods. Our goal is to evaluate performance based on base accuracy, throughput/timing, and cost; goals that must be met to improve the scale of high-quality genome assembly. Recognizing that even 100kb reads are insufficient to scaffold through the most repetitive regions of the human genome, we will augment this sequencing with other technologies to facilitate scaffolding and haplotype phasing.

**1804T**

**Sequencing by expansion: A novel technology enabling clinical DNA sequencing.** *M. Kokoris, B. McRuer, M. Nabavi, J. Tabone, C. Machacek, M. Prindle, A. Jacobs, S. Vellucci, T. Lehmann, K. Collins, S. Keller, C. Cech, S. Zabezhinsky, R. Busam, J. Horsman.* Stratos Genomics Inc., Seattle, WA.

While the use of DNA data to inform clinical decisions is increasing at a rapid rate, there are still significant barriers to the widespread adoption of DNA sequencing. To address impediments to sequencing, Stratos Genomics has developed a novel, rapid and low-cost sequencing technology, utilizing a simple workflow that facilitates a wide variety of uses across both research and healthcare settings. Sequencing By Expansion (SBX) encodes DNA sequence into a highly-measurable surrogate polymer called an Xpandomer. To enable this technology, we developed expandable nucleoside triphosphates (X-NTPs) for template-dependent, polymerase-based Xpandomer synthesis. Much like PCR, Xpandomer synthesis uses the natural function of DNA replication, utilizing custom engineered polymerases to synthesize Xpandomers from targeted DNA templates. Once cleaved, the Xpandomer extends to 50X the original DNA length, encoding the sequence information in high signal-to-noise reporters that enable high-fidelity, single molecule sequencing in a low-cost nanopore instrument. Features unique to SBX solve many challenges presented by clinical DNA sequencing. Here we present SBX nanopore sequencing data showing accurate and specific detection of clinically relevant mutations. The simple Xpandomer workflow allows us to demonstrate sample to sequence in less than 2 hours. Further, SBX enables accurate homopolymer sequencing by utilizing a unique reporter as a molecular "clock" between each base, ensuring every base is called. SBX is specifically designed for versatility, which, in addition to meshing with current protocols, facilitates unique workflows such as direct sequencing of degraded, fragmented or rare DNA. SBX promises to expand the value of DNA data in the clinic. SBX's simple, flexible workflow and rapid time-to-data combined with the benefits of direct, single molecule nanopore sequencing are key to realizing the promise of clinical genomics, reducing the time required for personalized sequencing tests from weeks to hours.

**1805F**

**Single-tube solutions to streamline DNA library preparation and improve sequencing results while lowering costs.** *H. Liu, Y. Jin, M. Bolduc, D. Bays, E. Kolossovski, B. Komorous, D. Schuster.* QuantaBio, Beverly, MA.

Reliable, simple and rapid solutions for high quality next-generation sequencing (NGS) library preparation are in great demand as the technology has become widely adopted in research, clinical and many other fields. To offer streamlined and high-quality library preparation solutions for Illumina® sequencing platform, we have developed two high-quality library prep solutions, with and without enzymatic fragmentation, to streamline sequencing workflows on Illumina platforms for a variety of applications. The sparQ DNA Frag & Library Prep Kit supports easily tunable enzymatic fragmentation and end polishing in a single step, followed by high efficiency adapter ligation in the same tube without intervening purification steps. The streamlined workflow can be completed in under 2.5 hours with minimal hands-on time (30 min) accommodating DNA input amounts from 1 ng to 1 µg. The optimized chemistry leads to higher library yield (up to 2 folds), lower duplication rate, better sensitivity and better uniformity across broad range of GC content. This results in lower upfront library prep, bead purification, sequencing as well as processing costs. For sample types not requiring initial DNA fragmentation, the sparQ DNA Library Prep Kit provides a fast, single-tube library preparation solution ensuring great sensitivity (down to 250 pg) and efficiency, while maximizing library yields with minimal hands-on time. A high efficiency, low bias and high-fidelity PCR master mix was also developed to complete the workflow that requires library amplification. Our library solutions are ideal for whole genome sequencing, FFPE sample, and various target enrichment workflows. Leveraging our innovative chemistries, world-class enzyme purity and rigorously controlled production and ISO13485 quality system, both kits offer unmatched library solutions to address quality, speed, reproducibility and throughput while remaining a cost-effective option.

**1806W****Nanobind magnetic disks for rapid high MW DNA extraction and library preparation in long-read sequencing and optical mapping applications.**

*K.J. Liu<sup>1</sup>, J.M. Burke<sup>1</sup>, D. Kilburn<sup>1</sup>, R. Fedak<sup>1</sup>, V. Wallace<sup>1</sup>, M. Kim<sup>1</sup>, R. Workman<sup>2</sup>, W. Timp<sup>2</sup>, H. Ferrao<sup>3</sup>, K. Bjornson<sup>3</sup>, B. Galvin<sup>3</sup>, H. Sadowski<sup>4</sup>, C. Proskow<sup>4</sup>.* 1) Circulomics Inc, Baltimore, MD; 2) Johns Hopkins University, Baltimore, MD; 3) Pacific Biosciences, Menlo Park, CA; 4) Bionano Genomics, San Diego, CA.

Long-read sequencing and optical mapping technologies from PacBio, Oxford Nanopore, and Bionano Genomics are rapidly becoming the de facto methods for de novo sequencing, phasing, and structural variant analysis. However, these capabilities are predicated on stringent requirements for high purity, high molecular weight (MW) DNA. The gold-standard method for high MW DNA extraction is plug lysis, a tedious two day method that can only process a handful of samples. Conventional spin columns and magnetic beads result in insufficient purity and fragment DNA resulting in compromised read lengths. We present methods for rapid high MW DNA extraction and library preparation based on our Nanobind magnetic disks. Each polymer disk is covered with a high density of micro- and nanostructured silica that protects DNA from damage and enables higher extraction yield and higher purity than conventional methods. High MW (300+ kb) and megabase (1+ Mb) DNA can be obtained from most sample types in less than 1 hour. High MW DNA extraction is readily automated using the Thermo Fisher KingFisher instrument. Two extraction chemistries have been developed. The Nanobind CBB Big DNA Kit has been validated for cultured cells, gram negative and gram positive bacteria, and whole blood. Sequencing on PacBio® Sequel® System and Oxford Nanopore GridION resulted in read length N50s of 26 – 49 kb with yields of 3 – 10 Gb depending on platform and sample type. Optical mapping of whole blood with Bionano Genomics Saphyr compared favorably to plug lysis with mapping metrics indicating comparable assembly performance and molecule length N50s greater than 250 kb. The Nanobind Plant Nuclei Big DNA Kit has been tested on samples including pine needles and maize. Sequencing on PacBio Sequel System and Oxford Nanopore GridION resulted in read length N50 up to 32 kb and yields up to 10 Gb. In addition to DNA extraction, Nanobind can be used for size selection purification with superior library yields and process time. Nanobind can achieve tunable size selection up to 10 kb with >80% recovery of high MW DNA and >99% removal of short DNA. Library prep can be completed in less than 4 hours with yields that are 2-5X higher than standard methods. Typical read length N50 of 22 kb – 30 kb and yields of 5 – 8 Gb are demonstrated on PacBio Sequel System and Oxford Nanopore GridION. In aggregate, these data demonstrate that Nanobind is a powerful platform for purification and preparation of high MW DNA.

**1807T****Normalase – a novel library normalization tool for high-throughput NGS.**

*D. Masser, V. Makarov, J. Lenhart.* Swift Biosciences, Inc., Ann Arbor, MI.

Normalase is an enzymatic NGS library normalization procedure that produces libraries with a specified molar concentration. This eliminates the need for library quantification and concentration adjustment prior to library pooling, resulting in optimal clustering density and index balance. Normalase is bead-free and does not use a limited capacity immobilization step which saves time and improves performance. Instead, following PCR amplification, each library is incubated with Normalase reagents to produce a set of equimolar samples for simple pooling. Normalized libraries can then be directly sequenced without additional purification. Normalase allows for more than 10-fold variation in input quantity, while generating less than 10% variation in sample clustering within a pool. Sequence analysis of normalized libraries indicates that performance metrics such as coverage, complexity, base composition and coverage uniformity are not affected. At the same time, the Normalase procedure offers a significant reduction in time, number of steps, cost and the likelihood of errors in loading when preparing samples for high throughput sequencing without affecting biological data endpoints such as allele frequency. In addition, size-independent normalization by Normalase is beneficial for libraries produced by transposon-mediated or enzymatic fragmentation where a broad size distribution complicates molarity calculation. It can also be used for library normalization and pooling in hybridization-capture protocols.

**A multi-omics approach to reappraising the protein-coding gene count in GENCODE.** A. Frankish on behalf of the GENCODE Consortium. European Molecular Biology Laboratory, European Bioinformatics Institute, Cambridge, Cambridgeshire, United Kingdom.

Accurate and complete annotation of human genes supports both genome biology and clinical genomics, with missing and mis-annotated genes having the potential to significantly affect the validity of downstream analysis. While the question 'how many protein-coding genes are there in the human genome?' may seem like a legacy of the early 2000s, it remains unanswered – and indeed hotly debated - to this day. There are two reasons why current gene annotation catalogues may contain imprecise counts: firstly, as yet unannotated protein-coding genes could remain to be discovered; secondly, existing coding annotations may be incorrect. We produce the GENCODE reference gene annotation for human and mouse as part of the Ensembl project, and a key focus of our current effort is to provide more accurate annotation of coding sequences (CDS). Here, we will discuss the creation of a multi-faceted workflow that has allowed us to identify both prospective novel protein-coding loci and potentially dubious loci still retained in our current geneset, and its implementation in human. This workflow incorporates experimental data generated by both short and long transcriptomic methods, proteomics assays, evolutionary analyses based on PhyloCSF and comparative annotation, and a consideration of the spectrum of genetic variation in human populations. Application of this workflow has led to the addition of 144 protein-coding genes to the GENCODE human geneset, as well as additional coding annotations to over 300 existing loci. The majority of these annotations are truly novel and do not appear in any other geneset or protein sequence database. Conversely, survey of potentially dubious protein-coding genes has found nearly 200 loci in our annotation that when reviewed light of the experimental data and bioinformatic algorithms available today appear unlikely to produce genuine protein products. While these changes may appear modest in number, we shall demonstrate that they could have dramatic consequences on the results of user analyses. Most obviously, we are able to present new interpretations of dozens of variants linked to diseases or traits.

**Quantitation and QC measurements for predicting downstream NGS success with FFPE and circulating cell-free DNA plasma samples.** J. Mook, D. Wieczorek, S. Hermanson, C. Knox, D. Horejsh, E. Vincent, D. Storts, T. Schagat. Promega Corporation, 2800 Woods Hollow Rd, Madison, WI.

Introduction: Quantity and quality of DNA from formalin fixed, paraffin embedded (FFPE) tumor tissue samples is highly variable, with degradation and crosslinking due to the fixation process leading to issues with amplification and difficulty in downstream applications. An alternative to FFPE is circulating cell-free DNA (ccfDNA) from plasma or other biological fluids. Compared to genomic DNA, ccfDNA yields are typically low, with tumor cell present at significantly lower frequencies. Due to the inherent variability of FFPE and ccfDNA sample quality, DNA quantity is not in itself reliably predictive of downstream application success. Here we describe methods for predicting sequencing result quality utilizing the ProNex® DNA QC Assay. Methods: DNA was purified from matching tumor and normal FFPE tissue types as well as ccfDNA from plasma samples. DNA quantity was measured via single-target qPCR and used for NGS library construction with a 56 gene oncology panel. Discrepancies between quantity of DNA input into library preparation and expected library yield and sequencing coverage uniformity were noted. To investigate if downstream library yield and sequencing quality could be better predicted, samples were retroactively assayed with the ProNex® DNA QC Assay that includes three different amplicon sizes (75, 150, and 300bp). The quantitative differences between the increasingly larger amplicon sizes were calculated as ratios. FFPE samples with high 75/300bp ratios are indicative of highly degraded samples, and ccfDNA samples with low 150/300bp ratios are indicative of high molecular weight DNA contamination. Results: Retroactive testing with the ProNex® DNA QC Assay showed a strong correlation between high degradation ratios with low library yield and poor coverage uniformity. Samples with equal concentration and library input performed better, when degradation ratios were low. Conclusions: FFPE samples with high degradation ratios clearly correlated with poor coverage uniformity of sequencing, enabling users of the ProNex® DNA QC Assay to predict downstream performance. Use of a QC method allows researchers to qualify samples and make informed decisions about what downstream library method to use. Concentrating on less complex panels vs. highly multiplexed panels or whole exome sequencing for degraded samples can ensure getting the most useful information out of an individual sample, thus saving time, cost, and lost information on precious samples.

**Automated FFPE purification using Maxwell HT DNA FFPE Isolation System.** *L. S. Steffen, A. Zegers, E. Vincent.* Promega Corporation, Madison, WI.

FFPE tissues remain the most common sample type for solid tumor oncology research, including prospective and retrospective studies. While FFPE samples are ideal for storage and histological applications, the fixation process crosslinks and irreversibly damages nucleic acids, which provides challenges for achieving suitable performance in molecular techniques such as next-generation sequencing (NGS) and qPCR. Methods for purifying nucleic acids from FFPE samples have also historically been time-consuming, low-throughput manual methods using organic solvents. This study introduces a set of tools for genetic assessment of DNA from FFPE samples. The Maxwell HT FFPE DNA Isolation System enables high-throughput purification of DNA from FFPE tissues. This system can be implemented on a variety of automation platforms, is scalable, and reduces cost and hands-on time. When compared to other products, the Maxwell HT FFPE DNA Isolation System improves purification yields of amplifiable DNA as demonstrated using the ProNex DNA QC Assay for amplification-based quantification. Increased yields of amplifiable DNA improves the chance of success in downstream molecular assessment, including qPCR, ddPCR, and NGS applications.

**No-amp targeted SMRT sequencing using a CRISPR-Cas9 enrichment method.** *I. McLaughlin, Y. Tsai, B. Bowman, J. Ziegler.* Pacific Biosciences of California, Menlo Park, CA.

Targeted sequencing of genomic DNA requires an enrichment method to generate detectable amounts of sequencing products. Genomic regions with extreme composition bias and repetitive sequences can pose a significant enrichment challenge. Many genetic diseases caused by repeat element expansions are representative of these challenging enrichment targets. PCR amplification, used either alone or in combination with a hybridization capture method, is a common approach for target enrichment. While PCR amplification can be used successfully with genomic regions of moderate to high complexity, it is the low-complexity regions and regions containing repetitive elements sometimes of indeterminate lengths due to repeat expansions that can lead to poor or failed PCR enrichment. We have developed an enrichment method for targeted SMRT Sequencing on the PacBio Sequel System using the CRISPR-Cas9 system that requires no PCR amplification. Briefly, a preformed SMRTbell library containing the target region of interest is cleaved with Cas9 through direct interaction with a sequence-specific guide RNA. After ligation with new poly(A) hairpin adapters, the asymmetric SMRTbell templates are enriched by magnetic bead separation. This method, paired with SMRT Sequencing's long reads, high consensus accuracy, and uniform coverage, allows sequencing of genomic regions regardless of challenging sequence context that cannot be investigated with other technologies. The method is amenable to analyzing multiple samples and/or targets in a single reaction. In addition, this method also preserves epigenetic modifications allowing for the detection and characterization of DNA methylation which has been shown to be a key factor in the disease mechanism for some repeat expansion diseases. Here we present results of our latest No-Amp Targeted Sequencing procedure applied to the characterization of CAG triplet repeat expansions in the *HTT* gene responsible for Huntington's Disease. We demonstrate the ability to isolate and sequence hundreds of individual on-target molecules from a challenging enrichment target from multiple samples representing a range of repeat element expansion sizes in a single reaction.

**Rapid library preparation using a bead-linked transposome for enrichment (eBLT).** *R.C. Tim<sup>1</sup>, S. Gross<sup>1</sup>, J. Zhao<sup>1</sup>, A. Slatter<sup>2</sup>, R. Kelley<sup>3</sup>, S. Snow<sup>1</sup>, K. Shen<sup>1</sup>, S. Deshmukh<sup>1</sup>, A. Barr<sup>1</sup>, A. Mai<sup>1</sup>, M. You<sup>1</sup>, J. Rodriguez<sup>1</sup>, E. Vermaas<sup>1</sup>, G. DeSantis<sup>1</sup>, G. Schroth<sup>1</sup>.* 1) Core Applications Group, Illumina, Inc., San Diego, CA; 2) Advanced Platform Tech Dev, Illumina, Inc., San Diego, CA; 3) Bioinformatics, Illumina, Inc., San Diego, CA; 4) Product Development, Illumina, Inc., San Diego, CA.

Improving the efficiency and reducing the turnaround time for next-generation sequencing (NGS) library preparation is key for enabling faster sample-to-answer workflows. We have developed a novel and flexible self-normalizing, bead-linked transposome (eBLT) system for library preparation, that is compatible with targeted enrichment chemistry. Enzymatic tagmentation on-bead eliminates quantification of DNA, reduces sample extraction burden, creates self-normalizing libraries with very consistent fragment sizes and reduces both hands-on time and overall processing time. The fine-tuned and consistent fragment sizes achieved with eBLT reduces reliance on expensive and laborious methods for size selection. Using the eBLT technology, a simple single-day workflow for library preparation and targeted enrichment is possible. We describe the performance and application of a bead-linked transposome designed for enrichment applications (eBLT) for targeted NGS applications. The system is compatible with saliva, whole blood and FFPE treated samples. In most cases, library quantification and normalization can be eliminated. Library yields with < 20% CV were obtained using samples with an input range of as low as 10 ng and as high as 1000 ng. The eBLT system provides either short library sizes, well suited to enrichment applications or, long library sizes, suited to whole genome applications and enrichment applications that require phasing. We have also developed an array of unique dual (UD) indexes, which support both low-plexity and high-plexity pooling and substantially reduce index hopping missassignment. The eBLTs may also be applied to RNA for whole or targeted transcriptome applications.

**1813T**

**Clinical metabolomics: A pivotal tool for the diagnosis and treatment of inherited metabolic disorders to enable precision medicine.** *N. Liu<sup>1</sup>, R. Raina<sup>2</sup>, L. Hubert<sup>1</sup>, J. Alaimo<sup>1</sup>, Y. Yang<sup>1</sup>, J. Xiao<sup>1</sup>, K. Pappen<sup>2</sup>, V. Sutton<sup>1</sup>, A. Kennedy<sup>2</sup>, Q. Sun<sup>1</sup>, S. Elsea<sup>1</sup>.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Metabolon Inc., Durham, NC; 3) Texas A&M University, Houston, TX.

The diagnosis of inborn errors of metabolism (IEMs) is challenging due to the complexity and variability of metabolic disorders, including clinical presentation and metabolic features. Clinical metabolomics, which is defined as the comprehensive analysis of small molecules in body fluids, is an emerging technology that holds promise of providing new insights into human diseases and serving as a primary diagnostic screening tool for IEMs. This method is capable of detection of >900 metabolites in a single test for the analysis of perturbations in biochemical pathways that would otherwise require multiple targeted tests. Consequently, the application of metabolomics leads to the discovery of novel biomarkers, monitoring of the treatment and improvement of interpretation of genetic variants. Metabolomic profiling of plasma was performed in 1302 individuals with diverse ethnicity and wide clinical spectrum with 90% having neurological phenotypes. Metabolites were analyzed by high resolution UPLC-MS/MS, and data were generated as Z-scores by comparing to a normal reference population. Of the total 1302 samples, metabolomic analysis contributed to identification and/or confirmation of the diagnosis in 91 cases by detecting the biochemical abnormalities that were consistent with the identified conditions, achieving a 7% diagnostic rate. Further, 21 cases were further confirmed by targeted biochemical tests, supporting the reliability of metabolomics. In total, we identified 33 known conditions including but not limited to aminoacidopathies, organic acidurias, fatty acid disorders, vitamin deficiencies, pentose pathway disorders, peroxisomal disorders, purine disorders, and neurotransmitter abnormalities, indicating that metabolomics can be utilized as an initial screening tool for diagnosis of known and novel or very rare IEMs. Using this method, we were also able to monitor therapies, detect disorders at the mild end of the phenotypic spectrum, identify novel biomarkers, and provide strong functional evidence in genetic variants interpretation. We here present the capability of clinical metabolomics in improving the diagnosis and treatment of IEMs, as well as the power of integrating clinical metabolomics with other molecular genetic data to provide a definitive diagnosis for metabolic disorders. The utilization of clinical metabolomic profiling facilitates the development of precision medicine approaches to personalized treatment, diagnosis, and prognosis.

**New application of human-based methyl-capture sequencing for DNA methylome analysis in non-human primate.** *J.R. Lee<sup>1</sup>, S.B. Yoon<sup>1</sup>, Y. Son<sup>1</sup>, D.H. Lee<sup>1</sup>, S.I. Lee<sup>1</sup>, K.J. Kim<sup>1</sup>, J.W. Huh<sup>2,3</sup>, J.S. Kim<sup>1,3</sup>.* 1) Primate Resource Center, Korea Research Institute of Bioscience and Biotechnology, Jeongeup 56216, Republic of Korea; 2) National Primate Research Center, Korea Research Institute of Bioscience and Biotechnology, Cheongju 28116, Republic of Korea; 3) Department of Functional Genomics, KRIBB School of Bioscience, Korea University of Science and Technology (UST), Daejeon 34113, Republic of Korea.

The non-human primate (NHP) have long been considered important animal models in biomedical research. The characterization of genomic or epigenomic variation in human disease models could advance the development of pathophysiological investigation, disease diagnosis, and research of clinical intervention. However, non-human primate-specific methods applicable to genomic or epigenomic analyses are still lacking. The recent development of methyl-capture sequencing (MC-seq) has a numerous advantage of cost-effectiveness, rapid sample processing time, broader genome coverage, and avoidance of the bias due to CpG-rich repeats. Here, we used a human probe-designed MC-seq method in cynomolgus monkey and African green monkey DNA samples to determine the applicability for these animal model. To effectively adapt the human probe-designed target region for methylome analysis in NHP, we redefined the MC-seq target region focusing on the sequence homology and variation in the promoter regions of the same genes between the NHP and human genomes. Methyl-capture efficiency was controlled by the sequence identity between the captured probes based on the human reference genome and the cynomolgus monkey and African green monkey genome sequences, respectively. Using reasonable guidelines, 65 and 56% of the human-based capture probes could be effectively mapped for DNA methylome profiling in the cynomolgus monkey and African green monkey genome, respectively, according to numeric global statistics. In particular, our method could cover up to 87 and 89% of the regulatory regions of the cynomolgus monkey and African green monkey genome, respectively. Therefore, adaptation of the established human-based MC-seq for NHPs can be a powerful tool for DNA methylation profiling, and help provide novel information about DNA methylation alteration patterns with direct clinical translation.

**Combining barcode libraries with targeted gene expression for single-cell genetic analysis.** *A. Chenchik<sup>1</sup>, M. Makhanov<sup>1</sup>, P. Diehl<sup>1</sup>, L. Kobzik<sup>2</sup>, C. Frangou<sup>1</sup>.* 1) Cellecta, Mountain View, CA; 2) Harvard School of Public Health, Harvard Medical School, Boston, MA.

Labeling of target cells with lentiviral barcode libraries offers an effective approach for monitoring cell phenotype in time-course experiments *in vitro* and *in vivo* using single-cell molecular analysis. Cellecta's CellTracker libraries, with millions of different barcodes, enable rapid labeling of each cell in a large population with a unique sequence that is detectable in next-generation sequencing (NGS) RNA expression profiling assays such as RNA-seq. These barcodes then provide a key to identifying the sub-population of progeny cells derived from a single barcoded progenitor cell in a single-cell analysis data set. Furthermore, the progeny cells could be phenotypically characterized by expression profiles, such as stem cells, differentiated cells, activated or apoptotic cells, etc. Further, cell barcodes may be incorporated together with genetic effector libraries, such as CRISPR sgRNA libraries, to identify clonal phenotypic changes induced by specific genetic disruptions in progeny cells derived from the single progenitor cell. However, while barcoding provides an effective way to group cells based on clonal origin in heterogeneous cell populations, comprehensive single-cell expression profiling of large numbers of cells remains challenging. Generating genome-wide, quantitative RNA-seq data from thousands of cells is cost-prohibitive. With standard RNA-seq analysis of single cells, the depth of sequencing is limited and only highly expressed transcripts can be reliably measured. To address this limitation, quantitative single-cell gene expression profiling requires a targeted method that focuses on key genes involved in cell-specific biomarkers, signaling pathways or biological responses of interest. We will demonstrate how the combination of the DriverMap Targeted RNA Expression Profiling assay and CellTracker lentiviral barcode libraries provides a complete platform for highly sensitive single-cell expression profiling. Data will be presented showing how targeted DriverMap RNA expression profiling of single cells combined with cell barcoding could significantly improve phenotyping of distinct cell populations.

**Demonstration of the successful extraction, library preparation, and sequencing of RNA from exosomes from plasma/serum samples frozen from the last decade.** J. Garifallou<sup>1</sup>, C. Vaccaro<sup>1</sup>, L. Tian<sup>1</sup>, A. McGarry<sup>2</sup>, H. Hakonarson<sup>1</sup>, R. Pellegrino<sup>1</sup>. 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Cooper University Hospital at Rowan University.

**Introduction:** Human exosomes and extracellular vesicles contain nucleic acids such as mRNA, precursor miRNA, mature miRNA, noncoding RNA, and DNA that are released during cellular processes. Exosomes are involved in cell to cell signaling, immune response, and tumor progression. The RNA contained within these vesicles is protected by a lipid bilayer from degradation and lysis by RNAses contained in the blood and therefore provides valuable, raw genetic information within the real-time context at the time of extraction. This genetic information has demonstrated value in gene expression analysis during disease development. Huntington's disease (HD) is an autosomal dominant disorder that is characterized by expansion CAG repeats within the HTT gene, with patients that have greater than 36 CAG repeats displaying the mutated gene. HD shows varying degrees of progression within patients (slow versus fast). In this study, we examined the exosomal RNA from plasma/serum taken at two different time points to assess the exosomal RNA for HD progression. **Methods:** RNA was extracted from plasma/serum using two separate kits, the Norgen Plasma/Serum Purification Mini Kit and the Norgen Plasma/Serum Exosome Purification and RNA Isolation Mini Kit. Following extraction, the RNA samples were quality assessed using the Nanodrop for RNA, the TapeStation RNA assay, the Qubit miRNA assay, and Qiagen miScript RT-qPCR assay. RNA quality was difficult to assess with these assays based on the small RNA samples that were extracted. However, the yield was sufficient to proceed with library preparation and sequencing. The samples were prepared using the Norgen Small RNA Library Prep Kit for Illumina. Sequencing was performed using the Illumina MiSeq instrument. **Results:** The sequencing produced 20 million reads for analysis. The sequencing did pass the standard QC metrics for the MiSeq, with cluster density of 1099K/mm<sup>2</sup> and the percent of reads greater than or equal to Q30 was 97.4%. **Conclusion:** This workflow was effective based on the successful sequencing of the libraries generated from long-term frozen plasma/serum samples. Sequencing data from exosomal RNA will continue to be valuable in assessing disease progression through real-time RNA transcriptome analysis as well as the treatment effectiveness in real-time. In addition to HD, exosome sequencing has potential utility in a wide-range of disease progression studies, including tumor development in cancers.

**1817F**

**Sensitive and specific detection of low-frequency variants from degraded and cell-free DNA samples using a novel library preparation method.** A.H. Potts<sup>1</sup>, U.D. Chakravarty<sup>1</sup>, Z. Zwirko<sup>1</sup>, Y. Zheng<sup>1</sup>, M. Light<sup>1</sup>, K. Giorda<sup>1</sup>, K. Lai<sup>1</sup>, K. Bryan<sup>2</sup>, S. Rose<sup>2</sup>, Y. Bao<sup>1</sup>, M. Jarosz<sup>1</sup>, C. Chen<sup>1</sup>. 1) Integrated DNA Technologies, Redwood City, CA; 2) Integrated DNA Technologies, Coralville, IA.

Next generation sequencing (NGS) has become a critical diagnostic tool that can be used to identify single nucleotide variants (SNV), indels, and copy number variations associated with diseases. However, clinically relevant samples, such as cell-free DNA (cfDNA) or FFPE DNA, present significant challenges for NGS analysis. DNA isolated from these samples is often of limited quantity and highly degraded, which makes both library preparation and bioinformatics analysis difficult. Existing library preparation methods require stringent size selection to eliminate adapter-dimers, which reduces library complexity and sensitivity. In addition, identification of low frequency mutations is hampered by the artifacts arising from poor sample quality, DNA extraction, library construction, PCR, and sequencing. We present a novel library preparation method that achieves a high level of conversion, eliminates adapter-dimers, and incorporates duplex unique molecular identifiers (UMIs) for *in silico* error correction. The method employs a 2-step ligation that does not require size-selection or adjustment of Ampure ratios during cleanups, which greatly reduces sample loss during library construction. In addition, maximal library conversion is achieved with a unique T4 DNA ligase and proprietary sequencing adapters that increase ligation efficiency and suppress chimera formation. The duplex UMIs in these adapters enables confirmation of the presence of mutations on both strands of input DNA. In this study, we tested the performance of our library preparation method using sheared genomic DNA, cfDNA, and FFPE DNA across a wide input range (1–250 ng). To mimic degraded DNA, we created libraries from mixtures of DNA isolated from NA12878 and NA24385 cell lines and sheared to an average length of 150 bp. We used 1–250 ng of input DNA with 0.25% mutant allele fractions (MAFs). To highlight its clinical applications, we also analyzed cfDNA (5–25ng) and FFPE DNA (25–100 ng) samples with 1% MAFs in each sample type. Libraries were enriched using a 75 kb xGen® Lockdown® Probes panel, followed by deep sequencing and SNV variant calling. Our results demonstrate that this new library preparation method yields a 50–100% increase in library complexity and substantially improves sensitivity for <1% variants compared to other commercially available methods. In addition, the inclusion of duplex UMI error correction virtually eliminates all false-positive calls, maintaining 100% specificity.

**1818W**

**Xdrop: A new droplet-based technology for targeted long-read sequencing.** A. Ameur<sup>1</sup>, I. Höjjer<sup>1</sup>, E.B. Madsen<sup>2</sup>, T. Kvist<sup>1</sup>, M. Mikkelsen<sup>2</sup>. 1) Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 2) Samplix, Herlev, Denmark.

Short-read next-generation sequencing (NGS) technologies are based on generation of millions of reads, typically 100-500 bp in length. As the sequence information is broken up in millions of short sequence fragments it is crucial that the reads subsequently are assembled correctly in order not to lose sequence information. This is a particularly challenging task in regions with repetitive sequence or with structural rearrangements. Long-read NGS technologies like Pacific Biosciences (PacBio) and Oxford Nanopore are capable of reading DNA molecules of tens to hundreds of kilobases in length, thereby practically solving the issue with assembling the sequence reads correctly. However, the long-read technologies come with an increased cost per sequencing unit as compared to short-reads. The cost can be reduced by enriching the DNA sample for the genomic regions of interest, and thereby increasing the number of reads covering those specific regions. Here we present the Xdrop technology, a novel microfluidic-based system that allows for targeted enrichment of long DNA fragments. The technology is based on isolation of long DNA fragments in millions of picoliter double emulsion droplets, which are fluorescently labelled and sorted on a cell sorting (FACS) instrument, resulting in an enriched population of long DNA molecules covering a target of interest. This approach is fundamentally different from other target enrichment methods. The enriched DNA can either be sequenced on a long-read sequencing platform, or alternatively provide long-fragment information from short-read sequencing. Only ~150 bases of sequence information is needed to perform enrichment of DNA fragments of up to 40kb in size, and the protocol requires as little as 1 ng of genomic DNA as input. Since all amplification reactions are performed in small droplets, the risk of forming chimeric molecules from a specific target is virtually eliminated. We have successfully used the Xdrop technology in combination with PacBio sequencing for a variety of applications, such as to determine integration sites of human papillomavirus 18 (HPV18) in the HeLa cell line, to obtain phasing information of co-existing mutations in TP53 gene, and to enrich for the Epstein Barr Virus (EBV) in a sample containing a 2200-fold excess of human genomic DNA. Our results demonstrate that the Xdrop technology is suitable for wide range of genomics experiments where long-read information is of importance.

**1819T**

**Leveraging advances in uniformity and on-target rates to maximize coverage and reduce sequencing in first-pass designs of custom NGS target enrichment panels.** R.I. Zeitoun, L. Arbiza, K.D. Butcher, S. Chen, E.H. Chilton, R.W. Gantt, C. Thompson. Twist Bioscience, San Francisco, CA.

Target enrichment has been an enabling approach to sequencing specific regions of the genome and calling variants while reducing sequencing cost per sample. The ability to create customizable panels has been a key driver for increased utilization of target enrichment within various workflows and applications. However, slow turn around times, challenges leading to context-specific biases, and lack of uniformity can strongly affect the quality and efficiency of results. These factors can be particularly evident in first-pass custom designs without optimization and can be especially evident for smaller panels and spike-ins where a lack of uniform enrichment and low on-target rates will quickly increase the cost per sample by requiring that samples are over-sequenced in order to cover all regions to a minimum sequencing depth. In order to create first-pass optimized custom panels, we focused on understanding the underlying variables that are critical for ensuring high on-target and uniform capture. Based on this understanding, we implemented innovative panel design rules and workflow chemistry ensuring high capture uniformity while providing fine control of off-target capture without compromising target coverage. To demonstrate the advantage of this design strategy and workflow, we designed two custom panels (40 kb and 800 kb) and an exome spike-in panel (120 kb) consisting of cancer targets. This resulted in first-pass custom panel designs with >40% improved capture efficiency, ~2-5 fold improvements in off-target, and exceptional uniformity (fold 80 base penalty of 1.2), relative to naïve design and standard conditions. In addition, we show that the same design principle can be used to create very high quality spike-in panels to work in conjunction with our exome sequencing sequencing solution. In all, this study provides a clear demonstration of our approach to create high-performing custom target enrichment panels that effectively reduce per-sample costs with substantial gains in quality.

**A fast and reproducible RNA-seq library prep with improved sensitivity and specificity across a broad range of RNA inputs.** *Y. Jin, M. Bolduc, S. Li, H. Liu, E. Kolossovski, B. Komorous, D. Schuster.* QuantaBio, Beverly, MA.

RNA-Seq is the most popular method for whole transcriptome analysis and provides valuable information to quantify, profile, and uncover RNA. We have developed a rapid and streamlined directional RNA-Seq kit with increased sensitivity and specificity. The optimized chemistry and consolidated workflow greatly increases the library efficiency, reduces the hands time and overall cost to generate high quality RNA-Seq libraries. Together with the mRNA enrichment module, our RNA-Seq kit provides a fast (less than 5 hour), robust and highly reproducible solution with industry-leading sequencing performance for strand specificity, coverage uniformity, library complexity, and accuracy.

**1821W**

**GRASS-C: Graph-based RNA-seq analysis in single cell level subgraph clustering.** *H. Yang.* UCLA, Los Angeles, CA.

Single-cell RNA Sequencing (scRNA-Seq) has enabled quantification of gene expression in the resolution of a single cell. The characterizing of different cell populations in cellular heterogeneity can be potentially utilized for biological and clinical applications. In order to utilize the high resolution of scRNA-Seq, new methods must overcome the computational challenges arising from high dimensionality of the data and sparsity in gene expression from technical artifacts. Various statistical approaches have been applied to resolve these computational issues, but most methods are parameter-dependent and fail to fully characterize subpopulations. We present Graph-based RNA-Seq Analysis in Single-cell level Subgraph Clustering (GRASS-C), a clustering tool for identifying cell subpopulations in scRNA-Seq data. First, GRASS-C models the observed gene expression as a mixture of two Gaussian distributions, one representing the high expression signals, while the other indicating low expression and technical noises such as dropout. GRASS-C leverages a low-cut filter based on the Gaussian mixture estimate to keep important biological signals intact while minimizing the impact of noises in the data. We demonstrate that the low-cut filter can isolate biologically important signals from various biological and technical noises. Using cells as nodes and the similarity of gene expression between cells as edge weight, GRASS-C successfully identifies clusters with cells that share similar expression pattern with the Louvain algorithm for community identification. We show that GRASS-C successfully identifies different cell-types in six publicly available scRNA-Seq datasets comprised of different cell sizes, and experimental and biological backgrounds. Furthermore, GRASS-C is able to perform the clustering with higher accuracy than any other publicly available tools tested. Also, we demonstrate that the clustering information by GRASS-C can elucidate potential underlying biological insights through differential expression analysis on cell clusters.

**1822T**

**Utilizing a PCR-based method to generate high confidence indel genotyping results as an orthogonal confirmation of NGS-identified variants.**

*K. Larkin<sup>1</sup>, J. Wang<sup>2</sup>, K. Beltz<sup>1</sup>, M. Schnackel<sup>1</sup>, K. Lai<sup>2</sup>, W. Lee<sup>2</sup>, S. Fiedler<sup>1</sup>.* 1) Research & Development, Integrated DNA Technologies, Coralville, IA; 2) Research & Development, Integrated DNA Technologies, Redwood City, CA.

Insertion and deletions (indels) are important sequence variants in human biology and disease, and are the second most common type of genomic variation only secondary to single nucleotide polymorphisms (SNPs). Reliable indel detection is therefore increasingly important in the era of personalized medicine. However, conventional methods such as next generation sequencing (NGS) have known limitations in detecting and calling indels. Because reads from large indel targets are often difficult to align to a reference genome, they may be removed or result in low-confidence genotype calls. Thus, an orthogonal method to confirm target genotypes is critical for obtaining high-confidence calls. Here, we compare the indel detection capabilities of two different methodologies. The first is an NGS-based hybridization capture (hybrid capture) method performed with xGen® Lockdown® Probes; the second is the PCR-based rhAmp® SNP Genotyping System. PCR-based genotyping methods offer a fast and cost-effective method to confirm NGS results, allowing for resolution of indel genotypes that is challenging with current NGS analysis methods. A combination of several elements makes the rhAmp SNP Genotyping System a particularly useful orthogonal strategy for high confidence indel detection and genotype calls: its allele-specific primer designs are highly successful with large indel targets; its dual-enzyme system provides high discrimination and sensitivity; and its universal reporter mix provides high signal-to-noise ratios. Our results show concordance in indel genotyping calls between the NGS hybrid capture method and the PCR-based rhAmp SNP Genotyping System across a panel of 46 human genomic DNA samples. We targeted indels ranging from 1 to 27 bases, allowing us to calculate concordance across a variety of indel sizes. Our results show that the PCR-based rhAmp SNP Genotyping System generates high-confidence calls for indels and successfully confirms NGS indel data.

**1823F**

**Molecular barcode thresholding and unique dual sample indices reduce/eliminate index cross talk/hopping between NGS libraries to improve variant calling accuracy.**

*B. Mullinax<sup>1</sup>, K. Chen<sup>1</sup>, L. Niu<sup>2</sup>, C. LeCocq<sup>2</sup>, G. Amparo<sup>2</sup>, C. Pabon<sup>2</sup>, B. Arezi<sup>1</sup>, H. Hogrefe<sup>1</sup>.* 1) Agilent Technologies, La Jolla, CA; 2) Agilent Technologies, Santa Clara, CA.

The introduction of Illumina's ExAmp chemistry and patterned flow cell on the HiSeq 3000/4000/X Ten allow for the sequencing of multiplexed samples at high read depth and quality at a low cost per sample. While these advances provide advantages, they have also resulted in the misidentification of up to 5-10% of the sequencing reads in multiplexed samples. The misidentification is partly the result of "index hopping" believed to be due to the presence of unincorporated indexed primers in the pooled sample. Other potential sources of misidentification are cross-contamination of sample indices prior to use, index cross-contamination due to index hopping during post-capture amplification of multiple pooled libraries, and demultiplexing errors. The detection of variants at frequencies of 0.1-1.0% in heterogenous samples is often the goal of biomedical research and diagnostics. Index hopping or cross-contamination at a rate of up to 5-10% therefore has the potential to result in incorrect variant calls, especially false positives. As we will demonstrate, molecular barcode thresholding (i.e., removing all reads that have only a single molecular barcode) removes 90% of hopped reads thereby reducing the hopping rate to that of the HiSeq 2500 (0.3%) and significantly reducing the number of false positive calls on the HiSeq 4000. Thresholding leads to removing a significant number of sequencing reads, but with low DNA input and deep sequencing, panel sensitivity and specificity are comparable to the HiSeq 2500. Furthermore, the addition of a second sample index to be used in a unique combination with the first sample index, allows for the complete removal of all index hopped reads.

**Cell-type specific expression of circular RNAs in human pancreatic islets.** S. Kaur<sup>1</sup>, A.H. Mirza<sup>2</sup>, F. Pociot<sup>1,3</sup>. 1) Steno Diabetes Center Copenhagen, Gentofte 2820, Denmark; 2) Weill Cornell Medicine, Department of Pharmacology, New York, NY, USA; 3) Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen DK-1165, Denmark.

**Background:** Understanding distinct cell-type specific gene expression in human pancreatic islets is important for developing islet regeneration strategies and therapies to improve  $\beta$ -cell function in type 1 diabetes (T1D). While numerous transcriptome-wide studies on human islet cell populations have focused on protein-coding genes, their non-coding repertoire such as long non-coding RNA, including circular RNAs (circRNAs) remains mostly unexplored. Here, we explored transcriptional landscape of human  $\alpha$ ,  $\beta$  and exocrine cells and identified cell-type specific circRNAs. **Methods:** Total RNA-Seq dataset of FACS sorted  $\alpha$ ,  $\beta$  and exocrine cells from 3 human donors was retrieved from GEO (GSE50386). The raw fastq files were trimmed, cropped and adapters removed using Trimmomatic v.0.36. The resulting reads were aligned to human genome (GRCh38) using tophat-fusion and unaligned reads were further processed by CIRCexplorer2 (v.2.2). Intronic circRNA (ciRNA) candidates were discarded from the analysis and exonic circRNAs with  $\geq 2$  junctions spanning reads in  $\geq 2$  samples were considered expressed. **Results:** We identified 1526, 1007 and 456 circRNAs expressed in human  $\alpha$ ,  $\beta$  and exocrine cells, respectively. Only 219 circRNA candidates were commonly expressed in all three cell-types. The most highly and commonly expressed candidates were *MAN1A2* and *HIPK3* ( $\geq 100$  junction spanning reads). Alternate circular isoforms were observed indicative of potential distinct functions in these cell-types. For example, *PTK2* had 12 and 10 circular isoforms in  $\alpha$  and  $\beta$  cells, respectively, whereas only 2 isoforms in exocrine cells. We also observed cell-type specific expression of circRNAs. Functional annotation analysis revealed enrichment of  $\beta$ -cell-specific circRNAs in pathways related to regulation of apoptosis, DNA damage response and proteasome degradation. Non  $\beta$ -cell-specific circRNAs were mostly enriched for pathways related to diseases of signal transduction, SMAD2/3/4 transcriptional activity and insulin receptor signaling. **Conclusion:** Our study showed that circRNAs are highly abundant in both  $\alpha$  and  $\beta$ -cells. We also showed that circHIPK3, previously implicated in  $\beta$ -cell dysfunction (Stoll et al. (2018)), is a non  $\beta$ -cell-specific circRNA and is globally expressed in all cell-types in human islets. We are currently investigating the potential roles of  $\alpha$ ,  $\beta$ -cell specific circRNA candidates in regulating  $\beta$ -cell function.

## 374T

**Fast calling of copy number variants from population scale high-depth whole genome sequencing.** A. Gilly<sup>1</sup>, G. Png<sup>1,2</sup>, D. Suveges<sup>1,3</sup>, Y.C. Park<sup>1,2</sup>, K. Walter<sup>1</sup>, K. Kundu<sup>1</sup>, I. Ntalla<sup>1</sup>, E. Tsafantakis<sup>5</sup>, M. Karaleftheri<sup>6</sup>, G. Dedousis<sup>7</sup>, E. Zeggini<sup>1</sup>. 1) Human Genetics, Wellcome Sanger Institute, Hinxton, United Kingdom; 2) University of Cambridge, Cambridge, UK; 3) European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton CB10 1SH, UK; 4) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK; 5) Anogia Medical Centre, Anogia, Greece; 6) Echinus Medical Centre, Echinus, Greece; 7) Department of Nutrition and Dietetics, School of Health Science and Education, Harokopio University of Athens, Greece.

Copy number variants (CNVs) are large deletions or duplications at least 50 to 200 base pairs long. They play an important role in multiple disorders, however accurate calling of CNVs is still a challenge today. Several large-scale high-depth whole-genome sequencing (WGS) efforts are underway, yet most current approaches to CNV detection use raw read alignments, which are computationally intensive to process. Here, we introduce UN-CNVC, a regression tree-based CNV detection algorithm that produces population-wide callsets at unprecedented speed, using depth at variant calls from WGS. As a proof-of-principle, we applied UN-CNVC to WGS ( $>18\times$ ) from 6,898 samples across four European cohorts, and describe a rich, large variation landscape comprising 2,059 CNVs. 38.4% of detected events were previously reported in the Database of Genomic Variants, a dbSNP equivalent for CNVs. 18% of high-quality deletions excised entire genes, and we recapitulated known phenotype-altering events such as those affecting the *GSTM1* and *RHD* genes. We then tested for deletions associated with 275 protein levels in 1,457 individuals to assess the potential clinical impact of the detected CNVs. We describe the LD structure and copy number variation underlying an association between levels of the *CCL3* protein and a complex common structural variant affecting *CCL3L3*, a paralog of the *CCL3* gene (MAF=0.15,  $p=3.6\times 10^{-12}$ ), expanding on previous evidence of copy-number variation at this locus. We also present a cis-association between a low-frequency *NOMO1* deletion and the protein product of this gene (MAF=0.02,  $p=2.2\times 10^{-7}$ ) for which no cis- or trans- single nucleotide variant-driven pQTL has been documented to date. This work demonstrates that existing population-wide WGS callsets can be mined for CNVs with minimal computational overhead, delivering insight into a little-studied, yet potentially impactful class of genetic variant.

**Genome-scale sequencing to study the contribution of structural variation to human complex traits.** *K. Walter<sup>1</sup>, B. Howell<sup>1</sup>, E. Gardner<sup>1</sup>, J. Danesh<sup>1,2,3</sup>, A. Butterworth<sup>2,3</sup>, M.E. Hurler<sup>1</sup>, N. Soranzo<sup>1,3,4,5</sup>*, *The INTERVAL Study*. 1) Human Genetics, Wellcome Sanger Institute, Hinxton, United Kingdom; 2) MRC/BHF Cardiovascular Epidemiology Unit, Department of Public Health and Primary Care, University of Cambridge, Cambridge, UK; 3) The National Institute for Health Research Blood and Transplant Unit (NIHR BTRU) in Donor Health and Genomics, University of Cambridge, Strangeways Research Laboratory, Wort's Causeway, Cambridge, UK; 4) Department of Haematology, University of Cambridge, Cambridge Biomedical Campus, Long Road, Cambridge CB2 0PT, UK; 5) British Heart Foundation Centre of Excellence, Division of Cardiovascular Medicine, Addenbrookes Hospital, Hills Road, Cambridge, UK.

Structural variations (SV) are changes in the human genome usually larger than 50bp which include deletions, insertions, duplications and inversions. They are responsible for the majority of nucleotide variation among human genomes, and they are also implicated in various diseases and associated phenotypes such as cognitive disabilities to predispositions to obesity, cancer and other diseases. We are using whole genome sequence data (WGS) at 15X coverage from up to 12,000 samples in the INTERVAL study (<http://www.intervalstudy.org.uk>), which is a prospective cohort study of approximately 50,000 blood donors, who are 18 years and older, and who were consented and recruited from 25 National Health Service Blood and Transplant donor centers across England between 2012 and 2014. Participants are predominantly healthy individuals, they also completed online questionnaires containing basic lifestyle and health-related information, including self-reported height and weight, ethnicity, current smoking status, alcohol consumption, doctor-diagnosed anemia, use of medications (hormone replacement therapy, iron supplements) and menopausal status. The WGS data allow calling of SVs, including copy number variations (CNV) in coding as well as non-coding regions. After applying stringent quality control criteria and in-depth annotation, we evaluate the contribution of SVs and CNVs on blood cell phenotypes and a range of phenotypes related to inflammation and immunity. In particular, we assess the heritability of SVs that is not already explained by SNPs and INDELS, and we are investigating the burden of rare SVs on genes or exons, as well as their functional impact on the non-coding, regulatory part of the genome to study the genetic architecture of complex traits. The availability of WGS data at 15X coverage also allows detection of possible mosaicisms that could be linked to predisposition to disease.

**Defective gene splicing with mutant alleles of the ankyrin 1 gene isolated from patients with hereditary spherocytosis.** *V. Alencar<sup>1</sup>, A. Tondin<sup>1</sup>, J. Klemm<sup>1</sup>, J. Elliott<sup>1</sup>, W.H. Cho<sup>2</sup>, M. Carcao<sup>3</sup>, T. Lentz<sup>1</sup>, A. Driver<sup>1</sup>, G. Fischer<sup>2</sup>, L. Drury<sup>2</sup>, D. Caporale<sup>1</sup>*. 1) Biology, University of Wisconsin Stevens Point, Stevens Point, WI; 2) Prevention Genetics, 3800 South Business Park Avenue, Marshfield, WI; 3) Hospital for Sick Kids, Department of Hematology, 555 University Avenue, Toronto, Ontario.

Hereditary spherocytosis (HS) is a genetic disorder characterized by hemolytic anemia due to defective red blood cell morphology. The biconcave disc morphology of red blood cells enables them to traverse narrow capillaries. ANKYRIN1, encoded by the *ANK1* gene, tethers integral membrane proteins to the underlying spectrin-actin cytoskeleton. This interaction structurally supports the biconcave disc shape of the red blood cells. Loss-of-function variants in the *ANK1* gene lead to autosomal dominant forms of HS. We have identified a number of undocumented intronic variants in *ANK1* alleles from patients affected with HS. Computational analysis predicted these intron variants produce defects in gene splicing, resulting in formation of atypical mRNA and non-functional protein. To evaluate the effect of these intronic variants on splicing, gene fragments comprised of exon and *ANK1* intron sequences carrying each variant were cloned into the RHCglo minigene expression plasmid. Constructs carrying the wild-type allele sequences were also produced as controls. Plasmids were transfected into NIH/3T3 cells and total RNA was recovered at 72 hours. RT-PCR was performed to convert minigene transcripts to cDNA for sequencing. Constructs carrying wild-type allele sequences produced the minigene transcripts expected from wild-type splicing. Constructs carrying intronic variant sequences produced varied results, including altered and/or heterogeneous splice products. Many of the altered minigene splice products predicted by computational analysis were observed. These results were corroborated in replicate transfections. Extrapolation of observed minigene splicing to *ANK1* gene expression indicates many of these previously undocumented variants likely produce defective transcripts and altered ANKYRIN1 protein.

**TRBV polymorphism predicts adverse events during checkpoint blockade immunotherapy.** *T. Looney<sup>1</sup>, E. Lynch<sup>2</sup>, L. Miller<sup>2</sup>, G. Lowman<sup>2</sup>, F. Hyland<sup>1</sup>.* 1) Thermo Fisher Scientific, South San Francisco, CA; 2) Thermo Fisher Scientific, Carlsbad CA.

Introduction Identifying predictive biomarkers for the emergence of immune mediated adverse events (IMAEs) during immunotherapy is a key objective of current immunotherapy research. Polymorphism within the TCRB variable gene (TRBV) has been implicated in autoimmune disease and may be mechanistically linked to IMAEs. Previous efforts to evaluate TRBV polymorphism have been hampered by the repetitive nature of the TCR locus and incomplete genome assembly. Here we employed a novel long-amplicon TCRB repertoire sequencing approach to evaluate the link between TRBV polymorphism and adverse events in 54 Caucasian research subjects receiving checkpoint blockade immunotherapy for cancer. We find that approximately one third of Caucasians possess a TRBV allele haplotype that appears protective against grade 3 or higher IMAEs. TRBV polymorphism may serve as a predictive biomarker of IMAEs to advance precision immunotherapy for cancer. Methods To measure TRBV polymorphism we used next generation sequencing of rearranged TCRB chains via RNA extracted from peripheral blood. We employed multiplex PCR to create amplicons spanning the three beta chain CDR regions to enable detection of polymorphism within the germline-encoded framework and CDR1 and 2 regions in addition to CDR3 profiling. TCRB receptor repertoires produced for each research subject were used to construct variable gene allele profiles to allow for inference of TRBV allele haplotypes. Results TRBV allele typing revealed the presence of distinct sets of co-inherited TRBV alleles, which we classified into major TRBV allele haplotype groups. We then evaluated the frequency of severe (grade 3 or higher) adverse events across haplotype groups. Strikingly, we find that the frequency of adverse events varies markedly between groups: one group, accounting for approximately one third of the sample set, appears protected from severe adverse events, while other groups showed moderate to elevated frequency of adverse events. Conclusions These data suggest that TRBV polymorphism may play a mechanistic or predictive role in autoimmune toxicity during checkpoint blockade immunotherapy. Current and future studies will further explore the utility of TRBV polymorphism as a predictive biomarker for IMAEs.

**Gene diversity of immunoglobulin variable domains among three ethnic groups in Nigeria: Implication for HIV vaccine development.** *R.A. Ahmed<sup>1</sup>, C. Scheepers<sup>2</sup>, K.A. Adekoya<sup>1</sup>.* 1) Medical Genetics Unit, Cell Biology and Genetics, University of Lagos, Yaba, Lagos State, Nigeria; 2) Centre for HIV and STIs, National Institute for Communicable Diseases, University of Witwatersrand, South Africa.

The quest of developing efficacious human immunodeficiency virus (HIV) vaccine is ongoing while crucial factors associated with past failure of vaccine efficacy trials are being critically considered. Identification of vaccine-compatible immunoglobulin or potent antibodies capable of eliciting vaccine-mediated protection via broadly neutralizing and effectors-activation responses is an essential factor of consideration. Several novel alleles of immunoglobulin gene are being reported recently from an ethnic group in Africa part of which contributed to functional antibodies against HIV infection. It is therefore hypothesized that significant novel and functional immunoglobulin gene variants are embedded in Africa population which are missing in the public databases. This may therefore have implications in the global development of a quality and efficient HIV vaccine. Nigeria, with the largest population in Africa and diverse ethnic group may harbor some of these novel and functional immunoglobulin gene variants. We started a study to sequence the entire rearranged antigen naive variable domain of heavy and light Immunoglobulin chain (VH, VK and VL) gene repertoire in 105 individuals from three major ethnic groups of Nigeria using Illumina Miseq. Data will be analysed using a new bioinformatics tool called IgDiscover that will enable the identification of novel and known germline gene segments. Novel alleles will further be assessed for functional HIV antigenic responses. Expected outcome of this study includes identification of large and diverse alleles from the heterogeneous study samples and novel alleles which will be vaccine compatible and capable of eliciting HIV broadly antigenic responses. This study will contribute to general knowledge of antibody especially towards utilization for a quality HIV vaccine development and other infectious diseases. It will also be of great importance to the Antibodyomics project which is aimed to provide holistic and cross-sectional information on human antibodies especially against HIV infection.

## 379W

**Mosaic events in 181,022 Japanese individuals provide novel molecular insights into clonal hematopoiesis and hematopoietic malignancy.** C. Terao<sup>1,2,3</sup>, P. Loh<sup>4</sup>, Y. Momozawa<sup>5</sup>, M. Kubo<sup>5</sup>, Y. Kamatani<sup>1</sup>. 1) Laboratory for Statistical Analysis, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 2) The Department of Applied Genetics, The School of Pharmaceutical Sciences, University of Shizuoka, Shizuoka, Japan; 3) Clinical Research Center, Shizuoka General Hospital, Shizuoka, Japan; 4) Division of Genetics, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 5) Laboratory for Genotyping Development, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan.

Clonal hematopoiesis produces DNA mosaicism in peripheral blood cells and can lead to hematopoietic malignancies. Previous studies have identified multiple inherited genetic variants associated with acquired *JAK2* mutation and myeloproliferative diseases. However, most mosaic events remain unexplained, and population differences in mosaicism have been largely unexplored. Here we investigated mosaicism in 181,022 individuals in BioBank Japan (BBJ) by developing a new method for processing signal intensities from DNA microarrays into clean B allele frequencies (BAF) and log R ratios (LRR) optimized for Illumina Infinium systems. We called mosaic events from this data using a recently-developed hidden Markov model-based method in combination with long-range phasing. We identified 59,491 mosaic events, an increase of 4-to-6 fold versus the number of events callable using 'raw' BAF and LRR and the number of events called in the largest previous study of mosaicism (151,202 UK Biobank participants). The genomic distribution of mosaic events in BioBank Japan was broadly similar to the distribution in UK Biobank, but we observed Japanese-specific focal deletions and co-occurrences of mosaic events. We also observed a marked reduction in the frequency of trisomy 12 events (a precursor of chronic lymphocytic leukemia) in BBJ, consistent with reduced CLL incidence in East Asians. We conducted genome-wide association studies to detect inherited variants which predispose carriers to mosaicism. We identified 10 cis associations ( $p \leq 2.2 \times 10^{-10}$ ) including rare, highly-penetrant deleterious coding variants ( $OR \geq 37$ ). We also found four trans associations ( $p \leq 1.0 \times 10^{-11}$ ). The associations mapped to novel genes in the double strand break repair complex (*NBN* and *MRE11A*), a ploidy-related gene (*CTU2*), and hematopoietic malignancy-associated genes (*MPL*, *DLK1* and *NEDD-8*) in addition to *JAK2* and *TERT* which are known to associate with acquired *JAK2* mutation. The presence of mosaic events strongly associated with future development of hematopoietic malignancy, mortality from hematopoietic malignancy (HR:1.18,  $p=1.3 \times 10^{-12}$ ), and overall mortality (HR:1.13,  $p=3.7 \times 10^{-10}$ ) not due to hematopoietic malignancy. Furthermore, we found specific chromosomal mosaic events to be strong drivers of the associations (five events with HR  $\geq 8.3$  and  $p \leq 1.0 \times 10^{-9}$  and three events with HR  $\geq 1.31$  and  $p \leq 3.5 \times 10^{-4}$  for mortality from hematopoietic malignancy and overall mortality, respectively).

## 380T

***USP8*-wildtype pituitary corticotroph tumors harbor recurrent *TP53* somatic mutations and have a distinct aneuploid molecular subtype compared to *USP8*-mutated tumors.** K. Ying<sup>1</sup>, P. Javanmard<sup>2</sup>, A. Roehnel<sup>2</sup>, P. Taik<sup>1</sup>, K. Cheesman<sup>2</sup>, M.Y. Fink<sup>1</sup>, A.S. Moe<sup>1</sup>, E.E. Schadt<sup>1,4</sup>, R. Sebra<sup>1,4</sup>, K. Post<sup>5</sup>, R. Chen<sup>1,4</sup>, E.B. Geer<sup>6</sup>, A.V. Uzilov<sup>1,4</sup>. 1) Sema4 Genomics (a Mount Sinai venture), 333 Ludlow Street, Stamford CT, 60902; 2) Department of Medicine, Division of Endocrinology, Diabetes, and Bone Disease, Icahn School of Medicine, The Mount Sinai Hospital, 1 Gustave L Levy Place, Box 1055, New York, NY 10029, USA; 3) Division of Endocrinology, Department of Medicine, Multidisciplinary Pituitary and Skull Base Tumor Center, Memorial Sloan Kettering Cancer Center, 1275 York Avenue, Box 419, New York, NY 10065, USA; 4) Department of Genetics and Genomic Sciences, Icahn Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, 1 Gustave L. Levy Place, New York, NY 10029, USA; 5) Department of Neurosurgery, Icahn School of Medicine at Mount Sinai, 1 Gustave L. Levy Place, New York, NY 10029, USA.

Pituitary corticotroph adenomas are rare tumors that can be associated with excess adrenocorticotrophic hormone (ACTH) and adrenal cortisol secretion, resulting in the endocrine condition Cushing's syndrome. Rarely, corticotroph tumors are 'silent' and do not result in elevated systemic ACTH and cortisol levels. Published whole-exome sequencing (WES) results are limited to only 23 such tumors across 3 studies, which revealed recurrent somatic mutations in ubiquitin specific peptidase 8 (*USP8*), the only driver gene known to date. Validation studies identified *USP8* driver mutations in 17-62% of ACTH tumors, with most studies reporting 31-36% prevalence; this leaves most corticotroph tumors without a genetic or molecular explanation of the driver mechanism. Moreover, while somatic copy number variant (sCNV) characterization of corticotroph tumors has been reported, it has not been integrated with molecular driver analysis. We carried out WES of corticotroph tumors and patient-matched normals from 18 patients that, compared to previous reports, are enriched for aggressive corticotroph tumor subtypes, including silent ACTH tumors, Crooke's cell adenomas, macroadenomas (>10 mm), and tumors with ki67 >3% or p53 positivity (14/18, 77.8%), including the first reported WES of an ACTH carcinoma. We performed integrative analysis of small somatic mutations (SNVs/indels) and large-scale genome rearrangements (sCNV and loss-of-heterozygosity, LOH). We found that *USP8*-wildtype tumors had a significantly higher proportion of the genome affected by sCNV and LOH, primarily via aneuploidy, than *USP8*-mutated patients, indicating different mutational mechanisms during tumorigenesis. We also found recurrent *TP53* mutations (in three *USP8*-wildtype tumors, 16.7%) at well-known hotspots. *USP8* and *TP53* somatic mutations had higher tumor allelic fractions (>20%) compared to somatic mutations in other candidate driver genes (<5%); comparison of allelic fractions with tumor purity estimates from WES suggests that these mutations are drivers occurring early in tumorigenesis and clonal expansion. We propose that corticotroph tumors may exhibit a *USP8*-mutated, genome-stable subtype versus a *USP8*-wildtype, genome-unstable subtype, the latter of which has a *TP53*-mutated subtype. These findings may inform our understanding of aggressive corticotroph tumor subtype pathogenesis, for which there are limited treatment options, with the aim to guide development of tumor-directed therapies.

**Changes in 3D genome architecture following chondrocyte differentiation as a model to understand skeletal disorders.** I. Song, I.D. Bochkov, Y. Bae, E.L. Aiden, B.H. Lee. Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Recent studies applying whole exome sequencing revealed that there are many aspects of skeletal dysplasia pathogenesis that cannot be explained by DNA coding regions. Accumulating evidences from genome-wide association studies and whole genome sequencing suggested that SNPs, copy number variations and structural variants in non-coding regions can play major roles in disease pathogenesis. Therefore, in this study, we aimed to identify the genome-wide 3D chromatin contact alterations associated with during chondrocyte differentiation and to explore their roles in skeletal disorders. We cultured ATDC5 cells using regular (undifferentiated) or chondrogenic (differentiated) medium for 21 days and performed loop-resolution *in situ* Hi-C on each cell population to obtain global 3D genome interaction profiles. We generated 8 replicate Hi-C libraries for each group and attained a total of 2 billion high-quality Hi-C contacts in each summed map. We do not observe dramatic changes following differentiation at the scale of topologically associated domains (TADs, median length = 175Kb in the control group, 170Kb in the differentiated group). However, we consistently observe a strengthening and reinforcement of loops throughout the genome in the differentiated cells. Using the Hi-C Computational Unbiased Peak Search (HiCCUPS) loop caller, we identified 10,020 and 13,145 loops in control and differentiated chondrocytes, respectively (median length = 300Kb and 305 Kb, respectively). To pinpoint cell stage-specific loops that may contribute to the regulation of the chondrogenesis, we performed a "diffHiCCUPS" differential loop analysis followed by manual curation of the identified DNA differential loops. We found 24 high-confidence control-specific and 146 high-confidence differentiation-specific loops. Currently, we are working on 1) elucidating the structural proteins that shape the chromatin during chondrocyte differentiation and 2) associating the differential loops with potential skeletal phenotypes, especially those known to have noncoding regulatory elements. This study is the first genome-wide profile of unbiased 3D chromatin contacts in the skeletal system. Additionally, this study will increase the understanding of how these interactions contribute to skeletal dysplasia pathogenesis as well as help to advance diagnosis and identify novel therapeutic strategies.

**Background** Leprosy type-1 reactions (T1Rs) are a major contributor to nerve damage and disability in leprosy patients. Early recognition of patients with T1R is a key element in efforts to prevent nerve damage in leprosy but useful biomarkers for advanced diagnosis are lacking. In the present study, we asked if the transcript isoform response of whole blood to *Mycobacterium leprae* antigens could be used as biomarker to identify patients that are at increased risk of developing T1R. **Methods** Whole blood aliquots at times of diagnosis from 41 leprosy patients were stimulated for 26 hrs with PBS or PBS + *M. leprae* sonicate. Of these patients 10 developed T1R over a 3-year follow-up. Stranded 75-bp paired-end reads were aligned, transcript quantification was performed with RSEM-v1.3.0, differential isoform expression test with limma and differential isoform usage analysis with DRIMSeq-v1.6.0. Gene ontology (GO) analysis, was carried out with PANTHER-13.1. **Results** For T1R-free subjects we identified 5,378 up and 1,286 down-regulated isoforms while for T1R-destined group 4,512 isoforms were up and 952 down-regulated. Groups had high overlap of differentially expressed (DE) isoforms, both at the gene and isoform levels and with respect to fold change direction, which yielded no DEI between groups. GO testing for up-regulated isoforms implicated GO terms representing processes such as phagocytosis, antigen processing, presenting and clearing of bacterial antigens. Due to the strong overlap in DE isoforms between both groups, no significant GO term was found specifically for either group. For DIU analysis we identified 15,565 isoforms being differentially used (DU). Intriguingly only a fraction of isoforms (T1R-destined: 1,509, T1R-free: 1,638) had differences in proportion changes above 10% when contrasted with baseline conditions. Genes with isoform usage difference above 10% also presented a strong overlap between tested groups, however 36 isoforms (20 genes) were significant after testing for interaction with 9 genes presenting a prevalent isoform switch. GO analysis failed to detect significant terms for any DU isoforms lists, however inspection of non-significant GO terms revealed that they were subsets of gene ontology identified for DE isoforms. **Conclusion** Our work failed to detect whole blood RNA isoforms that could serve as predictive biomarkers for increased T1R risk.

**383T**

**TREM2 expression differs by cell type and genetic content.** *R. Akhter<sup>1</sup>, Y. Shao<sup>1</sup>, E. Dyne<sup>2</sup>, M. Khrestian<sup>1</sup>, G. D'Aleo<sup>1</sup>, S. Formica<sup>1</sup>, J. Leverenz<sup>2</sup>, L. Bekris<sup>1</sup>.* 1) Cleveland Clinic Lerner Research Institute, Cleveland, OH; 2) School of Biomedical Sciences, Kent State University, Kent, Ohio; 3) Cleveland Clinic Lou Ruvo Center for Brain Health, Cleveland Clinic, Cleveland, Ohio.

Genetic variation in triggering receptor expressed on myeloid cells 2 (TREM2) is associated with Alzheimer's disease (AD) and plays a role in neuroinflammation in AD mouse models. In the human brain, TREM2 mRNA is differentially expressed in multiple brain regions and human cell types. Little is known about how the expression of TREM2 is differentially regulated. In this study it was hypothesized that trans-acting factors present in certain cell types modulate TREM2 regulatory element activity. Therefore, TREM2 protein levels, cleaved soluble TREM2 (sTREM2), or TREM2 promoter activity will differ according to tissue or cell type. The objectives were to demonstrate that: 1) Cerebrospinal fluid (CSF) and plasma sTREM2 levels are elevated in AD. 2) Cell line, hippocampus and cerebellum TREM2 protein expression varies by tissue type. 3) Genetic variants in the *TREM2* promoter and the 3' UTR influence expression in certain human cell lines. Human DNA, plasma and CSF samples were obtained from the Cleveland Clinic Center for Brain Health Aging and Neurodegeneration Biobank. Post-mortem brain samples were obtained from the University of Washington Alzheimer's Disease Research Center. CSF and plasma sTREM2 were evaluated using a custom capture sandwich immunoassay. Brain TREM2 was analyzed by Western blot. PCR amplification of genomic DNA was performed using TREM2 primers located outside of the promoter or 3'UTR region. TREM2 PCR products were cloned into a Luciferase reporter constructs. A transient transfection using these reporter constructs were performed in human cell lines. CSF sTREM2, but not plasma, levels were marginally higher in carriers of the AD GWAS rs7748513 risk allele suggesting that TREM2 genetic variation might influence gene expression depending on tissue type. Post-mortem brain and multiple human cell lines also showed differential expression by tissue or cell type. TREM2 promoter + 3'UTR reporter levels showed differential expression depending on genetic content of the promoter in human neuronal SHSY5Y cell lines. TREM2 promoter reporter inhibition in the presence of the TREM2 3'UTR was cell type specific. This inhibition was lost in the presence of genetic variants located in the TREM2 promoter region suggesting that SHSY5Y cells contain inhibitory factors that target this region. This finding is important because it will allow us to identify factors that regulate TREM2 expression and therefore potentially modulate neuroinflammation in AD.

Due to high levels of heterogeneity, furthering the understanding of the genetic basis of Autism Spectrum Disorder (ASD) requires detailed characterisation of both genetic and phenotypic data from individuals across the clinical range of the disorder. The Autism Speaks MSSNG resource is a database of whole genome sequencing and phenotypic data for individuals from families affected with ASD. All data are available to ASD researchers via an open (but controlled) data access process and can be accessed in a cloud-based environment or through a web-based portal. Currently there are 7,231 samples available, all sequenced at high depth on Illumina platforms or by Complete Genomics. A further 1,710 in the process of being sequenced with a total of 10,000 sequenced samples anticipated by the end of 2018. From our earlier analysis, 61 genes were implicated as contributing to ASD risk based on *de novo* or X chromosome single nucleotide variants (SNVs) and small indels, with 18 of these genes identified for the first time from the MSSNG data. Subsequently, we have focused on the identification and characterisation of copy number variants (CNVs) and structural variants (SVs). We have detected CNVs >1 kb in size using our established pipeline combining ERDS and CNVnator, or from Complete Genomics data, and we are now adding SVs detected using algorithms Manta, LUMPY and DELLY. Of the 3,427 affected subjects currently available, 6.6% carry an ASD-risk rare CNV, falling into one of four categories: chromosome abnormalities (0.8%), large CNVs >3Mb (0.9%), CNVs corresponding to known genomic disorders (3%) and deletions at known ASD-susceptibility genes or loci (1.9%). A further 1.7% of subjects have rare duplications impacting ASD-risk genes, and we are combining CNV and SV data to resolve the structure of these duplications to facilitate their interpretation. Of 36 of these variants for which the structure has been analysed, 28 are tandem duplications and 8 are more complex in nature, including inversions, translocations and others with deletions or triplications embedded within the duplication. We are also analysing all SV data to include small CNVs (<1 kb), insertions and balanced rearrangements. Additional updates expected for the MSSNG resource include improved phenotype querying capabilities, re-analysis of data with hg38, inclusion of epigenetic data and availability of induced pluripotent stem cell lines from selected subjects.

Church<sup>1</sup>. 1) 10x Genomics, Pleasanton, CA; 2) The Institute of Cancer Research, Division of Genetics & Epidemiology, London, UK; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA.

Traditional Short-read approaches struggle to access repetitive regions of the genome and fail to resolve the human genome into its component haplotypes. We describe an approach that identifies a more complete spectrum of genomic variation by retaining long range information while harnessing the power and cost-effectiveness of short-reads. From ~1ng of DNA, we produce barcoded short-read libraries in partition. Novel informatic approaches allow for the barcoded short-reads to be associated with their original long molecules producing a new datatype known as 'Linked-Reads'. Linked-Read whole genome sequencing (lrWGS) expands the amount of the genome that can be accessed and analyzed. We prepared 14 libraries for 3 individuals derived from the 1000 Genomes sample set and assessed high quality exonic mapping for each replicate. Using lrWGS enabled significantly more high-quality read coverage at coding regions ( $\geq 5$  x coverage; MAPQ  $\geq 30$ ) than PCR-Free TruSeq. On average, lrWGS also provided an additional 38Mb of high-quality total bases containing medically relevant genes such as *SMN1*, *STRC*, and *NAIP*. The same trend of increased high-quality coverage is evident between Linked-Read Whole Exome (lrWES) preparations vs. traditional short-read whole exome preparations. lrWGS and lrWES provide the ability to reconstruct long haplotypes over the vast majority of the human genome which is essential to improved variant calling and interpretation. In five samples with known clinically-relevant compound heterozygous variants we were able to call all the known variants, phase them with respect to each other, and demonstrate that they are present in trans by 60x lrWES without the need for parental information. Being able to do long range haplotype reconstruction is also important for the identification of exon scale duplications or deletions. We show the advantage of this approach in notoriously difficult regions such as, *PMS2*, *BRCA1*, and *BRCA2* wherein all known small dups/dels that were phased were also called without the need for ultra-deep sequencing or known normal reference panels, when we could reconstruct haplotypes. The data presented here show that Linked-Reads provide a scalable approach or comprehensive genome analysis that is not possible using short-reads alone. We demonstrate the ability of both lrWGS and lrWES to accurately call small variation, to phase and call clinically-relevant variation, and to detect single exon deletions and single exon duplications.

**386T****Analysis of rare coding variants in ALS *C9orf72* hexanucleotide repeat expansion carriers.** A. Chubick<sup>1</sup>, A.P.S. Ori<sup>2</sup>, T. Wu<sup>2</sup>, R.H. Baloh<sup>3,4</sup>, C.

Lomen-Hoerth<sup>5</sup>, M. Wiedau<sup>6</sup>, N. Zaitlen<sup>7</sup>, L.M. Olde Loohuis<sup>2</sup>, R.A. Ophoff<sup>1,2</sup>. 1) Department of Human Genetics, University of California Los Angeles, Los Angeles, CA; 2) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA; 3) Department of Biomedical Science, Cedars-Sinai Medical Center, Los Angeles, CA; 4) Department of Neurology, Cedar-Sinai Medical Center, Los Angeles, CA; 5) Department of Neurology, University of California San Francisco, San Francisco, CA; 6) Department of Neurology, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA; 7) Department of Medicine, University of California San Francisco, San Francisco, CA.

Amyotrophic lateral sclerosis (ALS) is a late-onset neurodegenerative disease that primarily affects motor neurons and often results in death from respiratory failure 2-5 years after diagnosis. The hexanucleotide repeat expansion (HRE) in chromosome 9 open reading frame 72 (*C9orf72*) is the most common genetic cause of ALS, present in roughly 6% of patients with no obvious genetically inherited component and explains one-third of all patients with a positive family history of the disease. Since an oligogenic basis of ALS has been reported, we hypothesized that this may also be the case for ALS patients with the *C9orf72* HRE. We therefore performed a whole exome sequencing (WES) burden analysis in  $n=96$  of these patients and examined enrichment of rare damaging protein-coding variants in different gene sets: (i) known ALS genes ( $n=30$ ), (ii) DNA helicase genes as precursors for sporadic development of the HRE ( $n=30$ ), (iii) differentially expressed genes in motor neurons of ALS patients ( $n=220$ ), (iv) ALS implicated genes identified by GWAS ( $n=387$ ), and (v) loss-of-function (LoF) intolerant genes ( $n=3230$ ). We used the non-Finnish European population of the Exome Aggregation Consortium (NFE ExAC;  $N_{\text{subject}}=33,370$ ) as controls. To compare against NFE ExAC, variants in protein-coding regions were filtered by allele frequency ( $AF < 0.01$  and  $NFE\_ExAC\_AF < 0.001$ ), variant type (variants predicted to be damaging by Polyphen2) and normalized by the number of non-damaging protein-coding variants. We observed no evidence for enrichment or depletion of rare damaging protein-coding variants in any of the ALS-linked gene sets, providing no further evidence for an oligogenic inheritance of ALS among *C9orf72* HRE carriers. Significance was calculated using 1,000 permutations, which randomly selected genes for each gene set to generate the distribution of rare damaging protein-coding variants in cases compared to NFE ExAC. Interestingly, we did observe a significant depletion of rare damaging protein-coding variants in the LoF intolerant gene set in cases compared to NFE ExAC (permutation 1,000 times;  $P = 0.001$ ). However, we observe a similar depletion in another WES data set of ALS patients without the *C9orf72* HRE ( $n=60$ ), suggesting that this result may be due to a technical artifact. While the aim of our study was to learn more about the genetic architecture of ALS patients with the *C9orf72* HRE, it also demonstrates both the potential and challenge of utilizing ExAC as a control.

**Chemical chaperone screening for Pelizaeus-Merzbacher disease.** *T. Kouga*<sup>1</sup>, *S. Koizume*<sup>2</sup>, *E. Jimbo*<sup>1</sup>, *T. Yamagata*<sup>1</sup>, *K. Inoue*<sup>2</sup>, *H. Osaka*<sup>1</sup>. 1) Pediatrics, Jichi Medical University, Tochigi, Japan; 2) Kanagawa Prefectural Cancer Center, Yokohama, Japan; 3) National Center of Neurology and Psychiatry, Kodaira, Japan.

**Background and Objective:** Pelizaeus-Merzbacher disease (PMD) is caused by the mutation or overexpression of proteolipid protein 1 (PLP1). PLP1 is abundantly expressed in mature oligodendrocytes and located mainly in the cell membrane. When PLP1 is mutated due to an amino acid substitution, the protein is unable to fold properly and is subsequently degraded, resulting in a failure to localize. The objective of this study was to screen the drug for PMD from change of the amount of protein level and intracellular localization. **Methods:** Among the various substitutions of PLP1, we selected PLP1<sup>A242V</sup> because of the marked difference in the amount and intracellular localization of this protein compared with the wild-type protein and the availability of naturally occurring mutant mice. We established a stable cell line expressing PLP1<sup>A242V</sup> fused with turbo GFP (tGFP) in MO3.13 cells, which are derived from oligodendrocytes. As the first screening, we analyzed the whole-cell intensity of PLP1<sup>A242V</sup> after adding chemical libraries using an In Cell Analyzer® (GE Healthcare UK, Ltd., England) and selected agents that showed a tGFP intensity more than 1.5 times that of the control. As the second screening, we analyzed the cell membrane intensity of PLP1<sup>A242V</sup> by images taken using a confocal microscope and selected the agents that significantly increased the tGFP intensity at the cell membrane compared with the control. Finally, we analyzed the change in the endoplasmic reticulum (ER) stress response of XBP1 based on the luciferase activity and the change in the gene expression using a micro array analysis after adding candidate chemicals. **Results:** After the first screening, nine agents were selected from a triplicate analysis. After the second screening, two agents significantly increased the tGFP intensity at the cell membrane compared with the control. In addition, both reduced the ER stress response. We then showed that one chemical reversed the gene expression changes by PLP1<sup>A242V</sup> in a micro array analysis. **Conclusion:** We successfully identified a chemical that increase the protein level and proper localization of PLP1. This chemical is a promising candidate, as it normalizes the gene expression pattern and decreases the ER stress response. .

**High-throughput repeat expansion sequencing on PromethION: An ABCA7 VNTR case study.** *A. De Roeck*<sup>1,2</sup>, *W. De Coster*<sup>1,2</sup>, *T. De Pooter*<sup>3</sup>, *S. D'Hert*<sup>3</sup>, *J. Van Dongen*<sup>1,2</sup>, *M. Strazisar*<sup>3</sup>, *C. Van Broeckhoven*<sup>1,2</sup>, *K. Sleegers*<sup>1,2</sup>. 1) Neurodegenerative Brain Diseases group, Center for Molecular Neurology, VIB - University of Antwerp, Antwerp, Belgium; 2) Institute Born-Bunge, University of Antwerp, Antwerp, Belgium; 3) Neuromics Support Facility, Center for Molecular Neurology, VIB - University of Antwerp, Antwerp, Belgium.

Tandem repeats (TRs) can cause disease through the number of repetitions, genetic variants in the TR units, and nucleotide modifications. For many TRs, however, these features are very difficult - if not impossible - to assess, and require low-throughput and labor intensive assays. One example is a VNTR in *ABCA7*. We recently discovered that expanded *ABCA7* VNTR alleles strongly increase risk of Alzheimer's disease. Currently, this GC-rich TR can only be studied through Southern blotting, which hampers further molecular characterization and clinical applications. Here, we investigated the potential of long-read whole genome sequencing to overcome these challenges, using the high-throughput Oxford Nanopore Technologies PromethION platform. We optimized wet-lab and bioinformatic protocols, and we developed an algorithm to study the size, sequence, and nucleotide modifications of TRs. Since the release of PromethION in early 2018, we were able to sequence eleven human genomes originating from dementia patients and healthy elderly controls. All individuals were Southern blotted for the *ABCA7* VNTR, with VNTR allele sizes ranging from 1kb to 10kb. We obtained an average output of 71 gigabases (Gb) per flowcell, and a maximum yield of 98 Gb (30 X genome coverage; at this time the highest reported yield in the field). *Albacore*, *Guppy*, and *Scrappie events* basecallers were capable of processing all VNTR alleles. The VNTR strand (either cytosine-rich or guanine-rich) affected the estimated TR length, but when corrected for this bias, estimates were comparable to Southern blotting. *Scrappie raw* produced the most accurate sequence and length estimates, but failed to detect expanded VNTR alleles. The available tools, however, could not be used to detect differences between TR units due to a high basecalling error rate, strand bias, and the need for non-trivial TR reference genomes. To circumvent these issues and enable the analysis of (modified) nucleotide composition, we developed a novel algorithm based on dynamic time warping to identify and classify repetitive patterns in raw PromethION sequencing data. Each *ABCA7* VNTR allele presented a unique combination of alternative TR units, which was confirmed by multiple sequencing reads per allele. In this study, we demonstrate the feasibility of long-read human genome sequencing on PromethION, and subsequent in depth analysis of the *ABCA7* VNTR. We hope that this work will lead to high-throughput whole genome analysis of TRs.

**389T****Targeted enrichment and long-read sequencing to genotype medically-relevant genes that cannot be assayed using short-read technologies.**

A. Wallace<sup>1</sup>, K. Varley<sup>2</sup>, S. Gibson<sup>3</sup>, J. Schiffman<sup>4</sup>, A. Quinlan<sup>1</sup>. 1) Department of Human Genetics, School of Medicine, University of Utah, Salt Lake City, UT; 2) Department of Oncological Sciences, Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 3) Department of Neurology, School of Medicine, University of Utah, Salt Lake City, UT; 4) Department of Pediatrics, Huntsman Cancer Institute, University of Utah, Salt Lake City, UT.

While repeat-expansion polymorphisms are known to underlie several developmental and neurological disorders, technological limitations have inhibited the ability to resolve accurate genotypes for these variants. A pertinent example is the (CCCCGG)<sub>n</sub> repeat expansion in *C9orf72* that segregates with up to 40% of familial amyotrophic lateral sclerosis (ALS) cases. There is a clear relationship between this repeat expansion and neurodegeneration. However, widely-used short-read sequencing is ill-suited to characterize the *C9orf72* repeat expansion due to polymerase slippage over low complexity sequences and the inherently limited mapping/haplotype resolution of redundant short sequences. Consequently, researchers and physicians must rely on crude variant characterization methods (e.g. Southern blots), which limit direct genotype-phenotype associations and create challenges for the diagnosis of disease in patients with atypical clinical presentation. In contrast, ultra-long (e.g., 10-150kb) sequencing reads generated by Oxford Nanopore Technologies (ONT) enable direct measurement of loci containing complex structures without being subject to amplification or alignment bias. We are therefore developing a molecular and computational framework for targeted sequencing and quantification of pathogenic repeat expansions by combining cas9 and amplification-free sequence capture methods with Nanopore long-read sequencing technology. First, extracted high molecular weight DNA is digested with cas9 nickase and exonuclease resistant adapters are ligated to the resulting sticky ends. Non-target DNA is degraded and the remaining sample is sequenced using the ONT MinION sequencer. Then, base-called reads are aligned to the target locus and phased into haplotypes by the presence of flanking heterozygous variants. Haplotype-specific repeat counts are then estimated using Tandem Repeat Finder software. We will present our application of this molecular and computational framework to 30 ALS patients with *C9orf72* repeat expansions to demonstrate its generalizability as a new genomic medicine diagnostic that is faster, cheaper, and more accurate than currently available tests. This rapid, adaptable method can be used illuminate other structurally complex "blind spots" in the human genome, which include over 600 genes, >30 of which have known clinical relevance, and perhaps more intriguingly and generally, regions of the genome that remain unstudied as sources of disease heritability.

**390F****The 15q11.2 BP1–BP2 microduplications are enriched in patients with anorexia nervosa.**

X. Chang, H. Qu, Y. Liu, J. Glessner, P. Sleiman, H. Hakonarson. Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Anorexia nervosa (AN) is a complex psychiatric disorder with significant morbidity and mortality. Multiple lines of evidence suggest a strong genetic component in susceptibility to AN. For example, family studies indicated that first-degree relatives of patients with AN have an increased risk of the disease. Twin studies have estimated the heritability of AN at 50-60%. Recent genome-wide association studies (GWAS) also identified a significant locus of AN at 12q13.3. Given the critical role of copy number variations (CNV) in psychiatric disorders, we conducted a genome-wide CNV study of 1033 AN cases and 7529 controls. In addition to the previously detected 1.5 Mbp deletion at 13q12, we uncovered that the 15q11.2 BP1–BP2 microduplications are enriched in individuals with AN (AN cases: 1.26% (13/1033); Controls: 0.32% (24/7529); Fisher's Exact Test *P*-value = 0.00023). There are five breakpoints BP1–BP5 located in the proximal long arm of chromosome 15, which mediate multiple pathogenic deletions and duplications via non-allelic homologous recombination, such as Prader-Willi syndrome and Angelman syndrome (BP1–BP3 or BP2–BP3). The BP1–BP2 region spans approximately 500 kb and contains four evolutionarily conserved genes (*NIPA1*, *NIPA2*, *CYFIP1*, and *TUBGCP5*). Both BP1–BP2 deletions and duplications are emerging as a recognized syndrome. Affected individuals have been reported with developmental, motor, and speech delays, and neurological and/or behavioral issues, specifically autism, autistic spectrum disorder and attention deficit hyperactivity disorder. Taken together, our results suggest that the 15q11.2 BP1–BP2 microduplications may confer risk to the development of AN.

**391W****Characterization of obesity in individuals with 16p11.2 deletions using electronic health record derived phenotypes in the DiscovEHR cohort.**

A.E. Hare-Harris<sup>1,2</sup>, S.M. Myers<sup>2</sup>, K.P. Flannery<sup>1</sup>, K.J. Haddock<sup>2</sup>, A.L. Morehouse<sup>1</sup>, E. Maxwell<sup>1</sup>, L. Habegger<sup>3</sup>, J. Overton<sup>3</sup>, J. Reid<sup>3</sup>, D.H. Ledbetter<sup>2</sup>, C.L. Martin<sup>2</sup>. 1) Biological and Allied Health Sciences, Bloomsburg University, Bloomsburg, PA; 2) Autism & Developmental Medicine Institute, Geisinger Health System, Lewisburg, PA; 3) Regeneron Genetics Center, Tarrytown, NY.

Deletions of 16p11.2 BP4-5 (16pdel) are associated with neurodevelopmental and psychiatric disorders (NPD), including depression and anxiety. In addition to NPD, obesity that begins in adolescence and persists into adulthood has also been observed in these individuals. Although many studies have characterized the NPD phenotype associated with 16pdel, few have focused on the obesity phenotype, particularly in adult cohorts. In this study, we used a genotype-first approach to identify 35 individuals with a 16pdel (mean age = 48 years) from ~60,000 patient-participants in the Geisinger-Regeneron Genetics Center (RGC) DiscovEHR project, which includes exome and electronic health record (EHR) data. We used EHR-derived phenotypes to assess the prevalence of NPD and obesity in these individuals. NPD diagnoses were more common in the 16pdel group (57%) than in those without a pathogenic recurrent CNV (NoCNV) (48%). Mean body mass index (BMI) among the 16pdel group was 51.3 (range 27.3-85.8), and was also greater than the mean BMI of 35.8 in the NoCNV group (n=48,064; p<.001). We investigated whether this increased BMI could be influenced by increased use of weight gain-associated psychotropic medications (WGP). We assessed the relationship between BMI and WGP in the 16pdel and NoCNV groups. Overall, 66% of the 16pdel group and 63% of the NoCNV group had 1+ EHR-documented WGP. Despite the increased NPD prevalence, the 16pdel group did not have a higher number of WGP (5.9 vs. 6.0) or longer duration of WGP use (36.1 vs. 32.7 months) than the NoCNV group (p=ns). A greater number of WGP and duration of WGP use were predictive of higher BMI in the NoCNV group (p<.001) but not in the 16pdel group (p=ns). We next compared the 16pdel group to individuals with other recurrent pathogenic CNVs associated with NPD (CNV; n=315). The 16pdel group had higher mean BMI than the other CNV group (38.2; p<.001), but the prevalence of NPD diagnoses was the same in both groups (57%; p=ns). Overall, the 16pdel group had fewer WGP than the CNV group (5.9 vs. 15.8; p<.001). Unlike the 16pdel group, CNV individuals with at least one WGP (55%) had higher BMIs than those without a WGP (36.5 vs. 39.6; p=0.015). We observed similar results when considering non-psychotropic medications that may cause weight gain as a side effect. These findings suggest that the biological effects of the 16pdel have a greater influence on the increase in BMI observed in these individuals than the effect of WGP.

**392T****Non-coding structural variation in whole genome sequencing data impacts attention-deficit hyperactivity disorder (ADHD) and reveals population differences between African American and Caucasian ADHD Children.**

Y. Liu<sup>1</sup>, X. Chang<sup>1</sup>, J. Glessner<sup>1</sup>, L. Tian<sup>1</sup>, Y. Guo<sup>1</sup>, D. Li<sup>1</sup>, H. Qiu<sup>1</sup>, K. Nguyen<sup>1</sup>, H. Hakonarson<sup>1,2,3</sup>, P. Sleiman<sup>1,3</sup>. 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Division of Human Genetics, Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Attention-deficit hyperactivity disorder (ADHD) is a common, highly heritable syndrome with a poorly understood molecular mechanism. Previous studies have suggested that structural variants play an important role in ADHD but these were mainly focused on coding regions and in populations of European ancestry. In this study, we generated deep (>30x) whole genome sequencing data on 205 ADHD cases, including 116 African Americans (AA) and 89 Americans of European ancestry (CEU) and 506 matched controls. Structural variants (SVs) were called from the WGS data in all subjects using MANTA. SVs were classified as coding or non-coding if they encompassed exonic or intronic/intergenic regions respectively. We tested for enrichment of both classes of SVs in ADHD vs controls in AAs and CEU and subsequently determined if the impacted genes were overrepresented for pathways or gene ontology terms. Coding SVs showed a marginal enrichment in ADHD cases compared to controls (adjusted p value = 0.012). Whereas, non-coding SVs were significantly enriched in ADHD, impacting genes involved in neuronal functions, including nervous system development (p 1.1x10<sup>-11</sup>) neuroactive ligand-receptor interaction (p 1.9x10<sup>-5</sup>), axon guidance (p 1.4x10<sup>-3</sup>) and the glutamatergic synapse (p 0.047). Comparing SVs between ancestries showed no significant differences in the distribution of coding SVs between AA and CEU. However, we observed significant differences in non-coding SVs impacting the same ADHD associated pathways. Taken together, these results suggest that non-coding SVs may play important roles in ADHD and that genomic structural differences exist between AA and CEU ADHD cases. We conclude that WGS is a powerful discovery tool for studying the molecular mechanisms of ADHD and associated drug targets.

**Modeling regional rates of structural mutation and selection in the human genome.** *P. Tandon, O. Shanta, D. Antaki, M. Kleiber, O. Hong, J. Sebat.* University of California, San Diego, San Diego, CA.

Genome rearrangement is a driving force in human evolution and a contributor to complex traits and disease. Structural variants (SVs), which include deletions and duplications, exhibit significant clustering in the genome, reflecting regional differences in mutation rate and natural selection. However, factors that shape patterns of SV mutation are poorly understood. We developed a model to predict SV mutation rates based on DNA sequence features. We then applied our SV mutation model to population genetic data to identify functional elements that are under significant selection. The SV mutation model was developed using the phase-3 SV call set of the 1000 genomes project. We first determined the correlation of genetic features (including GC content and repetitive elements) with the frequency of SV breakpoints. A regression model was constructed to determine the major effects driving frequencies of multiple classes of SVs measured in windows of various scale (1KB-1MB bp). We then used the model to predict SV mutation probabilities throughout the genome. The model was validated via demonstration of similar mutation patterns on multiple cohorts including an independent sample of 49,604 deletions and 5,619 duplications from our genetic studies of autism (PMID:29674594). Our model has better statistical fit (deletion  $r$ -squared=0.15, duplication  $r$ -squared=0.08) compared to previous efforts (deletion  $r$ -squared=0.09, duplication  $r$ -squared=0.02) due to the inclusion of a greater variety of DNA features and modeling of effects at multiple scales. At scales of 1 KB and 100 KB, estimated regional mutation rates varied from the mean by up to 9-fold and 3-fold respectively. Patterns differ by SV length. Major drivers of smaller (<10KB) SVs include short interspersed nuclear elements (SINEs) and short tandem repeats (STRs). Larger SVs (>100KB) are driven by segmental duplications and long terminal repeats (LTRs). Mutation rates of small SVs are negatively correlated with evolutionary conservation, but trends can vary based on SV length, suggesting that genes and other functional elements are predisposed to large scale rearrangements. We demonstrate that promoters and enhancers that are ubiquitously expressed in tissues from the Epigenome Roadmap Project are under significant functional constraint. Our results provide a more detailed view of SV mutation rates and help to delineate categories of non-coding functional elements that are under strong selection.

**Detecting inversion polymorphisms at population scale with linked read sequencing.** *C.W. Whelan<sup>1,2,3</sup>, R.E. Handsaker<sup>1,2,3</sup>, S.A. Gagliano<sup>5</sup>, L.J. Scott<sup>6</sup>, O.V. Evgrafov<sup>6</sup>, C. Armoskus<sup>6</sup>, J.A. Knowles<sup>6</sup>, M. Cippichio<sup>4</sup>, S. Gabriel<sup>4</sup>, M. Boehnke<sup>5</sup>, M.T. Pato<sup>6</sup>, C.N. Pato<sup>6</sup>, S.A. McCarrroll<sup>1,2,3</sup>.* *The InPSYght Consortium.* 1) Stanley Center for Psychiatric Research, Broad Institute, Cambridge, MA; 2) Medical and Population Genetics Program, Broad Institute, Cambridge, MA; 3) Department of Genetics, Harvard Medical School, Boston, MA; 4) Genomics Platform, Broad Institute, Cambridge MA; 5) School of Public Health, University of Michigan, Ann Arbor, MI; 6) SUNY Downstate Medical Center College of Medicine, Brooklyn, NY.

Inversions of genomic segments have been one of the most difficult forms of genetic variation to detect accurately: alignment errors, non-inversion sequence variation, and inverted duplications often present the same signatures in short-read sequencing data as real inversion alleles, resulting in high false discovery rates. Long-read sequencing or optical mapping technologies better detect inversions, but their cost has made it difficult to survey variation beyond a few individuals. Linked-read sequencing technology – in which droplet-based barcoding of DNA sequences from the same high-molecular weight molecules allows reads from the same genomic segment to be analyzed together – has the potential to enable analysis at the scale of cohorts and populations. Here we present an analysis of segmental inversions in a schizophrenia case/control cohort of 545 individuals sequenced with the 10x Genomics Chromium linked-read technology. Our analysis cohort includes similar numbers of African-American and European-ancestry samples, allowing for the study of variant frequency in more than one ancestral background. After manually curating preliminary calls produced by the Long Ranger analysis software from 10x Genomics, we identified 40 high-confidence inversion variants (30-500 kilobases in length), of which 6 were flanked by large deletions or other inversions and the rest had simpler architectures. We observed a range of allele frequencies: from 11 singletons to 5 events visible in nearly every sample. The latter represent likely errors in the reference assembly. 14 of the variants disrupted annotated transcripts. 7 of the more common variants exhibited significant differences in allele frequency between African-American and European-ancestry subcohorts. We discuss the challenges of identifying inversions from linked-read data and provide comparisons of published computational methods including GROC-SVs (Spies et al., 2017) and NAIBR (Elyanow et al., 2018), as well as our own algorithms under development, on benchmark samples and several samples with technical replicates. Discovering structural variants with linked-read sequencing, and using the long-range phasing information the technology provides to impute their presence into larger cohorts for which only short-read or SNP array data are available, can enable the study of additional classes of segregating genomic variation at population scale.

In the pre- and postnatal period, structural variations (SVs) such as supernumerary chromosomal markers (sSMCs), apparently balanced translocations and inversions *de novo* are evidenced by karyotype. The presence of these SVs raises, especially during pregnancy, a difficult issue of prognosis due to the risk of intellectual disability. The advent of new technologies such as Whole Genome Sequencing (WGS) makes it possible to consider the detection and characterization of SVs. The goal is to use the WGS to identify and characterize SVs, and secondarily to improve our pipeline. A WGS was performed in 19 patients with *de novo* SVs found in postnatal for 11 patients and in prenatal for 8 patients. Bioinformatic analysis of the raw data was performed with Lumpy algorithms for translocations and inversions and ControlFreeC for CNVs. The analyzes show that 7/8 translocations are identified, one of which interrupts the *GRIN2B* gene at the breakpoint compatible with the phenotype of the patient. Undetected translocation involves pericentromeric breakpoints. The 7 complex chromosomal rearrangements are identified with, sometimes, the discovery of more than 10 breakpoints, in favor of a chromothripsis type mechanism. Of the 4 sSMCs, 2 with euchromatin are detected by WGS and 2 with heterochromatin are not detected. The use of the WGS is therefore particularly effective in characterizing the breakpoints of the SVs (16/19) in both prenatal and postnatal period. The project allowed us to identify SVs and improve our WGS pipeline.

**A multi-genic model accounts for the pathogenicity of variably expressive CNVs.** M. Jensen<sup>1</sup>, S. Girirajan<sup>1,2</sup>. 1) Bioinformatics and Genomics Program, Pennsylvania State University, University Park, PA; 2) Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA.

Classical studies of pathogenic copy-number variants (CNVs) have relied on atypical deletions and translocations for identifying specific causative genes in CNV syndromes, such as *RAI1* in Smith-Magenis syndrome and *NSD1* in Sotos syndrome. A lack of genomic events to delineate critical intervals for causative genes and variable expressivity of phenotypes in another class of CNVs, including duplications and deletions at chromosomes 1q21, 15q11.2, and 16p11.2, have made causative gene discovery challenging. Here, we analyzed genomic and phenotypic data from 37,625 individuals with neurodevelopmental disorders and functional data on 402 genes in four model organisms to identify causative genes within 18 disease-associated CNVs. We first analyzed microarray and clinical data of 28,499 affected individuals, and found that each CNV contributed to a range of 18 neurodevelopmental phenotypes at varying degrees of penetrance (average of 29%) and expressivity. We next searched for causative genes in these CNV regions by comparing exome sequencing data of 9,126 affected individuals in three separate cohorts to unaffected individuals. Although these cohorts were well-powered (>0.8) to detect an enrichment of mutations in individual genes, we found that none of the 113 genes in these CNV regions were enriched for rare pathogenic mutations among affected individuals (FDR>0.05), even though 26% (29/113) of the CNV genes were highly intolerant to variation (RVIS <20<sup>th</sup> percentile). We further examined the functional effects of each CNV gene by systematically analyzing 27 categories of phenotypes from mouse, zebrafish, *Xenopus* and *Drosophila* models curated from model organism databases, and found that 65% (73/113) of the CNV genes presented neurodevelopmental phenotypes in at least one model organism. In fact, CNV genes were enriched for developmental phenotypes as well as for genes under evolutionary constraint (RVIS<20<sup>th</sup> percentile or pLI >0.9) compared to the entire genome (p<0.05). Additionally, animal models of individual CNV genes did not fully recapitulate the phenotypes of models for the entire CNV. Overall, our data show that a single causative gene model is not sufficient to account for the incomplete penetrance and variable expressivity of these CNVs. We instead propose a multi-genic model for CNV pathogenicity, where multiple causative genes within CNVs interact in an additive or synergistic manner and are in turn modulated by genes outside of the CNV region.

**Novel evidence of high resolution and high field diffusion mri reveal a primate LGN-LGN connection.** *J.R. Korenberg<sup>1</sup>, L. Dai<sup>1</sup>, D. Pritchett<sup>2</sup>, A. Van-Hoek<sup>2</sup>.* 1) Pediatrics, Medical Genetics, University of Utah, Salt Lake City, UT; 2) Neurology/Korenberg Research, University of Utah, Salt Lake City, UT.

Establishing a primate brain connectivity and linking it function and human diseases remain an elusive goal. Diffusion MRI, which quantifies the magnitude and anisotropy of water diffusion in brain tissues, offers unparalleled opportunity to link the macroconnectome to histological-based microconnectome at synaptic resolution, providing opportunity to confirm the known connection and propose novel connection. In this report, we show evidence using high resolution diffusion spectrum imaging (DSI) in primate brain to support the existence of a novel brain connection between the left and right lateral geniculate nucleus (LGN). We obtained high resolution diffusion MRI data on *ex vivo* brain from *Macaca fascicularis*: MRI 7T, resolution 0.5 mm isotropic, 515 diffusion volumes up to b-value (aka diffusion sensitivity) of 40,000 s/mm<sup>2</sup> with scan time ~100 hrs. Tractography results show direct connection between the left and right LGN. This finding is supported by previous functional and neuro-anatomic data. First, Gitlin and Lowenthal (1969), reviewing 150y of literature including and post Gudden, there is no evidence from either Gudden or others, for the existence of a commissure connecting the two medial geniculate (MGN) in humans or even rabbits. Rather, the "medial root of the optic tracts" likely is what has been seen connecting the optic chiasma-related to optic tract bulges that go to the ventral medial aspect of the LGN. Second, although a number of very well done papers referred to above, identify other tracts in the region, no reports find or confirm the predicted Commissure of Gudden. It is interesting that Dougherty's review (2018) set out the possible modulatory circuitry responsible for binocular modulation, in the LGN, something they refer to as "an apparent paradox", and note that this may be explained not only by their proposals but also "through mechanisms yet to be uncovered". We propose that simplest explanation for their data may be found in the multiple paths of evidence for the LGN-LGN connection supported by our new finding. In conclusion, by combining the previous data in literature and our new tractography results, we hypothesize that there is direct LGN-LGN connection, and this finding will provide a flush of new interest and funding for the field to identify the mechanisms, the molecules responsible, the embryo/fetogenesis and pruning, and the consequences for disease malfunction and correction.

**Genetic modulation of RNA splicing with a CRISPR-guided cytidine deaminase.** *X. Chang.* Shanghai Institute for Biological Sciences, Shanghai, Shanghai, China.

**RNA splicing is a critical mechanism to modify transcriptome, and its dysregulation is the underlying cause of many human diseases. It remains challenging, however, to genetically modulate a splicing event in its native context. Here, we demonstrate that a CRISPR-guided cytidine deaminase (*i.e.* Targeted-AID mediated mutagenesis (TAM)) can efficiently modulate various forms of mRNA splicing. By converting invariant guanines to adenines at either 5' or 3' splice sites (SS), TAM induces exon skipping, activation of alternative SS, switching between mutually exclusive exons or targeted intron retention. Conversely, TAM promotes downstream exon inclusion by mutating cytidines into thymines at the polypyrimidine tract. Applying this approach, we genetically restored the open reading frame and dystrophin function of a mutant *DMD* gene in patient-derived induced pluripotent stem cells (iPSCs). Thus, the CRISPR-guided cytidine deaminase provides a versatile genetic platform to modulate RNA splicing and intervene human diseases associated with aberrant splicing..**

**PAX6 deep intronic single nucleotide variants as a cause of congenital aniridia.** A.V. Marakhonov<sup>1,2</sup>, A.Yu. Filatova<sup>1</sup>, T.A. Vasilyeva<sup>1</sup>, R.A. Zinchenko<sup>1,3</sup>, M.Yu. Skoblov<sup>1,2</sup>. 1) Research Center for Medical Genetics, Moscow, Russian Federation; 2) Moscow Institute of Physics and Technology (State University), Dolgoprudny, Russian Federation; 3) Pirogov Russian National Research Medical University, Moscow, Russian Federation.

Aniridia is a rare autosomal dominant panocular disorder caused by either mutations in the *PAX6* gene or chromosomal 11p13 rearrangements. Molecular analysis (Sanger sequencing and MLPA) of a large cohort of aniridia patients from Russia (91 unrelated families) conducted earlier revealed a significant proportion of *PAX6* mutations affecting splicing (14 mutations including 5 deep intronic sequence variants). Five intronic SNVs located outside constitutive splicing site dinucleotides are chosen for functional analysis. DNA samples for analysis were obtained from patients with congenital aniridia, in which 5 SNVs near and at some distance from the canonical splice sites (4–14 nucleotides) were identified. Intronic SNVs pathogenic status was established according to ACMG/AMP recommendations for interpretation of sequence variants. Human Splicing Finder and IntSplice on-line tools predict them to disrupt *PAX6* pre-mRNA splicing. To determine the effects of each sequence variant on *PAX6* pre-mRNA splicing we used an *in vitro* minigene assay. To create minigene plasmids, three different genomic regions were amplified for cloning into splicing reporter vectors depending on the location of the investigated splice sites. Then, the constructs were transfected into HEK293T and A375 human cell line, and splicing products were identified with RT-PCR using plasmid-specific primers. *In vitro* analysis showed all five intronic variants located deeper than splicing site constitutive dinucleotides lead to alterations of splicing pattern: either exon skipping or exon elongation. These SNVs should result in open reading frame shifting, premature termination codon formation and subsequent aberrant mRNA degradation by nonsense-mediated decay. They produce a null allele and haploinsufficiency of the *PAX6* function. So investigated variants of unknown clinical significance were reclassified as loss-of-function mutations. Our results emphasized the necessity of functional analysis and advanced search for *PAX6* mutations. This work is supported by RFBR grant 17-04-00475.

**Microcephaly associated to 5pter deletion in patients with Cri du chat syndrome.** S.N. Chehimi<sup>1</sup>, E.A. Zanardo<sup>1</sup>, J.R.M. Ceroni<sup>1</sup>, F.A.R. Madia<sup>1</sup>, A.T. Dias<sup>1</sup>, L.L. Vieira<sup>1</sup>, G.M. Novo-Filho<sup>1</sup>, M.M. Montenegro<sup>1</sup>, A.M. Nascimento<sup>1</sup>, T.V.M.M. Costa<sup>1</sup>, Y.G. Oliveira<sup>1</sup>, A.F. Brasil<sup>1</sup>, J.G. Damasceno<sup>1</sup>, C.A. Kim<sup>2</sup>, L.D. Kulikowski<sup>1</sup>. 1) Departamento de Patologia, Faculdade de Medicina FMUSP, Sao Paulo, Brazil; 2) Unidade de Genetica, Departamento de Pediatria, Instituto da Crianca, Hospital das Clinicas HCFMUSP, Faculdade de Medicina, Universidade de Sao Paulo, Sao Paulo, SP, BR.

Deletions in the short arm of the chromosome 5 (5p-) result in a genetic disorder associated to a wide spectrum of phenotypic features that include high-pitched cry, developmental delay, hypertelorism, broad nasal bridge and microcephaly. The delineation of the chromosomal breakpoints that involve the 5p deleted region enable a more detailed recognition of the missed genomic content, allowing the selection of critical regions associated with the phenotype. Using Illumina Infinium CytoSNP-850K we evaluated 14 patients with previously detected deletions in 5p in order to investigate a region potentially associated with microcephaly. This experiment provided us copy number variation (CNV) regions in all the chromosomes, including chromosome 5. We were able to detect 5p terminal deletions in 13 patients, with the initial breakpoint in 25,328 basepairs (bp), and one patient with interstitial deletion starting in 4,788,892 bp. The patient with the interstitial deletion had p=10 for head circumference while the others had p<3. CNVs in other chromosomes were analyzed and these were found to have no phenotypic effects concerning to microcephaly. All the patients presented other phenotypic features unrelated to the presence of microcephaly. Since microcephaly is characterized by a head circumference below the third percentile, our results indicate that the region associated with the presence of microcephaly is narrowed to a 4,7 Mb region between 25,328 bp and 4,788,892 bp. That observation explains the absence of this specific features in the patient with interstitial deletion. Multiple critical regions have been reported for microcephaly in patients with 5p- syndrome but it was always implied with other features making it difficult to delineate a genomic region corresponding to this particular phenotype. The findings in this study highlights the importance of using cytogenomic techniques to detect regions that contribute to the phenotype and therefore provide personalized clinical care for these patients.

**Investigation of the altered gene expression in cases with trisomy 18.** *I. Albizua, M.J. Gambello, S.L. Sherman, S.T. Warren.* Human Genetics, Emory University School of Medicine, Atlanta, GA.

Trisomy 18, also called Edward syndrome, occurs in 1/6000 live births and is associated with significant morbidity and mortality. The extra copy of chromosome 18 causes the altered expression of many genes and leads to substantial brain, heart and kidney malformations as well as other medical problems. Due to the low rate of survival and the massive genetic imbalance (an extra copy of an entire chromosome representing 300-400 genes), very little research has been aimed at understanding the molecular consequences of trisomy 18. To fill this gap in knowledge, we have initiated a study to show that the extra copy of the chromosome 18 provokes genome wide expression dysregulation. Starting with fibroblasts samples from two live births with trisomy 18 and two age and sex matched controls, we used RNAseq (in triplicate) to examine genome-wide expression differences. As a first approach to data analysis, we have performed a mixed effects model with case/control status as the outcome and using sex and individual ID as co-variables. We adjusted for sex due to the observed higher loss of male fetuses that translates into a reduced male-to-female ratio at birth for trisomy 18. Our preliminary analysis has yielded promising results. We have identified genes as well as metabolic pathways significantly different between cases and controls. Among the most significant ones we find pathways involved in heart development and limb morphogenesis. For example, *TBX5*, a gene involved in heart development, had much lower expression levels in cases compared with controls. Altered expression of genes involved in limb development included *ALX3*, *ALX4*, *EN-1* and *FMN1*. Additionally, we found *PIEZO2* to be dysregulated, a gene known for its association with distal arthrogyriposis and a feature of trisomy 18. We are in the process of using qPCR to confirm these results obtained through RNAseq. Our preliminary results show, for the first time, candidate genes that begin to explain some of the phenotypes observed in Edward syndrome. Our planned studies will confirm our current results and further investigate the alterations in gene expression due to the extra chromosome 18.

**Integration of next-generation mapping and sequencing technologies for identification of pathogenic structural variants.** *E. Vilain<sup>1,2</sup>, S. Bhattacharya<sup>1</sup>, J. LoTempio<sup>1,3</sup>, M. Almalvez<sup>1</sup>, B. Dufault<sup>1</sup>, R. Wang<sup>4</sup>, E. Douine<sup>4</sup>, E. Délot<sup>1,2</sup>, S. Nelson<sup>4</sup>, H. Barseghyan<sup>1</sup>, UCLA UDN Clinical Site, Undiagnosed Diseases Network.* 1) Center for Genetic Medicine Research, Children's National Health System, Children's Research Institute, Washington, DC 20010, USA; 2) Genomics and Precision Medicine, George Washington University Washington, DC 20052, USA; 3) Institute for Biomedical Science, George Washington University Washington, DC 20052, USA; 4) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, California 90095, USA.

Next-generation sequencing (NGS) provides clinical diagnosis for ~30% of undiagnosed cases. However, due to innate methodological limitations, NGS fails to identify large structural variants (SVs), such as deletions, insertions, inversions, translocations and copy number variants, especially in repetitive regions of the genome. To overcome these limitations, we performed next-generation mapping (NGM), which captures a pattern of fluorescent labels in native-state, megabase-size DNA molecules in nanochannel array for de novo genome assembly and SV calling. We recently reported on NGM's clinical utility and capacity to identify large pathogenic SVs in a series of 10 Duchenne muscular dystrophy cases. We successfully identified all major SV types (deletions, insertions and balanced inversions) ranging from 13 kbp to 5.1 Mbp impacting the DMD locus. We have now performed NGM on an additional 100 patient trios with a variety of phenotypes, including autism, developmental delay, and disorders of sex development. On average, we identified ~2000 insertions, ~1000 deletions, ~250 inversions and 0-1 translocations per individual, showing that, while less common than single nucleotide variants, SVs account for a substantial fraction of genetic variation. The Database of Genomic Variants, internal dataset frequency and data from 150 healthy individuals were used to filter out common variants. In addition, we identified 2-5 rare de novo SVs in each proband. One of the defining features of NGM is its capability to generate de novo genome assembly with contiguous maps spanning entire chromosome arms. However, SV breakpoint resolution is limited by the intervals between fluorescent dye labeling motifs (6-10 kb intervals in the human genome). Using the available whole genome sequencing data for many of these cases to realign short reads around the SV breakpoints predicted by NGM decreased breakpoint uncertainty from 3-5 kbp to a few bases. Additionally, RNA sequencing was performed on whole blood for identification of variants affecting gene expression and splicing. Here, we show the ability of NGM to detect large pathogenic structural variants otherwise missed by sequencing or chromosomal microarrays. We developed methods to integrate NGS and NGM data to provide the ability to survey variants ranging from single nucleotide to large SVs and link them with changes in gene expression. Integration of this triad of technologies is poised to identify novel disease causing variants.

## 403W

**Identification of genetic modifiers by next-generation sequencing (NGS) of candidate genes in a 22q11.2 deletion syndrome patient.** A.G. Dantas<sup>1</sup>, N. Nunes<sup>1</sup>, L.C. Santos<sup>1</sup>, C.A. Kim<sup>2</sup>, D.C.Q. Soares<sup>2</sup>, V.A. Meloni<sup>1</sup>, S.I. Belan-gero<sup>1</sup>, G.G. Carvalheira<sup>1</sup>, M.I. Melaragno<sup>1</sup>. 1) Genetics Division, Universidade Federal de São Paulo, São Paulo, Brazil; 2) Genetics Unit, Instituto da Criança, Universidade de São Paulo, São Paulo, Brazil.

The 22q11.2 deletion syndrome (22q11.2DS) results from hemizygous deletions of chromosome 22, being the 3 Mb the most frequent one. It is a multi-system syndrome with a remarkable variability in the severity among individuals. Approximately 180 clinical manifestations have been described, including congenital cardiac malformations. Even though most 22q11.2DS patients present similar size deletions, the phenotype is highly variable among individuals, suggesting a role of single nucleotide variants (SNV) in genes mapped outside the deleted region. Here, we report on a female patient with 22q11.2DS in which we sequenced candidate genes to the phenotype of the syndrome, mapped on the remaining allele of 22q11.2, and also on chromosomes 1, 8, and 11. We found a missense SNV on *ZFPM2* (Zinc Finger Protein, FOG Family Member 2) (chr8:106813942 G>A), predicted as deleterious through the *in silico* tools *SIFT* and PolyPhen2. This variant was annotated on the dbSNP (rs187043152), where it was also classified as pathogenic. In the same patient, we found another SNV on the 3'UTR of *MAPK1* (Mitogen-Activated Protein Kinase 1) (chr22:22117065 G>A), predicted as deleterious by the tools FATHMM and Mutation Taster and already annotated on the dbSNP (rs58437134). Mutation Taster inferred that the variant leads to signal's change of mRNA PolyA tail of *MAPK1*. The function of *ZFPM2* was previously associated with heart disease. Its protein act as a cofactor of *GATA4* (GATA Binding Protein 4) during embryonic heart development. The *MAPK1* gene is mapped distal to the deleted region, and it is one of the factors that may contribute for craniofacial and cardiac outflow tract defects observed in patients with distal 22q11 deletions, due to deficiencies in neural crest *MAPK1* signaling (Breckpot et al, 2012). Interestingly, our patient does not present any cardiac defects, such as the patient with 22q11.2DS reported by Chung et al (2015), who also presents a variant on *ZFPM2* and no cardiac defect. It has been suggested that a loss-of-function variant on one allele of *ZFPM2* may normalize expression of *GATA4* or other downstream genes, suppressing the cardiac phenotype observed on the patient. Thereby, the pathogenic variant found in the *ZFPM2* gene in our patient could have a role in the modulation of the cardiac phenotype, even with the presence of the 3 Mb deletion and the variant on *MAPK1*. **Financial support: FAPESP, Brazil.**

**Single-cell analysis of somatic mutations in aging of human liver.** K. Brazhnik<sup>1</sup>, S. Sun<sup>1</sup>, A.Y. Maslov<sup>1</sup>, O. Mohammed<sup>2</sup>, M. Kinkhabwala<sup>3</sup>, A.W. Wolcott<sup>4</sup>, J. Vijg<sup>1</sup>. 1) Department of Genetics, Albert Einstein College of Medicine (AECOM), Bronx, NY, USA; 2) Division of Transplant Surgery, Montefiore Medical Center, AECOM, Bronx, NY, USA; 3) Marion Bessin Liver Research Center, Division of Hepatology, AECOM and Montefiore Medical Center, Bronx, NY, USA; 4) Department of Anatomy and Structural Biology, AECOM, Bronx, NY, USA.

Liver is an essential organ with a high regenerative capacity that plays a central role in homeostasis and detoxification. It is associated with various age-related pathological processes, such as fatty liver disease, cirrhosis, hepatitis, infections and cancer, including primary liver cancer and metastatic invasion from other organs. Many functional changes in liver have been observed with aging, including a severe reduction in its metabolic capacity. Due to the intense metabolic activity liver is a highly genotoxic tissue with many sources of spontaneous mutagenesis. Hence, somatic mutagenesis in liver cells may be an important causal factor in human aging and disease. Indeed, genome instability, i.e. genome structural variants (SVs; also called large genomic rearrangements), base substitutions and small indels, copy number variation and retrotransposition, is a hallmark of aging and likely to be a major causal contributor to age-related diseases, including but not limited to cancer. However, *de novo* mutations cannot be assessed in bulk DNA from the whole tissue due to their dispersed nature and low abundance. Each individual cell has its own unique mutations, which cannot be detected by analyzing cells collectively. Nevertheless, mutation loads may rise to levels in each cell that affect their function. We used our advanced next-generation sequencing (NGS)-based approach to analyze the mutational landscape across the genome in individual human liver cells in relation to age, liver health status, and differentiation stage, i.e., stem or mature cells. We found that somatic mutations in human liver (1) dramatically accumulate with age; (2) accumulate faster in diseased liver as compared to age-matched normal liver; (3) occur at lower frequency and spectrum in liver stem cells than in differentiated hepatocytes; (4) display signatures that reflect age level, disease status and stem versus differentiated cells. Potentially, these mutations affect the functional genome, e.g., occur in transcribed, liver-specific genes and, hence, may contribute to liver functional failure and aging. **References:** 1. Dong, X. *et al.* Accurate identification of single-nucleotide variants in whole-genome-amplified single cells. *Nat Methods* **14**, 491-493, doi:10.1038/nmeth.4227 (2017).

**Genome-wide analysis of stem cell mutational signatures in healthy tissues.** *M. Eriksson<sup>1</sup>, H. Helgadottir<sup>1</sup>, I. Franco<sup>1</sup>, A. Moggio<sup>2</sup>, P. Vrtacnik<sup>1</sup>, M. Larsson<sup>3</sup>, N. Norgren<sup>4</sup>, A. Johansson<sup>5</sup>, P. Lundin<sup>6</sup>, P. Stenvinkel<sup>7</sup>, L. Wennberg<sup>8</sup>, T. Lundgren<sup>8</sup>.* 1) Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 2) Dept of Medicine Huddinge, Karolinska Institutet; 3) Science for Life Laboratory, Dept of Physics, Chemistry and Biology, Linköping University; 4) Dept of Molecular Biology, National Bioinformatics Infrastructure Sweden, Science for Life Laboratory, Umeå University; 5) Science for Life Laboratory, Dept of Cell and Molecular Biology, Uppsala University; 6) Science for Life Laboratory, Dept of Biochemistry and Biophysics, Stockholm University, and Department of Biosciences and Nutrition, Karolinska Institutet; 7) Dept for Clinical Sciences, Intervention and Technology; Division of Renal Medicine, Karolinska University Hospital, Huddinge; 8) Dept for Clinical Sciences, Intervention and Technology; Division of Transplantation Surgery, Karolinska University Hospital, Huddinge, Sweden.

Aging is associated with reduced health and a significant part of the population suffers from age-related diseases or diseases mostly seen in the elderly. Somatic mutation burden increases during a lifetime as a result of accumulating errors, occurring either during cell division or because of environment-induced DNA damage. While somatic mutations are well studied in the context of cancer, less is known about the consequences of mosaicism for aging-related degeneration of generally healthy tissues. In the last years, we have developed a protocol that analyze somatic mutation load in cell clones from single-cell plated stem cells from various tissues. Our results show that somatic mutations (SNVs and indels) accumulate with aging in skeletal muscle, kidney, skin, subcutaneous and visceral fat progenitor cells. The rate of somatic mutation accumulation is highest in a subset of kidney progenitors, with 60 SNVs per year, compared to other progenitors that range 10-30 SNVs per year. The process of somatic mutation accumulation is not random and show a protection of functional regions, including exons. In certain progenitors this protection is reduced with aging resulting in the accumulation of mutations in exons. Somatic mutation accumulation follows specific mutational signatures, including signatures 1, 5 and 8 previously associated with certain forms of cancer. Clustering of samples on tri-nucleotide context identified three major sample groups, less dependent of age and tissue. This suggest that the majority of progenitors are subjected to the same mutational events, where specific cell-type and/or its location within tissues are less important determiners of somatic mutagenesis.

**406W**

**Multi-tissue discovery of postzygotic variation in healthy humans.** *S. Vattathil<sup>1,2</sup>, R. de Vito<sup>2,3</sup>, B. Engelhardt<sup>2,3</sup>, J.M. Akey<sup>1,2</sup>.* 1) Dept. of Ecology and Evolutionary Biology, Princeton University, Princeton, NJ; 2) Lewis Sigler Institute, Princeton University, Princeton, NJ; 3) Dept. of Computer Science, Princeton University, Princeton, NJ.

Somatic mutations are known to drive many forms of cancer and contribute to an increasingly large catalog of human diseases. Yet, theoretical and empirical studies suggest that the burden of somatic mutation in humans is high and imply substantial genomic robustness to post-zygotic variation. Therefore, understanding the patterns and pressures of somatic variation in normal tissues is critical for estimating the impact of variants observed in disease. Specific questions of interest include the frequency with which cancer-linked mutations occur without precipitating a cancer phenotype, the distribution of observable mosaic mutations over developmental time and how mutational timing affects spatial distribution and mutation frequency, and the variation of mutational signatures across tissues. In an effort to address these questions, as part of the enhanced Genes, Tissues, and Expression (eGTE<sub>x</sub>) Project, we sought to identify somatic single-nucleotide variants from high-coverage (>150x) exome sequencing of 267 tissue samples collected through rapid autopsy from 14 donors. Samples were collected from a wide range of tissue types including skin, gastrointestinal organs, muscle, kidney, liver, and brain. Each donor was represented by 11 to 32 tissue samples, with a median of 18 tissue samples per donor. We designed a novel somatic variant calling framework to take advantage of the unique structure of our data set, and jointly called variants across tissues. The multi-tissue sampling structure also allowed us to infer the developmental timing of mutations by classifying mutations as tissue-specific or multi-tissue, and to compare somatic mutation profiles across tissue types. Finally, we leveraged RNA sequence data available for our study samples to both confirm somatic mutations and assess their regulatory consequences. We expect that our observations will further illuminate the landscape and determinants of human somatic variability, deepen our understanding of human development and mutational processes and mechanisms, and improve interpretation of mutations observed in cancer samples.

**Genetic basis for APOBEC3H alternative splicing, L1 exonization, and interaction with HIV-1 protease in sub-Saharan African populations.** D. Ebrahimi<sup>1</sup>, C. Richards<sup>1</sup>, M. Carpenter<sup>1,2</sup>, R. Harris<sup>1,2</sup>. 1) University of Minnesota, Minneapolis, MN; 2) Howard Hughes Medical Institute.

Human APOBEC3H (A3H) is a single-stranded DNA cytosine deaminase and RNA binding protein with roles for innate antiviral immunity and in cancer mutagenesis. Seven haplotypes (I-VII) and four splice variants haplotype (SV154/182/183/200) have been described. A3H-II predominates in sub-Saharan Africa and is a potent viral restriction factor. In contrast, A3H-I is common outside Africa and has weak antiviral activity. Other A3H haplotypes encode defective proteins and/or are less common. Here we report the discovery of 6 additional A3H haplotypes (VIII-XIII) and, most strikingly, an intronic deletion ( $\Delta$ ctc) embedded within the A3H-II genotype. This deletion induces the exonization of pieces of an antisense LINE1 element leading to alternative mRNA splicing and ultimately, production of 200 amino acid A3H enzyme (SV200). Our data indicate that A3H SV200 enzyme is present in 80% of sub-Saharan African populations and is at least 4-fold more HIV-1 restrictive than the other shorter splice variants. Furthermore, virus infectivity experiments revealed an unexpected role for HIV-1 protease in cleaving SV200 isoform into a variant with less restriction activity inside virus particles. Our further genomic and transcriptomic analyses revealed that  $\Delta$ ctc and SV200 expression are not present in non-human primates but  $\Delta$ ctc is present in the Neanderthal and Denisovan genomes. Taken together, these data suggest that A3H-mediated immunity against pathogens is more diverse and complex than previously thought, and HIV-1 uses its cognate protease, in addition to vif, as an additional layer of protection against restriction by A3H in sub-Saharan Africa.

**The commitment complex *in vivo* over long intron genes.** G. Lev Maor, Y. Leader, G. Ast. Tel Aviv University, Tel Aviv, Israel.

The first and critical step in mRNA splicing is identification of the two splice sites delimiting an intron and bring them into proximity – termed the commitment complex. Within the commitment complex U1 small nuclear ribonucleoprotein particle (snRNP) binds the 5' splice site and form a protein bridge with U2AF65 (also called U2AF2) that binds the 3' end of that intron. Although the commitment complex was study extensively *in vitro*, how the same pairing occurs *in vivo* for splice sites separated by long introns is still obscure. Our laboratory proposed a new model, suggesting a dynamic pairing between the two splice sites involving interplay of RNA polymerase II (RNAPII), splicing factors and chromatin organization. We propose that U1 snRNP and U2AF65, associate with the CTD of RNAP II when that travels from one end of an intron downstream. We propose that U1 binds to 5' splice site while being associates to the CTD of RNAPII. When the 3' end of the intron is synthesized, U2AF65 binds the 3' splice site and the commitment complex is formed. Our research aim to uncover paramount mechanistic aspects of co-transcriptional splicing by experimental means; by identify and characterize co-transcriptional associations between splicing factors and pre-mRNA that are RNAPII-dependent; and by revealing the fashion by which the splicing reaction and splicing complex assembly occur in relation to RNAPII processivity. This will be performed using novel methodologies, including CRISPR interference-based and single cell techniques. We aim to reveal, for the first time how exons are selected by the splicing machinery co-transcriptionally *in vivo*, even when flanked by vastly longer introns.

**Comparison of chitinolytic properties of mouse Chit1 and AMCase with *Serratia marcescens* chitinase** B. M. Kimura, T. Umeyama, S. Wakita, K. Okawa, M. Sakaguchi, F. Oyama. Department of Chemistry and Life Science, Kogakuin University, Hachioji, Tokyo, Tokyo, Japan.

Chitinases hydrolyze chitin, a polymer of  $\beta$ -1, 4-linked *N*-acetyl-D-glucosamine (GlcNAc). Humans and mouse express two active chitinases, chitotriosidase (Chit1) and acidic mammalian chitinase (AMCase). Chit1 is synthesized by activated human macrophages and neutrophils. Chit1 is increased in individuals with Gaucher disease, atherosclerosis disease and Alzheimer's disease. AMCase is increased in individuals with mouse models of asthma. However, the contribution of mammalian chitinases to the pathogenesis of these diseases and the physiological condition remains to be determined. *Serratia marcescens* express high levels of chitinases, Chitinase A (*Serratia* ChiA), Chitinase B (*Serratia* ChiB) and Chitinase C (*Serratia* ChiC). *Serratia* ChiB is a well-studied bacterial chitinase and structurally similar to the mammalian chitinases. Previously, we successfully expressed mouse AMCase and Chit1 as recombinant proteins (Protein A-AMCase-V5-His and Protein A-Chit1-V5-His, respectively) in *Escherichia coli*. In this study, we compared mouse mammalian chitinases with *Serratia* ChiB. AMCase had the highest activity at around pH 2.0 among their enzymes. Chit1 and AMCase show about 1/2 lower chitinolytic activity than *Serratia* ChiB under acidic to neutral conditions. Our results indicate that mammalian chitinases possess chitinolytic activity comparable to *Serratia* ChiB.

**410T**

**Evaluations of enzymatic properties for human and mouse chitotriosidase.** T. Watanabe, M. Kimura, S. Wakita, K. Sekine, M. Sakaguchi, F. Oyama. Department of Chemistry and Life Science, Kogakuin University, Hachioji, Tokyo, Japan.

Chitin, a linear polymer of  $\beta$ -1, 4-linked *N*-acetyl-D-glucosamine (GlcNAc), is an integral component of the exoskeletons of crustaceans and insects, the microfilarial sheaths of parasites and the fungal cell walls. Although mammals do not produce chitin, two active chitinases, chitotriosidase (Chit1) and acidic mammalian chitinase (AMCase), have been identified in mouse and human. Chit1 was the first mammalian chitinase to be purified and cloned. Chit1 have attracted considerable attention due to their increased expression in individuals with different pathological conditions including Gaucher disease, chronic obstructive pulmonary disease (COPD), Alzheimer's disease and diabetes mellitus. Thus, Chit1 may play important roles in many pathophysiological conditions. However, the contribution of Chit1 to the pathophysiology of these diseases remains to be determined. Mouse Chit1 shows 75% identity and 78% similarity to human Chit1 based on their primary structure alignment. In this study, we compared the enzymatic functions between human and mouse Chit1 under the same conditions. To characterize their properties, we examined the chitinolytic activity using 4-nitrophenyl *N,N'*-diacetyl- $\beta$ -D-chitobioside as a substrate under various pH conditions. Human Chit1 was active in more wider pH range than mouse Chit1. Furthermore, when the products from the substrate were analyzed using fluorophore-assisted carbohydrate electrophoresis (FACE) method, human Chit1 exhibited more transglycosylation activity than mouse enzyme under tested condition. Our results suggest that there are remarkable differences between human and mouse Chit1 proteins.

**Time and space dimensions of gene dosage imbalance of aneuploidies revealed by single cell transcriptomes.** *F.A. Santoni<sup>1</sup>, G. Stamoulis<sup>2</sup>, M. Garieri<sup>2</sup>, A. Letourneau<sup>2</sup>, M. Guipponi<sup>4</sup>, N. Panousis<sup>2</sup>, E. Falconnet<sup>2</sup>, P. Ribaux<sup>2</sup>, C. Borel<sup>1</sup>, S.E. Antonarakis<sup>2,3,4</sup>.* 1) Service of Endocrinology, Diabetes and Metabolism, University Hospital of Lausanne - CHUV, Lausanne, Switzerland; 2) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 3) iGE3 Institute of Genetics and Genomics of Geneva, University of Geneva, Geneva, Switzerland; 4) Geneva University Hospitals, Service of Genetic Medicine, Geneva, Switzerland.

The mechanisms underlying cellular and organismal phenotypes due to copy number alterations (CNA) are not fully understood. Aneuploidy is a major source of gene dosage imbalance due to CNA and viable human trisomies are model disorders of altered gene expression. To understand the cellular impact of gene dosage imbalance, we studied gene and allele specific expression (ASE) of 9668 single-cell fibroblasts in trisomies T21, T18, T13 and T8. To limit the bias of interindividual noise, all comparisons between euploid and trisomic single-cells were performed on an isogenic setting for all trisomies studied. Initially we examined 928 single cells with deep RNA-Seq. For T21 we used fibroblasts from one pair of monozygotic twins discordant for T21 and from mosaic T21. For T18, T13 and T8 we analyzed single cells from mosaic individuals. Single-cell analyses revealed inconsistencies concerning the overexpression of some genes observed in differential trisomic vs euploid bulk RNAseq while this imbalance was not detectable in trisomic vs. euploid single cells. Moreover, ASE profiling of all single cells uncovered a substantial monoallelic pattern of expression in the trisomic fraction of the genome. By classifying genes according to the level of mono and bi-allelic transcription, we have observed that, for genes with monoallelic and low-to-average expression, the altered gene dosage is mainly due to the higher fraction of cells simultaneously expressing these genes in the trisomic samples. These results were confirmed in a further experiment of 8740 single fibroblasts from the monozygotic twins discordant for T21 samples. We conclude that gene dosage imbalance is of bidimensional nature: over time (simultaneous expression of all alleles resulting in increased accumulation of RNA of copy altered genes in each single cell) as previously stated, and over space (increased fraction of cells simultaneously expressing copy altered genes). These results strongly suggest that each class of genes contributes to the phenotypic variability of trisomies according to its temporal and spatial behavior and propose an improved model to understand the effects of copy number alterations.

**412W**

**Chitinase 3-like-1 with amino acid substitutions at the active site remains inactive.** *N. Kishigami, K. Okawa, M. Sakaguchi, F. Oyama.* Department of Chemistry and Life Science, Kogakuin University, Hachioji, Tokyo, Japan.

Chitinase-like proteins (CLPs) are structurally homologous to chitinases but lack the ability to degrade chitin. Based on sequence similarities, CLPs belong to the family 18 of the glycosyl hydrolases. The conserved sequence involved in catalysis in family 18 of the chitinases is DXXDXDXE. It is generally assumed that the lack of chitinase activity in CLPs is due to the mutation of crucial residues within the conserved catalytic sequence. Chitinase 3-like-1 (Chi3l1), one of the CLPs, is expressed in mouse. Its levels are increased in individuals with asthma, chronic obstructive pulmonary disease (COPD), inflammatory bowel disease, cancer, Alzheimer's disease and different types of malignant tumors. Presently, the exact physiologic and biological functions of Chi3l1 remain to be determined. Despite Chi3l1 has a relatively high sequence identity to chitotriosidase (Chit1), it lacks chitinase activity. In this study, we attempted to activate Chi3l1 by introducing two substitutions of amino acid (A139D and L141E) in the active center of the wild type Chi3l1. The Chi3l1 with amino acid substitutions at the active site remains inactive. This result suggests that lack of chitinase activity in Chi3l1 is not due to merely the simple amino acid substitution in the conserved catalytic motif.

**Quantification of chitinases mRNA levels by qPCR in crab-eating monkey tissues: Comparison with mouse and human.** *M. Uehara, E. Tabata, M. Ohno, M. Sakaguchi, F. Oyama.* Department of Chemistry and Life Science, Kogakuin University, Hachioji, Tokyo, Japan.

Chitin is a polymer of *N*-acetyl-D-glucosamine. Although mammals do not contain endogenous chitin, mammals express two active chitinases, acidic mammalian chitinase (AMCase) and chitotriosidase (CHIT1). Because the level of expression of these chitinases is increased in many inflammatory conditions including Gaucher disease and mouse models of asthma, both chitinases may play important roles in the pathophysiological conditions. Crab-eating monkey is one of the most important nonhuman primate animal models in basic and applied biomedical researches. We performed gene expression analysis of two chitinases in normal crab-eating monkey tissues by quantitative real-time PCR (qPCR) system to quantify the chitinases and reference genes on the same scale. Levels of AMCase and CHIT1 mRNAs were highest in the stomach and the lung, respectively, among tested other tissues. Next, we performed comparative gene expression analysis of mouse, monkey, and human. Gene expression of AMCase and CHIT1 varies between tested species. The differences of mRNA expression between the species in the stomach tissues were basically reflecting the levels of the chitinolytic activities. These results indicate that difference of their gene expression level between mammalian species and requiring special attention in handling data in chitinase-related studies in particular organisms.

**RegulomeDB: A resource for the human regulome.** *Y. Luo<sup>1</sup>, S. Dong<sup>2</sup>, T. Dreszer<sup>1</sup>, N. Ouyang<sup>2</sup>, B. Hitz<sup>1</sup>, J. Cherry<sup>1</sup>, A. Boyle<sup>2,3</sup>.* 1) ENCODE Data Coordination Center, Department of Genetics, School of Medicine, Stanford University, Stanford, CA; 2) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

The rapid growth of human genome sequencing has identified a large number of genetic variants present in the human genome relevant to human disease and other phenotypes. The majority of sequence variation is found within the noncoding regions of the genome where it is presumed to affect gene regulatory elements. We have developed a unique web-accessible database, RegulomeDB, which provides integrated knowledge of existing information describing regulatory elements that lie within noncoding regions. The RegulomeDB v1.1 (<http://www.regulomedb.org/>) was originally built from ENCODE and other community data, and has proven to be a useful tool for noncoding variant annotation. Various genomic information, including eQTL, transcription factor binding, chromatin modification and DNA methylation have been integrated into a common database and displayed at nucleotide resolution. Researchers are able to compare variants of their interest to the wealth of information in RegulomeDB, and rapidly gain insight into possible mechanism of gene regulation. In order to keep up with emerging genome sequencing projects and provide an up to date regulome annotation, we have integrated RegulomeDB into the ENCODE portal, as RegulomeDB v2.0. We are also investigating improved annotation with new data types and integration of novel, statistical scoring methods. Overall, we expect this unique resource to have wide impact in the biomedical community.

**Structural and functional network abnormalities in the human brain of XYY syndrome.** S. Liu, L. Clasen, F. Lalonde, J. Blumenthal, A. Raznahan. Developmental Neurogenomics Unit, National Institutes of Mental Health, Bethesda, MD.

XYY syndrome (47, XYY) is one of the frequent sex chromosome aneuploidy disorders (1/1000 live male births) characterized by duplication of Y-Chromosome in males. It has been associated with cognitive deficits and previous studies identified abnormal gray matter volume (GMV) changes in isolated brain regions using the plain T1 anatomical magnetic resonance imaging (MRI). Here we ask whether XYY syndrome further alters the structural and functional networks in the human brain, which could be measured using advanced MRI techniques. In the current study, we recruited 65 XYY participants (age [mean/SD]: 13.0/5.7 years) and 62 age-matched healthy male participants (13.2/5.1 years) as controls, to our knowledge, which represents the largest neuroimaging study of XYY to date. Genetic diagnosis of XYY was confirmed by karyotype. All MR images were collected on a 3T GE whole-body scanner (Discovery MR750). For each participant, a high-resolution T1 weighted anatomical image, a set of 10-minute resting-state functional MRI (rs-fMRI) images, and a group of 60-direction diffusion tensor imaging (DTI) images were obtained. Standard pipelines were used to analyze the data and two-sample t-tests were used to compare XYY and controls. The significance level of family wise error (FWE<0.05) was used to correct for multiple comparisons across voxels. We reproduced previous T1 findings and identified more regions showing group differences, which is likely due to the higher degrees-of-freedom in this study. In brief, compared to controls, XYY participants showed significant GMV loss in bilateral insula and anterior cingulate cortices, cerebellum and subcortical structures including the caudate, putamen and thalamus, as well as gain in the posterior cingulate and bilateral prefrontal and inferior parietal cortices. Further DTI and fMRI analyses of structural and functional connectivity confirmed the convergent and divergent findings in these highlighted regions. Taken together, abnormal changes in these areas and their connections, which have been linked to executive control and other high-order cognitive functions, may entail the increased risk of behavioral deficits in XYY syndrome.

**416T**

**Simultaneous analysis of long-range chromatin interactions and DNA methylation by bulk and single cell Methyl-HiC.** G. Li<sup>1</sup>, Y. Liu<sup>2,4</sup>, M. Kellis<sup>3,4</sup>, B. Ren<sup>1,2</sup>. 1) Ludwig Institute for Cancer Research, La Jolla, CA; 2) University of California, San Diego, School of Medicine, Department of Cellular and Molecular Medicine, La Jolla, CA; 3) Broad Institute of MIT and Harvard, Cambridge, MA; 4) Massachusetts Institute of Technology, Computer Science and Artificial Intelligence Laboratory, Cambridge, MA.

DNA methylation plays an important role in mammalian gene regulation. Although genome-wide bisulfite sequencing can measure DNA methylation levels at a single nucleotide resolution, it is difficult to measure the methylation status of two cytosines in single DNA molecule separated by a large genomic distance due to short DNA fragment sizes below kilobases scale. Here, we developed a new approach to study relationships between methylated cytosines across large genomic distances genome-wide. This approach, named Methyl-HiC, combines *in situ* Hi-C with bisulfite sequencing to simultaneously capture chromosome conformation and methylation status of cytosines on the same DNA molecules. Methyl-HiC generates consistent information to both *in situ* Hi-C and WGBS data from the same cell line when treated separately. We can detect allelic-specific methylation over a large genomic distance by incorporating allelic nucleotides and CpG methylation on the same DNA molecules. By analyzing the CpG methylation from the single molecule, we found that DNA methylation status is generally concordant between two cytosines that are spatially close. The levels of concordance vary depending on the chromatin states of the interacting DNA. We showed that this long-range DNA methylation concordance is further enhanced in cells lacking the Ten-eleven Translocation (TET) methylcytosine dioxygenases. We further developed the MethylHiC method to single cell level, which showed comparable quality to previous single cell HiC and single cell DNA methylome. Chromosome conformation difference can be observed in subpopulations divided by DNA methylation signature. Our method here paves the road to evaluate the direct long-range effect of genetic and epigenetic alterations in different pathological conditions in genome-wide and single cell level.

**Deep characterization of the contribution of short tandem repeats (STRs) to gene expression across tissues.** *S.Feupe, Fotsing, M.G. Gymrek.* UC San Diego, La Jolla, CA.

The identification of STRs contributing to the variation of gene expression in relevant tissue can be helpful in the identification of disease causing gene or other phenotype causing genes. Thousands of genetic variants contributing to gene expression variation have been identified in the past years through large scale studies and traits focused studies. However, these efforts have largely focused on SNPs, ignoring more complex variants such as repetitive regions and structural variants. This is due both to bioinformatic limitations in genotyping complex variants from short reads and low coverage sequencing data, and the challenges of performing traditional association tests at highly multiallelic loci. STRs have been implicated in dozens of Mendelian diseases such as Huntington's disease and Fragile X Syndrome and have been shown to affect human phenotypes through a variety of mechanisms. Recent evidence suggest an important role of STRs in gene regulation. For instance, a genome-wide survey of the effects of STRs on gene expression identified more than 2,000 STRs whose lengths were linearly associated with expression of nearby genes (eSTRs). These STRs explained 10-15% of gene expression heritability due to cis variants, suggesting an important role for STRs in complex traits. That study along with others have faced several limitations: Short read lengths and low coverage sequencing resulted in low quality genotypes, reducing power to detect true associations - Restriction to single tissue or cell type, limiting biological insight and generalizability of the results in different contexts. Here we look at influence of STRs on gene expression across multiple tissue types. We used HipSTR, a new and accurate STR profiling algorithm to genotype STRs in 650 high coverage (30x) whole genome sequencing dataset from the Genotype-Tissue Expression (GTEx) project. We performed association tests relating STR lengths and expression levels of nearby genes, and identified more than 9000 genes with eSTRs (eGenes) across seventeen tissues at 10% FDR. 38.7% of eGenes were shared by two or more tissues. Finally, using the extensive GTEx resource we fine-map the contribution of different variants classes to gene expression, identify putative causal regulatory variants overlapping GWAS loci, and characterize tissue-specific features of predicted causal eSTRs. Overall, our analysis provides a valuable resource for future efforts to integrate STRs into complex trait analyses.

**Gene expression analysis of mammalian chitinases in common marmoset (*Callithrix jacchus*) tissue.** *E. Tabata<sup>1,2</sup>, A. Kashimura<sup>1</sup>, M. Uehara<sup>1</sup>, S. Wakita<sup>1</sup>, M. Sakaguchi<sup>1</sup>, Y. Sugahara<sup>1</sup>, T. Yurimoto<sup>3</sup>, E. Sasaki<sup>3</sup>, F. Oyama<sup>1</sup>.* 1) Department of Chemistry and Life Science, Kogakuin University, 2665-1 Nakano, Hachioji, Tokyo 192-0015, Japan; 2) Research Fellow of Japan Society for the Promotion of Science (DC1), Koujimachi, Chiyoda-ku, Tokyo 102-0083, Japan; 3) Central Institute for Experimental Animals, Tonomachi, Kawasaki, Kanagawa, 210-0821, Japan.

Chitin, a polymer of *N*-acetyl-D-glucosamine (GlcNAc), functions as a major structural component in crustaceans, insects and fungi and is the second most abundant polysaccharide in the nature. Although mammals do not produce chitin and its synthase, genes encoding chitotriosidase (CHIT1) and acidic chitinase (CHIA) and their translation products have been found in both human and mouse. CHIT1 levels are elevated in the plasma of Gaucher disease and the bronchoalveolar lavage fluid of smokers with chronic obstructive pulmonary disease (COPD). CHIA expression and activity is upregulated in allergic airway responses in mouse models of asthma. However, the expression levels of chitinases in the other mammals have remained unknown. Common marmoset is an insectivorous New World monkey and attractive as a biomedical model for human diseases due to its handling size and genetic similarities. Here, we quantified expression levels of the chitinases and reference genes in common marmoset tissues on the same scale using a quantitative reverse transcriptase-coupled PCR. The relatively high levels of CHIT1 mRNA were detected in the lung, liver and spleen. Clear tissue-specific pattern was observed in CHIA mRNAs expression. CHIA mRNA was predominantly detected in the stomach and the other tissues were similar to or lower than that of CHIT1. Our study suggests that CHIA functions as a digestive enzyme that breaks down chitin in common marmoset stomach tissues.

**Composite *de novo* Armenian human genome assembly and haplotyping via optical mapping and ultra-long read sequencing.** *H. Barseghyan*<sup>1</sup>, *S. Bhattacharya*<sup>1</sup>, *J. LoTempio*<sup>1,2</sup>, *A. Almalvez*<sup>1</sup>, *B. Dufault*<sup>1</sup>, *E. Vilain*<sup>1,3</sup>. 1) Center for Genetic Medicine Research, Children's National Health System, Children's Research Institute, Washington, DC 20010, USA; 2) Institute for Biomedical Science, George Washington University Washington, DC 20052, USA; 3) Genomics and Precision Medicine, George Washington University Washington, DC 20052, USA.

Commercialization of short-read sequencing (SRS) in the past decade allowed characterization of millions of small genetic variations across thousands of human genomes for genetic diagnosis and disease susceptibility associations. However, due to its innate methodological limitations, SRS misses on identification of large structural variants (SVs), such as deletions, insertions inversions, translocations and copy number variants, which account for the largest human-to-human genetic variability and have been shown to be implicated in disease. Hence, there is a need for large-scale hybrid technology approach for *de novo* human genome assembly and variant calling. Advances in genomic technologies now allow researchers to survey the diploid architecture of human genomes across different ethnic groups. Here, we report the *de novo* assembly and phasing of the Armenian human genome with the precise localization of epigenetic markers. The hybrid genome assembly and phasing was performed by incorporating optical mapping and long-read nanopore sequencing (LRS). Optical mapping molecule N50 values were >200 kbp whereas the LRS N50 values were > 100 kbp. Coupling of both technologies allowed for an assembly of highly contiguous haplotype specific scaffolds covering entire chromosome arm lengths. Direct comparison of the assembly with the human genome reference GRCh38 identified thousands of SVs, many of which were previously unseen. Epigenetic modifications were also detected from LRS analysis and localized across the scaffolds generating the epigenetic profile of the Armenian genome. This is the first report of its kind that includes both *de novo* genome assembly of an isolated ethnic group (Armenia) as well as localization of epigenetic markers. This work serves as a precursor of precision medicine as the identified Armenian-specific structural variants may have a clinical relevance in diseases such as Familial Mediterranean Fever, which has a higher frequency in the Armenian population.

**420F**

**Use of nanopore sequence to validate and refine genome assembly.**

*D. Mohr, A.F. Scott.* Institute of Genetic Medicine, Johns Hopkins University School of Medicine, 1812 Ashland St., Baltimore MD 21205.

*De novo* genome assembly is becoming increasingly common as technologies and analysis tools improve and become more cost-effective. One limitation that remains is that long runs of repetitive sequence are difficult to resolve and can lead to gaps within scaffolds or breaks between scaffolds. We previously used linked read sequencing and optical mapping to create a genome for an endangered species. Overall sequence contiguity was excellent with an N50 of 61.7 Mb and 99% of the predicted genome occurring in 104 scaffolds. However, we observed some regions of disagreement between DNA lengths estimated from the optical maps and the actual sequence assembled with Supernova. These occurred, as expected, at regions of repetitive DNA where they manifested as read pile-ups. Because nanopore sequencing is agnostic to repetitive motifs we made long DNA libraries using Rapid chemistry (RAD004) and ran these on Oxford Nanopore R9.4.1 flow cells on a GridION instrument using MinKNOW 1.11. Reads were aligned to our existing scaffolds using minimap2, with ~91% identity. We obtained reads with an N50 of over 30kb and up to 235kb, >90% of which aligned extremely well with our published genome, thereby validating the linked-read approach used for assembly. Several regions were identified where the assembly improved with the use of long nanopore reads. We also have tested new approaches for the isolation of high molecular weight DNA from lymphocytes that produced long DNA suitable for nanopore sequencing. We conclude that nanopore sequencing is a valuable adjunct to more conventional NGS approaches and as throughput increases and accuracy improves will become an important tool in genome assembly.

**421W****Validation of copy number variations on TA repeat regions using MinION.**

*T. Takahashi, C. Nakashima, F. Kitaoka, N. Amano, N. Takasu, M. Nomura.*  
Kyoto University, Kyoto, Japan.

We are developing a stock of clinical-grade induced pluripotent stem (iPS) cells. For their clinical sequencing, we have used illumina HiSeq to detect genomic mutations such as single nucleotide variations, insertions, deletions and copy number variations (CNVs). On occasion, we have detected low sequence depths on TA repeat regions, which may indicate deletion-like CNVs. However, because many of these regions have no clear breakpoints, we consider them to be false positives. To test this hypothesis, we conducted amplicon sequencing of TA repeat regions of human genome NA24385 using Oxford Nanopore MinION, which can handle much longer reads than HiSeq. We selected target TA repeat regions based on the RepeatMasker database. We sorted the TA repeat regions and chose the top 100 regions by length, but excluded 24 regions that proved difficult for sequencing. We designed 46 primer pairs for the remaining 76 regions and also for 4 known CNVs of NA24385. We performed long PCR to amplify 40 random candidate regions and 4 known CNVs. We sequenced three of the CNVs to compare deletion-like CNV on TA repeat regions and confirmed clear patterns of deletions in depth and breakpoints. Though these known CNVs are hetero-deletions, two of them appeared as homo-deletions when using MinION. The reason is that the short DNA molecules between primer pairs outside the CNVs were increased dominantly by the PCR reaction of the amplicon generation and that MinION preferentially sequenced the shorter amplicons. In fact, we got complete reads that support the existence of intact allele. Next, we sequenced 9 candidate TA repeat regions. Among them, 8 had no clear deletion patterns of CNVs, although they did show gradual changes in read depths and no breakpoints. We confirmed all 8 were false positives, but could make no conclusions about the remaining one. Our results suggest that amplicon sequencing with MinION is recommended to validate ambiguous CNV candidate regions found using HiSeq.

**422T****A comprehensive map of cis-regulatory elements and 3D structure of the zebrafish genome.**

*T. Liu<sup>1</sup>, H. Yang<sup>1</sup>, Y. Luan<sup>1,2</sup>, Y. Wang<sup>1</sup>, G. Gerhard<sup>3</sup>, D. Balcunas<sup>4</sup>, K. Chen<sup>1</sup>, F. Yue<sup>1</sup>.* 1) Penn State College of Medicine, Hershey, PA; 2) Key Laboratory of Agricultural Animal Genetics, Breeding 17 and Reproduction of Ministry of Education and Key Laboratory of Swine Genetics and Breeding of Ministry of Agriculture, Huazhong Agricultural University, Wuhan 430070, China; 3) Dept of Biology, Temple University; 4) Dept of Medical Genetics and Molecular Biochemistry, Temple University.

Zebrafish has been widely used for the study of human diseases, as ~70% of the protein-coding genes are conserved between the two species. Moreover, zebrafish embryos are transparent and thus can serve as an ideal model for genetic studies in animal development. Surprisingly, the functional annotation of zebrafish genome itself has been severely lagging when compared with other model systems such as mouse and drosophila. Here we took a similar approach adopted by the ENCODE and Roadmap Epigenomics projects, and performed RNA-Seq and ChIP-Seq for H3K27Ac and H3K4me3 histone marks to generate a comprehensive map of transcriptomes and regulatory elements in a variety of zebrafish tissues, including brain, heart, liver, skeletal muscle and kidney. We predicted over 100,000 cis-regulatory elements in the zebrafish genome, the most comprehensive functional annotation effort in zebrafish so far to our knowledge. By comparing the data generated by the ENCODE and Roadmap Epigenomics projects, we also defined a set of functionally conserved and species-specific regulatory sequences among zebrafish, mouse and human. To further explore the three-dimension (3D) structure of zebrafish genome, we performed chromosome conformation capture (Hi-C) experiment using zebrafish adult brain and muscle. Our Hi-C matrix shows that topologically-associating domains (TADs) are also conserved among zebrafish, mouse and human. Muscle specific enhancer and promoter interactions predicted from ChIP-seq data are further validated by muscle Hi-C matrix. In summary, we generated a great genomics/epigenomics resource for the functional annotation and the 3D structure of the zebrafish genome and further expanded the value of zebrafish as a model of human disease. .

**423F**

**Progression of the molecular immune response in patients infected with *Andes orthohantavirus (ANDV)*.** G.Esteves. Ribeiro<sup>1</sup>, P. Vial<sup>1</sup>, A. Cuiza<sup>1</sup>, M. Ferrez<sup>2</sup>, M. Calvo<sup>3</sup>, J.Luis. Perez<sup>4</sup>, L. Ferreira<sup>5</sup>, M. Rioseco<sup>6</sup>, J. Graff<sup>7</sup>, L. Leon<sup>8</sup>, C. Vial<sup>1</sup>. 1) Instituto de Ciencia e Innovación en Medicina, Universidad del Desarrollo, Santiago, Santiago, Chile; 2) Departamento de Enfermedades Infecciosas e Inmunología Pediátricas; 3) Hospital Base de Valdivia, Facultad de Medicina, Universidad Austral de Chile; 4) Hospital Base San José de Osorno, Facultad de Medicina; 5) Hospital Clínico Regional Guillermo Grant Benavente; 6) Hospital Puerto Montt Dr. Eduardo Schütz Schroeder; 7) Clínica Alemana, Facultad de Medicina, Universidad del Desarrollo; 8) Instituto de Ciencias Biomédicas, Ciencias de la Salud, Universidad Autónoma de Chile.

Hantavirus are important human pathogens that cause a severe zoonotic disease called hantavirus cardiopulmonary syndrome (HCPS). HCPS presents a fatality rate of ~30% in Chile. Clinical manifestations may present as a mild condition with moderate respiratory failure or progress quickly to a severe condition with shock that can be fatal. This progression towards HCPS is a complex multifactorial process that involves mechanisms directly induced by the virus or by the host response, but it is not known exactly what are the host response factors associated with the progression towards HCPS. Our goal is to better understand the role of the host's immune responses in this progression towards HCPS, by longitudinally characterize the transcriptional profile of the peripheral blood mononucleated cells (PBMCs) isolated from ANDV infected patients, and healthy subjects as controls. Total RNA was extracted from PBMCs isolated from peripheral blood of healthy controls and patients infected with ANDV on days 1, 3, 5 post hospitalization, during the acute phase of the disease, and on day 60, during the convalescent phase. Isolated RNA was sequenced at the Broad Institute (Boston, USA) using Illumina's HiSeq platform (50M reads aligned in pairs). We analyzed 10 patients and four healthy controls. Transcriptome analyzes were performed with STAR, Kallisto, Deseq2 and ShinyGO. The results show different patterns of gene expression during the progression of HCPS. Evaluation of gene ontology (GO) biological processes enrichment, showed a difference between samples from the acute phase and convalescent phase or healthy controls. We found that during the acute phase (days 1 and 3), there was an enrichment of GO processes related to cell activation, humoral immune response and inflammatory response. Then they decrease on day 5, and continues to decrease on day 60 to levels similar to healthy controls, suggesting the full recovery of these patients. Future directions of this study include the analysis of differential expression by gene, to help us understand the mechanisms involved in the pathogenesis of HCPS.

Gudbjartsson<sup>1,4</sup>, K.S. Stefansson<sup>1,3</sup>. 1) deCODE genetics / Amgen Inc., Sturlugata 8, Reykjavik, Iceland; 2) Department of Pediatrics, Landspítali University Hospital, Reykjavik, Iceland; 3) Faculty of Medicine, School of Health Sciences, University of Iceland, Reykjavik, Iceland; 4) School of Engineering and Natural Sciences, University of Iceland, Reykjavik, Iceland; 5) School of Science and Engineering, Reykjavik University, Reykjavik, Iceland; 6) Department of Anthropology, University of Iceland, Reykjavik, Iceland.

Somatic and germ cells are derived from a single zygote. De novo mutations (DNMs) that occur early may result in mosaicism and can be transmitted to more than one offspring. Rare diseases of childhood are often caused by DNMs and therefore early DNMs can cause recurrence of disease in siblings. We searched for early DNMs by scanning 1,007 sibling pairs from 251 families for DNMs shared by siblings (ssDNMs). To avoid excluding early DNMs, we used absence of a mutation in the blood of a haplotype-sharing sibling to detect DNMs in addition to absence of the DNM from the blood of the parents. We estimated the probability of DNM recurrence based on presence in the parental blood, sharing by other siblings, parent-of-origin, mutation type, and genomic position. We identified 878 DNMs shared by siblings (ssDNMs) at 448 genomic sites and found that majority of ssDNMs is present in parental blood (57.2%). The probability of a DNM being shared goes down by 2.27% per year for paternal DNMs and 1.78% for maternal DNMs. Shared paternal DNMs are more likely to be T>C mutations than maternal ones, but less likely to be C>T mutations. Depending on DNM properties, the probability of recurrence in a younger sibling ranges from 0.011% to 28.5%. The data available on a DNM can be used to assess the recurrence probability. We have launched an online DNM recurrence probability calculator, to explore our results in the context of genetic counselling.

**Associations of *CHRNA3*, *CYP2B6* and *UGT2B28* gene variants and urine levels of nicotine metabolites.** G. Borrego-Soto<sup>1</sup>, A. Rojas-Martinez<sup>1</sup>, Y.X. Perez-Paramo<sup>2</sup>, S.K. Santuario-Facio<sup>1</sup>, R. Ortiz-Lopez<sup>1</sup>. 1) Tecnológico de Monterrey, Monterrey, Mexico; 2) Washington State University, US.

Tobacco consumption is a risk factor for 6 of the top-eight causes of death. The metabolism of nicotine, tobacco's addictive substance, may be subject of genetic variability and differences in addiction susceptibility and detoxification. Nicotine addiction is associated to variants in acetylcholine receptors in the basal ganglia while nicotine detoxification involves two phases: in phase I, 70 - 80% of nicotine is metabolized to cotinine and this is subsequently metabolized to trans-3'-hydroxycotinine (3HC) by *CYP2A6* and *CYP2B6* (90 and 10%, respectively). In the phase II, nicotine, cotinine, and 3HC undergo detoxification by UDP glucuronosyltransferases (*UGT*) generating products that are eliminated in the urine. These enzymes are highly polymorphic. This study aimed at analyzing the levels of nicotine and its metabolites in the urine of Mexican smokers (1-5 cigars/day) to determine genotype-phenotype associations for variants involved in nicotine addiction and metabolism. 95 smokers (18 - 35 y.o.) were genotyped and their urine nicotine metabolites were measured by UPLC-MS-MS. Associations between nicotine metabolites and genetic variants were analyzed with the Mann-Whitney test (significance level  $p \leq 0.05$ ). The CC genotype of rs2869547 (*CHRNA3*) was associated with high concentrations of cotinine-Gluc and low levels of HPBA. The GG genotype of rs2279343 (*CYP2B6*) was associated with low concentrations of free nicotine. Finally, the GG genotype of rs6828191 (*UGT2B28*) was associated with low levels of 3HC-Gluc. No associations were found with *CYP2A6* variants. This study suggests three genetic consequences for nicotine addiction and metabolism in Mexicans: The *CHRNA3* variant is possibly involved in tobacco addiction and the *CYP2B6* and *UGT2B28* variants maybe related to increased nicotine toxicity. These variants have been scarcely evaluated regarding their role in tobacco pharmacogenomics.

**Transcriptome response of human skeletal muscle to divergent exercise stimuli.** M. Naymik<sup>1</sup>, J. Dickerson<sup>2</sup>, A. D'Lugos<sup>2</sup>, A. Siniard<sup>1</sup>, A. Wolfe<sup>1</sup>, D. Curtis<sup>2</sup>, M. Huentelman<sup>1</sup>, C. Carroll<sup>1,4</sup>. 1) Translational Genomics Research Institute, Phoenix, AZ; 2) School of Nutrition and Health Promotion, Healthy Lifestyles Research Center, 9 Exercise Science and Health Promotion, Arizona State University, Phoenix, AZ; 3) Midwestern University, Glendale, AZ; 4) Department of Health and 12 Kinesiology, Purdue University, West Lafayette, IN.

Aerobic (AE) and resistance exercise (RE) elicit unique adaptations in skeletal muscle that have distinct implications for health and performance. The purpose of this study was to identify the unique transcriptome response of skeletal muscle to acute AE and RE. In a counter-balanced, cross-over design, six healthy, recreationally active young men (27±3y) completed acute AE (40 min cycling, ~70% maximal HR) and RE (8 sets, 10 reps, ~65% 1RM), separated by ~1wk. Muscle biopsies (vastus lateralis) were obtained before and at 1 and 4h post exercise. Whole-transcriptome RNA sequencing (HiSeq2500, Illumina) was performed on cDNA synthesized from skeletal muscle RNA. Sequencing data were analyzed using HTSeq and differential gene expression was identified using DESeq2 (adjusted P value (FDR) < 0.05, > 1.5-fold change from preexercise). RE resulted in a greater number of differentially expressed genes at 1h (67 vs. 48) and 4h (523 vs. 221) compared to AE. We identified 348 genes that were differentially expressed only following RE, whereas 48 genes were differentially expressed only following AE. Gene clustering indicated AE targeted functions related to zinc interaction, angiogenesis, and ubiquitination, whereas RE targeted functions related to transcription regulation, cytokine activity, cell adhesion, kinase activity and the PI3K/Akt pathway. *ESRRG* and *TNFSRF12A* were identified as potential targets related to the specific response of skeletal muscle to AE and RE, respectively. These data describe the early post exercise transcriptome response of skeletal muscle to acute AE and RE and further highlight that different forms of exercise stimulate unique molecular activity in skeletal muscle.

**Functional annotation of eSNPs by CRISPR-Cas9 mediated genome editing.** R. Tian<sup>1</sup>, Y. Pan<sup>2</sup>, T. Etheridge<sup>2</sup>, G. Bao<sup>2</sup>, C. Lee<sup>2</sup>, G. Gibson<sup>1</sup>. 1) Center for Integrative Genomics, Georgia Institute of Technology, Atlanta, GA; 2) Department of Bioengineering, Rice University, Houston, TX.

Precision identification of causal variants that are responsible for disease risk is one of the major challenges in interpretation of the molecular basis of genome-wide association signals. Since the majority of disease risk signals are located in the non-coding regions of loci, they are thought to influence phenotypes by altering gene expression. We have identified a number of autoimmune-disease associated loci for which at least two independent eQTL influence transcript abundance in whole blood and monocytes, and are testing CRISPR-Cas9 mediated site-specific gene editing strategies for scanning across the credible intervals of each eQTL, to define the most likely causal variant. The first strategy utilizes qRT-PCR to quantify target gene expression in multiple single cell clones with characterized microdeletions induced by up to 5 different guide RNAs for each eQTL. The major limitation of this approach is heterogeneity of gene expression across clones and batches. Bulk RNA sequencing of 7 single cell clones of HL60 and a derivative cell line, HL60/S4, found that PC1 (57% of the variance explained) captured differences between the two cell lines, while PC2 (10%) captured differences between single cell clones within the lines. Following chemically induced differentiation of these clones toward macrophage and neutrophil identity, the between-clone variability increased further, largely because different single cell clones grown in different batches have distinct growth and differentiation rates. Consequently, power to detect a 50% reduction in transcription with 3 biological replicates of each guide RNA is only around 30%, implying that this careful but labor-intensive approach is inefficient. Subsequently, we are now evaluating the performance of single cell RNASeq following parallel lentiviral transfection of cells with distinct guide RNAs. Simulations under the assumption of negative binomial/ Poisson distribution models suggest 80% power at experiment-wide  $p < 0.05$  to detect 20% expression reduction. Results of scans across multiple eQTL credible intervals will be presented and discussed with respect to the potential of this type of approach for fine mapping causal eSNPs.

## 428T

**A *de novo* CNV deletion of the *FOXF1* enhancer in 16q24.1 unmasks a rare noncoding SNP that likely prevented a lethal ACDMPV phenotype.** P. Szafranski<sup>1</sup>, V. Poisson<sup>2</sup>, D. Bérubé<sup>2</sup>, L. Oligny<sup>2</sup>, J.L. Michaud<sup>2</sup>, P. Stankiewicz<sup>1</sup>. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) CHU Ste-Justine, Montreal, Canada.

Haploinsufficiency of the *FOXF1* gene is causative for a neonatal lethal lung developmental disorder Alveolar capillary dysplasia with misalignment of pulmonary veins (ACDMPV). In addition to over 50 pathogenic point mutations, we have identified 22 CNV deletions involving *FOXF1* and 22 overlapping CNV deletions mapping upstream to *FOXF1*, defining an ~ 60 kb transcriptional enhancer region located ~ 272 kb to *FOXF1*. In all but one case, the deletions arose *de novo* on maternal chromosome 16q24.1, suggesting genomic imprinting at this locus. This enhancer region harbors fetal lung-expressed long non-coding RNA (lncRNA) genes and multiple binding sites for transcriptional regulators. Recently, we have narrowed it to a 15 kb core interval featuring binding sites for the lung-expressed transcription factors GATA3, ESR1, and YY1 (PMID: 19500772, 23034409, 27071622, 27822317). Here, we report a 6-year-old French-Canadian girl with pulmonary hypertension in whom we have identified a *de novo* ~ 2.5 Mb deletion on maternal chromosome 16q23.3q24.1 involving the entire enhancer region and leaving *FOXF1* intact. Lung biopsy showed no features of ACDMPV. DNA sequence comparison of the patient enhancer on the remaining paternal allele with the reference genome revealed 59 SNPs. Interestingly, analysis of their status in 13 patients with histopathologically-verified ACDMPV and heterozygous deletions of the entire *FOXF1* enhancer revealed the presence of G to A conversion (rs150502618) absent in the ACDMPV patients. This SNP maps to the ChIP-seq-determined overlapping binding sites for chromatin structure regulators: CTCF and an essential component of cohesin, RAD21. We propose that the SNP acts as a hypermorphic modifier of *FOXF1* expression by affecting the insulator function of CTCF or CTCF-cohesin-mediated chromatin folding. Changes in enhancer architecture and/or its interactions with the *FOXF1* promoter might increase *FOXF1* expression compensating for the deletion of its maternal copy, and preventing the development of lethal ACDMPV features in the patient.

**SEMP: Predicting the effects of single nucleotide polymorphisms on transcription factor binding affinity.** S.S. Nishizaki<sup>1</sup>, A.P. Boyle<sup>1,2</sup>. 1) Human Genetics Department, University of Michigan, Ann Arbor, MI., United States; 2) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI., United States.

One of the most surprising results to emerge from genome-wide association studies (GWAS) is 95% of all disease associated single nucleotide polymorphisms (SNPs) identified by this method reside in non-coding regions of the genome. Despite this finding, non-coding SNPs remain hugely understudied, due in part to the uncertain functional consequences of such mutations. However, a large proportion of these SNPs reside within regulatory regions of the genome, such as transcription factor binding sites (TFBSs). TFBSs only cover 8.1% of the genome, yet they contain 31% of GWAS SNPs. SNPs in these binding sites may alter the binding affinity of transcription factors, leading to changes in downstream gene expression, and ultimately human disease. Here, we propose a novel screening tool that estimates transcription factor (TF) binding affinity through observation of SNPs in TFBSs genome-wide. This tool utilizes publically available data from the ENCODE database to generate SNP effect matrixes (SEMs). We hypothesize that SEMs will allow us to predict disease causing SNPs in TFBSs genome wide.

**In vivo enhancer analysis with zebrafish.** T. Kimura, I. Inoue. National Institute of Genetics, Mishima, Japan.

Genome-wide association studies have discovered tremendously large number of associations between single nucleotide polymorphisms (SNPs) and human diseases. However, there are little knowledges about functional impact of causal polymorphisms on disease onset. Indeed, we do not know the causal or functional SNP related with the disease. Informative analyses have shown that large part of the diseases associated SNPs were located on regulatory regions marked by deoxyribonuclease I hypersensitive sites, in other word, open chromatin regions. This suggested that the disease-associated SNPs perturbed transcription factor recognition sequence and altered enhancer activity. On the other hand, biological experiments have showed that enhancer activities were highly cell type specific. In order to analyze an enhancer activity of all cell types, we performed the in vivo enhancer analysis using zebrafish. As fertilized egg of zebrafish makes all types of cells, we can easily test enhancer activity throughout all types of cells by microinjection of reporter construct. We made a Tol2 transposon-based vector which harbored cfos minimal promoter and EGFP gene. We amplified regions containing glaucoma-associated SNPs in 9p21 by PCR and made reporter constructs by cloning these regions into upstream of the promoter. One of these constructs containing a rs2157719 showed EGFP signals in eye of F0 fish. Another construct containing a rs6475604 showed EGFP signal in eye and neuron. As we expected, enhancer signal was observed mostly in eye and enhancer activity differs depend on the functional SNP. Most of the enhancer studies have been performed in cell lines or primary cells, however, in vivo enhancer activity needs to be measured, particularly allele specific enhancer activity needs to be studied in vivo using zebrafish system.

**431T**

**A pedigree-based estimate of the human germline retrotransposition rate.** J. Feusier<sup>1</sup>, W.S. Watkins<sup>1</sup>, J. Thomas<sup>1</sup>, A. Farrell<sup>1,2</sup>, L. Baird<sup>1</sup>, M. Leppert<sup>1</sup>, L.B. Jorde<sup>1</sup>. 1) Human Genetics, University of Utah, Salt Lake City, UT; 2) USTAR Center for Genetic Discovery, Salt Lake City, UT.

Non-LTR retrotransposons are active and continue to contribute new structural variation in the human genome. However, the current germline retrotransposition rates have been estimated from either phylogenetic or disease studies. We report the first direct estimate of the retrotransposition rates in a large series of 3-generation human pedigrees. We performed whole genome sequencing at 32x average coverage on blood-derived DNA from 603 CEPH individuals, comprising 33 multi-generation pedigrees. The families were joint-called using Mobile Element Locator Tool (MELT) and RUFUS to identify *de novo* Alu, LINE1, and SVA elements. We also looked for but did not detect any *de novo* HERV-K or pseudogene retrotransposition events. The three-generation families allowed us to estimate a false-negative detection rate of 5% using MELT. All candidate *de novo* mobile element insertions (MEI) were validated using PCR and Sanger sequencing. PCR validation demonstrates a false-positive rate of 0% after evaluation of candidate loci with the Integrative Genomics Viewer (IGV). Flanking SNPs were typed to determine parental chromosome of origin. *De novo* MEIs were transmitted at a 3-fold higher rate on the paternal chromosome than the maternal, with no apparent parental age bias. All *de novo* elements present in generation 2 were transmitted to generation 3, and there is one identified case of maternal germline mosaicism. The retrotransposition rate estimate for Alu elements, one in 41, is roughly half the rate estimated using phylogenetic analyses, a difference similar to that observed previously for single nucleotide variants. The SVA and LINE1 retrotransposition rates are both approximately one in 70-100 births, which is higher than phylogenetic estimates, and significantly higher for the SVA elements. We observed at least one case of endonuclease-independent LINE1 retrotransposition, which acts as a retrotransposition-mediated DNA-repair mechanism.

**Global protein-protein and protein-DNA interactions of DNA topoisomerases.** L. Uuskula-Reimand<sup>1,2</sup>, P. Samavarchi-Tehrani<sup>3</sup>, H. Hou<sup>1,4</sup>, K. Abe<sup>3</sup>, R. Ostadsharif Memar<sup>1</sup>, S. Akhtar Alvi<sup>1</sup>, J. Reimand<sup>5,6</sup>, A.C. Gingras<sup>3,4</sup>, M.D. Wilson<sup>1,4</sup>. 1) Genetics and Genome Biology Program, SickKids Research Institute, Toronto, Ontario, Canada; 2) Department of Gene Technology, Tallinn University of Technology, Tallinn, Estonia; 3) Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Toronto, ON, Canada; 4) Department of Molecular Genetics, University of Toronto, ON, Canada; 5) Ontario Institute for Cancer Research, Toronto, ON, Canada; 6) Department of Medical Biophysics, University of Toronto, Toronto, ON, Canada.

Type II DNA topoisomerases (TOP2) regulate DNA topology by generating transient double stranded breaks during replication and transcription. Vertebrates possess two TOP2 proteins, TOP2A and TOP2B. Unlike TOP2A, which is essential for cell proliferation, ubiquitously expressed TOP2B facilitates rapid post-mitotic gene activation and functions at the later stages of development and differentiation. We previously applied proteomics (BioID), chromatin immunoprecipitation sequencing (ChIP-seq), and high-throughput chromosome conformation capture (Hi-C) approaches to identify novel proximal TOP2B protein interactions and characterize the genomic landscape of TOP2B binding. These experiments revealed close interactions between TOP2B, the cohesin complex, and CTCF, including a distinct spatially constrained DNA occupancy at the borders of topologically associating domains. However, the extent to which TOP2B's interactions are distinct from, or shared with, TOP2A and other topoisomerases such as the type I topoisomerase TOP1 is not known. Here we extend our TOP2B protein-protein interactome by performing BioID of TOP2B interacting proteins CTCF, the cohesin complex subunit RAD21, and TOP2A. For comparison, we also profiled TOP1 which is known to play a critical role in transcription and resolving DNA supercoils near CTCF sites. In addition to finding biologically relevant and distinct protein-protein interactions for each of the above proteins, several protein-protein interactions shared by TOP2B and RAD21 or TOP2B and CTCF were detected. For example, in contrast to TOP2A and TOP1, the cohesin complex proteins and loading factors showed robust protein proximal interactions with TOP2B. Our extended topoisomerase interactome reveals known and novel proteins involving of cellular processes such as transcription regulation, cell cycle, DNA repair, and chromatin organization among the interacting proteins, highlighting the interplay of gene regulatory and DNA architectural processes.

**Structural complexity at 3q29 locus: Contributions of genomic architecture to genomic disorders.** *T. Mosley<sup>1</sup>, M. Zwick<sup>1</sup>, J. Mulle<sup>1,2</sup>*. 1) Department of Human Genetics, Emory School of Medicine, Atlanta, GA, USA; 2) Department of Epidemiology, Emory Rollins School of Public Health, Atlanta, GA, USA.

**Introduction:** 3q29 deletion syndrome is a rare genomic disorder that occurs in approximately 1 in 30,000 births. It is caused by a recurrent, typically *de novo* deletion on the third chromosome spanning 1.6 Mb and 21 genes. It is associated with increased risks for anxiety and intellectual disability, a 30-fold increase in risk for autism, and a 40-fold increase in risk for schizophrenia. The 3q29 region is flanked by three inversely and directly oriented low-copy repeats (LCRs), suggesting the region undergoes non-homologous allelic recombination (NAHR) to form the 3q29 deletion, as well as other structural variants. Inversions, specifically, have the potential to predispose the region to structural rearrangement. Thus, individuals who carry inversions in the 3q29 region may have increased risk for forming the deletion. **Methods:** As part of the Emory 3q29 Project ([genome.emory.edu/3q29](http://genome.emory.edu/3q29)), we performed Bionano<sup>®</sup> Saphyr<sup>™</sup> whole-genome mapping on six 3q29 trios and Bionano<sup>®</sup> provided mapping data for 155 control individuals. We searched for additional structural variants, especially inversions, at the 3q29 locus and assessed the frequency of the variants in the control population versus the 3q29 population. **Results:** We observed a 1.9-Mb inversion in 2/155 (0.01%) control samples screened. Additionally, we uncovered a second 350-kb inversion adjacent to the 3q29 deletion interval in 27/157 (17%) control samples. Analyses are ongoing for the 3q29 trios; so far, we have identified the 350-kb inversion in the father of one 3q29 trio. Additional data from the collected six 3q29 trios will be presented. **Conclusion:** These data suggest an underlying structural complexity at the 3q29 locus that may influence the formation of the 3q29 deletion. There may be population-level risk factors, such as inversions or more complex structural variants that predispose the 3q29 region for structural rearrangement. **Implications:** The genomic architecture encompassing a region at risk for structural rearrangement is a critical contributing factor underlying the formation of structural variants. Ultimately, understanding the genomic architecture and risk factors contributing to structural instability in the 3q29 region can be extrapolated to other loci associated with genomic disorders. Identifying the specific factors contributing to the structural mutagenesis at the 3q29 locus (and other loci) will provide a guide for standards to identify individuals at risk for genomic rearrangement.

**434T**

**Measuring the rate of spontaneous structural variation through whole-genome sequencing of three generation human pedigrees.** *J.R. Belyeu<sup>1</sup>, R.M. Layer<sup>1,2</sup>, A.R. Quinlan<sup>1,2,3</sup>*. 1) Department of Human Genetics, University of Utah; 2) USTAR Center for Genetic Discovery, University of Utah; 3) Department of Biomedical Informatics, University of Utah.

Accurate measurement of the rate of *de novo* structural variation (SV) in human genomes is difficult due to the historic lack of genome sequences from nuclear families, the complexity of structural variant calling, and the apparently lower mutation rate as compared to spontaneous single-nucleotide mutation. SV callsets are also dominated by false positives, which are difficult to remove without employing insufficiently specific filtering techniques, which can decrease detection of real variants. These complications have led to disagreements in previous measurements of the spontaneous SV rate, with recent estimates of the number of events per genome ranging from ~1/6 to ~1/12. To address this problem, we have measured *de novo* SV mutations in whole genome sequences from 33 large, three-generation CEPH pedigrees, comprising an average of ~9 children per F2 generation (603 individuals in total). Multi-generation pedigrees provide an ideal experimental design for directly validating putative *de novo* SVs, as true mutations in the F1 generation should be transmitted to at least one child in the F2 generation. Using this approach, we manually curated the resulting set of candidate SVs using our tool SV-plaudit, by plotting the evidence supporting the variant calls in P0, F1, and F2 generations. This allowed us to remove additional false positive variants and finalize a set of highly accurate *de novo* SV calls. We further identified candidate *de novo* SVs in the F2 generation, and again manually curated variant calls. Using the large number of F2 individuals, we will report a revised estimate of the rate of *de novo* SV mutation, as well as the prevalence of *de novo* SVs arising from germline mosaicism. Finally, we used results from both sets of curated SV calls to create a set of reproducible filters for the removal of false-positive SV calls from additional SV datasets. We applied these filters to >3000 family quartets from the Simons Foundation Autism Research Initiative (SFARI) to explore the *de novo* SV rate in a larger cohort, assess how the rate changes with parental age, and compare the rate in affected vs unaffected siblings. We anticipate that a better understanding of the *de novo* SV rate will improve our understanding the mutation of the human genome and that these filters will become a commonly used tool to identify true *de novo* SVs in many family datasets.

**Comprehensive structural variant identification and genomic characterization using 720 deeply sequenced whole genomes.** D. Jakubosky<sup>1,2</sup>, M. D'Antonio<sup>3</sup>, C. DeBoever<sup>4</sup>, M.J. Bonder<sup>5</sup>, C. Smail<sup>6</sup>, W.W. Greenwald<sup>4</sup>, H. Matsui<sup>6</sup>, A. D'Antonio-Chronowska<sup>3</sup>, S.B. Montgomery<sup>7,8</sup>, O. Stegle<sup>9,10</sup>, E.N. Smith<sup>11</sup>, K.A. Frazer<sup>9,11</sup>, *i2QTL Consortium*. 1) Biomedical Sciences Graduate Program, University of California, San Diego, La Jolla, CA 92093, USA; 2) Department of Biomedical Informatics, University of California, San Diego, La Jolla, CA 92093, USA; 3) Institute of Genomic Medicine, University of California San Diego, 9500 Gilman Dr, La Jolla, CA 92093, USA; 4) Bioinformatics and Systems Biology Graduate Program, University of California San Diego, La Jolla, CA 92093, USA; 5) European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Trust Genome Campus, Cambridge, UK; 6) Departments of Pathology and Biomedical Data Science, Stanford University School of Medicine, Stanford, CA 94305, USA; 7) Department of Pathology, Stanford University, Stanford, CA 94305, USA; 8) Department of Genetics, Stanford University, Stanford, CA 94305, USA; 9) European Molecular Biology Laboratory, European Bioinformatics Institute, Hinxton, UK; 10) European Molecular Biology Laboratory, Genome Biology Unit, Heidelberg, Germany; 11) Department of Pediatrics, University of California San Diego, La Jolla, CA 92093, USA.

Structural variants (SVs) and short tandem repeats (STRs) encompass at least 11% of the human genome and are important sources of genetic and phenotypic diversity; however, their functional impact remains poorly understood. Previous efforts have focused on specific non-SNV subtypes, contained few samples, or utilized low coverage sequencing data. To thoroughly characterize the functional landscape of non-single nucleotide variants (non-SNV), high-resolution mapping of all known SV and STR classes is needed. Here we assembled a set of 720 blood, fibroblast, and induced pluripotent stem cell samples (478 individuals) with deep whole genome sequencing (WGS) data (mean 42x) and: 1) profiled SV and STR variation using 5 algorithms, 2) applied a systematic filtering strategy to enable the identification of variants with highly reproducible genotype calls, and 3) characterized the genomic properties of different variant classes, thereby producing one of the most complete and well characterized maps of structural genetic variation to date. We obtained WGS data from participants of the iPSCORE and HipSci studies as part of the i2QTL Consortium and called SVs and STRs using HipSTR, Genome STRIP, MELT, LUMPY, and CNVnator. To obtain high quality variants, we filtered to achieve an overall replication rate of >90% for calls in genetically duplicated samples (25 MZ twin pairs and 152 fibroblasts with matched iPSC). Filtered calls included over 200,000 STR variable regions and 66,471 SVs, of which ~15.4% were mobile element insertions (MEI), 4.3% reference MEI, 29.5% deletions (DEL), 5.5% duplications (DUP), 3.3% multi allelic copy number variants (mCNV), and 41.3% unspecified breakends (BND). These calls were highly concordant (FDR 5%) with data from orthogonal genotyping arrays. Moreover, we performed enrichment analyses of variant classes in functional regions of the genome and observed that DUPs and mCNVs were more likely to overlap genes than DELs and MEIs, and that DELs were more likely to occur in intergenic regions. Additionally, DELs, DUPs, and mCNVs occurred less often in active chromatin compared to inactive chromatin. Finally, rare variants of all classes were more likely to occur in conserved regions (PhyloP) than common variants. Overall, this study establishes the largest set of high quality SV and STR genotype calls in samples with paired gene expression data that can be used to interrogate the functional impact of non-SNV variation in the human genome.

**The impact of structural variation on human gene expression.** A.J. Scott<sup>1</sup>, C. Chiang<sup>1</sup>, L. Ganel<sup>1</sup>, A. Wilfert<sup>2</sup>, D.F. Conrad<sup>2,3</sup>, I.M. Hall<sup>1,4</sup>. 1) McDonnell Genome Institute, Washington University School of Medicine, St. Louis, MO; 2) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 3) Department of Pathology & Immunology, Washington University School of Medicine, St. Louis, MO; 4) Department of Medicine, Washington University School of Medicine, St. Louis, MO.

Structural variants (SVs) are an important but poorly understood source of human genome variation. The Genotype-Tissue Expression (GTEx) project provides an unprecedented opportunity to address the contribution of SV to traits, disease, and gene regulation due to the generation of deep (50X) WGS data and multi-tissue RNA-seq data. Here we present results from ongoing analysis of 613 individuals from the GTEx cohort. We used comprehensive detection methods to map 64,568 high confidence SVs, including copy number variants, inversions, reference and non-reference mobile element insertions, and novel adjacencies of indeterminate type. We performed *cis* expression quantitative trait loci (eQTLs) analyses in 48 tissues via joint analysis of common (>1% MAF) SVs, SNVs, and short indels. Based on haplotype structure and heritability partitioning, we estimate that 2.7-5.3% of eQTLs are caused by common SVs, a relatively modest contribution that nonetheless represents a 17- to 33-fold enrichment relative to their abundance in the genome. We assessed the contribution of different classes of regulatory elements at SVs predicted to causally alter gene expression and observed an enrichment in features such as enhancers and promoters. By evaluating linkage disequilibrium between SVs, SNVs, and indels, we nominate 104 SVs as plausible causal variants at published genome-wide association study (GWAS) loci from UK Biobank, including smoking status, sleep duration, and basal cell carcinoma. In contrast to the modest contribution of common SVs, we observe a remarkable abundance of rare SVs associated with highly aberrant expression of nearby genes. These predicted causal rare SVs are nominally enriched in several regulatory elements including genic enhancers and CTCF binding sites, which may be useful for improving rare variant interpretation methods. Our results indicate that both common and rare SVs play an important role in causing gene expression differences in the human population and that comprehensive SV analyses will improve the power of WGS-based association studies.

**Germline copy number variants are associated with methylation variation in the genome.** S.R. Setlur<sup>1</sup>, X. Shi<sup>2</sup>, J.Y. Chen<sup>1</sup>, S. Radhakrishnan<sup>1</sup>, J. Wen<sup>2</sup>, B.A. Lam<sup>2</sup>, R.E. Mills<sup>3</sup>, B.E. Stranger<sup>4</sup>, C. Lee<sup>5</sup>. 1) Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) University of North Carolina at Charlotte; 3) University of Michigan; 4) University of Chicago; 5) The Jackson Laboratory for Genomic Medicine.

Large consortium efforts like the International HapMap Project and the 1000 Genomes Projects, have generated a detailed catalog of genetic variants in human populations. The two major classes of genetic variants include single nucleotide polymorphism (SNPs) and copy number variation (CNVs). The effect of SNPs on cellular phenotypes and disease, has been shown by various studies. However, the effects of CNVs, the more recently recognized class of germline genetic variants, on gene regulation and phenotype is not well-elucidated. CNVs can influence gene expression by overlapping either genes or non-coding regulatory regions in the genome. In addition to being genetically influenced, gene expression can also be epigenetically regulated. One such epigenetic regulatory mechanism is DNA methylation. Similar to CNVs, DNA methylation has been reported to vary between individuals and among different tissues within an individual. Studies have shown that monozygotic twins exhibit inter-individual variability in both DNA copy number and methylation. Despite these similarities, we know very little about the relationship between germline CNVs and variation in DNA methylation. We investigated the association between germline CNVs and DNA methylation by genome-wide methylation quantitative trait locus (mQTL) analysis. Using CNV genotypes and DNA methylation data from individuals profiled in the 1000 Genomes and the HapMap projects, we identified 851 genome-wide CNV-CpG associations (CNV-mQTLs,  $p$ -value  $< 0.01$ , permutation test). We found instances where a single CNV was associated with CpG methylation of multiple genes and vice-versa. CNV-associated methylation changes were also correlated with gene expression. We found that CNV-mQTLs were enriched for regulatory regions as defined by the ENCODE consortium including transcription factor binding sites. Analysis of Hi-C data, to assess for long-range physical interactions between CNVs and the associated CpGs, revealed that the associated CNV-CpG pairs were enriched for Hi-C interactions suggesting a potential functional association. Finally, we found that some of the CNV-mQTLs and/or associated genes were previously reported to confer disease risk by genome-wide association studies. In summary, we demonstrate for the first time, that germline CNVs are associated with variable DNA methylation in the human genome. These findings suggest a distinct universal mechanism by which structural variation may affect phenotype.

**The effects of structural variation on 3D chromatin structure.** O. Shanta<sup>1</sup>, A. Noor<sup>2</sup>, D. Gorkin<sup>3,4</sup>, Y. Qiu<sup>4</sup>, B. Ren<sup>3,4</sup>, J. Sebat<sup>2</sup>. 1) Department of Electrical and Computer Engineering, University of California San Diego, La Jolla, CA; 2) Beyster Center for Genomics of Psychiatric Diseases, Department of Psychiatry, University of California San Diego, La Jolla, CA; 3) Department of Cellular and Molecular Medicine, University of California San Diego, School of Medicine, La Jolla, CA; 4) Ludwig Institute for Cancer Research, La Jolla, CA.

Human chromosomes exhibit three-dimensional spatial organization whereby regions of the genome form highly self-interacting regions termed Topological Associating Domains (TADs). TADs are separated by discrete boundaries in which the chromatin interactions cease abruptly. We hypothesize that structural variants (SVs) in the human genome contribute to heritable variation in chromatin structure. We investigated the effects of SVs on 3D chromatin organization by chromosome conformation capture sequencing (Hi-C) of lymphoblastoid cell lines from 19 subjects enrolled in the 1000 genomes project. The correlation of deletions with the frequency of long-range contacts was tested by principal component regression. We demonstrate that quantitative variation in TADs is strongly influenced by confounding variables including local copy number variation and genome-wide variation in Hi-C data, which can be controlled for statistically. After eliminating these confounders, significant effects of deletions on TAD structure were evident and such effects were strongest for deletions  $>10$  kb in length and deletions that occur in the boundary region between TADs. Deletions result in the disruption of interactions in the flanking regions within  $\sim 200$  kb and an increase in contacts that span the deletion. These results indicate that deletion of the boundary regions between TADs promotes interactions between discrete chromatin domains. However, the overall structure of domains remains largely intact, suggesting that regulatory elements within the boundaries are not required to establish TADs.

**Discovery and genotyping of new short and variable number of tandem repeats in the human genome.** A. Sulovari<sup>1</sup>, P.A. Audano<sup>1</sup>, M.J.P. Chaisson<sup>1</sup>, C. Lee<sup>2,3</sup>, J.O. Korbel<sup>4</sup>, E.E. Eichler<sup>1,5</sup>, *The Human Genome Structural Variation Consortium (HG SVC)*. 1) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA 98195, USA; 2) The Jackson Laboratory for Genomic Medicine, Farmington, CT 06032, USA; 3) Department of Graduate Studies – Life Sciences, Ewha Womans University, Ewhayeodae-gil, Seodaemun-gu, Seoul, South Korea; 4) European Molecular Biology Laboratory, Genome Biology Unit, Heidelberg, Germany; 5) Howard Hughes Medical Institute, University of Washington, Seattle, WA 98195, USA.

Short and variable number of tandem repeats (STRs and VNTRs) are an important source of disease-causing variation, but they have been problematic to resolve in the reference genome and to genotype with short-read technology. We recently sequenced three human parent–child trios of Yoruban, Chinese and Puerto Rican descent using a multiplatform approach involving short- and long-read sequencing as well as linking technologies. Using Phased-SV, we systematically detected and sequence-characterized STRs and VNTRs of variable length with a particular emphasis on those missing from the human reference genome. We sequence-resolved 21,442 tandem repeats representing 2,767 STRs (1–8 bp) and 3,319 VNTRs ( $\geq 9$  bp) per haplotype, all missing from the human reference genome, GRCh38. 1,300 insertions (1.5 Mbp) were shared by all six haplotypes suggesting that the reference human genome carries a smaller minor allele or is in error at these locations. 7,087 loci overlapped a gene region and 458 intersected an exon. These include large repeats such as a 56-copy hexamer located 4 kbp upstream of *RNASE10*, a 6-copy 5,608-mer overlapping with *LPA*, 2–3 kbp protein-encoding expansions in mucin repeats, and expanded trinucleotide repeats in a variety of disease-associated genes. 45% of VNTRs and 18% of STRs are located in the last 5 Mbp of the telomeric ends representing an enrichment of 5.5- and 2-fold for VNTRs and STRs, respectively. This distribution correlates with biases in chromosomal double-strand breaks (average  $r = 0.7$ ,  $p < 2 \times 10^{-16}$ ), suggesting a mechanistic relationship. We developed a VNTR genotyping approach for short-read data using these alternate alleles. To test its accuracy, we used high-coverage Illumina genome data (150 bp paired-end reads) from the same trio individuals and focused on the top 3% most polymorphic VNTRs across the six haplotypes. We show that most of these VNTRs can be genotyped with  $\geq 80\%$  accuracy, which allows expansions and contractions to be readily identified, while approximately 35% of VNTRs (average size of 5.6 kbp) can be genotyped with an accuracy  $\geq 99\%$ . We are now applying this strategy to  $>2,000$  previously uncharacterized STRs and VNTRs in over 10,000 autism genomes and will present our findings for events that are hyperexpanded in cases compared to unaffected siblings. The strategy we have developed can be more broadly applied to discover expanded STRs and VNTRs for other Mendelian and common complex diseases.

**De novo human genome assemblies reveal novel sequences in diverse populations.** K.H.Y. Wong<sup>1</sup>, M. Levy-Sakin<sup>1</sup>, P. Kwok<sup>1,2,3</sup>. 1) Cardiovascular Research Institute, University of California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 3) Department of Dermatology, University of California, San Francisco, San Francisco, CA.

The human reference genome is used extensively in modern biological research. However, a single consensus genome representation is inadequate to provide a universal reference structure because it is a haplotype among many in the human population. Using 10x Genomics “Linked-Read” technology, we performed whole genome sequencing and *de novo* assembly on 17 individuals across five populations: African, American, East Asian, European, and South Asian. Using an alignment- and *de novo* assembly-based approach, we identified 1,842 breakpoint-resolved Non-reference Unique Insertions (NUIs) that, in aggregate, added up to 2.1Mb of new genomic content not currently represented in the human reference genome. These NUIs displayed an underlying population structure, as principal component analysis could faithfully stratify these individuals based on their geographic origins. Furthermore, 64% of these NUIs aligned to non-human primate references, suggesting that they are ancestral sequences. We found that at least 14% of these NUIs likely originated from Alu-mediated recombination. Additionally, 37% of the NUIs aligned to either entries in the expressed sequence tag database or reads from RNA-sequencing experiments, indicating that they are in the human transcriptome. Our results demonstrate that as the genomic variant catalogs continue to expand, the human reference genome must include a more comprehensive set of alternative haplotypes to depict the complete spectrum of genetic diversity across populations.

**Patterns and mechanisms defining tissue specificity of human regulatory variation.** S.E. Castel<sup>1,2</sup>, F. Aguet<sup>3,8</sup>, E. Flynn<sup>1,2,8</sup>, S. Kim-Hellmuth<sup>1,2,8</sup>, P. Mohammad<sup>4,8</sup>, Y. Park<sup>6,8</sup>, B. Strober<sup>6,8</sup>, V. Wucher<sup>7,8</sup>, T. Lappalainen<sup>1,2</sup>, GTEx Consortium. 1) New York Genome Center, New York, NY; 2) Columbia University, New York, NY; 3) Broad Institute, Cambridge, MA; 4) The Scripps Research Institute, La Jolla, CA; 5) University of Pennsylvania, Philadelphia, PA; 6) Johns Hopkins University, Baltimore, MD; 7) Center for Genomic Regulation, Barcelona, Spain; 8) equal contribution, listed in alphabetical order.

Quantitative trait loci (QTL) studies that map regulatory variation can bridge the gap between genetic associations to disease and molecular phenotypes. In this work, we studied the tissue specificity of regulatory variation in the v8 release of the Genotype Tissue Expression (GTEx) project, consisting of 838 individuals with 15,201 samples across 49 human tissues, to shed light on its biological mechanisms and interpret disease associations. We quantified tissue specificity of regulatory variation by cross tissue meta-analysis of *cis* and *trans* expression QTLs, as well as splicing QTLs. We also estimated *cis* regulatory effect sharing using individuals with allelic expression data from multiple tissues. Comparison of tissue clustering by shared regulatory effects, gene expression, and inferred cell type composition indicated shared cellular mechanisms but also complex relationships between these factors that define tissue identity. Leveraging on estimates of gene expression sharing between GTEx tissues and other data sets, we demonstrated the use of GTEx tissues as a proxy for diverse tissues. To study the mechanisms underlying eQTL tissue specificity we modeled it using genomic annotations and chromatin states from relevant ENCODE cell types while controlling for confounding effects. This model could predict whether an eQTL was shared between a discovery and replication tissue with an AUC of 0.73. Post-transcriptional effects were more likely to be shared than transcriptional effects, with stop gain ( $p=4.74e-31$ ) and splice variants ( $p=1.89e-19$ ) having the strongest sharing. On the transcriptional level, when compared to eQTLs in unannotated regions, those in promoters had a higher probability of sharing ( $p=1.49e-46$ ), while those in enhancers had a lower probability ( $p=6.55e-224$ ). Furthermore, active chromatin states were associated with higher tissue sharing ( $p = 0.011$ ) while inactive states were associated with lower sharing ( $p=9.98e-110$ ). Finally, we studied two main dimensions of tissue-specificity: eQTL strength and eGene expression level across tissues. These were correlated in 3,477 out of 26,499 tested eQTLs ( $FDR<5\%$ ), and in lower expressed genes eQTL effect size tended to increase with expression level, while highly expressed genes showed the opposite pattern ( $p=6.58e-107$ ). Altogether, our findings illustrate the power of studies that span broad tissues for determining the tissue specificity of regulatory variation and elucidating its mechanism.

**New methods for discovery and interpretation of allelic diversity in human genomes.** R.S. Fulton<sup>1,2</sup>, T. Graves-Lindsay<sup>1,2</sup>, A. Regier<sup>1,3</sup>, N. Das<sup>1</sup>, C. Tomlinson<sup>1</sup>, E. Belter<sup>1</sup>, N. Stitzel<sup>1,2,3</sup>, I. Hall<sup>1,2,3</sup>. 1) McDonnell Genome Institute at Washington University School of Medicine, St. Louis, MO; 2) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 3) Department of Medicine, Washington University School of Medicine, St. Louis, MO.

Interpretation of genomic sequencing data is currently reliant upon the human genome reference sequence. The public reference is a linear representation of a mosaic human genome with associated alternate alleles representing regions of significant allelic diversity. Although adequate for many regions of the genome, allelic diversity presents challenges where genomes being interrogated differ from the reference, or that variation lies in regions recalcitrant to short read mapping. Additionally, the common tool chain utilized in most genomic studies does not take advantage of alternate alleles and thus does not exploit many of these alternate representations. In an effort to unveil additional allelic diversity and to develop methods to discover such diversity through reference-free approaches, we at the McDonnell Genome Institute have initiated a project as part of our NHGRI Center for Common Disease Genomics (CCDG) program to generate and characterize >500 human genome assemblies from individuals of diverse ancestry and ethnicity. We are currently generating haplotype-resolved whole genome assemblies from ~60X long linked-read WGS data from the 10X Genomics platform using the Supernova assembly algorithm. A key aspect of this project is our effort to develop optimized laboratory processes that enable the highest quality assemblies possible from these data. We are constructing a pan-genome representation of genetic variation identified in these assemblies, using highly sensitive reference-free assembly comparison methods. We will then use variant graph alignment methods to genotype these variants in a larger cohort comprising tens of thousands of short-read WGS datasets generated for CCDG trait mapping studies. This reference-free trait association experiment will allow us to identify and genotype variants that would otherwise be missed by current reference-based analysis methods due to biases caused by regional fluctuations in ancestry and allelic diversity. This presentation highlights early findings and progress towards the ultimate goal of carrying out comprehensive and unbiased WGS-based human genetics studies that improve our understanding of disease risk in diverse human populations.

**443T**

**Systematic dissection of transcription factor co-binding as a positive predictor of regulatory activity.** A.A. Hardigan<sup>1,2</sup>, R.C. Ramaker<sup>1,2</sup>, E.C. Partridge<sup>2</sup>, S.B. Chhetri<sup>2,3</sup>, K.M. Newberry<sup>2</sup>, S. Goh<sup>4</sup>, B. Wold<sup>4</sup>, E. Mendenhall<sup>2,3</sup>, S.J. Cooper<sup>2</sup>, R.M. Myers<sup>2</sup>. 1) University of Alabama at Birmingham, Birmingham, AL; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 3) University of Alabama at Huntsville, Huntsville, AL; 4) California Institute of Technology, Pasadena, CA.

Transcription factors (TFs) are proteins that regulate gene expression through binding to regulatory DNA regions in the genome such as enhancers and promoters. Multiple TFs often interact at these regulatory regions and determining the nature of this cooperative binding on gene expression and genome regulatory architecture is critical to better understand TF biology. Using chromatin immunoprecipitation sequencing (ChIP-seq), our group recently determined the genome-wide occupancy of 208 TFs in the HepG2 cell line. We found a striking range of co-occupancy amongst TFs in this data set, with ~80% of loci containing <10 TFs, while 10% of loci contained >50 TFs. Using ENCODE ChIP-seq data, we also identified these highly bound loci, or “high occupancy target” (HOT) regions, in the K562 and GM12878 cell lines and identified shared and cell-type specific HOT regions. We found that the number of TFs bound at a given locus correlated significantly with gene expression levels of the nearest gene, and IDEAs promoter and strong enhancer annotations. Using DNase hypersensitive site sequencing (DNase-seq) data from ENCODE and TF footprinting, we replicated our analysis of TF occupancy and HOT regions and found a similar correlation of the number of TF footprints to gene regulatory metrics. However, only a minority of TFs with ChIP-seq binding sites in a given loci also had a DNase-seq TF footprint, indicating that the majority of factors bound at a site do so indirectly. To further dissect the importance of individual motifs and sequence variation in these HOT regions, we performed a massively parallel reporter assay using the self-transcribing active regulatory region (STARR-seq) method. We designed a custom library of 245 unique 130-bp test regions with tiled single nucleotide variants (SNVs) and 5-mer mutations across the length of the elements. We identified critical nucleotides governing TF motif and overall element activity, with a significantly higher proportion of mutations in DHS TF footprints, and found a significant correlation of between LS-GKM predicted motif disruptions and differential activity of mutant elements. Finally, we found a significant negative correlation between the number of motifs in an element and its overall vulnerability to mutation. This work helps support the important regulatory role of HOT regions, and furthermore provides a more complete understanding of the regulatory dynamics of TF occupancy and cooperation in the genome.

**444F**

**Latest improvements in the human genome reference assembly (GRCh38).** T. Rezaie<sup>1</sup>, T. Graves-Lindsay<sup>2</sup>, K. Howe<sup>3</sup>, P. Flicek<sup>4</sup>, V.A. Schneider<sup>1</sup> for the Genome Reference Consortium. 1) National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD; 2) McDonnell Genome Institute at Washington University, St. Louis, MO; 3) Wellcome Sanger Institute, Hinxton, Cambridge, UK; 4) European Molecular Biology Laboratory, European Bioinformatics Institute, Hinxton, Cambridge, UK.

The Genome Reference Consortium (GRC) provides users with updates to the human reference genome assembly. In this era of cutting-edge sequencing and assembly technologies, big data, and diagnostic genome sequencing, the reference genome continues to serve as a foundation for many types of research. It provides the coordinate system for genomic-based analyses and gene annotations, supports the identification of disease-associated variants and offers representation for the diversity of the human population. Our ongoing curation of this reference, the highest quality model of the human genome, provides assembly corrections and new variants, improving the representation of highly complex and clinically important genomic regions. Since the 2013 release of GRCh38, the latest coordinate-changing update to the human reference, the GRC has provided a total of 12 public assembly updates in the form of non-coordinate changing patch releases. As of GRCh38.p12 (GCA\_000001405.27), the reference includes 70 fix and 70 novel patch scaffolds, which represent chromosome path changes and alternate representations of sequences, respectively. These patches, which are stand-alone accessioned scaffolds, are given chromosome context via alignments that are available for download with the rest of the assembly. The current suite of patches covers 48 Mb (~1.5% of the total chromosome length), of which 2.23 Mb is novel sequence, and includes coding regions. We will describe our latest analyses to identify and update rare alleles (MAF<5%) affecting coding sequences in the reference. We will present examples of the use of sequence from highly contiguous WGS assemblies and optical maps data from different populations to close remaining GRCh38 gaps and add additional diversity to the reference. We will present GRC policies for data contributions to the reference and our plans for future assembly updates. We will show examples of recent updates, including those not yet released, that close assembly gaps, improve gene representations at clinically important loci, add genomic diversity and discuss their usage in basic and clinical analyses. The GRC is committed to making its curation efforts publicly accessible. Information about assembly issues and updates are available at <https://www.genomereference.org> and in genome browsers via the GRC track hub. We will review these resources available at the GRC website and mechanisms for contacting the GRC with assembly questions and curation requests.

**445W**

**A comprehensive characterization of mitochondrial DNA variants in 1,256 healthy Northern Virginian families.** *W. Zhu<sup>1</sup>, W. Wong<sup>1</sup>, X. Liu<sup>1</sup>, J. Deeken<sup>1,2</sup>, J. Niederhuber<sup>1,3</sup>.* 1) Bioinformatics, Inova Translational Medicine Institute, Fairfax, VA; 2) Virginia Commonwealth University School of Medicine, Richmond, VA; 3) Johns Hopkins University School of Medicine, Baltimore, MD.

Mitochondria play critical roles in cellular energy production and metabolism, and fully characterization of mitochondrial variants is essential for any large genome study. In this study, we whole-genome sequenced (~40X) 3,768 healthy subjects from 1,256 Northern Virginian trios (newborns and their parents), who participated in the "Childhood Longitudinal Study" at the Inova Translational Medicine Institute. Over 30% (N=810) of the total 2,512 parents from those families were born in Central America (N=652) or South America (N=158). We called mitochondrial variants using the bioinformatic tools MTool-Box and freebayes, and assigned haplogroup via the program HaploGrep2 (<http://haplogrep.uibk.ac.at>) with the mtDNA tree Build 17. Altogether, we found 17,456 mitochondrial variants in the 2,512 parents (an average of 6.9 per individual), including 16,468 homoplasmies and 988 heteroplasmies, from various haplogroups leading by A2 (20.1%, N=504) and B2 (6.8%, N=172). 88.2% of the identified homoplasmies are haplogroup markers, while only 26.3% of the heteroplasmies are haplogroup markers. Some homoplasmies like 8896A and 4227G have not been fixed in any known haplogroups, but were uniquely found in the Native American haplogroup A2w. The result indicated the emergence of novel subhaplogroups in the A2w lineage. Most of heteroplasmies found in the mothers were also inherited by their children but with fluctuated allele frequencies, suggesting the genetic bottleneck during the transmission. It is believed that there is co-evolution between mitochondrial DNA and nuclear DNA, and the disruption of such mitonuclear crosstalk may lead to the mitochondrial diseases. The disease-associated mitochondrial DNA mutations are well curated in the MitoMap database (<http://mitomap.org>). We found 3.4% of the homoplasmies were mitochondria disease related according to the MitoMap database, which is slightly lower than 5.4% in the heteroplasmies. Interestingly, some of the disease-associated variants are also haplogroup markers, suggesting that the pathogenic effects of those mitochondrial variants might be conditioned upon the nuclear DNA context. Further study may warrant enhancing our understanding in the association between the mtDNA variants and the mitochondrial diseases.

**446T**

**Shared patterns of variation between human individuals and cells: Somatic and germline mutation rates usefully predict each other.** *W. Meyerson<sup>1,2</sup>, M. Gerstein<sup>1,3,4</sup>.* 1) Program in Computational Biology & Bioinformatics, Yale University, New Haven, CT; 2) Yale School of Medicine, Yale University, New Haven, CT; 3) Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT; 4) Department of Computer Science, Yale University, New Haven, CT.

Human genetic variants occur in two settings: germline variants between individuals in a population and somatic variants between cells in our bodies. The former explains much human phenotypic diversity and disease risk; the latter drives cancer and affects aging and autoimmunity. To identify pathogenic mutations in either setting, we must understand the normal range of human variation as well as sequencing artifacts. While much is known about neutral somatic and germline variants, few studies have compared germline and somatic variants with each other. Such comparative analysis offers unique insight into ubiquitous mutational processes and sequencing artifacts and enables the principled combination of somatic and germline variants to yield a much greater effective sample size for mutation modeling, which is key for discovering the long tail of pathogenic variants of small effect at the frontier of genomics. The completion of two vast, uniformly processed whole-genome sequencing databases - the genome aggregation database (gnomAD) of 15,000 healthy germline samples and the PanCancer Analysis of Whole Genomes (PCAWG) of 2,500 somatic and germline samples from cancer patients - permits the interrelation of somatic and germline variant patterns at unprecedented scale. After excluding sites that are non-uniquely mappable, poorly covered in either database, or sites of common human variation, both gnomAD and PCAWG germline had a single nucleotide variant (SNV)-level overlap with PCAWG soma 2-3 times higher than expected by chance, higher still in cancers with a large prevalence of clock-like Signature 1. A similar overlap with soma was found using *de novo* germline variants from denovo-db, indicating that these results do not derive from the misclassification of true PCAWG germline variants as somatic variants. Mutation rates by heptamer showed high concordance between soma and germline, sometimes with surprising consistency. Megabase-level mutation rates also showed a high somatic-germline correlation, especially in low meiotic recombination regions. Most importantly, when predicting germline mutation rates by region from epigenetic features, somatic mutation rates enhanced accuracy and *vice versa*. These findings demonstrate a large shared component in somatic and germline SNV call-sets and highlight the utility of somatic and germline variants for modeling each other, a critical task in the search for variants that matter in human disease.

**Nuclear genetic regulation of the mitochondrial transcriptome across multiple tissue types.** A. Hodgkinson, A. Ali. Department of Medical and Molecular Genetics, School of Basic and Medical Biosciences, King's College London, London, United Kingdom.

Mitochondria play an important role in fundamental cellular processes and disease, however little is known about how the transcriptional regime of the mitochondrial genome varies across individuals and tissues. By analyzing >13,000 RNA sequencing datasets across 36 tissue/cell types, we find considerable variation in mitochondrial gene expression along the mitochondrial transcriptome, across tissue types and between individuals, highlighting the importance of cell-type specific and post-transcriptional processes in shaping cellular mitochondrial RNA levels across tissues. Using whole-genome genetic data we identify 64 nuclear loci associated with the expression levels of genes encoded in the mitochondrial genome, including missense variants within genes involved in mitochondrial function, implicating genetic mechanisms that act in *trans* across the two genomes. We replicate ~21% of associations with independent tissue-matched datasets and find genetic variants linked to these nuclear loci that have been associated with cardio-metabolic phenotypes and Vitiligo, supporting a role for variable mitochondrial gene expression in complex disease.

**DNA methylation age in type 1 diabetes.** *D. Roshandel<sup>1</sup>, Z. Chen<sup>2</sup>, B.H. Braffett<sup>3</sup>, J.M. Lachin<sup>4</sup>, A.J. Canty<sup>4</sup>, S.B. Bull<sup>5,6</sup>, R. Natarajan<sup>2</sup>, A.D. Paterson<sup>1,6</sup>, DCCT/EDIC Research Group.* 1) Genetics and Genome Biology Program, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Diabetes Complications and Metabolism, Beckman Research Institute of City of Hope, Duarte, CA, USA; 3) The Biostatistics Center, The George Washington University, Rockville, MD, USA; 4) Department of Mathematics and Statistics, McMaster University, Hamilton, ON, Canada; 5) Lunenfeld–Tanenbaum Research Institute, Sinai Health System, Toronto, ON, Canada; 6) Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada.

The levels of DNA methylation (DNAm) at some sites across the genome show age-related changes and have been used to accurately predict age in general population across a broad spectrum of human tissues. We investigated DNAm age and the factors affecting it in subjects with type 1 diabetes (T1D). T1D subjects were randomly assigned to intensive or conventional treatment groups in the Diabetes Control and Complications Trial (DCCT) in 1983–9. At DCCT close-out in 1993, intensive therapy was recommended for all and participants have since been followed through Epidemiology of Diabetes Interventions and Complications (EDIC). DNAm was measured in 63 subjects using Infinium HumanMethylation450K BeadChip in whole blood (WB) collected in 1992–3 and monocytes (MC) collected in 2009–10 (3 missing). These included 32 cases from conventional group with mean HbA1c>9.1% during DCCT and significant progression of retinopathy/nephropathy from DCCT closeout to EDIC year 10, and 31 controls from intensive group with mean HbA1c<7.3% and no progression of retinopathy/nephropathy. DNAm age and age acceleration (AA), the difference between DNAm and chronological age, were estimated using the Horvath method. The associations of sex, age at T1D diagnosis, T1D duration, and treatment group with AA were tested by multivariable linear regression. WB DNAm age was on average greater than chronological age in both cases and controls ( $p<0.0001$ ): AA=6.77 (range -0.09–16.50) and 5.14 yrs (range -0.27–17.08), respectively. Similarly, MC DNAm age was 4.31 (range -3.75–15.08) and 1.62 yrs (range -8.69–9.48) greater than chronological age in cases ( $p<0.0001$ ) and controls ( $p=0.068$ ), respectively; but the difference was only significant in cases. WB and MC AA were not significantly different between cases and controls ( $p=0.14$  and  $0.08$ , respectively). T1D duration from DCCT eligibility to DNAm measurement was associated with WB AA ( $\beta$  (SE)=0.07(0.03),  $p=0.017$ ). Age at T1D diagnosis was associated with MC AA ( $\beta$  (SE)=-0.23(0.08),  $p=0.008$ ). WB and MC AA were highly correlated within individuals (spearman  $\rho=0.62$ ,  $p<0.0001$ ). In conclusion, DNAm age was on average higher than chronological age in T1D. Longer T1D duration was associated with higher WB AA. Older age at T1D diagnosis was associated with lower MC AA. Caution in generalizing the results is required as the subjects were highly selected in terms of glycemic control and diabetic complications; and conventional therapy is no longer recommended.

**Allelic differences in adipocyte chromatin accessibility identify putative functional variants and mechanisms at loci associated with adipose tissue gene expression.** *K.W. Currin<sup>1</sup>, H.J. Perrin<sup>1</sup>, C.K. Raulerson<sup>1</sup>, A. Ko<sup>2</sup>, J. Luo<sup>3</sup>, M. Wabitsch<sup>4</sup>, P. Pajukanta<sup>2,5</sup>, M. Laakso<sup>6</sup>, K.L. Mohlke<sup>1</sup>.* 1) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 2) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA; 3) Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 4) Department of Pediatrics and Adolescents Medicine, Division of Pediatric Endocrinology and Diabetes, University of Ulm, Ulm, Germany; 5) Molecular Biology Institute at UCLA, Los Angeles, CA, USA; 6) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland.

To identify functional variants and mechanisms at cis-expression quantitative trait loci (eQTLs), we identified sites of allelic imbalance (AI) in chromatin accessibility in adipocytes derived from the Simpson Golabi-Behmel Syndrome (SGBS) cell strain. We genotyped SGBS cells using the Infinium Multi-Ethnic Global array, imputed additional genotypes (1000G phase 3), excluded non-diploid regions, and analyzed ~46M genotypes with posterior probability > 0.9. We profiled SGBS chromatin accessibility after day 14 of differentiation using ATAC-seq (3 replicates), resulting in 138M–156M non-duplicated nuclear alignments (mapq>=20). We removed ATAC-seq reads showing allelic mapping biases using WASP, resulting in 3.08M–3.45M reads overlapping heterozygous SNPs. To identify AI, we performed a beta-binomial test separately in each replicate using 13,127 SNPs with at least 20 total overlapping reads and at least 1 read per allele in all replicates. After combining AI p-values across replicates (Stouffer) and correcting for multiple testing (Benjamini-Hochberg), 623 SNPs showed significant AI (FDR<5%). All SNPs showed the same direction of imbalance in all replicates, and 497 (80%) were nominally significant ( $p<0.05$ ) in at least 2 replicates. The majority of AI SNPs (440, 70%) were found in promoter or enhancer chromatin states in Roadmap tissue-derived adipocytes. Using adipose tissue cis-eQTLs from the METabolic Syndrome in Men study ( $n=434$ ), we identified 85 AI SNPs that were an eQTL for 1 or more of 79 genes (FDR<5%) and were in high linkage disequilibrium ( $r2>=0.8$ ) with the lead eQTL variant for the same gene. 14 genes had lead eQTL variants in high LD with multiple AI SNPs, resulting in multiple candidate functional variants at these loci. For 69 AI SNPs that were eQTLs for only 1 gene, the allele with increased chromatin accessibility was most often associated with increased gene expression ( $n=51$ , 74%), suggesting AI SNPs mainly occur in regions of allelic binding of transcriptional activators; the remaining loci may occur in regions of allelic binding of transcriptional repressors or insulators. In most of the 16 cases when an AI SNP was an eQTL for 2 genes, the expression of both genes changed in the same direction ( $n=12$ , 75%). Our results suggest mapping chromatin accessibility AI in cultured cells can identify genetic variants that influence transcriptional regulatory elements and gene expression in tissue and help uncover how these variants function.

**Type 2 diabetes epigenome data repository and resource.** *Y. Sun, P. Kudtarkar, S. Morabito, K. Gaulton, AMP-T2D consortium.* Department of Pediatrics, University of California San Diego, School of Medicine, La Jolla, CA.

Genetic risk of type 2 diabetes (T2D) maps largely to the non-coding genome and affects gene regulation. The availability of functional genome and epigenome data from diabetes-relevant tissues has increased dramatically with the rapid progression of high-throughput molecular assay and sequencing technologies. However, this leaves a major challenge in connecting the epigenome with T2D genetic data to enable mechanistic and therapeutic discovery. Here we describe the Diabetes Epigenome Atlas ([www.t2depigenome.org](http://www.t2depigenome.org)) project which is a web service and database based on open source software developed by the ENCODE DCC. The goal of this project is to collect and centrally organize epigenome data from diabetes and complications-relevant tissues, provide a resource for researchers to query, obtain and analyze these data, and serve as a collaborative space for researchers to share and analyze proprietary data. The database currently hosts more than 1,050 published experiments of ChIP-seq, ATAC-seq, RNA-seq, WGBS, and scRNA-seq from pancreatic, adipose, liver, muscle, and brain tissue, primary cells, iPSC-derived cells and cell lines. Many of these experiments were fully re-processed from raw data using ENCODE pipelines. In addition, the database hosts 44 curated annotations of chromatin state, accessible chromatin sites, transcription factor binding sites, gene expression level in islets and other tissues. Examples of additional experimental and annotation data being added over time include chromatin interactions, high-throughput allelic assays, and expression and chromatin quantitative trait loci (QTL), and data from different disease states and cellular conditions. Available and proprietary tools for interacting with these data include querying genetic variant overlap with annotations, visualization of variant regulatory networks, enrichment analyses (e.g. fgwas, LD-score regression), and integration with T2D fine-mapping data. These tools will help prioritization and interpretation of T2D risk variants and identification of disease-relevant annotations. Furthermore, our database provides further integration with T2D genetic data through interface with the T2D Knowledge Portal ([www.type2diabetesgenetics.org](http://www.type2diabetesgenetics.org)). In total our resource, data and tools should facilitate studies to understand the genetic mechanisms underlying T2D pathogenesis.

**Parallel accelerated evolution in hibernating mammals identifies novel non-coding regions for shaping behavioral and metabolic traits linked to various human diseases.** *E. Ferris, C. Gregg.* Neurobiology and anatomy, University of Utah, Salt Lake City, UT.

**Introduction.** Hibernating mammals store large amounts of fat each year to be used as their primary metabolic fuel during torpor. As these mammals transition between metabolic fuels, entering and exiting hibernation, they go through changes including states of reversible insulin resistance and adiposity. Hibernation also involves dramatic modulation of blood clotting and the immune system. Understanding the genetic basis of these transitions may inform future treatment of human diseases like obesity and diabetes, as well as autoimmune and clotting disorders. Hibernation is an ancient trait and its frequent reappearance in different mammalian lineages suggests that the genes involved may be conserved, but gene regulatory mechanisms changed in hibernators compared to homeotherms. **Methods.** To identify non-coding elements shaping hibernation-related phenotypes, we compare genomic patterns of accelerated evolution in four distantly related and phenotypically distinct hibernators: thirteen-lined ground squirrel, mouse lemur, little brown bat and lesser hedgehog tenrec. We tested for parallel hibernation accelerated regions (ARs) in the genome and determine whether parallel hibernation ARs are enriched at seasonally regulated genes in hibernating species. We examine the nature of human homologs of hibernation ARs. **Results.** We identify 2,370 ARs with evidence for parallel, accelerated evolution in at least two of the four hibernators tested. These ARs are enriched near genes seasonally regulated in hibernating lemurs and squirrels. Human homologs of hibernation ARs are putative functional non-coding elements and are significantly overrepresented near genes linked to body mass index (BMI) in humans and genes differentially expressed in the hypothalamus of people with Prader-Willi syndrome compared to healthy controls. **Conclusion.** Our study identifies non-coding genetic elements that may regulate hibernation related traits in mammals. Further study of the functional properties of these novel elements in the mammalian genome may reveal novel mechanisms for shaping behavioral and metabolic traits involved in various human diseases.

**Functional genomics implicates folliculin as putative causal gene for diabetic retinopathy.** M. Grassi<sup>1</sup>, S. Jung<sup>2</sup>, A. Skol<sup>3</sup>, S. Chen<sup>4</sup>, S. Faza<sup>1</sup>, D. Cao<sup>1</sup>, B. Stranger<sup>1</sup>, The DCCT/EDIC Study group. 1) University of Illinois at Chicago, Chicago, IL; 2) Computation Institute, The University of Chicago, Chicago, IL; 3) Department of Medicine, The University of Chicago, Chicago, IL; 4) Cellular Screening Center Institute for Genomics & Systems Biology The University of Chicago, Chicago, IL.

Diabetic retinopathy is the leading cause of irreversible vision loss in the western world. We sought to identify and validate genes contributing to the genetic basis of diabetic retinopathy through changes in gene expression. We hypothesized that genes that display differential responses to glucose in diabetic subjects with and without retinopathy may contribute to genetic risk of diabetic retinopathy. To test this, we identified genes differentially expressed in diabetic patients with and without retinopathy. We tested for differential responses between diabetic subjects with proliferative diabetic retinopathy and without retinopathy matched for age, gender and ethnicity in EBV-transformed lymphoblastoid cell lines (LCLs). We measured gene expression before and after exposure to high glucose, defining a response to glucose phenotype for each LCL. Using genotype data from over 2.5M SNPs in each of 2829 diabetic subjects, we determined whether the association of expression quantitative trait loci (eQTLs), was consistent with our experimental observations of gene expression in the LCLs. Our analysis of a total of 15,569 genes identified 103 genes that exhibited significant differential expression in the response to glucose ( $p$ -value  $< 0.01$ ) between subjects with proliferative retinopathy and no retinopathy. We identified all of the genetic variants (eQTLs) that control gene expression for these genes and tested them for association to proliferative diabetic retinopathy. The 7253 eQTLs for these 103 genes demonstrated significant association with diabetic retinopathy ( $q$ -value  $< 0.05$ ,  $p$ -value = 0.003 vs. all eQTLs, and  $p$ -value = 0.006 vs. all SNPs). We identified *Folliculin* (*FLCN*), which plays a role in modulating AMPK signaling, as one of the putative susceptibility genes for diabetic retinopathy. *FLCN* expression was up-regulated in response to glucose in subjects with proliferative diabetic retinopathy compared to diabetic subjects without retinopathy ( $\log_2FC=0.276$ ,  $p$ -value=0.003). rs11867934, an eQTL of *FLCN* was significantly associated with proliferative diabetic retinopathy in two large cohorts of subjects with type 1 diabetes (meta  $p$ -value  $6.7 \times 10^{-6}$ , Bonferroni-corrected  $p$ -value  $< 0.05$ ). Therefore, *FLCN* may be a putative causal gene for diabetic retinopathy.

**Loss of star strand miR-192 resulted in liver steatosis to compensate for hyperglycemia in diabetes.** KK. Miu, X. Zhang, S. Hao, HH. Cheung, W. Chao, B. Feng, WY. Chan. School of Biomedical Sciences, The Chinese University of Hong Kong, NT, Hong Kong, China.

Liver steatosis is a sign of lipid overload often alongside impaired insulin signaling. In parallel, steatosis in diabetic mice is manifested by the microvesicular feature associated with poor disease prognosis. Circulating levels of miR-192 (5p, the guiding strand) was demonstrated for its prognostic value in diabetic complications, whilst being of high *in situ* expression suggested it has functions in liver. Reports indicated that it affects hepatic lipid metabolism via targeting SREBF1 and SCD1 along the *de novo* lipogenesis (DNL) pathway. Since the miRNA is tightly linked to diabetes, we screened and noted a lower expression of miR-192\* (3p, the star strand) but not 5p in the liver of diabetic mice when compared to heterozygous lean control. As its expression in visceral adipose tissue was reported to correlate with serum fat, its loss in the liver may represent a cause for liver steatosis—a co-morbidity in diabetes. To recapitulate the loss of miRNA in the diabetic liver, adenoviral sponge overexpression was used to deplete it in wild type mice given 30% fructose in drinking water. In these animals, hepatic lipid accumulation was increased with mild microvesicular steatosis after 2 months. To examine the action of its replenishment, we constructed an artificial shRNA stem-loop construct for star-strand specific overexpression. Diabetic mice with the construct demonstrated significant reduction of hepatic steatosis despite impaired glucose tolerance. To investigate the rationale for reduced steatosis, hepatic cell lines with star overexpression had reduced DNL under oil red staining when exogenously supplemented with fatty acids (FAs). We also observed that these cell lines promoted mitochondrial oxidation of FAs measured by Seahorse XF cell mito stress test, therefore potent in dissipating lipid load. Careful examination of transcriptome analysis in hepatic cell line overexpressing the construct revealed that it modulated the expression of key genes along the insulin signaling pathway such as IRS2, PEPCCK & INSIG1, etc., in addition to those affected by 5p. In fact, forced overexpression of the star miRNA also raised the level of its guiding counterpart. Gene ontology analysis revealed altered AMPK signaling resulting in lipid mobilization. With accumulating reports suggesting malfunctioned glucose utilization as a potential cause for liver steatosis, we argue the overlooked importance of miR-192\* in withholding glycerolipid homeostasis in the liver.

**1830W****The accessible chromatin landscape of pancreatic islet cell populations.**

*M. Okino<sup>1</sup>, J. Chiou<sup>2</sup>, S. Huang<sup>1</sup>, K. Gaulton<sup>1</sup>.* 1) Department of Pediatrics, UC San Diego School of Medicine, La Jolla, CA, 92093; 2) Biomedical Sciences Graduate Program, UC San Diego, La Jolla, CA, 9209.

Pancreatic islets are comprised of multiple endocrine cell types that regulate glucose homeostasis, and genetic variants affecting islet regulatory activity are a major contributor to type 2 diabetes (T2D). Islet cell types have distinct functions and secrete different hallmark hormones including beta (insulin) and alpha (glucagon) cells which together account for around 90% of the total cell mass. Rarer islet cell types include delta (somatostatin), gamma (PP), and epsilon (ghrelin) cells. While previous studies have mapped accessible chromatin in alpha and beta cells sorted by surface markers, the chromatin landscape of rarer cell types is currently uncharacterized. To address this question, we fixed primary islets using formalin and FACS-sorted fixed cells using antibodies targeting intracellular markers for insulin, glucagon and somatostatin. We then optimized an ATAC-seq protocol for fixed cells to map regions of accessible chromatin from the resulting sorted cell populations. Preliminary analyses of accessible chromatin generated from alpha cells identified 66.5k peaks and passed ENCODE quality metrics (e.g. FRiP>0.3) and showed high correlation to published alpha cell data (Spearman  $r>0.8$ ). We identified clear peaks at the promoters of alpha cell-specific genes such as *GCG* and *DPP4* and no signal at promoters for marker genes of other cell types such as insulin (*INS*) or somatostatin (*SST*). At distal enhancer peaks, we observed motif enrichment for known transcription factors important for alpha cell function and glucagon expression such as *FOXA1* and *MAFB*. We integrated alpha cell peaks with genetic fine-mapping data for 107 T2D signals and found high probability candidate causal variants in alpha cell peaks at 10 signals including *TCF7L2*, *ADCY5*, *CDC123* and *ZMIZ1*. We are currently sequencing sorted alpha, beta and delta cells from an initial three islet donors and are extending and scaling up this strategy to sort cells from all islet cell types in larger sample numbers. Our data will provide high-quality reference maps of common and rare islet cell populations to define cellular regulatory programs and understand their specific roles in T2D risk. Furthermore, our results provide an optimized method for generating accessible chromatin profiles from fixed cells that should be widely applicable to studies of human samples.

**1831T****Impact of pre-gestational body mass index and midgestational weight gain on DNA methylation of candidate CpG sites.** *J.O. Opsahl<sup>1</sup>, G.H. Moen<sup>2</sup>, K.I. Birkeland<sup>1,3</sup>, C. Sommer<sup>2</sup>.*

1) Institute of Clinical Medicine, University of Oslo, Oslo, Norway; 2) Dep. of Endocrinology, Morbid Obesity and Preventive Medicine, Oslo University Hospital, Oslo, Norway; 3) Department of Transplantation Medicine, Oslo University Hospital, Oslo, Norway.

Weight status prior to pregnancy and gestational weight gain during pregnancy is associated with increased risk of gestational diabetes (GDM). GDM increases the possibility of adverse pregnancy outcomes and increased risk of developing type 2 diabetes for both the mother and her offspring. The underlying mechanisms for the association between gestational weight status and gestational diabetes are largely unknown, but epigenetic alterations such as DNA methylation may be important. There are few published studies that have explored how pre-pregnant BMI and/or gestational weight gain are associated with DNA methylation in women, and the sample sizes are generally quite small. Here we explore how pre-gestational body mass index and mid-gestational weight gain from week 15-28 are associated with DNA methylation of candidate CpG (5'-C-phosphate-G-3') sites in European and South Asian women. The Stork Groruddalen study is a population-based multi-ethnic cohort of 823 pregnant women performed in Groruddalen, Oslo, Norway, 2008-2010. We have quantified DNA methylation at 850 000 CpG sites (Infinium MethylationEPIC BeadChip, Illumina) in the European (n=314) and South Asian (n=166) women who participated in the study. We here report candidate CpG sites detected in an epigenome-wide association study (EWAS) as well as candidate CpG sites found in studies outside of pregnancy. This study will provide a unique possibility to explore epigenetic factors, and will increase our understanding of how pre-pregnant BMI and weight gain are associated with DNA methylation. We will discuss the results of the analysis and their potential implications in the understanding of weight gain in pregnancy and pre-pregnancy BMI. Our results may increase our understanding of the mechanisms behind the detrimental effect of obesity on diabetes risk.

Genome-wide association studies (GWAS) have identified thousands of SNP associations to complex diseases, and the vast majority of them are located in intergenic regions. Molecular characterization of GWAS signals can therefore reveal key gene regulatory mechanisms underlying complex disease risk. Recent studies have linked specific risk loci to disrupted transcription factor (TF) binding and chromatin accessibility. However, most risk variants have not been systematically characterized for their effects on TF binding. Here, we adapted a modified HT-SELEX pipeline using 40bp human genomic sequences as ligands to quantitatively survey allelic imbalance of TF binding, termed SNP-SELEX. In total, we reported allelic binding specificities for 270 distinct human TFs at 95,887 candidate variants. The SNP-SELEX results showed a strong correlation with *in vivo* allele-biased TF binding and explained allelic imbalance in chromatin accessibility and enhancer activity. We then extended results of SNP-SELEX to predict regulatory variants affecting TF binding genome-wide through machine learning models. Specifically, we adapted deltaSVM to train a model for each TF using enriched sequences in SELEX experiments which we benchmarked using candidate variants assayed experimentally. In total, we trained models for 167 TFs with median AUROC (area under the receiver operating characteristic curve) 0.96 and AUPRC (area under PR curve) 0.75. We showed that SNP-SELEX models outperformed PWM models, and that predicted allelic TF binding is equivalent to experimental SNP-SELEX allelic TF binding with regard to *in vivo* allelic TF ChIP-seq binding, allelic imbalance in chromatin accessibility, and enhancer activity. We applied SNP-SELEX models to T2D GWAS data and found that variants affecting TF binding are enriched for T2D risk variants. Finally, we performed *in situ* Hi-C in HepG2 cells and normal human islet tissue to impute the target genes of variants with allelic TF binding. We found that allelic TF binding variants predicted by SNP-SELEX models are correlated with allelic gene expression of target genes, suggesting that SNPs affecting TF binding also affect gene expression. In sum, our study addresses an important gap in our knowledge about the impact of variants on TF binding and provides a valuable resource to interpret regulatory functional variants at disease risk signals through allelic TF binding.

**DNA methylation of TGF- $\beta$ 1 gene in T2DM associated nephropathy.** S. Singh<sup>1</sup>, S. Sonkar<sup>2</sup>, G. Sonkar<sup>2</sup>, A. Mahdi<sup>1</sup>. 1) Biochemistry, King George's Medical University, Lucknow, India; 2) Medicine, King George's Medical University, Lucknow, India.

Diabetes is a systemic disorder, over the course of time it affects almost every vital organ and ranked among leading causes of morbidity and mortality due development of micro and macro vascular complications in various organ. Diabetes also affects kidney and is now become the leading cause of End Stage Renal Disease. A total of 98 subjects were recruited in study including 37 T2DM, 22 DN and 39 healthy controls. Estimation of serum TGF- $\beta$ 1 was done by ELISA kit according to manufacturer's protocol. Methylation study was performed using methylation specific PCR. There was significant association of family history with T2DM. About 62.12% patients with T2DM had positive family history for diabetes. In 32.43% patients with T2DM and 27.27% patients with DN had tobacco chewing habit. Systolic pressure was found significantly increased in T2DM as well as DN group as compared to control group ( $p = 0.006$  and  $0.001$  respectively) while diastolic pressure was significantly increased in DN group as compared to control ( $0.002$ ). Glycosylated Haemoglobin was significantly decreased in T2DM and DN in our study group while serum creatinine was significantly raised in DN group. Circulatory levels of TGF- $\beta$ 1 was significantly higher with mean value  $256.07 \pm 62.72$  ng/ml in T2DM ( $p=0.006$ ), in DN  $349.81 \pm 76.12$  ng/ml ( $<0.0001$ ) as compared to control ( $213.06 \pm 69.57$  ng/ml). ROC analysis of TGF- $\beta$ 1 showed that area under curve was 87.0% and when we take the cut off value 297.5 ng/ml than sensitivity of this ELISA is 81.8% and Specificity is 77.6%. TGF- $\beta$ 1 had significant correlation with serum creatinine ( $p=0.044$ ) and HbA1c ( $p=0.037$ ). About 68.18% patients with DN group, 13.51% DM patients had unmethylation in CpG island and hypomethylation of TGF- $\beta$ 1 was significantly increased ( $p= <0.001$ ) in DN group. TGF  $\beta$ 1 had significant correlation with blood urea, serum creatinine and glycosylated haemoglobin. Therefore, TGF  $\beta$ 1 is better predictor for progression of nephropathy in our study group. .

**1834T**

**Of the relationship between the adipose transcriptome and diabetes, insulin resistance and polygenic risk scores: thousands of transcripts in adipose tissue are associated with diabetes status, fasting insulin levels and insulin resistance PRS.** K.S. Small<sup>1</sup>, C.A. Glastonbury<sup>2</sup>, A.C. Alves<sup>1</sup>, J.S. El-Sayed Moustafa<sup>1</sup>. 1) King's College London, London, United Kingdom; 2) Big Data Institute, University of Oxford, Oxford, United Kingdom.

Diabetes affects over 400 million adults worldwide, with type 2 diabetes (T2D) accounting for ~90% of cases. T2D GWAS have highlighted the role of beta-cell dysfunction, with increasing recognition of the role of adipose tissue, through its contribution to insulin resistance (IR). Disentangling the relationship between gene expression and diabetes, and underlying quantitative traits such as fasting glucose (FG) and fasting insulin (FI), will be key to understanding the contribution of tissues beyond the beta cell to diabetes. We investigated the relationship between genetics, gene expression and concurrently measured FI, FG, and T2D/IR case-control status using RNASeq gene expression data from adipose tissue, skin and LCLs in ~800 females from TwinsUK. Glycemic trait–gene expression associations were adipose-specific, with no significant associations in skin or LCLs, but 8212, 111, and 2671 genes associated with FI, FG and T2D/IR, respectively in adipose tissue (FDR 5%). Adipose expression-glycaemic trait results replicated in an external adipose dataset (N=770). Expression levels of 60% of T2D and glycaemic trait GWAS genes were associated with FI (enrichment OR=1.9; P=0.001), including *CDKN2B*, *IDE*, *IRS1*, *KCNQ1*, *KLF14*, *PPARG* and *TCF7L2*. Genes associated with each of FI and T2D/IR were enriched for functional categories including NIDDM (FI:  $Q_{\text{Bonferroni}}=6 \times 10^{-10}$ ; T2D/IR:  $Q_{\text{Bonferroni}}=6 \times 10^{-9}$ ), response to glucose (T2D/IR:  $Q_{\text{Bonferroni}}=1 \times 10^{-9}$ ) and cellular response to insulin (FI:  $Q_{\text{Bonferroni}}=3 \times 10^{-2}$ ). To investigate shared genetic aetiologies between T2D/IR and adipose gene expression, we calculated polygenic risk scores (PRS) for both T2D and IR using published GWAS SNPs. In TwinsUK (N=6448), both IR and T2D PRS were associated with T2D (IR PRS  $P=1 \times 10^{-4}$ ; T2D PRS  $P=1 \times 10^{-9}$ ) and T2D/IR case-control status (IR PRS  $P=6 \times 10^{-7}$ ; T2D PRS  $P=3 \times 10^{-3}$ ). After BMI correction, IR, but not T2D PRS was strongly associated with DXA-derived adiposity traits (IR PRS  $P_{\text{min}}=9 \times 10^{-22}$ ). The two PRS showed a strikingly different relationship to the adipose transcriptome; after BMI correction, at an FDR 5% 6,191 genes were associated with the IR PRS, but zero genes with the T2D PRS. This may reflect overrepresentation of beta-cell-driven effects among T2D GWAS hits, or mediation of adipose-specific effects at these loci through BMI. This study helps further elucidate the role of adipose gene expression in risk of type two diabetes and mediation of downstream complications.

**1835F**

**Integration of epigenomic profiles from islet developmental precursors with genome-wide association data reveals contributions of developmental processes to type 2 diabetes risk.** A. Wang<sup>1,2</sup>, R. Geusz<sup>1,2</sup>, J. Chiou<sup>1,2</sup>, N. Wetton<sup>1,2</sup>, J. Wang<sup>1,2</sup>, S. Kefalopoulou<sup>1,2</sup>, I. Matta<sup>1,2</sup>, A. Aylward<sup>1,2</sup>, B. Ren<sup>3,4</sup>, K.A. Frazer<sup>1</sup>, K.J. Gaulton<sup>1,2,5</sup>, M. Genetic risk of type 2 diabetes (T2D) is primarily driven by variation within the non-coding genome. T2D risk variants largely impact genomic elements that regulate pancreatic islet function or other tissues involved in glucose homeostasis such as liver, adipose, and skeletal muscle. In this work, we aimed to uncover novel mechanisms of T2D genetic risk beyond the mature tissues typically associated with disease pathogenesis. Specifically, we focused on the embryonic pancreas to investigate whether pancreatic developmental processes contribute to T2D risk. To address this question, we generated genome-wide chromatin accessibility (ATAC-seq), and chromatin state (histone modification ChIP-seq) maps representing early (stem cell, definitive endoderm, gut tube) and late (pancreatic progenitor) stages of an *in vitro* human pluripotent stem cell (hPSC) differentiation model of human pancreas development. We observed enrichment of T2D-associated variants in regions of open chromatin within 'stretch' enhancer elements specific to late pancreatic progenitors which are turned off in differentiated islets. Genes proximal to these elements were predicted to regulate core developmental processes such as cell proliferation, polarity, and morphogenesis; processes which play critical roles in pancreatic cell allocation and determination of islet cell mass. Among known fine-mapped T2D risk signals that mapped in progenitor-specific 'stretch' enhancers and not in islet enhancers was *LAMA1*. Further integration of progenitor-specific enhancer and genome-wide T2D association data revealed novel candidate T2D risk loci with proximal genes predicted to also regulate developmental processes. To functionally validate the stretch enhancers harboring T2D risk variants, we employed CRISPR-Cas9 genome editing in hPSCs and differentiated these hPSCs toward pancreas. We determined that multiple T2D-risk stretch enhancers at both known and novel risk loci are required for proper expression of *LAMA1* and other T2D risk-associated genes in pancreatic progenitor cells. Altogether, our results support a novel role for genetic variants affecting pancreatic developmental regulatory programs in T2D risk, independent of genetic effects on mature islet cells and other T2D-relevant cell types.

**Role of breastfeeding on epigenetic mechanisms underlying early-life growth trajectories.** L. Briollais<sup>1</sup>, D. Rustand<sup>1,2</sup>, P. McGowan<sup>3</sup>, S. Matthews<sup>3</sup>, S. Lye<sup>3</sup>. 1) Lunenfeld-Tanenbaum Research Institute, Toronto, Canada; 2) ISPED, University of Bordeaux, France; 3) University of Toronto, Toronto, Canada.

**Introduction:** Previous research has clearly established a link between early environment (pre-natal and post-natal), genetic, and behavioural factors on the development origin of health and diseases (DOHaD). Among the environmental factors, breastfeeding has been advocated in the prevention of overweight/obesity and is recommended by WHO as the "perfect food for the newborn". Each month of breastfeeding results in a 4% reduction in risk of being overweight. The biological mechanisms underlying the role of breastfeeding remain unclear, but a plausible explanation could be through the regulation of epigenetic mechanisms involved in developmental programming. Our goal here was to identify new epigenetic marks associated with birth weight, BMI at birth and longitudinal BMI and to assess whether the duration of exclusive breastfeeding (EXBF) affects these marks during child development. **Methods:** We studied approximately 1,000 children from the British Avon Longitudinal Study of Parents and Children (ALSPAC) cohort and conducted an epigenome-wide association study (EWAS) of birth weight and BMI at birth as well as a longitudinal analysis of child BMI up to 17 years of age in relation to methylation of the EWAS hits, several candidate genes and EXBF. **Results:** The EWAS identified several CpG sites where methylation profile correlated significantly with either birth weight or BMI at birth. We also found several EWAS hits (in genes *NCOR2*, *TMEM30A*, *CHD5*) and CpG sites from candidate genes (*IGF1R*, *IGF2R*, *IGF2BP2*, *IGF2*, *LEP*, *LEPR*, *NPY*, *SLC2A4*, *CDKN2A*) where methylation profile was modulated by EXBF and impacted children longitudinal BMI through infancy and adolescence. Many of the differential methylated genes form part of the mTOR signaling pathway. These CpG sites could be hyper- or hypo-methylated by EXBF but the interaction with EXBF systematically resulted in reduced BMI in the first year of life. The CpG sites involved could have differential age- and sex-specific mechanisms. **Conclusion:** Our study demonstrates that EXBF could regulate early life epigenetic modifications of key genes involved in developmental programming, especially via modulation of the mTOR pathway, which in turn could impact the risks of overweight/obesity in children. Our study could have implications for the future prevention of overweight and obesity in both children and adults.

**Differentially methylated loci in NAFLD cirrhosis are associated with key signaling pathways.** J.K. DiStefano<sup>1</sup>, I. Malenica<sup>1</sup>, L. Laci<sup>1</sup>, X. Chu<sup>2</sup>, A.T. Petrick<sup>3</sup>, C.D. Still<sup>2</sup>, G.S. Gerhard<sup>2</sup>. 1) Translational Genomics Research Institute, Phoenix, AZ; 2) Geisinger Obesity Institute, Danville, PA; 3) Temple University School of Medicine.

Altered DNA methylation events contribute to the pathogenesis and progression of metabolic disorders, including nonalcoholic fatty liver disease (NAFLD). Investigations of global DNA methylation patterns in liver biopsies representing severe NAFLD fibrosis have been limited. The purpose of this study was to investigate global patterns of DNA methylation in NAFLD-related cirrhosis. Patients with biopsy-proven NAFLD fibrosis/cirrhosis (N=14), and age- and sex-matched controls with normal histology (N=15) were recruited from the Bariatric Surgery Program at the Geisinger Clinic Center. Whole genome methylation was performed using the 450K Infinium Methylation BeadChip assay. Methylation levels for each CpG residue were estimated as the ratio of the methylated signal intensity over the sum of the methylated and unmethylated intensities at each locus and differential methylation between fibrotic and normal samples was determined using the City of Hope CpG Island Analysis Pipeline (COHCAP) and the minfi software. Hepatic gene expression was measured using RNA-sequencing. To identify gene-methylation correlations, we compared beta-values for each CpG site to read counts of its corresponding gene obtained from RNA-sequencing analysis. Ingenuity Pathways Analysis software was used to identify canonical signaling pathways and establish network connections associated with dysregulated CpG islands. We identified 208 CpG islands (CGI), including 99 hypomethylated and 109 hypermethylated CGI, showing statistically significant evidence (FDR <0.05) for differential methylation between cirrhotic and normal samples. Comparison of beta-values for each CGI to the read count of its corresponding gene revealed negative correlation (FDR <0.05) for 34 transcripts. Functional enrichment analysis of the differentially methylated CGI identified 113 significantly enriched canonical pathways, many classified as cell signaling. Comparison of our results with previously published studies identified 86 shared sites showing differential methylation, suggesting that genes common to multiple diverse studies may be important in disease pathogenesis. These findings provide additional evidence supporting a role for CpG methylation in the pathogenesis of NAFLD-related cirrhosis, including replication of previously reported differentially methylated CGIs, and contribute new insight into the molecular mechanisms underlying the initiation and progression of liver fibrosis and cirrhosis.

**Characterization of open chromatin and chromosomal interactions in human primary adipocytes reveals environment-responsive cardiometabolic GWAS loci.** K.M. Garske<sup>1</sup>, Y. Bhagat<sup>1</sup>, D.Z. Pan<sup>1,2</sup>, M. Alvarez<sup>1</sup>, P. Pajukanta<sup>1,2,3</sup>. 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 2) Bioinformatics Interdepartmental Program, UCLA, Los Angeles, USA; 3) Molecular Biology Institute at UCLA, Los Angeles, USA.

We hypothesized that environmental contexts affect genomic regulatory elements underlying cardiometabolic disease. To detect adipocyte-specific open chromatin regulatory regions that respond to lipid challenge, we first performed Assay for Transposase-Accessible Chromatin (ATAC)-sequencing in human primary adipocytes and their precursors. We found that 32.5% (50,336/154,647) of the ATAC-peaks were more accessible in the adipocytes than in preadipocytes. Compared to all ATAC-peaks, these adipocyte-accessible peaks exhibit an enrichment in both the CCAAT-Enhancer Binding Protein (CEBP) transcription factor motif ( $p$ -value=1.0x10<sup>-393</sup>) and in imputed enhancer annotations for adipocytes (1.46X larger effect size). Next, to detect regions responding to lipid challenge, we treated the human primary adipocytes with monounsaturated or saturated fatty acids and performed ATAC-seq, which resulted in 1,653 differentially accessible, lipid-responsive (LR) peaks, 572 of which (34.6%) are adipocyte-accessible peaks. A total of 75.1% of the adipocyte-accessible LR peaks fall within enhancers and 14.8% within promoters, suggesting that these regions are highly important for adipocyte gene regulation. Then, to detect active enhancers and their target genes, we performed promoter Capture Hi-C in the adipocytes and found that 277/572 (49.3%) of the adipocyte-accessible LR peaks either fall within an interacting promoter or within a promoter-interacting enhancer fragment. GWAS variants within these regions can give insight into environment-responsive mechanisms contributing to disease phenotypes. We found that 23 cardiometabolic GWAS SNPs fall within the adipocyte-accessible LR peaks involved in chromosomal interactions, including promoters of 8 genes. These SNPs included lipid-associated SNPs in the *FADS1/2* promoter. Supporting our data, SNPs at the *FADS1/2/3* locus have been shown to exhibit positive selection in Inuits, likely due to selective pressure from their high-fat diet. Other environment-responsive GWAS loci we identified include the promoter regions for *HOXC9* (waist-hip-ratio), *CARM1*, and *MLXIPL* (serum lipids). Taken together, our data identify 8 novel environment-responsive metabolic GWAS genes at open chromatin, promoter-enhancer regulatory circuits in human primary adipocytes. This implies that some cardiometabolic GWAS loci are influenced by the environmental context, providing strong candidates for gene-environment interaction analysis in large cohorts.

A deeper epigenomic understanding of spatial and functional organization of cells in human tissues is an important challenge. Here we report the first combined positional analysis of transcriptomes and methylomes across three micro-dissected zones (pericentral, intermediate and periportal) of human liver. We identify pronounced anti-correlated transcriptional and methylation gradients including a core of 271 genes controlling zoned metabolic and morphogen networks. A prominent porto-central gradient of DNA methylation at binding sites for 46 ENCODE transcription factors points towards a methylation gradient dependent control of transcription. The gradient includes specific epigenetic and transcriptional signatures in the wnt pathway supporting the concept of a pericentral hepatocyte regeneration pathway in humans under steady-state conditions. Surprisingly, while metabolic gene expression changes across zones are observed with increasing severity of non-alcoholic fatty liver disease, the relative zoned expression and methylation differences across zones remain unchanged. This observation suggests a maintained molecular zonation during reversible early NASH states. Overall our data provide a wealth of new positional insights into zonal networks controlled by epigenetic and transcriptional gradients in the human liver lobule.

**1840T****Genetic variation affects browning potential of white adipose tissue through genome-epigenome interactions at the *Ucp1* enhancer.** Y. Hiraike<sup>1</sup>, H. Waki<sup>1,2</sup>, S. Tsutsumi<sup>3</sup>, H. Aburatani<sup>3</sup>, T. Yamauchi<sup>1</sup>, T. Kadowaki<sup>1,4</sup>.

1) Department of Diabetes and Metabolic Diseases, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan; 2) Department of Molecular Science on Diabetes, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan; 3) Genome Science Division, Research Center for Advanced Science and Technology, The University of Tokyo, Meguro-ku, Tokyo, Japan; 4) Department of Prevention of Diabetes and Lifestyle-Related Diseases, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Japan.

While white adipose tissue (WAT) stores energy as lipids and expands in obesity, brown adipose tissue (BAT) dissipates energy as heat, mainly by means of the uncoupling protein-1 (Ucp1) on the mitochondrial inner membrane. Ucp1-positive adipocytes are also found sporadically in WAT depots after cold and sympathetic stimulation, and this phenomenon is called "browning" or "beiging" of WAT. Stimulating development and/or function of brown and beige adipose tissue is highly anticipated as a novel strategy for the treatment of obesity and its complications including diabetes. However, it is well known that there are more than ten-fold variations in BAT activity among human individuals. The same is also true for mice. Inbred mice strains such as A/J and 129 are resistant to diet-induced obesity compared to B6 strain, and browning potential of WAT of A/J and 129 is much higher than that of B6. Here, we have developed a primary beige adipocyte culture system from WAT of B6, 129 and F1 offspring of B6 and 129 to perform comprehensive, genome-wide analyses to dissect the mechanisms underlying the strain difference. Expression levels of Ucp1 is much higher in 129 than in B6 in a cell-autonomous manner. Transcriptome analyses led us to identify a transcription factor Lim homeobox protein 8 (Lhx8), whose expression is significantly higher in 129 than in B6, as a novel browning regulator. Nevertheless, based on the analyses using the F1 cells, we argue that the difference in *Ucp1* expression between B6 and 129 strain primarily comes from the *cis* effect rather than the *trans* effect. In the F1 cells, we observed significant and strong (>70%) allelic imbalance of the *Ucp1* mRNA transcripts favoring 129. At the *Ucp1* enhancers, we also observed 129-favored imbalance of transcription factor binding including PPAR $\gamma$  and NFIA, a transcription factor which we recently identified as a crucial regulator of the BAT gene program. Through promoter capture Hi-C and computational analyses, we identified candidate SNPs responsible for the strain difference at the *Ucp1* -11.7kb enhancer, as well as a candidate transcription factor which negatively regulates *Ucp1* expression and its binding might be negatively affected by one of the SNPs in the 129 alleles. These results would offer a platform for understanding the mechanisms underlying the substantial variation in human BAT activity and for the implementation of "precision medicine" in BAT-targeted anti-obesity therapy.

**1841F****Epigenome-wide association study of change in body mass index and glycaemic trait levels from young- to middle adulthood in 595 Northern Finland Birth Cohort 1966 participants.** I. Prokopenko<sup>1</sup>, M. Kaakinen<sup>1,2</sup>, L. Prelot<sup>3</sup>, M.D. Anasanti<sup>3</sup>, Z. Balkhiyarova<sup>1</sup>, M. Wielscher<sup>3</sup>, S. Sebert<sup>1,4</sup>, M.-R. Jarvelin<sup>3,4</sup>, H. Draisma<sup>1</sup>.

1) Section of Genomics of Common Disease, Department of Medicine, Imperial College London, London, United Kingdom; 2) Centre for Pharmacology and Therapeutics, Department of Medicine, Imperial College London, London, United Kingdom; 3) Department of Epidemiology and Biostatistics, School of Public Health, Imperial College London, London, United Kingdom; 4) Center for Life Course Health Research, University of Oulu, Oulu, Finland.

Genome-wide association studies (GWAS) have identified thousands of genetic loci for various phenotypes cross-sectionally, but GWAS haven't been successful in identifying *longitudinal* genetic effects. A number of associations of interindividual variation in adiposity and glycaemic trait levels with variation in the degree of DNA methylation have been reported. However, the relationship between *longitudinal* changes in these phenotypes and differential methylation is underexplored. We aimed to develop novel methodology for the detection of longitudinal effects on DNA methylation and tested it on the examples of change in body mass index (BMI), waist/hip ratio (WHR), fasting blood plasma glucose (FG) and fasting blood insulin (FI) levels in individuals without diabetes over time. For 595 individuals from the Northern Finland Birth Cohort 1966 for whom both phenotype and concurrent methylation data were available at both ages 31 (T1) and 46 (T2), we calculated the average change in phenotype value per year between T1 and T2. For all phenotypes we used change residuals corrected for sex to test for association with the degree of methylation measured in blood at T2 for 832,569 markers on the Illumina (San Diego, CA, USA) MethylationEPIC BeadChip using methylSCO-PA software, developed by us. We quality-controlled the methylation data, regressed out the effects of measured (potential) confounders, normalized the methylation signal intensity data, and mapped genomic locations to CGCh37/hg19. We detected epigenome-wide significant associations ( $P < 1 \times 10^{-7}$ ) with BMI change at cg14476101 (chr1:120,255,992;  $\beta = -0.05$ ,  $SE = 9.1 \times 10^{-3}$ ), cg11376147 (chr11:57,261,198;  $\beta = -0.01$ ,  $SE = 2.6 \times 10^{-3}$ ), and cg03067296 (chr17:76,274,577;  $\beta = -0.05$ ,  $SE = 8.1 \times 10^{-3}$ ) representing *PHGDH*, *SLC43A1*, and *LOC100996291* loci, respectively. *PHGDH* and *SLC43A1* are established for concurrent BMI and for BMI change, whereas the association with *LOC100996291* is novel. For FG change, we observed epigenome-wide significant association with cg20367077 (chr11:19,224,117;  $\beta = 0.11$ ,  $SE = 0.02$ ) annotated to *CSRP3*, implicated in obesity-induced insulin resistance in murine and human skeletal muscle. We didn't observe epigenome-wide significant associations with change in either WHR or FI. We implemented a novel method to detect associations between change in phenotype over time and DNA methylation and provide the first account of its use on the example of longitudinal changes in measures of obesity and glycaemic trait levels.

**1842W**

**High-dimensional mediation analysis in causal inference framework.** Y. Song<sup>1</sup>, X. Zhou<sup>1</sup>, M. Zhang<sup>1</sup>, W. Zhao<sup>2</sup>, J. Smith<sup>2</sup>, B. Needham<sup>2</sup>, B. Mukherjee<sup>1,2</sup>. 1) Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI; 2) Department of Epidemiology, School of Public Health, University of Michigan, Ann Arbor, MI.

Causal mediation analysis aims to examine the role of a mediator or a group of mediators that lie in the pathway between an exposure and an outcome. Recent studies often involve a large number of potential mediators based on high-throughput technologies. Most of the current analytic methods focus on settings with one or a moderate number of potential mediators. With the expanding growth of omics data, joint analysis of molecular-level genomics data with epidemiological data through mediation analysis is becoming more common. However, this requires methods that can simultaneously accommodate high-dimensional mediators. To address this problem, we develop a Bayesian inference method using continuous shrinkage priors to extend previous causal mediation analysis techniques to a high-dimensional setting. Simulations demonstrate that our method improves the power of global mediation analysis and has decent performance to identify true non-null mediators. We also construct tests for natural indirect effects using a permutation procedure. We applied our method to Multi-Ethnic Study of Atherosclerosis (MESA) and identified DNA methylation regions that actively mediate the effect of neighborhood characteristics / socioeconomic status (SES) on health outcomes.

**Integrating epigenetic maps and genetic fine-mapping implicates tissues of action and effector transcripts at loci associated with type 2 diabetes.** J.M. Torres<sup>1,2</sup>, A. Mahajan<sup>1</sup>, M. Abdalla<sup>1</sup>, A. Payne<sup>1</sup>, J. Fernández-Tajes<sup>1</sup>, M. Thurner<sup>1,2</sup>, V. Nylander<sup>2</sup>, A.L. Gloyn<sup>1,2</sup>, M.I. McCarthy<sup>1,2</sup>, DIAMANTE Consortium. 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology, and Metabolism, University of Oxford, United Kingdom.

The number of loci associated with type 2 diabetes (T2D) has recently expanded to >400 in Europeans. However, resolving the molecular mechanisms that drive genetic risk to T2D largely remains a challenge as most genetic associations are non-coding and their relevant tissue(s) of action is unclear. To meet this challenge, we developed a framework for integrating tissue specific gene expression and epigenetic maps to obtain tissue-of-action (TOA) scores by systematically dividing SNP-level posterior probabilities of association (PPA) from Bayesian fine-mapping. PPA signals are partitioned by membership in a set of genomic annotations that are weighted by their enrichment for T2D-associated variants. We applied this scheme to a set of 380 loci from a large and densely-imputed GWAS meta-analysis (>74K T2D cases and >824K controls; imputed to a reference panel of >30K haplotypes) and obtained TOA scores for each locus for islet, liver, skeletal muscle, and subcutaneous adipose tissue. Unsupervised clustering analysis of TOA scores showed primary separation of loci with high islet scores from those with high scores for peripheral insulin-responsive tissues. We next assigned each locus to a most likely tissue-of-action and found that most were classified as islet-driven (45%) followed by adipose (14%), liver (12%) and muscle (7%). Proximal genes annotated to each set of tissue-classified loci exhibited significant co-expression in the corresponding tissue. Moreover, loci classified as islet were enriched for loci at which multi-trait profiles indicated a primary effect on insulin secretion (p-value = 0.013). Conversely, loci assigned as adipose, liver, or muscle were most enriched for loci with trait profiles consistent with insulin action and/or dyslipidemia. Credible SNPs for each set of classified loci were enriched for accessible DNA regions and expression quantitative trait loci (eQTLs) in the corresponding tissue. Furthermore, only islet loci showed improved fine-mapping in a functional GWAS using chromatin states based on islet DNA methylation, ATAC-seq peaks, and histone modifications (p = 0.005). Lastly, we used these TOA scores in conjunction with an eQTL colocalization analysis to jointly prioritize relevant tissues and effector transcripts at T2D loci. This integrative framework guides mechanistic inference by directing functional validation studies to the most relevant tissues and can be incorporated into process-specific genetic risk scores.

**1844F****Exploration of DNA methylation sites associated with adiponectin levels based on a gene co-expression network and DNA methylation data analysis.**

*M. Nakatochi<sup>1</sup>, S. Ihichara<sup>2</sup>, K. Yamamoto<sup>3</sup>, T. Matsubara<sup>4</sup>, M. Yokota<sup>5</sup>.*

1) Center for Advanced Medicine and Clinical Research, Nagoya University Hospital, Nagoya, Japan; 2) Department of Environmental and Preventive Medicine, Jichi Medical University School of Medicine, Shimotsuke, Japan; 3) Department of Medical Biochemistry, School of Medicine, Kurume University, Kurume, Japan; 4) Department of Internal Medicine, School of Dentistry, Aichi Gakuin University, Nagoya, Japan; 5) Department of Genome Science, School of Dentistry, Aichi Gakuin University, Nagoya, Japan.

**Aims** Abnormal secretion of adiponectin is strongly correlated with the development of lifestyle-related diseases. The serum adiponectin level is known to be affected by single nucleotide polymorphisms (SNPs); however, such SNPs account for only a small proportion of the heritability of the adiponectin concentrations. In this study, we explored DNA methylation (DNAm) sites associated with the adiponectin levels using a gene co-expression network analysis and integration analyses with DNAm levels. **Methods** We applied a three-step approach to identify DNAm sites associated with adiponectin. First, we performed a gene co-expression network analysis using seven publicly available microarray datasets to extract a module most significantly associated with the expression level of the *ADIPOQ* gene that encodes adiponectin protein (*ADIPOQ* module). In the seven datasets, a total of 855 adipose tissue samples were included. The co-expression network analysis was performed using the weighted correlation network analysis. Second, we explored DNAm sites significantly associated with *ADIPOQ* expression levels from DNAm sites located near *ADIPOQ* module genes. The exploration analysis was performed using 626 adipose tissues from a Caucasian population. In addition, we verified whether these DNAm sites were associated with the serum adiponectin levels in 191 whole blood samples from a Japanese population. Finally, we assessed whether the DNAm sites and adiponectin-associated SNPs were independently associated with serum adiponectin levels. **Results** In the gene co-expression analysis, we obtained an *ADIPOQ* module most significantly associated with the *ADIPOQ* expression level. An integration analysis identified three DNAm sites, which were located near *ADIPOQ* module genes, associated with both *ADIPOQ* and serum adiponectin levels. Out of the three sites, DNAm site X was located near *PPARG*, which regulates the expression of *ADIPOQ* ( $\beta=0.375\pm 0.105$ ,  $P=0.0004$  in adipose tissues,  $\beta=0.340\pm 0.149$ ,  $P=0.024$  in whole blood). Two DNAm sites, including DNAm site X, remained significantly associated with serum adiponectin levels after adjustment for adiponectin-associated SNPs (DNAm site X:  $\beta=0.362\pm 0.163$ ,  $P=0.028$ ). **Conclusions** A gene co-expression analysis and integration analyses with DNAm data identified three DNAm sites associated with both *ADIPOQ* expression levels and serum adiponectin levels. These results provide new insights into the regulation of adiponectin via epigenetic effects.

**1845W****Association of miR-421 expression with adiponectin homeostasis and insulin resistance in metabolic syndrome patients.**

*R.H. Bortolin<sup>1,2</sup>, A.A. Braga<sup>1,2</sup>, G.M. Bastos<sup>2</sup>, M.E.G. Saldarriaga<sup>1,2</sup>, R.C.C. Freitas<sup>1,2</sup>, H-T.L. Wang<sup>2</sup>,*

*J.B. Borges<sup>1,2</sup>, L.R. Castro<sup>2</sup>, M.F. Sampaio<sup>2</sup>, J.I.D. França<sup>2</sup>, R.D.C. Hirata<sup>1,2</sup>, M.H. Hirata<sup>1,2</sup>.* 1) Faculdade de Ciências Farmacêuticas, Universidade de São Paulo, São Paulo, SP, Brasil; 2) Laboratório de Investigação Molecular em Cardiologia, Instituto Dante Pazzanese de Cardiologia, São Paulo, SP, Brasil.

Metabolic syndrome (MetS) is a cluster of metabolic disorders that can affect the over 20% of global adult population. Effective treatment of MetS and its complications have been challenging. Understanding the molecular mechanisms involved in the adipokines homeostasis may contribute to identify novel biomarkers and/or drug targets in MetS. We investigated the association of plasma miRNA profile with metabolic and adipokines variables in MetS Brazilian patients. MetS (n=88) and non-MetS (n=144) subjects were classified according International Diabetes Federation criteria. Biodemographic information was recorded and blood samples were obtained for clinical laboratory testing and miRNA profile analysis. Higher values of waist-to-hip ratio, fat (%), body weight, triacylglycerols, VLDLc, glucose, glycated hemoglobin (Hb1Ac), HOMA-IR, usCRP, PAI-1, fibrinogen, TNF- $\alpha$ , IL-6, resistin, and lower values of HDLc, apolipoprotein AI and adiponectin were found in MetS than in non-MetS subjects ( $p<0.05$ ). Insulin resistance (RI) was found in 85.4% of the MetS patients (85.4%). miRNA PCR array (372 targets) was used for initial screening in a small group of MetS patients (n=6) and health control subjects (n=6). Seven miRNAs (miR-542-5p, miR-424-3p, miR-326, miR-421, miR-301a-3p, miR-183-5p and miR-574-3p) were differentially expressed ( $p<0.05$ ; FC<-2 and >2) and the miR-421 and miR-183-5p remained upregulated in the larger group of MetS when compared to non-MetS group ( $p<0.05$ ). Plasma miR-421 expression was inversely correlated with and adiponectinemia ( $r=-0.242$ ,  $p=0.038$ ). Linear regression analysis showed that plasma miR-421 expression explains variability in 9.5% the adiponectin ( $R^2=0.095$ ,  $p<0.05$ ), 12.5% the HOMA-IR ( $R^2=0.125$ ,  $p<0.05$ ) and 7.5% the HbA1c ( $R^2=0.075$ ,  $p<0.05$ ). Interestingly, the plasma miR-421 expression was also upregulated in RI in comparison with non-RI subjects ( $p=0.029$ ). These results are suggestive that miR-421 may have a potential role in adiponectin homeostasis and insulin resistance. Even though further functional studies are necessary to confirm these interesting findings.

**1846T**

**Investigation of the impact of a nutritional intervention in the first year of life on DNA methylation in a cohort of children.** V.S. Mattevi<sup>1</sup>, J.K. Castilhos<sup>1</sup>, P.D.B. Campagnolo<sup>2</sup>, S. Almeida<sup>1</sup>, M.R. Vitolo<sup>1</sup>. 1) Federal University of Health Sciences of Porto Alegre, Porto Alegre, RS, Brazil; 2) Universidade do Vale do Rio dos Sinos, São Leopoldo, RS, Brazil.

Experimental models of fetal programming have demonstrated that changes in the gestational and neonatal periods alter DNA methylation, affecting gene expression and being associated with processes involved in the energy balance. Although the effect of the fetal and early childhood environment on health outcomes in adult life has been widely discussed, the empirical assessment of this hypothesis in humans remains a challenge. Therefore, the present study evaluated DNA samples collected at 4 years old from children submitted to a nutritional intervention in the first year of life in order to evaluate the effect of this intervention on global DNA methylation levels. This research is part of a cohort study carried out within a randomized field trial that included 500 children born from 2001 to 2002 in the main hospital from the city of São Leopoldo, Southern Brazil, which mainly serves a low-income population. The children were randomly assigned in control and intervention groups at birth. The intervention group followed a diet based on the "Ten Steps to Healthy Feeding", as advised by Brazilian Ministry of Health, during the first year of life. DNA samples were obtained from peripheral leukocytes using a standard salting-out technique from blood samples collected at 4 years old. DNA methylation was quantified using a commercial enzyme-linked immunosorbent assay. Methylation analysis was performed in 237 samples of these children aged 3-4 years old, being 145 samples from the control group and 92 from the intervention group, randomly selected. Higher mean global methylation values were found in the intervention group (intervention group mean:  $2.199 \pm 1.306\%$ ; control group mean:  $1.649 \pm 1.114\%$ ;  $P = 0.001$ ). There were no differences between groups for characteristics as gender, ethnicity and maternal smoking, while exclusive breastfeeding duration was higher in the intervention group. Mean anthropometric variables, such as BMI Z-score, weight at birth, 6 months, 12 months, 3-4 years and 8 years old were also compared between groups and no significant differences were observed. Our results indicate that this nutritional intervention in the first year of life, which had the main objective to increase breastfeeding and healthy weaning, increased the levels of global DNA methylation in children at age 4. These evidences, together with previous findings from other authors, suggest that breastfeeding might be associated with DNA methylation in the human genome.

**Type 2 diabetes risk variants affect NOTCH2 activity in the liver.** S.

Huang<sup>1</sup>, A. Aylward<sup>2</sup>, J. Chiou<sup>2</sup>, M. Okino<sup>1</sup>, K. Gaulton<sup>1</sup>. 1) Department of Pediatrics, UC San Diego School of Medicine, La Jolla, CA; 2) Bioinformatics and Systems Biology Graduate Program, UC San Diego, La Jolla, CA; 3) Biomedical Sciences Graduate Program, UC San Diego, La Jolla, CA.

Type 2 diabetes (T2D) is a complex disease that arises from a combination of environmental and genetic factors. Genome-wide association studies have identified hundreds of genetic loci influencing risk of T2D and which primarily map to non-coding sequence. The mechanisms of how risk variants affect gene regulation and contribute to T2D risk are largely unknown, prohibiting a deeper understanding of disease pathophysiology. Among T2D loci with unknown mechanisms are risk variants at the *NOTCH2* locus. We found T2D risk variants at this locus were correlated and co-localized with expression of the *NOTCH2* gene in human liver samples from GTEx but not for other genes or tissues. We prioritized candidate causal variants at this locus using fine-mapping data from the MetaboChip study, liver regulatory elements from the NIH Roadmap and HepG2 transcription factor binding sites from ENCODE. We identified two candidate variants in liver enhancer elements (rs2641317 and rs17186372) and which had allelic effects on gene reporter activity in HepG2 cells ( $P < 0.05$  for both). In preliminary data, we performed ChIP-seq to identify transcription factor binding sites of the NOTCH2 protein in HepG2 cells and which passed standard quality metrics (e.g.  $\text{RelCC} = 2.020$ ). NOTCH2 binding sites overlapped high probability variants at other fine-mapped T2D risk loci including *ADCY5* (PPA=0.23) and *KCNQ1* (PPA=0.84). The most enriched motif in NOTCH2 sites was for TCF-1 ( $P = 1e-15$ ), a factor which regulates the Notch signaling pathway. We are currently employing strategies to further determine the downstream effects of T2D risk variants on NOTCH2 genome binding and target gene regulation such as CRISPR/Cas9 to modify risk elements in liver and *trans* eQTL mapping. Together, these results will help determine the role of *NOTCH2* activity in the liver in the pathogenesis of T2D.

**CRISPR-derived deletion of *Crebrf* exon 5 in 3T3-L1 preadipocytes identifies *Rab12* as a major CREBRF target regulating mTORC1 activity and autophagy.** S.L. Rosenthal<sup>1</sup>, F. Liu<sup>1</sup>, E.C. Lawrence<sup>1</sup>, C.T. Su<sup>1,2</sup>, Z. Urban<sup>1</sup>. 1) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA, USA; 2) National Taiwan University Hospital, Yun-Lin Branch and Taipei, Taiwan.

Recently, our group identified a common variant in *CREBRF* that significantly increases both BMI and height in an additive fashion in Samoans. This missense variant, rs373863828 (G>A), results in a substitution of arginine for glutamine. *CREBRF* is a transcription factor, but little else is known about its function. In this project, we sought to identify downstream targets of *CREBRF*. Using 3T3-L1 mouse pre-adipocytes and the CRISPR/Cas9 system, we generated clones with (wild-type) and without (mutant) exon 5 of *Crebrf*, the location of our variant of interest. Sequencing and gel electrophoresis of RT-PCR products confirmed the in-frame deletion of exon 5 in two mutant clones. We selected two wild-type and two mutant clones for RNA sequencing experiments. Cells were grown in duplicates to 8 days post confluence, and total RNA was isolated with DNase treatment to remove contaminating DNA. Following quality control procedures, 2 micrograms of total RNA per duplicate were subjected to mRNA sequencing using an Illumina platform. All data quality control and analyses were performed using CLC Genomics Workbench. 5' and 3' adapters were trimmed, and FastQC reports were generated for both raw and trimmed reads. Reads were aligned to the mouse genome (*Mus musculus*, Ensembl version 80), and principal component analysis showed expected clustering of replicates within clone type. Following alignment, we compared differentially expressed genes (DEGs) between mutant and wild-type clones. After filtering genes with maximum group means  $\geq 1$ , there were 1,330 significant ( $p_{\text{FDR}} \leq 0.05$ ) DEGS with at least  $\pm 2$  fold change compared to wild-type expression levels. The most significant of these genes was *Pi15* ( $p_{\text{FDR}} < 1 \times 10^{-15}$ , fold change=888 compared to wild-type), a peptidase inhibitor expressed in subcutaneous fat in mice. The gene most differentially expressed based on fold change was *Rab12* ( $p_{\text{FDR}} < 1 \times 10^{-15}$ , fold change=1,814), a ubiquitously expressed enhancer of the mechanistic target of rapamycin complex 1 (mTORC1) and inhibitor of autophagy. We have shown previously that *CREBRF* is up-regulated by rapamycin treatment and nutrient starvation, and starvation assays illustrate that deletion of exon 5 decreases starvation resistance. These findings implicate *CREBRF*-*Rab12* axis in a feed forward inhibition of the mTORC1 pathway required for cellular adaptation to nutritional deprivation.

**Evaluation of X-chromosome inactivation in female heterozygotes with Fabry disease: Combination of methodical approaches.** M. Rebound<sup>1</sup>, A. Cerna<sup>1</sup>, M. Magner<sup>2</sup>, L. Golan<sup>1</sup>, H. Poupetova<sup>1</sup>, H. Wiederlechnerová<sup>1</sup>, D. Musalkova<sup>1</sup>, A. Linhart<sup>2</sup>, L. Dvorakova<sup>1</sup>. 1) Department of Pediatrics and Adolescent Medicine, 1st Faculty of Medicine Charles University in Prague and General University Hospital in Prague, Prague, Czech Republic; 2) 2nd Department of Medicine-Department of Cardiovascular Medicine, 1st Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Prague, Czech Republic.

Fabry disease (OMIM 301500) is a rare X-linked lysosomal storage disorder caused by  $\alpha$ -galactosidase A ( $\alpha$ -GalA) deficiency due to mutations in the *GLA* gene. Published data evaluating the impact of X-chromosome inactivation (XCI) on the disease manifestation in heterozygous females show controversial results, partly due to the choice of the studied tissues and applied methods. Our aim was to explore the XCI not only by methylation analysis but also with the use of transcriptional XCI ratio examination. 32 heterozygous female Fabry patients from 22 families were involved in our study. The analyses were performed in white blood cells (WBC) and buccal swabs (BS). Methylation analysis was based on inspection of polymorphic repeat region within the genes *AR*, *RP2*, *CNKSR2*. To assess RNA-transcriptional allele ratios single nucleotide variants (SNV) were examined using massive parallel sequencing (NexteraXT, Illumina). Three SNV loci were analyzed: causative mutations in *GLA*, and two common polymorphisms in *IDS* (rs1141608) and *LAMP2* (rs12097). *AR*, *RP2*, *CNKSR2*, *IDS*, and *LAMP2* assays were informative in 59%, 59%, 22%, 56%, and 31% of cases, respectively. The expression ratio of the wt/mutated allele in the *GLA* gene was evaluated in 84% of cases, variants affecting transcript stability (e.g. splicing variants or large deletions) were excluded from the analysis. Combining the described assays, XCI could be determined for each patient from the cohort, 94% of patients were informative for 2 or more assays. XCI measured by methylation analysis corresponded to results obtained by transcriptional XCI assessment. A good correlation was observed between the XCI status assessed in WBC and  $\alpha$ -GalA activity analyzed in leukocytes. Balanced XCI was found in 25 patients in both WBC and BS. However, in 6 patients with skewed XCI (>80%) in WBC, random XCI was observed in BS. *Vice versa*, XCI was skewed in 1 patient in BS but random in WBC. In conclusion, our results show significant tissue specificity of XCI status in the described cohort of patients. These findings strongly complicate the interpretation of XCI in the prediction of the disease severity in female Fabry patients. Grant support: MZ CR – RVO VFN64165, GAUK 580716, SVV No.260367.

**1850F**

**Chromatin accessibility differences between preadipocytes and adipocytes aid identification of regulatory elements at cardiometabolic trait GWAS loci.** *H.J. Perrin<sup>1</sup>, K.W. Currin<sup>1</sup>, S. Vadlamudi<sup>1</sup>, J.P. Davis<sup>1</sup>, M. Wabitsch<sup>2</sup>, K.L. Mohlke<sup>1</sup>.* 1) University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) University of Ulm, Ulm, Germany.

GWAS have identified hundreds of cardiometabolic trait loci but most lie in noncoding regions with mechanisms that remain poorly understood. At these loci, chromatin accessibility (CA) in relevant cells and contexts can guide identification of regulatory elements and mechanisms. To identify elements that differ between preadipocytes and adipocytes, we performed ATAC-seq in SGBS preadipocytes before (2 replicates) and after 14 days of differentiation (3 replicates). On average, we identified 158,182 CA regions per sample (MACS2 FDR<5%). We examined 20,767 regions that were significantly more accessible (DESeq2, log<sub>2</sub> fold change (LFC)>1, FDR<5%) in preadipocytes, and 9,601 regions that were stronger in adipocytes. Genes near preadipocyte CA regions were associated (GREAT P<1E-10) with five GO biological processes including positive regulation of angiogenesis and TGFβ receptor, while genes near adipocyte CA regions were associated with twenty processes including fat cell differentiation and triglyceride, acylglycerol, and cholesterol metabolism. Preadipocyte CA regions were enriched (HOMER P<1E-5) for 58 transcription factor motif families including AP, involved in differentiation control and proliferation, and GATA, involved in inhibiting adipogenesis, while adipocyte CA regions were enriched for 49 motifs including GRE, involved in glucocorticoid response, CEBP, involved in differentiation and immune response, and PPAR, involved in differentiation and metabolism. To identify potential regulatory variants at cardiometabolic GWAS loci, we examined 110 loci for which we previously reported a colocalized adipose eQTL. Of 6,692 candidate variants ( $r^2>0.8$ ), 65 variants at 35 loci were located in a region of differential CA. For example, at a GWAS locus for phospholipids colocalized with an adipose eQTL for *SCD* ( $P=8.4E-23$ ), we observed an adipocyte CA region (LFC=2.72) containing rs603424. This variant exhibited stronger allelic differences in transcriptional reporter activity in 3T3-L1 differentiated adipocytes (FC=2.09,  $P=0.01$ ) than in SGBS preadipocytes (FC=1.25,  $P=0.09$ ). These results demonstrate that CA differences between preadipocytes and adipocytes reflect biological cell context and, although further validation is needed, that epigenomic annotation in different cell contexts can guide discovery of regulatory variants at GWAS loci. Identification of CA regions in other disease-relevant contexts could aid identification of additional regulatory mechanisms.

**Down regulation of miR-574-3p associated with low HDLc concentration in obesity patients.** *R.C.C. Freitas<sup>1,2</sup>, A.A. Braga<sup>1,2</sup>, G.M. Bastos<sup>2</sup>, M.E.G. Saldarriaga<sup>1,2</sup>, R.H. Bortolin<sup>1,2</sup>, H-T.L. Wang<sup>2</sup>, J.B. Borges<sup>1,2</sup>, L.R. Castro<sup>2</sup>, M.F. Sampaio<sup>2</sup>, J.I.D. França<sup>2</sup>, R.D.C. Hirata<sup>1,2</sup>, M.H. Hirata<sup>1,2</sup>.* 1) Faculdade de Ciências Farmacêuticas, Universidade de São Paulo, São Paulo, SP, Brasil; 2) Laboratório de Investigação Molecular em Cardiologia, Instituto Dante Pazzanese de Cardiologia, São Paulo, SP, Brasil.

Obesity is a complex and multifactorial disease. Obesity-related lipid profile contributes to the development of cardiovascular risk. A better understanding epigenetic mechanism involved in obesity-induced dyslipidemia may contribute for new drugs targets discovery. The association of plasma miRNA profile and metabolic and inflammatory variables was investigated in Brazilian subjects. Non-obese (n=47), overweight (n=84), obesity class I (n=68), obesity class II (n=26) and obesity class III (n=8) patients were classified according to body mass index (BMI) values. Biodemographic information was recorded and blood samples were obtained for clinical laboratory testing and miRNA profile analysis. Seven miRNAs (miR-542-5p, miR-424-3p, miR-326, miR-421, miR-301a-3p, miR-183-5p and miR-574-3p) previously related to adipocyte metabolism and/or lipotoxicity and/or inflammation and/or adipogenic differentiation were analyzed by RT-qPCR. Triacylglycerols, VLDLc, leptin, IL-6, TNF-α plasma concentrations, as well as waist-to-hip ratio (WHR) and body fat (%) values were higher in obese patients than non-obese ( $p<0.05$ ). Lower concentrations of HDLc and apolipoprotein AI (ApoAI) were also observed in the obese group ( $p<0.05$ ). Plasma miR-574-3p and miR-183-5p were down regulated in obese class III patients compared to non-obese patients ( $p<0.05$ ). miR-574-3p expression was positively correlated with HDLc ( $r=0.169$ ,  $p=0.020$ ) and ApoAI ( $r=0.159$ ,  $p=0.028$ ) concentrations. Linear regression analysis showed that the miR-574 expression explains variability in 3.9% of HDLc in obese patients ( $R^2=0.039$ ,  $p=0.007$ ). A negative correlation was observed between the miR-574 expression and BMI ( $r=-0.168$ ,  $p=0.020$ ), hip ( $r=-0.187$ ,  $p=0.010$ ) and waist circumference ( $r=0.179$ ,  $p=0.014$ ), body weight fat ( $r=-0.174$ ,  $p=0.017$ ) and leptin (women,  $r=-0.222$ ,  $p=0.022$ ). The association between downregulation of miR-574-3p and obesity-related traits and low concentrations of HDLc and ApoAI is suggestive of a potential role of miRNA in the pathophysiology of obesity and obesity-related complications. Despite these previous evidences, further functional studies are necessary, and the found may to represent a tool to be explored, in order to better understand the association of epigenetic mechanisms and obesity.

**Identification of a transcriptional metabolic hub in adipose tissue using a cis mediated trans eQTL analysis.** D.Z. Pan<sup>1,2</sup>, Z. Miao<sup>1,2</sup>, K.M. Garske<sup>3</sup>, A. Ko<sup>2,3</sup>, Y.V. Bhagat<sup>4</sup>, J.S. Sinsheimer<sup>2,4</sup>, K.L. Mohlke<sup>5</sup>, M. Laakso<sup>6</sup>, P. Pajukanta<sup>1,2,3</sup>. 1) Bioinformatics IDP, UCLA, Los Angeles, CA, CA; 2) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 3) Molecular Biology Institute at UCLA, Los Angeles, USA; 4) Department of Biomathematics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 5) Department of Genetics, University of North Carolina, Chapel Hill, North Carolina, USA; 6) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland.

Although a significant proportion of the phenotypic variation in obesity is attributed to genetic variation, the mechanisms underlying this heritable component are still elusive. Even though cis-regulation is increasingly understood, there is little insight into long-range gene regulatory networks in human subcutaneous adipose tissue, a clinically relevant tissue for obesity. We hypothesize that a set of trans-eQTLs are mediated via expression of cis-regulated genes. As long non-coding RNAs (lncRNAs) are implicated in gene regulation, we further hypothesize that lncRNAs explain the effects of these cis-mediated trans-eQTLs. Using the subcutaneous adipose RNA-seq data (n=335) from the Finnish METSIM cohort, we performed weighted gene co-expression network analysis and identified network modules correlated with body mass index (BMI) (adjusted  $p < 0.05$ ). We selected lncRNAs from these BMI-correlated modules and identified their adipose cis-eQTLs, with each cis-eQTL (+/-1 Mb from TSS, FDR<0.05) and its target lncRNA replicated in subcutaneous adipose RNA-seq data (n=450) from GTEx. Next, we selected the cis-eQTLs which are also trans-eQTLs (FDR<0.05). The key identified set includes eQTL variant, rs13120966, in the promoter of the cis-gene *LINC00989*, which is also associated with the expression level of the trans-gene, *AC005225.2*. The trans-gene is an antisense transcript sharing 2 exons with *ACOT6*, a peroxisomal lipid metabolism gene. An additional 353 genes are correlated (genome-wide adjusted  $p < 0.05$ ) with the expression levels of the cis-gene and trans-gene. These genes are enriched for metabolism-related KEGG pathways (adjusted  $p < 0.05$ ), including those for biological processes involved in lipid metabolism (i.e. fatty acid beta oxidation). In addition, 162 of the 353 genes are enriched for lipid metabolism annotations associated with the 212 genes in lipid GWAS loci using the ToppGene suite (PMID 24097068,  $p < 5.00 \times 10^{-324}$ ). Furthermore, we performed mediation analysis between the eQTL variant, cis-gene, and trans-gene, which resulted in a significant cis-mediated trans-eQTL effect (mediated effect=0.096, residual direct effect=0.197;  $p=0.001$ ), suggesting a causal path from SNP rs13120966 to *AC005225.2*, mediated by the expression of *LINC00989*. In conclusion, our data from a BMI-correlated adipose network identified a novel cis-mediated trans gene that is significantly correlated with expression of 353 metabolically enriched genes in human adipose tissue.

## 1853F

**The long intergenic, non-coding RNA, OLMALINC, regulates lipid metabolism by regulating SREBP2 and SCD1.** J.N. Benhammou<sup>1,2</sup>, M. Alvarez<sup>2</sup>, A. Ko<sup>2,3</sup>, C. Rankin<sup>3</sup>, D. Padua<sup>4</sup>, K. Garske<sup>2</sup>, Y. Bhagat<sup>4</sup>, D. Kaminska<sup>4</sup>, J. Pihlajamäki<sup>4</sup>, J. Pisegna<sup>1,2</sup>, P. Pajukanta<sup>2,3</sup>. 1) Vache and Tamar Manoukian Division of Digestive Diseases, University of California Los Angeles, CA; 2) Department of Human Genetics, University of California Los Angeles, CA; 3) Molecular Biology Institute at University of California Los Angeles, CA; 4) Clinical Nutrition and Obesity Center, Kuopio University Hospital, Kuopio, Finland.

**Background:** The metabolic syndrome (MetS) has reached epidemic proportions in the US with a paralleled increase in nonalcoholic fatty liver disease (NAFLD), which can progress to nonalcoholic steatohepatitis (NASH), fibrosis, and cirrhosis. The pathophysiology of NAFLD includes both genetic and environmental factors. Long intergenic noncoding RNAs (lincRNAs) have emerged as regulators of disease processes. We performed RNA-sequencing (RNA-seq) on 259 liver samples from morbidly obese Finnish patients undergoing bariatric surgery, with the majority having a diagnosis of NAFLD/NASH. Using weighted gene co-expression network analysis (WGCNA), we identified 75 genes associated with statin use and fibrosis (Ko et al. submitted). Among those, we observed a lincRNA, *OLMALINC*, and hypothesize that it regulates cholesterol and lipid pathways. **Methods:** To confirm whether *OLMALINC* is a sterol and statin-responsive gene, we measured its expression together with cholesterol and lipogenic genes under sterol-rich and sterol-depleted conditions with statins by RT-PCR in HepG2 liver cells. To determine which genes are regulated by *OLMALINC*, we used transient knock-down with siRNA and performed RNA-seq. Inversely, we also over-expressed *OLMALINC* by generating activating CRISPR dead Cas9 (aCRISPR dCas9) cell lines and measured target gene expression by RT-PCR. **Results:** *OLMALINC* expression increases in sterol-depleted conditions with statins, consistent with up-regulation of the *SREBP2* gene pathway. RNA-seq after *OLMALINC* knock-down demonstrates the upregulation of *SREBP2*-dependent genes by up to 2-fold (FDR<0.05). Endogenous over-expression of *OLMALINC* using the aCRISPR dCas9 cell line demonstrates an increase in *SREBP2* and *SCD1* expression. Promoter capture Hi-C data from our lab and public data suggest that the *OLMALINC* promoter/enhancer region regulates *SCD1* by interacting in cis with the *SCD1* promoter. **Conclusions:** *OLMALINC* is a lincRNA we identified to be co-expressed with 74 genes responding to statin use in the liver RNA-seq data from obese patients. We show that *OLMALINC* expression is sterol- and statin-sensitive. Its knock-down results in an increase in the cholesterol biosynthesis pathway genes, while its over-expression also increases *SREBP2* and *SCD1* gene expression. Taken together our human liver RNA-seq and experimental data suggest that *OLMALINC* regulates *SCD1* in cis at the DNA and *SREBP2* at the mRNA level, and identify *OLMALINC* as a new statin-responsive gene.

**Identification of functional susceptibility variants in non-coding regions of genome and exploration of their regulatory mechanisms for asthma.** T.L. Yang, Y.Y. Duan, M. Yang, H. Chen, S.S. Dong. Key Laboratory of Biomedical Information Engineering of Ministry of Education, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, Shaanxi, China.

Genome-wide association studies (GWASs) have revealed numerous single nucleotide polymorphisms (SNPs) associated with asthma. However, over 90% of these SNPs are located in non-coding regions, leaving big challenge to the interpretation of asthma genetic mechanism. Therefore, we aimed to identify the potential functional noncoding variants and interpret the functions and mechanisms of these variants by integrating a series of bioinformatics analyses and functional assays. Firstly, 89 asthma associated SNPs ( $P \leq 5 \times 10^{-6}$ ) were obtained from GWAS Catalog database, through LD analysis and ANNOVA annotation, we found 1882 SNPs were residing in the noncoding region. By performing eQTL analysis in whole blood and lung tissue in Genotype-Tissue Expression project (GTEx) and another peripheral whole blood sample, we found that 482 SNPs might affect the expression of 21 genes. We further used the Hi-C data of IMR90 cell line and the interaction data of GM12878 cell line to analyze the interactions of the 482 SNPs and their affected genes. We found that 284 SNPs might interact with the promoter of 16 genes. Especially, 82 SNPs located in the 2q12.1 region were associated with expression of 3 important genes, *IL18R1*, *IL1RL1*, and *AC007278.3*, which are related to asthma. By performing epigenetic annotation of the SNPs in the 2q12.1 region, we found that 9 candidate functional SNPs, namely, rs72998585, rs11692065, rs3771180, rs72823646, rs13431828, rs56179005, rs3771166, rs2293223, rs2272127, are located in the regulatory region in asthma related cell lines. Dual luciferase reporter assay showed that 6 SNPs has the allele specific regulatory activity, which are rs11692065, rs3771180, rs72823646, rs13431828, rs56179005, rs2272127. By performing CRISPR/Cas9 in A549 cell line to knock out the regions where rs3771180 and rs56179005 located in, and the results showed that the knock-out of the two regions lead to significant decrease of the mRNA level of the target gene *IL18R1*, and *AC007278.3* respectively. We further analyzed the transcription factors (TFs) that can be allele-specific binding to the 6 SNPs, and detected the activity of the reporter gene after knock-down of the TFs in A549 cell line. We found that the different allele of SNP rs2272127 showed different regulatory activity via alteration of TF MLX binding. Our finding may illuminate the dark road of regulatory mechanisms of noncoding variants leading to underlying the development and progression of asthma.

**Changes in DNA methylation identify response to treatment with methotrexate and TNF inhibitors among rheumatoid arthritis patients.** C. Adams<sup>1</sup>, K. Marker<sup>1</sup>, D. Quach<sup>1</sup>, H. Quach<sup>1</sup>, M. Krueger<sup>1</sup>, L.F. Barcellos<sup>1</sup>, L.A. Criswell<sup>2</sup>. 1) Genetic Epidemiology and Genomics Laboratory, School of Public Health, UC Berkeley, Berkeley, CA; 2) Departments of Medicine and Orofacial Sciences, University of California, San Francisco.

Epigenetic modifications including DNA methylation are implicated in the development and progression of autoimmune diseases, such as rheumatoid arthritis (RA [MIM 180300]). Exogenous exposures such as smoking, diet, and medication can change DNA methylation and may contribute to immune cell autoreactivity. Methotrexate (MTX) and anti-TNF agents (a-TNFs) are effective treatments for RA. It is hypothesized they reverse epigenetic modifications which cause T-cell autoreactivity, improving RA symptoms. We conducted a study to identify DNA methylation profiles that may serve as biomarkers of response to treatment with MTX and a-TNFs. Blood samples, clinical data, and disease severity scores (DSS) were collected from 30 treatment naive subjects with RA at baseline and after 3-6 months of treatment with: MTX (n=10), a-TNFs (n=10), or MTX and a-TNFs (n=10). DSS included the Simple Disease Activity Index and Clinical Disease Activity Index. Genome-wide methylation profiles were generated using Illumina's Infinium Human MethylationEPIC BeadChip from PBMC samples. Quantile normalization and background subtraction with dye-bias normalization were performed using minfi and CpGs with high detection p-values, cross-reactive probes, and CpGs measuring SNPs were excluded. Treatment response was defined as difference in DSS from baseline to post treatment measurements. Differentially methylated positions (DMPs) and differentially methylated regions (DMRs) associated with, i) pre-post treatment, and ii) treatment response, were identified with limma and bumpHunter, respectively, using surrogate variables to adjust for confounders such as blood cell proportions, batch effects, and genetic ancestry. Next, baseline methylation levels in the top 1000 DMPs and 100 DMRs (by p-value) were used to predict observed treatment response. Principal component analysis (PCA) was done with the top DMPs and DMRs to identify clusters of pre- and post-treatment and "good" and "poor" response to treatment. Preliminary results found 38 DMPs associated with pre/post-treatment ( $p < 0.0001$ ). PCA found distinct clusters for study subjects pre- and post-treatment. Additionally, subjects clustered by treatment arm using baseline methylation only. These results indicate that treatment with MTX and a-TNFs alters DNA methylation and changes in DNA methylation are potential biomarkers of treatment response. Further research is needed with larger sample sizes and diverse study subjects.

**Genetic regulation of *FCGR2A* expression and its implications for immunity and disease.** J. Dahlqvist<sup>1</sup>, C. Fulco<sup>1,2</sup>, J. Ray<sup>1</sup>, C. de Boer<sup>1</sup>, T. Eisenhaure<sup>1</sup>, N. Hacohen<sup>1,3</sup>. 1) Broad Institute of Harvard and MIT, Cambridge, MA; 2) Department of Systems Biology, Harvard Medical School, Boston, MA; 3) Center for Cancer Research, Massachusetts General Hospital, Department of Medicine, Boston, MA.

Antibody-antigen immune complex (IC) formation is a common phenomenon in autoimmune disorders, such as SLE, and antibody-based treatment of malignancies. Fc gamma receptors (FCGR's) are significant factors in eradication of IC's, a capacity that is crucial in respect to clinical outcome of disease and therapy. We hypothesized that expression levels of specific FCGR's are important determinants of IC depletion, and might influence disease pathogenesis, and hence set out to investigate the regulation of the SLE-associated *FCGR2A* gene. We analyzed the FCGR locus for open chromatin using ATAC-seq and followed up on open regions using CRISPRi and CRISPR screens, identifying regulatory elements of importance for *FCGR2A*. Candidate transcription factors of importance for *FCGR2A* were identified and analyzed for common pathways. Genetic analysis of the putative promoter/enhancer regions raised hypotheses about disease-associated regulatory variants. Taken together, these results suggest a relationship between immune environment and genetic variation with an effect on *FCGR2A* levels and thus a role for this receptor in the complex networks underlying autoimmune disease.

**1857W**

**Functional dissection of cis-regulatory variants associated with autoimmunity.** A. Jajodia<sup>1</sup>, N. Javavelu<sup>1</sup>, A. Mishra<sup>1</sup>, R.D. Hawkins<sup>1,2</sup>. 1) Medical Genetics and Genome Sciences, University of Washington, Seattle, WA; 2) Institute for Stem Cell & Regenerative Medicine.

Variants from genome-wide association studies (GWAS) are often significantly enriched at functional non-coding regions. The current study focuses on the dissection of disease-susceptibility variants that influence enhancer function and identification of their target genes. We retrieved associated variants and those in linkage disequilibrium from 19 and 32 GWAS for type I diabetes (T1D) and rheumatoid arthritis (RA), respectively. We utilized H3K4me1 ChIP-seq data for enhancers from primary T helper cells to identify a total of 1832 enhancer variants. We measured the allelic effect on enhancer activity using massively parallel reporter assays (MPRA) in human, activated CD4+ T cells. We identified over 250 enhancer variants with a statistically significant difference in allele-specific expression of the reporter gene. Interestingly, 47%(T1D) and 30%(RA) of validated variants demonstrate an increase in enhancer activity relative to the reference allele. Further analysis suggests that functionally validated variants disrupt binding of transcription factors critical for CD4+ T-cell regulation and differentiation, including GATA and STAT factors, IRF2, and FOXO, as well as understudied factors like MEF2A and HNF4. Quantitative changes in predicted TF binding correlate with allele-specific enhancer activity. We leveraged promoter capture HiC and eQTL analysis for activated CD4+ T cells and whole blood, respectively, to identify 20(T1D) and 108(RA) target genes for validated enhancer variants, including known genes implicated in each disease. Pathway analysis of target genes identifies regulation of T-cell receptor signaling, T-cell activation, and inflammation-mediated cytokine signaling to be overrepresented. For RA, we identified important target genes, such as hypoxia-inducible factor-1 $\alpha$  (HIF1A), a promising target for autoimmune disease therapies; and CD6 a potential immunotherapeutic target. For T1D, target genes include PTPN2, a tyrosine phosphatase that modulates JAK/STAT signaling; and SOCS1, a negative regulator of cytokine signaling. We find that multiple validated enhancer variants can interact with a common target gene. This suggests that a genetic interaction may be mediated through physical looping interactions. A subset of validated enhancer variants also interacts with multiple target genes. This study provides a comprehensive view of disease-associated regulatory variants and a deeper understanding of the genetic complexity of autoimmunity.

Javierre*<sup>3</sup>, *K. Kundu*<sup>2</sup>, *L. Chen*<sup>4</sup>, *P. Fraser*<sup>5</sup>, *M. Frontini*<sup>2</sup>, *T. Pastinen*<sup>6</sup>, *M. Spivakov*<sup>7</sup>. 1) Human Genetics, Wellcome Sanger Institute, Hinxton, United Kingdom; 2) Haematology, University of Cambridge, Cambridge, United Kingdom; 3) Josep Carreras Leukaemia Research Institute, Barcelona, Spain; 4) Sichuan University, Sichuan, China; 5) Florida State University, United States; 6) Children's Mercy, Kansas City, United States; 7) MRC LMS, London, United Kingdom.

Results from genome wide association studies have revealed that the majority of causal genetic variants are located within intergenic regulatory regions. Recent studies have shown that DNA sequence variation is a major source of variability in chromatin states and gene expression within human populations. However, the extent to which this variability is mediated through DNA binding proteins and long-range DNA interactions remains largely unknown. We aimed to gain insights into how intergenic genetic variation perturbs transcription factor binding and its effect upon the downstream transcriptome. In this study we consider common genetic variation as a perturbation assay. For our model system we used primary immune cells; neutrophils and monocytes collected from healthy blood donors as part of the Blueprint Human variation project. We performed quantitative trait loci (QTL) analysis on transcription factors; PU.1 and CEBP $\beta$ , key proteins involved in the differentiation of the myeloid lineage and CTCF associated with chromatin architecture. In addition we generated two hQTL datasets for the histone modifications; active H3K4me3 and repressive H3K27me3. Finally, to map enhancer-gene long-range interactions in both cell types we generated Promoter Capture HiC data in six reference individuals with genotypes available. These data sets were integrated with recently published whole genome sequence data, enhancer and transcriptome QTL results. By association and through integration with long-range interaction data, we map genetic variants in distal regulatory elements to their target genes, therefore assessing the contribution of tfQTLs in modulating gene expression. In addition, by studying patterns of cell type specific transcription factor binding, chromatin structure and associated quantitative trait loci we identify genomic regions that may differentially influence functional changes in cellular phenotype, both neutrophil-specific and shared with monocytes. .

Cellular heterogeneity is a critical factor in genome-wide high-throughput functional sequencing analyses. Variable CpG methylation has been previously applied to HumanMethylation450 BeadArray data to estimate cell proportions, however, only limited direct biological validation has been performed and methods have not been adapted for next-generation sequencing (NGS) data. Deconvolution of cell-type proportions is critical in association studies, separating effects due to the gain or loss of specific cell-types from actual functional changes. Combining 219 genome-wide and capture methylation sequencing samples in 20 cell purification datasets, to 1215 heterogeneous whole blood samples in 7 datasets, with matching cell proportions from blood lab tests, we present the first genome-wide identification and validation of CpG methylation sites predicting cell-type proportion using sequencing. We use a combination of genome-wide (up to 26M CpG sites) as well as targeted (up to 6M sites) methylation sequencing datasets. Using these CpGs, we identify sites showing extreme methylation rate (mean methylation < 20% or > 80%) in one cell-type while having the opposite extreme methylation rate (> 80% or < 20%, respectively) in all other available cell types. We note improved correlation of hypomethylated CpGs with measured blood cell proportions of neutrophils (up to  $R=-0.93$ ,  $n=2,756$ ), lymphocytes ( $R=-0.90$ ,  $n=2883$ ), and monocytes ( $R=-0.81$ ,  $n=4944$ ). Find hypermethylated CpGs to be informative for lymphocyte proportions showing almost perfect correlations ( $R=0.97$ ,  $n=2459$ ). Initially, putative eosinophil-derived hypomethylated CpGs ( $n=1133$ ) were not predictive of cell proportions in blood samples but instead correlated to the neutrophil ( $R=-0.89$ ) cell proportions. However, by refining our analysis using whole blood methylation data, we identify a subset of 51 eosinophil-specific hypomethylated CpGs ( $R=-0.80$ ). Finally, we also show that the performance of our predictions directly relates to available sequencing depth – for the most highly correlated neutrophil-specific CpG we observe  $R=-0.56$  at min. 10X coverage increasing to  $R=-0.98$  at min 90X coverage. In conclusion, we show how methylation at cell-type specific CpG sites can deconvolute white blood cell proportions. Our method leverages data from purified and heterogeneous white blood cell samples, and allows for proper accounting of differing cell-type proportions among samples, to identify true changes in the methylome. .

**Slipping through the cracks: Migration through a small pore disrupts inactive chromatin organization in neutrophil-like cells.** *E. Jacobson<sup>1</sup>, J.K. Perry<sup>1</sup>, M.H. Vickers<sup>1</sup>, D.S. Long<sup>2</sup>, J.M. O'Sullivan<sup>1</sup>.* 1) Liggins Institute, University of Auckland, New Zealand; 2) Department of Biomedical Engineering, Wichita State University.

Mammalian cells are flexible and can rapidly change shape when they contract, adhere, or migrate. Their nucleus must be stiff enough to withstand cytoskeletal forces, but flexible enough to remodel as the cell changes shape. This is particularly important for cells migrating through a constricted space, when the nuclear shape must change in order to fit through. This occurs many times in the life cycle of a neutrophil, which must protect its chromatin from damage and disruption associated with migration. We hypothesize that chromatin reorganization during migration with constriction has a role in regulating transcriptional programs during the immune response. Neutrophil-like HL60 cells are 7µm in diameter and were migrated through pores that required constriction (5µm) or not (14µm), and collected within 30 minutes of migrating. Total RNA-seq was performed in triplicate, and differentially expressed genes were identified (FDR<0.05). The transcriptional changes associated with migration with or without constriction, compared to control, were enriched for inflammation and chemotaxis gene ontology terms (FDR<0.1). Differentially expressed genes specific to migration with constriction were enriched for cytoskeletal remodeling (FDR<0.1). Hi-C was used to compare genome organization in control and migrated cells. Chromatin did not switch between the active (A) and inactive (B) compartments after migration. There was a global depletion of mid- to long-range contacts after migration with constriction. Disrupted contacts (FDR<0.1) at this range were enriched in compartment B (p<0.0001), and contained lowly transcribed genes (p<0.05). We propose a model whereby mid- to long-range contacts are preferentially lost within inactive chromatin, thus protecting transcriptionally active contacts from the disruptive effects of constriction. This is consistent with current hypotheses implicating heterochromatin as the mechanoresponsive form of chromatin. Under this model, the lobed nucleus increases the force dispersion due to its higher surface area, providing a possible explanation for neutrophils' unusual nuclear shape. The protection vs flexibility compromise of nuclear stiffness is a problem for all migratory cells. Further investigating the contributions of heterochromatin to stiffness, flexibility, and protection of nuclear function is important for understanding cell migration in processes including brain development, bone healing, metastasis, and the immune response.

**Immune disease variants modulate gene expression through enhancers specific to CD4 regulatory T cells.** *L. Bossini-Castillo<sup>1</sup>, D. Glios<sup>1</sup>, N. Kunowska<sup>1</sup>, G. Golda<sup>1</sup>, A. Lamikanra<sup>2</sup>, D. Roberts<sup>2</sup>, G. Trynka<sup>1</sup>.* 1) Wellcome Sanger Institute, Hinxton, Cambridgeshire, UK; 2) John Radcliffe Hospital, Oxford, Oxfordshire, UK.

Despite hundreds of variants associated to immune-mediated diseases, little is known about the mechanisms through which these variants lead to disease. Previously we showed that immune SNPs are enriched in promoters and enhancers active in CD4 regulatory T cells (Tregs). Tregs play a critical role in controlling the immune response, however because of their very low numbers, less than 0.001% of whole blood cells, there are no genomic resources available for this cell type. To understand the role of immune-mediated disease variants in Treg function, we isolated Tregs from 100 healthy blood donors and generated a comprehensive resource of genomic assays for SNP fine-mapping (RNA-seq, ChIP-seq for H3K4me3 and H3K27ac, and ATAC-seq). We detected genetic effects on expression of 5,460 genes (eQTL), 3,543 accessible chromatin regions (caQTLs), 3,297 promoter regions (promQTLs) and 7,180 active regions (actQTL) (at FDR < 0.05). Over 35% of the eQTLs and over 55% of the actQTLs were Treg specific and not observed in naïve CD4 T cells from the BLUEPRINT project. We observed 69 immune-mediated disease signals colocalizing with Treg eQTLs, three times more than previously observed in macrophages. This allowed us to fine-map the association signal at 33 loci down to 134 potential functional variants. Twenty seven signals that colocalized with eQTL variants were also acting as actQTLs and caQTLs and directly resided within peaks. For example, one of the inflammatory bowel disease (IBD) associations colocalized with 47 SNPs with eQTL effect on the *BACH2* gene, three of these variants acted as actQTLs while one, rs62408233, also controlled chromatin accessibility. This suggests that the IBD protective allele of the rs62408233 may disrupt an active enhancer resulting in reduced chromatin accessibility, reduced enhancer activation, and consequently decreased *BACH2* expression. We observed that the Treg eQTL genes colocalizing with immune variants were significantly less tolerant to loss of function mutations (median pLI=0.26) compared to the non-colocalizing eQTL genes mapping to GWAS loci (median pLI=0.06). Our findings strongly implicate that a proportion of immune variants regulates gene expression through modulating activity of cell type specific enhancers, building evidence for the causal role of Tregs in the development of immune-mediated diseases.

**DNA methylation signatures of Crohn's disease largely a consequence of inflammation.** H.K. Sominen<sup>1</sup>, S. Venkateswaran<sup>1</sup>, V. Kilaru<sup>2</sup>, U.M. Marigorta<sup>3</sup>, K. Mondal<sup>1</sup>, D.T. Okou<sup>1</sup>, J.S. Hyams<sup>4</sup>, L.A. Denson<sup>5</sup>, D.J. Cutler<sup>6</sup>, G. Gibson<sup>3</sup>, K.N. Conneely<sup>6</sup>, A.K. Smith<sup>2</sup>, S. Kugathasan<sup>1,6</sup>. 1) Department of Pediatrics, Emory University School of Medicine & Children's Healthcare of Atlanta, Atlanta, GA; 2) Department of Gynecology & Obstetrics, Emory University, Atlanta, GA; 3) Center for Integrative Genomics, Georgia Institute of Technology, Atlanta, GA; 4) Division of Digestive Diseases, Hepatology, and Nutrition, Connecticut Children's Medical Center, Hartford, CT; 5) Division of Pediatric Gastroenterology, Hepatology, and Nutrition, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 6) Department of Human Genetics, Emory University, Atlanta, GA.

**Background:** Crohn's disease (CD) is a life-long relapsing-remitting disorder with flares of inflammation and a heterogeneous clinical course. A subgroup of patients with CD progress from an inflammatory phenotype (B1) to stricturing (B2) behavior. DNA methylation differences have been reported in CD but their role remains unelucidated; thus, it is critical to investigate the temporal relationship between methylation and disease to establish whether the methylome plays a causal role and can be leveraged for therapeutic benefits. **Methods:** Utilizing a subset of subjects recruited in the pediatric RISK study we generated genome-wide DNA methylation data using the Illumina HumanMethylationEPIC 850K array in blood DNA samples of 74 controls and 164 newly diagnosed CD cases (B1), of which 55 progressed to B2 within 36 months from diagnosis. We used genetic association and the concept of Mendelian randomization to test for causal relationships between methylation changes and CD. **Results:** We found differential methylation at 1189 CpGs associated with CD at diagnosis (FDR < 0.05). Estimated effects of methylation changes at these CpGs showed a strong correlation with plasma C-reactive protein levels, a marker of inflammation ( $R = 0.91$ ;  $P < 2.2 \times 10^{-16}$ ). When we performed within cases analysis comparing their methylation profiles at diagnosis to follow-up, the sign of the effect has reversed, while the magnitude of the change has remained the same at nearly all 1189 sites ( $R = -0.93$ ,  $P < 2.2 \times 10^{-16}$ ). We noted similar results even after stratifying patients based on disease progression to B2 ( $R = -0.91$ ,  $P < 2.2 \times 10^{-16}$  for progressors;  $R = -0.90$ ,  $P < 2.2 \times 10^{-16}$  for non-progressors). We further demonstrated that, while some methylation changes associated with CD might be causal ( $n = 6$  CpGs), the vast majority are a transient consequence of inflammation and thus a result of disease. **Conclusion:** We show convincing evidence that the methylation signatures of inflammation appear to primarily be a symptom of the disease rather than a cause, suggesting that treatment of inflammation signatures may fundamentally be treating the symptoms of CD rather than the cause. This may at least partially explain why CD often remains a life-long relapsing and relapsing disorder, despite effective treatment of the inflammation symptoms.

## 1863W

**Cis regulatory variation determines dynamic HLA-DQB1 allelic expression in response to T cell activation at RNA and protein levels.** M. Gutierrez-Arcelus<sup>1,2</sup>, Y. Baglaenko<sup>1,2</sup>, S. Hannes<sup>1,2</sup>, J. Arora<sup>3</sup>, N. Teslovich<sup>1,2</sup>, Y. Luo<sup>1,2</sup>, K. Slowikowski<sup>1,2</sup>, H.J. Westra<sup>1,2</sup>, D.A. Rao<sup>1</sup>, J. Ermann<sup>1</sup>, A.H. Jonsson<sup>1</sup>, M.B. Brenner<sup>1</sup>, S. Raychaudhuri<sup>1,2,4</sup>. 1) Division of Genetics and Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA. 3) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, 60 Fenwood Road, Boston, MA 02115, USA; 4) Max Planck Institute for Evolutionary Biology, Plön, Germany; 5) Faculty of Medical and Human Sciences, University of Manchester, Manchester, UK.

HLA class II genes contribute the greatest risk for autoimmune diseases, and *cis* regulatory HLA effects might play a role in CD4+ T cells. Most of the non-MHC causal variants for autoimmune diseases affect CD4+ T cell gene regulation (Trynka *et al.* 2013). Hence, understanding the genetic regulatory effects acting at CD4+ T cell states is critical to define autoimmune mechanisms. Since allelic expression is largely driven by *cis* genetic regulatory variation (Buil *et al.* 2015), it can be exploited to define regulatory effects in multiple cell states without the need of a large sample size. We queried CD4+ memory T cells with RNA-seq after non-antigenic stimulation at 8 time points over 72 hours in 24 individuals. We looked for cell-state specific *cis* regulatory effects by identifying **allele specific expression that changes with time**. We tested 224,924 heterozygote sites, and identified 841 sites with dynamic allele specific effects ( $P < 2.2 \times 10^{-7}$ , Bonferroni), representing 364 unique SNPs spanning 163 genes. Many genes are key in T cell activation (i.e. IL2, LTA, IL7R). Our most striking signal is *HLA-DQB1*. In detailed analyses, where we mapped reads to personalized HLA genomes, we observed 16/24 individuals had significant time-dependent allelic expression ( $P < 1 \times 10^{-18}$ , fold change > 2.7). For example, in one 0503/0301 heterozygote individual, the 0503 allele represents 61% of overall *DQB1* counts at 0 hours, and increases to 96% of counts at 72 hours. We observed that the same *DQB1* alleles in different individuals had similar expression patterns ( $P < 1 \times 10^{-4}$ ). **DQB1's dynamic allelic profiles during T cell activation cluster into 3 main regulatory programs.** The putative regulatory SNP (rSNP) driving the program with late activation over-expression is in the promoter. To assess whether these effects translate to protein levels, we applied flow cytometry to quantify HLA-DQ surface expression. We observed that the **protein levels recapitulate allelic RNA programs with a delay in time**. That is, at 7 days following stimulation, the median HLA-DQ protein levels were significantly higher in individuals homozygous for the highly expressing rSNP allele compared to the homozygous for the lowly expressing allele ( $P = 0.028$ ). This study brings **two main contributions**: 1) we identified **163 genes with time-dependent allelic expression**, 2) We discovered and characterized **dynamic cis regulatory variation for DQB1, a major autoimmune disease gene, at both RNA and protein levels.**

**1864T**

**Systematic identification of DNA regulatory elements for *GATA3* in human T cells.** *H. Chen, P. Fiaux, I. Luthra, G. McVicker.* Salk Institute, La Jolla, CA.

*GATA3* is a zing-finger transcription factor that is a master regulator of T helper Type 2 cell differentiation. The dose and timing of *GATA3* expression are controlled precisely throughout T cell development, and are critical for type 2 immune responses that are required for defense against extracellular pathogens such as helminthes. Dysregulation of type 2 immune responses leads to allergy and asthma, and potentially may be caused by improper expression of *GATA3*. Yet little is known about how *GATA3* expression is controlled in the human genome. While some *GATA3* regulatory elements have been identified in the mouse genome, these regions are not evolutionarily conserved. To systematically identify human regulatory elements that control *GATA3* expression, we used a new CRISPR/Cas9 regulatory screen known as CREST-seq. CREST-seq uses pairs of CRISPR guide RNAs to tile deletions across the genome and subsequently flow sorts cells into different pools based on the expression of a gene of interest. The guide RNAs that are present in each expression pool are then sequenced and tested for enrichment by comparing counts across pools. We performed CREST-seq in Jurkat T cells to systematically identify regulatory elements in a 2MB window centered at *GATA3*. We performed a statistical test for guide pairs that are enriched in the *GATA3* low-expression pool, and identified 44 putative regulatory elements (FDR is smaller than 10%). 26 of these elements fall within the topological-association domain where *GATA3* is located, and 8 elements are located in the introns of *GATA3* and neighboring genes. Some of the elements overlap with H3K27 acetylation signals, however others fall within regions that are devoid of epigenetic marks. The former elements are likely to be enhancers for *GATA3*, while the latter may regulate *GATA3* through different mechanisms. Our data suggest that there are a large number of elements that control the expression of *GATA3* and that its regulation is more complicated than anticipated.

**Characterizing human immune response with implications for understanding autoimmune trait architecture.** *D. Calderon<sup>1</sup>, M.L.T. Nguyen<sup>2</sup>, A. Mezger<sup>3,4</sup>, J.V. Ribado<sup>3</sup>, A. Kathiria<sup>3</sup>, B. Wu<sup>3</sup>, L.A. Criswell<sup>5</sup>, W.J. Greenleaf<sup>6,7</sup>, A. Marson<sup>2,7</sup>, J.K. Pritchard<sup>8,9</sup>.* 1) Program in Biomedical Informatics, Stanford University, Stanford, CA; 2) Department of Microbiology and Immunology, University of California at San Francisco, San Francisco, CA; 3) Department of Genetics, Stanford University, Stanford, CA; 4) Laboratory of Molecular Neurobiology, Department of Medical Biochemistry and Biophysics, Karolinska Institutet, 17177 Stockholm, Sweden; 5) Rosalind Russell/Ephraim P. Engleman Rheumatology Research Center, University of California at San Francisco, San Francisco, CA; 6) Department of Applied Physics, Stanford University, Stanford, CA; 7) Chan Zuckerberg Biohub, San Francisco, CA; 8) Department of Biology, Stanford University, Stanford, CA; 9) Howard Hughes Medical Institute, Stanford University, Stanford, CA.

The human immune system depends on a balanced interplay among a wide variety of specialized cell types transitioning between resting and stimulated states that can become dysregulated in autoimmune disorders. While there are large-scale efforts to map functional regions of resting immune cells, a limited number of cell types have been characterized in stimulated states. Thus, we collected ATAC and RNA-seq data from 25 cell types under resting and stimulated conditions from the blood of 4 healthy individuals. In general, we observed strong chromatin accessibility and transcriptional changes attributable to cell and stimulation-specific effects. Strikingly, stimulation-specific chromatin responses tended to be broadly shared within cell subsets and even across B and T cell lineages. To identify disease-relevant cell types and quantify the importance of stimulation, we performed a GWAS enrichment analysis on 39 traits with publicly available summary statistics. In addition to validating previously identified disease-relevant cells, we discovered a class of autoimmune traits, including rheumatoid arthritis ( $P = 3e-4$ ) and ulcerative colitis ( $P = 2e-3$ ), with enriched heritability in shared stimulation-response peaks. Finally, emphasizing the value of stimulation effects for clarifying disease mechanisms, we fine mapped rs6927172, which links stimulated T cell-specific chromatin dysregulation in the *TNFAIP3* locus to ulcerative colitis and rheumatoid arthritis. Overall, our results highlight the importance of characterizing immune stimulation and classify a set of complex disorders associated with shared stimulation response.

**1866W**

**lncRNA-HBBP1 promotes the imbalance degradation of  $\alpha$  and  $\beta$  globin by ubiquitin-dependent pathway to aggravate anemia in  $\beta$ -thalassemia.** J. Ma<sup>1</sup>, Q.X. Zhang<sup>2</sup>, N. Jiang<sup>1</sup>, J. Zhang<sup>1</sup>, X. Du<sup>2</sup>, D. Ma<sup>1</sup>. 1) Fudan University, Shanghai, China; 2) The Second People's Hospital, Shenzhen, China.

$\beta$ -thalassemia is a common monogenic life-threatening blood disorder and is caused by mutations of  $\beta$ -globin gene *HBB*. However, different degrees of anemia among  $\beta$ -thalassemia major patients can not completely be explained by *HBB* mutations. We have reported differential expression of lncRNAs and mRNAs among  $\beta$ -thalassemia major,  $\beta$ -thalassemia minor patients, and matched normal controls. What most interests us among so many changed lncRNAs in that study is the expression of hemoglobin beta pseudogene 1 (*HBBP1*, also called lncRNA-HBBP1) of human  $\beta$ -globin gene cluster was significantly higher in  $\beta$ -thalassemia major patients compared with other two groups. This difference was also verified in expanding clinical samples. We up-regulated the expression of lncRNA-HBBP1 in zebrafish and found that the amount of red blood cells and hemoglobin level were observed to be decreased significantly. Then we found that lncRNA-HBBP1 could bind to  $\alpha$  and  $\beta$  globin (HBA and HBB) and some proteins of ubiquitin-proteasome system (UBC, UHRF1, UBE2K and UB2V2) in K562 erythroleukemic cells tested with chromatin isolation by RNA purification (ChIRP) technology. The binding of lncRNA-HBBP1 to HBA and HBB was confirmed by RNA binding protein immunoprecipitation (RIP). Through overexpressing and interfering the expression of lncRNA-HBBP1 in K562 cell, we found lncRNA-HBBP1 may degrade HBA and HBB unbalancedly. What's more, using Co-IP, we identified the degradation of HBA and HBB may due to their combination with more Ub in K562 cell with high lncRNA-HBBP1 expression. Subsequently by interfering the expression of above-mentioned three ubiquitin proteins in overexpressed lncRNA-HBBP1 K562 cell, we found HBA and HBB bound to UBC and UBE2K respectively. With the prediction of transcription factors binding to regulatory sequence of lncRNA-HBBP1, the HIF1 $\alpha$  was detected and verified via ChIP-qPCR experiment. We also determined that high expression of HIF1 $\alpha$  may promote the transcription of lncRNA-HBBP1 in K562 cell. Finally, we observed significant negative correlation existed between the expression level of lncRNA-HBBP1 and some hematological parameters (Hb, HCT, MCV, MCH, MCHC and RDW) associated with anemia in large  $\beta$ -thalassemia major whole blood samples by statistical analysis. In Conclusions, more HIF1 $\alpha$  in  $\beta$ -thalassemia major leads to increase lncRNA-HBBP1 which by combining with  $\alpha/\beta$  globin and ubiquitin-proteasome complex, aggravate the imbalance of  $\alpha$  and  $\beta$  globin and increase the anemia. .

Multiple sclerosis (MS; MIM 126200) is a disabling chronic inflammatory autoimmune disease that affects the central nervous system. For approximately 5% of MS cases, onset occurs in individuals less than 18 years old (pediatric MS or "ped-MS"). Epigenetic influences are strongly implicated in MS pathogenesis in adults, including the contribution from miRNAs, small noncoding RNAs that target specific messenger RNAs and block their translation into proteins. SNPs can affect miRNA function in different ways depending on their location. These miRNA-related SNPs (miRSNPs) can impact miRNA expression levels or influence miRNA target interactions; either mechanism can affect disease susceptibility. Our objective was to assess miRNA involvement in the pathogenesis of ped-MS. We tested 52,586 miR-SNPs in 486 ped-MS cases and 1,362 controls drawn from the U.S. Pediatric MS Network and Kaiser Permanente Northern California membership using logistic regression models adjusted for genetic ancestry. miR-SNPs within the major histocompatibility complex (MHC) were also adjusted for the presence of the *HLADRB1\*15:01*, an MHC allele that is the strongest known genetic risk factor for MS. Additionally, we conducted a pilot gene expression study and examined levels of 1,979 miRNAs in four sorted peripheral immune cell types from eight treatment-naïve post-pubertal ped-MS female cases and eight female controls matched on age and race/ethnicity. No individual miR-SNPs were associated with ped-MS after accounting for multiple hypothesis tests. However, pathway analysis of top hits ( $p < 0.01$ ) implicated genes involved in immune signaling, specifically in pathways involving the histamine H<sub>1</sub> receptor, the serotonin 5-HT<sub>2</sub> receptor, and interferon gamma, all pathways that have plausible roles in MS pathogenesis. There were 88 miRNAs that were differentially expressed in immune cells of ped-MS cases compared to controls (unadjusted  $p < 0.1$ ), and these miRNAs were enriched for those that have previously been associated with MS in human adult or mouse studies. We conclude that miRNAs may play a role in ped-MS pathogenesis by affecting immune-signaling genes, and that miRNAs relevant to MS are expressed at different levels in ped-MS patients than healthy controls.

**The long non-coding RNA gene *NeST* influences basal immune state, antiviral responses, and ulcerative colitis phenotype in mice.** O.M. de Goede<sup>1</sup>, N.J. van Buuren<sup>2</sup>, A.T. Satpathy<sup>3,4</sup>, S.B. Montgomery<sup>1,3</sup>, H.Y. Chang<sup>1,4</sup>, K. Kirkegaard<sup>1,2</sup>. 1) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 2) Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford, CA; 3) Department of Pathology, Stanford University School of Medicine, Stanford, CA; 4) Center for Personal Dynamic Regulomes, Stanford University School of Medicine, Stanford, CA.

In mice, the lncRNA gene *NeST* (or *Tmevpg1*, *Ifng-as1*) influences immune responses to Theiler's virus and *Salmonella* infection, in part through *trans*-regulation of the overlapping gene *Ifng*. Here, we further classify functional effects of *NeST* through a knockout mouse model (*NeST*<sup>-/-</sup>), and define the changes in gene expression and chromatin accessibility that may be driving these responses. Compared to *NeST*-floxed (*NeST*<sup>fl/fl</sup>) controls, *NeST*<sup>-/-</sup> mice had significantly higher baseline numbers of splenic regulatory T cells and T-bet<sup>+</sup>/CD8<sup>+</sup> T cells, suggesting a more attenuated immune environment. No other baseline changes in immune cell compartments or cytokine levels were observed. RNA sequencing of CD8<sup>+</sup> T cells from *NeST*<sup>-/-</sup> and *NeST*<sup>fl/fl</sup> mice identified 211 differentially expressed (DE) genes, which were enriched for decreased activity in *NeST*<sup>-/-</sup> mice in pathways related to oxidative phosphorylation, responses to viral infection, and the cell cycle. Targeted examination of immunosuppressive genes revealed several that were upregulated in *NeST*<sup>-/-</sup> CD8<sup>+</sup> T cells, including *Tbx21* (T-Bet). ATAC-seq analysis identified 28 differentially accessible (DA) regions in unstimulated CD8<sup>+</sup> T cells, and 31 DA regions in CD8<sup>+</sup> T cells following *in vitro* stimulation with PMA/ionomycin. 19 of these DA regions were shared between the unstimulated and stimulated conditions, and 2 overlapped with DE genes. These baseline differences with *NeST* knockout yield dramatic phenotypes in response to immune challenges. *NeST*<sup>-/-</sup> mice intraperitoneally injected with poliovirus had significantly higher splenic viral titers, reductions in both number and proliferative capacity of CD8<sup>+</sup> T cells, and lower survival rate. This is consistent with the decreased gene expression in metabolic and cell cycle-related pathways we observed in *NeST*<sup>-/-</sup> CD8<sup>+</sup> T cells. Male *NeST*<sup>-/-</sup> mice also had an exacerbated DSS-induced ulcerative colitis phenotype, with greater decrease in body weight, shorter colon length, and more severe colon histology than their *NeST*<sup>fl/fl</sup> counterparts. This may be related to a region of increased accessibility in *NeST*<sup>-/-</sup> CD8<sup>+</sup> T cells located near *Ap1m2*, an epithelia-specific gene for which reduced expression has been associated with spontaneous colitis in mice and Crohn's disease in humans. While the functions of many lncRNAs are unknown, here we demonstrate that they can have broad immunological impacts influencing both antiviral responses and ulcerative colitis susceptibility.

**Characterizing host-pathogen gene interaction networks using weighted gene co-expression network analysis (WGCNA).** A.C. Shetty<sup>1</sup>, C. McCracken<sup>1</sup>, H. Liu<sup>2</sup>, S.G. Filler<sup>2,3</sup>, V. Bruno<sup>1,4</sup>. 1) Institute for Genome Sciences, University of Maryland Baltimore, Baltimore, MD; 2) Division of Infectious Diseases, Los Angeles Biomedical Research Institute, Harbor-UCLA Medical Center; 3) David Geffen School of Medicine at UCLA, Los Angeles, California; 4) Department of Microbiology & Immunology, University of Maryland School of Medicine, Baltimore, Maryland.

**Background:** There is an increasing interest in using dual-species transcriptomics to deduce potential host-pathogen gene interactions and understand molecular mechanisms of virulence and disease progression. Correlation network analysis is a powerful tool to study such multi-dimensional biological datasets. Weighted gene correlation network analysis (WGCNA) can find clusters of highly correlated genes in transcriptomic datasets. **Hypothesis:** WGCNA applied to the host and pathogen gene networks can be further correlated to identify novel host-pathogen interactions. **Methods:** We performed RNAseq analysis on *in-vivo* murine models of pulmonary aspergillosis in which mice were infected with pathogenic fungus, *Aspergillus fumigatus*. Total RNA, containing mouse and *A. fumigatus* transcripts, was collected from the lungs of infected mice at 2, 4, or 6 days post infection (DPI) in biological triplicate. RNAseq libraries were generated and also enriched for fungal transcripts using an Agilent SureSelect XT custom bait library designed against *A. fumigatus*. Unenriched and SureSelect captured libraries were sequenced to assay the host and fungal transcriptomes, respectively. Raw reads were aligned to the Mouse mm10 and *A. fumigatus* Af293 reference genomes using a splice aware aligner. We quantified and normalized gene expression values for both the host and pathogen genes. Normalized expression estimates were used to identify highly correlated gene clusters for the host and pathogen genome separately using WGCNA. Gene clusters significantly correlated with DPI (p-value<0.02) were selected. For each cluster, genes correlated with DPI ( $r>0.8$ ) showing high cluster membership ( $r>0.8$ ) were selected for host-pathogen interaction analysis. Using methods in WGCNA, we tested these host and pathogen genes for correlation with pathogen and host gene clusters respectively to identify potential host-pathogen gene coexpression. Finally, highly correlated host-pathogen gene pairs ( $r>0.8$ ) were selected to build interaction networks. **Results:** We observe 322 Mouse and 80 *A. fumigatus* genes correlated with DPI, respectively. Of these, 43 pathogen genes show expression that is highly correlated with the expression of 116 host genes. Gene pairs are visualized as an interaction network. **Conclusions:** Dual-species WGCNA facilitates the formulation of testable hypotheses regarding molecular mechanisms governing the interaction between pathogen and host in the context of pulmonary aspergillosis.

**Deciphering and modelling of the regulatory network controlling dendritic cell differentiation from human monocytes.** A. Medina-Rivera<sup>1</sup>, K. Nuñez-Reza<sup>1</sup>, P. Pozos<sup>1</sup>, P. Gonzalez<sup>2</sup>, J.E. Sotelo Fonseca<sup>2</sup>, A. Naldi<sup>3</sup>, C. Molina-Aguilar<sup>4</sup>, D. Gutiérrez-Reyna<sup>4</sup>, S. Spicuglia<sup>5</sup>, M.A. Santana<sup>4</sup>, M. Thomas-Chollier<sup>5</sup>, D. Thieffry<sup>5</sup>. 1) LIIGH, Universidad Nacional Autónoma de México, Queretaro, Queretaro, Mexico; 2) Functional and Evolutionary Genomics of Regulatory RNA, Laboratorio Nacional de Genómica para la Biodiversidad, Irapuato, México; 3) Computational Systems Biology team, Institut de Biologie de l'Ecole normale supérieure – PSL Université, Paris, France; 4) Centro de Investigación en Dinámica Celular (IICBA), Universidad Autónoma del Estado de Morelos, Cuernavaca, México; 5) INSERM, TAGC, Marseille, France.

The aim of this project is to determine the regulatory mechanisms that govern the differentiation of monocytes to dendritic cells (DCs) and integrate the regulatory information in a logical model for DC differentiation. In peripheral tissues, differentiation from monocytes into DCs occurs mostly in inflammatory conditions (Villadangos and Schnorrer, 2007). This differentiation can be reproduced *in vitro* (Segura et al, 2013). Albeit progresses in the field of DC differentiation, we still lack a comprehensive understanding of the underlying signaling pathways and regulatory circuits involved. We analyzed bulk ChIP-seq and RNA-seq of DCs and monocytes from the BLUEPRINT consortium (Stunnenberg et al, 2016). Regarding bulk RNA-seq analysis, we used the methods described in Law et al (2016). Our analysis pipeline for ChIP-seq includes quality control with FastQC tool, along with ENCODE QC and IDR analysis (Bailey et al, 2013). Peak calling was performed using MACS2 (Hung and Weng, 2017). Chromatin states were then defined using ChromHMM (Ernst and Manolis, 2012). RSAT tool peak-motifs was used to identify transcription factor binding sites (Thomas-Chollier et al, 2011). Using the software GINsim (Naldi et al, 2018), we are currently building a logical model of the regulatory network controlling dendritic cell differentiation from monocytes. This model includes the pathways previously described for CSF-2 and IL-4 signalling, taking into account the cross-talks between these pathways. CSF-2 and IL-4 activate the Jak/Stat pathway, leading to activation of the transcription factors STAT3, STAT5, STAT6, IRF4, NFKB2 and CEBA $\alpha$ , all reported to be involved in monocyte to dendritic cell differentiation. The results of ChIP-seq and bulk RNA-seq analysis will enrich our model, taking into account novel transcription factors and regulatory interactions. Model analyses will serve as a screening platform to select components and interaction to assess experimentally (Collombet et al, 2017; Rodriguez et al, unpublished data). DCs play an important role in the activation of the adaptive immune response, making them excellent candidates for cancer treatments and vaccines development. The construction of a predictive dynamical model of monocytes to dendritic cell differentiation should enable a better understanding of this process, to identify clinically relevant intervention points and ultimately design novel therapeutic strategies.

**Inflammatory bowel disease causal SNP rs1887428 regulates JAK2 expression via allele-specific binding of RBPJ and CUX1.** C.J. Cardinale<sup>1</sup>, A. Gutiérrez Uzquiza<sup>1</sup>, L.A. Spruce<sup>2</sup>, S.H. Seeholzer<sup>2</sup>, H. Hakonarson<sup>1</sup>. 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Proteomics Core Facility, Children's Hospital of Philadelphia, Philadelphia, PA.

Recently, 18 genetic variants conferring risk for inflammatory bowel disease were fine-mapped to single-variant resolution with greater than 95% confidence. One SNP so identified, rs1887428, is located 600 bp upstream of the transcriptional start site of the JAK2 gene. We used affinity purification-mass spectrometry (AP-MS) with oligonucleotide baits containing either the risk or protective allele of this SNP to purify two transcription factors with allele-specific binding from Jurkat cell nuclear extracts. Notch pathway member RBPJ binds preferentially to the risk allele, while transcriptional repressor CUX1 binds to the protective allele. This binding preference was confirmed *in vitro* using electrophoretic mobility shift assay (EMSA) and affinity purification. We constructed subclones from Jurkat using CRISPR/Cas9 genome editing with homology-directed repair (HDR) to carry either the risk or protective allele of rs1887428, and showed that the risk allele increases expression of JAK2. We used a dual luciferase reporter assay to assess the function of this SNP on the expression of a reporter driven by the 1.2-kb promoter region of JAK2. Depletion of CUX1 with siRNA raised expression of the reporter, as did co-expression of constitutively-active NOTCH1, partner of RBPJ. We conclude that causal noncoding SNPs, even in the absence of canonical transcription factor binding motifs, can be recognized by allele-specific proteins, resulting in differential gene expression.

**Does spacing matter? A comprehensive study on the spatial constraint of transcription factor binding sites in mouse macrophages.** Z. Shen<sup>1,2</sup>, J. Tao<sup>2,3</sup>, G.J. Fonseca<sup>2</sup>, C.K. Glass<sup>2,3,4</sup>. 1) Department of Bioengineering, University of California, San Diego, La Jolla, CA; 2) Department of Cellular and Molecular Medicine, School of Medicine, University of California, San Diego, La Jolla, CA; 3) Bioinformatics and Systems Biology Program, University of California, San Diego, La Jolla, CA; 4) Department of Medicine, University of California, San Diego, La Jolla, CA.

**Motivation.** Transcription factors regulate gene expression by binding to DNA regulatory sequences. In macrophages, lineage-determining transcription factors (LDTFs) bind collaboratively in order to select functional enhancers. Such collaboration relies on the arrangement of transcription factor binding sites that are embedded in DNA sequences, sometimes called "grammar". Natural genetic variants like single nucleotide polymorphisms (SNPs) and short insertions and deletions (indels) will interfere with the binding of LDTFs by directly affecting the sequence of binding sites of LDTFs or their collaborative transcription factors. Short indels can also alter the spacing between binding sites. Previous studies showed that the altered spacing could significantly affect gene regulation in *Ciona* embryos. Currently, there is no systematic study on the spatial relationships of transcription factors. It remains unknown to what extent the change of spatial relationship will affect the binding events in mammalian cells. **Method.** We used ChIP-seq to measure the binding of macrophage LDTFs, including PU.1, C/EBP beta, and c-Jun in murine bone marrow-derived macrophages. The binding sites were further annotated by searching for highly confident motifs within binding regions. We first revealed different spacing patterns of binding sites among LDTFs and of those between LDTFs and collaborating transcription factors. In addition, we analyzed the effects of altered binding sites and spacing on transcription factor binding by looking at small indels across 5 genetically diverse mouse strains, which have between 0.8 and 4 million indels depending on the pair-wise comparisons. Of the 50,000 binding regions of PU.1 in each strain, comparative studies were conducted between 690 regions with indels that affect LDTF binding sites and 1120 regions with indels that fall between LDTFs, changing the spacing. **Result.** We found that collaborative LDTFs have a tendency to bind close together with certain spatial relationships. Taking PU.1 as an example, we observed positive spatial relationships for 14 factors that include transcription factors previously established to be important for macrophage development and function. However, the spatial relationships are relatively broad. Consistent with this, at a genome-wide level indels that alter transcription factor binding sites are more likely to result in decreased binding than those that alter the spacing between binding sites.

**1873T**

**Identification of genes escaping X-inactivation and the variability of escape across cells, tissues and twin pairs.** A. Zito, K. Small. Department of Twin Research & Genetic Epidemiology, King's College London, London, United Kingdom.

To equalize the X-linked transcriptional dosages between the sexes, one X-chromosome is inactivated in somatic tissues of female mammals. However, X-inactivation (XCI) is incomplete; 15-20% of genes escape XCI and maintain X-linked bi-allelic expression. Escape from XCI has high biomedical relevance and may underlie sexual dimorphisms in autoimmunity and cancer incidence, and clinical phenotypes in poly-X karyotypes. The extent to which genetic and environmental factors influence escape, and the extent of variability across individuals and cell types is not well characterized. To address this, we investigated escape from X-inactivation in a multi-tissue sample of deeply phenotyped twins. We quantified escape with a metric (EscScore) that combines a gene's allele-specific expression with the overall XCI skew of the sample, and ranges from 0 to 1, with 0 = no escape (no expression from inactive X) and 1 = complete escape (equal expression from the active and inactive X). We applied our score to skewed samples (XCI-skew > 80%) with paired RNA-seq and WGS data; our dataset included LCLs (N = 145), whole blood (N = 20), fat (N = 45), skin (N = 54) and purified monocytes, B, CD4<sup>+</sup>, CD8<sup>+</sup> and NK cells from a monozygotic twin pair. Using previously published escape designations for ChrX genes, we find that our score distinguishes between genes designated as silenced (mean EscScore = 0.2, IQR = 0.24), variably escape (mean EscScore = 0.28, IQR = 0.46) and fully escape (mean EscScore = 0.57, IQR = 0.41). We identify 51 genes with novel tissue-specific escape patterns, 27 of which were previously classified as silenced and 24 classified as escapees but with no previous evidence of tissue-specificity. Within the purified immune cells, we identify 25 new escape genes, of which 14 show cell-type specific escape. We see a high degree of variability in EscScore(s) across individuals in a subset of genes, and are investigating whether this is concordant across twin pairs or correlates with phenotypic measures from these individuals. This study comprehensively quantifies escape in multiple immune cell types and tissues in a large cohort of women with skewed XCI patterns. By identifying new putative escapees, we conclude that escape from XCI is a complex and widespread event that can modulate gene expression in a cell-type-restricted manner.

## 1874F

**Epigenome-wide association study for IgA nephropathy in Chinese population.**

Y. Lin<sup>1</sup>, Z. Zhu<sup>1</sup>, P. Yin<sup>2</sup>, Y. Peng<sup>2</sup>, L. Liang<sup>1</sup>, X. Yu<sup>2</sup>. 1) Program in Genetic Epidemiology and Statistical Genetics, Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; 2) Department of Nephrology, The First Affiliated Hospital of Sun Yat-sen University, Guangzhou, China.

IgA nephropathy (IgAN) is the most common primary glomerular disease in China and worldwide. It is recognized that up to 50 percent of IgAN patients might end up with the end-stage renal disease, the etiology and pathogenesis is unclear. Accumulated evidences suggested that genetic factors and environmental factors were both involved in the pathogenesis of IgAN. Epigenetic modifications such as DNA methylation might play a significant role in gene regulation and disease susceptibility. However, few epigenome-wide association studies (EWAS) have investigated the relationship between DNA methylation variation genome-wide and IgAN. In this study, we applied the Infinium Methylation EPIC BeadChip, which interrogates 850,000 CpG sites, on 184 samples of CD19<sup>+</sup> B cells and 24 whole blood cells from Chinese descent. Data was normalized and adjusted for cell types, age, gender effect and residual batch effects via smart surrogate variable analysis (smartSVA). Linear regression model was used to analyze differentially methylated CpG sites associated with IgAN in both cell types, respectively. We use false discovery rate (FDR) less than 10% to detect significant CpGs in relation to IgAN. After normalization and adjusting clinical covariates and technical surrogate variables, we found that 3 CpGs were significantly associated with IgAN in CD19<sup>+</sup> B cells samples and the B-cell and whole blood combined analysis. Among them, one CpG was associated with *PLEKHA4*, and the rest CpGs were in close proximity to genes including *CLEC11A* and *C1orf127*. (FDR < 0.1). Specifically, *PLEKHA4* plays an important role in lipid binding and nucleic acid metabolism which may have potentiality to have effect on the genesis of IgAN. Moreover, *CLEC11A* was coding for stem cell growth factor which may have impact on the progressive damage associated with chronic kidney failure from IgAN. These findings suggested that DNA methylation variation might involve in the pathogenesis of IgAN. We will further illustrate the potential functional impact from the identified DNA methylation site and seek for replication in a large samples undergoing sample collection and methylation typing.

## 1875W

**Cyclin-dependent kinase inhibitor 1B (*CDKN1B*) promoter variant and Systemic Lupus Erythematosus (SLE) susceptibility.** B. Singh, J. Molineros, J. Kaplan, B. McDaniel, C. Sun, S. Nath. Oklahoma Medical Research Foundation, Oklahoma city, OK.

**Background:** Systemic Lupus Erythematosus (SLE) is an autoimmune disease with a strong genetic component and ethnic differences. Recently, cyclin-dependent kinase inhibitor 1B (*CDKN1B*) was reportedly associated with SLE risk in Han-Chinese. However, its validity and functionality are not thoroughly assessed. **Objectives:** The objectives of this study were to replicate *SLE-CDKN1B* association and characterization of the SLE-associated variants. **Methods:** First, we performed allelic association followed by a meta-analysis of rs34330 (*CDKN1B*) using ten independent cohorts (n = 34,017). Second, we used *in-silico* bioinformatics and epigenetic analyses to identify potential regulatory effects on gene expression and using data on histone marks, eQTLs across multiple tissues. Third, luciferase reporter assays in HEK293 and Jurkat cells were used to measure the allelic effects. Fourth, combination of DNA pulldown, Electrophoretic Mobility Shift Assay, Western blot, and Mass Spectrometry were used to identify DNA-bound proteins followed by ChIP-qPCR to assess the allele-specific binding of interacting proteins. Finally, mRNA and protein expression of candidate genes were compared between risk and non-risk genotypes. **Results:** We replicated genetic association between SLE and rs34330 ( $P_{meta}=1.16 \times 10^{-18}$ , OR=0.84). Bioinformatics predicted that rs34330, located in active chromatin, has potential promoter/enhancer effect. Gene regulation through rs34330 was further confirmed through methylation association with a CpG probe (cg27423445) and chromatin interactions. SNP rs34330 is an eQTL and risk allele increased expression of *CDKN1B* and a nearby *APOLD1*. Finally, we observed significant allele-specific promoter activity by luciferase in HEK293 and Jurkat cells, significant allele-specific bindings with histones (H3K27Ac, H3K4Me3, H3K4Me1) and transcription factors (Pol-II & IRF1). **Conclusions:** We replicated rs34330 association with SLE in multiple cohorts. Our results showed that rs34330 is a potentially functional variant, predicted to alter *APOLD1/CDKN1B* expression through its enhancer/promoter effects. Allele-specific histone modifications and binding with regulatory proteins may regulate the expressions of *APOLD1/CDKN1B* proteins, which could be a potential mechanism for exacerbating the susceptibility of lupus through rs34330.

## 1876T

**Whole genome sequencing shows contribution of *de novo* noncoding variants to congenital diaphragmatic hernia.** A. Kitaygorodsky<sup>1,2</sup>, H. Qi<sup>2,3</sup>, J. Wynn<sup>4</sup>, L. Congenital diaphragmatic hernia (CDH) is one of the most common and lethal birth defects. Many CDH patients have additional congenital anomalies or neurodevelopmental disorders. Although previous studies have identified significant contribution of *de novo* coding variants to both isolated and complex CDH, the impact of mutations in noncoding and regulatory regions is still not well understood. To further investigate the genetics of CDH and to better understand the role of noncoding mutations, we analyzed whole genome sequencing (WGS) from a total of 489 CDH parent-offspring trios and used 1606 parental-unaffected siblings trios from the Simons Simplex Collection as controls. We observed on average 72 *de novo* single nucleotide variants (SNV) or small insertions and deletions (indels) per subject in both cases and controls. We investigated the role of *de novo* noncoding variants by comparing the burden between cases and controls in biologically plausible regions, based on a combination of epigenomic features (histone marks), physical location relative to transcription start sites (TSS) or 3' untranslated regions (3' UTR), and proximity to genes that are highly expressed in developing diaphragm or candidate CDH risk genes from previous human or mouse studies. We observed a 2.1-fold enrichment of indels within H3K4me1 histone modification marks (associated with enhancers or promoters) in stem cells ( $p=1.6e-4$ ). When limited to TSS regions of candidate CDH genes, we further observed an 8.8-fold enrichment of SNPs and indels within H3K4me1 marks in stem cells ( $p=7.3e-4$ ); notably, two of these noncoding variants are close to *GLI3*, an important mediator of Sonic Hedgehog signaling that has been previously implicated in CDH. Finally, we observed an excess of 3' UTR regions with noncoding *de novo* variants in multiple cases ( $p=0.02$  by permutation; observed 743, expected 682). In particular, there are 4 noncoding *de novo* variants in 3'UTR of *ZNF408* ( $p=6e-5$  based on a background mutation model) and *USP12* ( $p=7e-5$ ), both with plausible roles in development. Overall, the whole genome sequencing data suggests a substantial role of regulatory noncoding *de novo* variants in CDH. Future studies with larger sample size and better assessment or prediction of genetic effect of noncoding variants will help to estimate precisely the contribution of noncoding variants and to discover new high risk genes.

Litwin<sup>3</sup>, K.H. Weiss<sup>4</sup>, C.L. Bowlus<sup>5</sup>, S. Sarkar<sup>6</sup>, S. Cooper<sup>6</sup>, Y.J.Y. Wan<sup>6</sup>, M. Alif<sup>6</sup>, V. Medici<sup>6</sup>, J.M. LaSalle<sup>1</sup>. 1) Medical Microbiology and Immunology, Genome Center, and MIND Institute, University of California - Davis, Davis, CA; 2) Internal Medicine, Gastroenterology and Hepatology, University of California - Davis, Davis, CA; 3) Institute of Psychiatry and Neurology, Warsaw, Poland; 4) Internal Medicine IV, Heidelberg University Hospital, Heidelberg, Germany; 5) California Pacific Medical Center, San Francisco, CA; 6) Surgery, School of Medicine, University of California - Davis, Davis, CA.

Wilson Disease (WD) is an autosomal recessive disease caused by mutations in the copper transporter encoding *ATP7B* gene, manifesting as variable phenotypes as a result of copper accumulation. WD presentation is characterized by hepatic, neurologic, and psychiatric symptoms without clear genotype-phenotype correlations. Based on prior evidence of effects of methionine metabolism and epigenetic alterations in WD, we hypothesized that alterations in DNA methylation could differentiate patients with WD from healthy subjects and from subjects with other liver diseases and could characterize different WD clinical trajectories. Whole-genome bisulfite sequencing was therefore performed on DNA from liver and whole blood of WD patients compared to healthy subjects, primary sclerosing cholangitis, and non-alcoholic fatty liver disease patients (liver  $n=21$ , blood  $n=72$ ). In liver, 1840 differentially-methylated regions (DMRs) specifically differentiated WD from both healthy and disease control subjects. Functional annotation of WD-specific liver DMRs revealed a highly significant enrichment for liver-specific enhancers in WD-hypermethylated DMRs ( $\log(\text{odds ratio})=11.6$ , FDR  $q\text{-value}=5.5E-278$ ). WD-hypermethylated DMRs were also enriched for binding sites of liver development transcription factors, including Hepatocyte Nuclear Factor 4 alpha (HNF4A), Retinoid X Receptor alpha (RXRA), Forkhead Box A1 (FOXA1), and FOXA2. Genes associated with WD-DMRs were enriched for functions in inflammatory response, as well as lipid and folic acid metabolism. 2458 DMRs discriminated liver samples from advanced compared to early stage WD patients. Genes with higher methylation in advanced WD patients were enriched for functions in complement activation (fold enrichment=18.2, FDR  $q\text{-value}=6.2E-5$ ). In blood samples from an independent patient cohort, 262 WD-specific DMRs were identified. Genes near WD-specific blood DMRs significantly overlapped with those in liver, including at the genes for the drug-targetable epigenetic regulators histone deacetylase 4 (HDAC4) and HDAC5 (Hypermethylated: odds ratio=6.1,  $p=6.8E-40$ ; Hypomethylated: odds ratio=3.7,  $p=4.1E-8$ ). 2860 DMRs in blood distinguished WD patients with hepatic versus neurologic symptoms and were enriched for traits in mental deterioration (fold enrichment=2.1, FDR  $q\text{-value}=0.04$ ). In conclusion, this novel epigenomic signature of WD reveals new insights into potential biomarkers and treatments for this complex genetic disease.

**Using epigenetic age to investigate tissue origin in endometriosis.** *K. Leap, J. Martinez-Agosto, S. Horvath.* UCLA, Los Angeles, CA.

Endometriosis is a common reproductive disorder defined by endometrial tissue that is found outside of the uterus. Despite its prevalence and high disease burden, it lacks effective treatment for both management of symptoms and recurrence of disease. Perhaps most surprising is that the origin of ectopic tissue is unknown. A focal question in the pathogenesis of the disease is whether ectopic tissue has an embryological origin or, according to Sampson's theory, arises from retrograde menstruation after puberty and menarche. We hypothesized that ectopic tissue would be younger, consistent with an embryological origin and contrary to Sampson's theory of retrograde menstruation. To determine biological age and compare it to chronological age, we used DNA methylation age, an established epigenetic clock. We analyzed Gene Expression Omnibus (GEO) DNA methylation data comparing ectopic diseased endometrial tissue, uterine tissue from affected women, and healthy uterine tissue. Our data analysis established that ectopic tissue is younger on average than both the woman's chronological age and the predicted DNA methylation age of the uterine tissue. We further explored the differences between these tissues through weighted gene co-expression network analysis (WGCNA). Using GEO gene expression data on ectopic and normally situated endometrial tissues in diseased women and healthy tissues, we identified biological networks relevant to differences between healthy and diseased women, as well as ectopic and eutopic tissues. These findings suggest that endometriosis may not result from a migration of uterine tissue to ectopic locations. The pathways and epigenetic state identified in this study will serve to explore additional hypotheses about biological origin of disease, including other conditions in which tissue origin is important in understanding pathogenesis, like cancer.

**Gene expression profiling of liver tissue biopsies, PBMCs, and monocytes to predict treatment response for patients with alcoholic hepatitis.** *N. Siddiqui<sup>1</sup>, C. Magnan<sup>1</sup>, Z.X. Liu<sup>2</sup>, J.M. Jacobs<sup>3</sup>, T.R. Morgan<sup>4</sup>, T.M. Norden-Krichmar<sup>1</sup>,* the Southern California Alcoholic Hepatitis Consortium. 1) University of California, Irvine, Irvine, CA; 2) Keck School of Medicine, University of Southern California, Los Angeles, CA; 3) Biological Sciences Division/ Integrative Omics, Pacific Northwest National Laboratory, Richland, WA; 4) Hepatology, VA Long Beach Healthcare System, Long Beach, CA.

Alcoholic Hepatitis (AH) is the most severe form of alcohol-induced liver disease and is associated with a high short-term mortality rate. Prednisolone, an established standard of care treatment for AH patients, does not successfully prevent the development of acute liver failure, multi-organ dysfunction, and death in all patients. To better understand this aspect of treatment, this study utilized transcriptomic profiling of human liver tissue biopsies, peripheral blood mononuclear cells (PBMCs), and isolated monocytes to explore how underlying variation in gene expression may be associated with differences in drug response. The protocol for this study was approved of by the IRB and written consent was obtained for all participants. Biological samples were collected at baseline, before the start of treatment administration, by the Southern California Alcoholic Hepatitis Consortium (SCAHC). RNA was extracted from these samples and sequenced at 2x100 paired-end on an Illumina HiSeq. Patients were clinically analyzed seven days after the administration of corticosteroid treatment for indication of drug response. Transcriptomic data for treatment responders (R) and non-responders (NR) for liver tissue (n = 12 R versus 6 NR), PBMCs (n = 9 R versus 7 NR), and monocytes (n = 7 R versus 3 NR) were aligned to the human genome and quantified. Differential expression analysis was conducted via the Cufflinks software, using upper quartile normalization between data files. Normalized differentially expressed genes were filtered to retain only those with an absolute value of log<sub>2</sub> adjusted fold change ≥ 1, FPKM ≥ 1, and p-value ≤ 0.05. Ingenuity Pathway Analysis software was utilized to determine significantly enriched pathways. There were observed differences in gene expression between responders and non-responders in all cases. Common significant pathways included those related to immune function and the inflammatory response. Proteomics data from a high mass accuracy LC-MS/MS platform was available for correlation. The preliminary results suggest that there are characteristic gene expression profiles that can be observed at baseline for responders and non-responders to corticosteroid treatment. These differences may be detected via liver tissue or blood samples with potential ramifications in predicting the outcome of drug response and guiding the administration of future treatment. (Supported by NIAAA #U01AA021838, #U01AA021886).

**Comparative developmental study of mesenchymal stem cell differentiation in primates.** G. Housman<sup>1</sup>, S. Pott<sup>1,2</sup>, Y. Gilad<sup>1,2</sup>. 1) Section of Genetic Medicine, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL.

Mesenchymal stem cells (MSCs) are multipotent adult stem cells that aid in the repair of tissue damage through their ability to differentiate into several mesodermal cell types, including bone, cartilage, muscle, and adipose. These features, in addition to their ability to be grown in culture, make MSCs ideal for the targeted treatment of skeletal injuries and diseases. However, current standards on the definition and purity measures of MSCs within and between species do not account for transcriptional heterogeneity. Gene expression profiles at the single-cell level may elucidate more accurate characterizations of MSCs. To evaluate this, we collect single-cell RNA expression patterns during the differentiation of human and chimpanzee iPSCs into MSCs, identify cellular subpopulations at different stages of differentiation, assess how well these subpopulations persist across technical replicates, and determine how differentiation-associated changes in gene regulation vary between humans and chimpanzees. We differentiated iPSCs from a human and a chimpanzee into MSCs using a well replicated study design and collected RNA at three time-points during each differentiation starting with the iPSC state (day 0), intermediate state (day 5), and MSC state (day 9). Standard imaging and FACS analyses were performed to confirm the progress of differentiation, and single-cell RNA sequence data (scRNAseq) were collected using a Drop-seq protocol. Cells progressed from round iPSC morphologies to elongated MSC morphologies and became plastic adherent during differentiation. Additionally, as expected, iPSCs only express the cell surface marker CD90, intermediate cells express CD90 and CD105, and MSCs express CD90, CD105, and CD73. Further, the dimensionality of the scRNAseq data reveals an initial increase in cellular heterogeneity during differentiation, as well as a maintenance of this subpopulation structure across technical replicates and conservation across species. Overall, these results begin to clarify the purity of MSCs at multiple comparative levels. This is the first study to assess gene expression patterns at the single-cell level in MSCs and to evaluate such differences across species. Continued work in this area will further clarify the expected heterogeneity of MSCs and thus, their feasibility for clinical applications.

**1881W**

**Identification of novel key genes and pathways related to Hidradenitis suppurativa and its comorbidities using genome-wide DNA methylation analysis.** S. Vishweswaraiah<sup>1</sup>, N.M. Sayed<sup>2</sup>, U. Ratnamala<sup>3</sup>, U. Radhakrishna<sup>1</sup>. 1) Oakland University William Beaumont School of Medicine, Royal Oak, MI., United States; 2) Biotechnology, Nirma Institute of Science, Nirma University, Ahmedabad, India; 3) Department of Pharmacology, Creighton University, Omaha, NE, United States.

Hidradenitis Suppurativa (HS), usually presents after puberty with deep-seated inflamed lesions in the apocrine gland-bearing areas of the body, including the armpit (axillae), groin, perianal, and breast regions, with a prevalence of 1% to 4% in the general population. HS results from a combination of genetic and environmental factors and is negatively influenced by various lifestyle factors. The condition is characterized by genetic heterogeneity and is traced to specific  $\gamma$ -secretase gene mutations in some families. However, in sporadic cases, these gene mutations are not present. The Infinium Methylation EPIC BeadChip array (Illumina) was performed in 24 HS subjects, previously excluded from  $\gamma$ -secretase mutations and 24 normal controls. Differentially-methylated genes were used to generate a heatmap using the ComplexHeatmap (v1.6.0) R package (v3.2.2). Ward distance was used for the hierarchical clustering of samples. A multiple logistic regression analysis was done using more stringent criteria (FDR  $p \leq 0.00001$  and  $\geq 2$ -fold change), to select candidate genes. Ingenuity Pathway Analysis (IPA) (Qiagen IPA) software was used to identify biological functions or interacting regulatory networks. The study identified a total of 20 cytosine loci which had excellent accuracy (AUC  $\geq 0.90$ ) for the detection of HS. IPA detected multiple signaling pathways implicated in the development of skin and other cancers, wound healing, immunological processes, inflammatory disorders, obesity, hypertension, and Type 2 diabetes mellitus. The study provided insights into the pathogenesis of HS by generating novel candidate genes and pathways.

**Global methylation and transcriptional changes following endothelial cell activation during infection and autoimmunity.** X. Shao<sup>1</sup>, B. Rhead<sup>1,2</sup>, O. Solomon<sup>1</sup>, P. Ghai<sup>3</sup>, L.F. Barcellos<sup>1,2</sup>, A.M. Bowcock<sup>3,4</sup>. 1) Genetic Epidemiology and Genomics Laboratory, University of California, Berkeley, Berkeley, CA; 2) Computational Biology Graduate Group, University of California, Berkeley, Berkeley, CA; 3) Imperial College, London, UK; 4) Icahn School of Medicine at Mount Sinai, New York, NY.

Endothelial cells are a primary site of leukocyte recruitment during inflammation. An increase in tumor necrosis factor- $\alpha$  (TNF) levels as a result of infection, or in some autoimmune diseases can trigger this process and a number of autoimmune diseases including rheumatoid arthritis, psoriatic arthritis and psoriasis are now treated with TNF inhibitors. However, the genomic alterations that occur as a result of TNF-mediated inflammation are not well understood. Psoriasis is a chronic inflammatory disease of the skin that is also accompanied by increased vascularization due to proliferation and differentiation of resident endothelial cells following an inflammatory trigger. We were interested in the molecular targets and networks of this process. To investigate this we examined altered CpG methylation and gene expression in both primary keratinocytes and endothelial cells following TNF $\alpha$  stimulation. We analyzed responses in 40 human umbilical vein endothelial cell (HUVEC) and 35 normal human epidermal keratinocyte (NHEK, 24 fetal and 11 adult) primary cell lines. Genome-wide DNA methylation and gene expression profiles were generated on all 75 cell lines via microarray, before and 24 hours after stimulation with TNF $\alpha$ . Genes with differential expression (DE) in response to TNF $\alpha$  were identified in each cell type separately using paired analyses in *limma*. Differentially methylated regions (DMRs) were identified with *DMRcate*. HUVEC cells showed marked differences after stimulation with TNF $\alpha$ , with 408 DE genes (163 up- and 245 down-regulated) after adjusting for multiple hypothesis tests. There were 330 DMRs in HUVEC cells after stimulation with TNF $\alpha$ , with a strong tendency toward hypomethylation: 309 regions were decreased and 21 regions increased. There were 17 highly significant DMRs in or near a DE gene. These included the promoters of a number of genes upregulated during the inflammatory response and playing a role in leukocyte proliferation, activation or adhesion including the interleukin 7 receptor (IL7R), vascular cell adhesion molecule 1 (VCAM1), CD69, and CCL2 where several upstream enhancers were also DM. Many sites harbored binding sites for NF $\kappa$ B transcription factors which are important inflammatory mediators. Although NHEK cells did not show significant DMRs or DE genes, which could be due in part to smaller sample size, the findings in HUVECS are providing novel insights into endothelial activation following an inflammatory stimulus.

**1883F**

**Identification of hypermethylation of rDNA as an epigenetic regulator of rRNA expression in brain of Alzheimer's disease's patients.** T.C. Faria<sup>1</sup>, D.A. Santana<sup>1</sup>, L.C. Santos<sup>1</sup>, S.L.M. Payao<sup>2</sup>, G. Turecki<sup>3</sup>, C.O. Gígek<sup>1</sup>, M.A.C. Smith<sup>1</sup>, E.S. Chen<sup>1</sup>. 1) Department of Morphology and Genetics, Genetics Division, Federal University of Sao Paulo, Sao Paulo, Brazil; 2) Genetics Division, Marília College of Medicine, Sao Paulo, Brazil; 3) Department of Psychiatry, Douglas Hospital Research Center, McGill University, Montreal, QC, Canada.

Alzheimer's disease (AD) is a neurodegenerative, irreversible and progressive disease, and the most common form of dementia. Alterations in rRNA expression have been previously associated with AD pathogenesis. In addition, hypermethylation of the rDNA promoter was associated with AD in parietal and prefrontal cortex. Nonetheless, it is unclear whether DNA methylation is the mechanism involved in rRNA expression regulation in AD. Hence, we aimed to investigate rDNA methylation pattern in 3 brain regions – auditory cortex, hippocampus and cerebellum – from AD and control individuals. We also analyzed gene expression of the DNA methylation machinery as well as the rRNA expression. Methylation was evaluated using bisulfite-conversion followed by NGS and gene expression was performed by qRT-PCR. Hypermethylation in 20 CpG sites (76.9%) of the rDNA promoter region was observed in AD cerebellum compared to controls; likewise, 6 CpGs sites (23%) were hypermethylated in AD hippocampus. Additionally, CpG#9 showed a methylation percentage higher than 40% in both groups in all regions when compared to all other CpGs sites, which presented a maximum average of methylation of 16.3%. Concerning gene expression, all evaluated methylation machinery genes showed increased expression in AD cerebellum and *MBD4* expression level was significantly higher in AD auditory cortex when compared to controls. We also verified increased expression of rRNA18S in AD in all brain regions and of rRNA28S in AD cerebellum. When brain regions were pooled, increased methylation in rDNA promoter and increased rRNA28S and *MBD2-3* expression were observed in AD compared to controls; moreover, a slight correlation between rDNA methylation and rRNA18S expression was verified. Additionally, strong correlations between rRNA18S and 28S expression levels were verified in AD in all brain regions. Furthermore, it was observed difference in rRNA18S expression level in AD between cerebellum and auditory cortex and, cerebellum and hippocampus; likewise, rRNA28S expression level differs in AD between cerebellum and auditory cortex and, auditory cortex and hippocampus. In conclusion, rDNA hypermethylation might be a mechanism involved in the regulation of rRNA expression; however, it may not be sufficient to silence rRNA expression in AD, suggesting that other mechanisms might be acting in rRNA expression. Also, some CpGs sites may have a relative importance in the dynamic methylation of rDNA promoter.

**Alzheimer disease associated changes of RNA editing in temporal cortex and whole blood affects targetable pathways.** O.K. Gardner<sup>1,2</sup>, L. Wang<sup>1,2,3</sup>, D. Van Booven<sup>1,2</sup>, P.L. Whitehead<sup>1,2</sup>, K.L. Hamilton-Nelson<sup>1,2</sup>, L.D. Adams<sup>1,2</sup>, S. Rolati<sup>1,2</sup>, N.K. Hofmann<sup>1,2</sup>, J.M. Vance<sup>1,2</sup>, M.L. Cuccaro<sup>1,2</sup>, W.S. Bush<sup>4</sup>, E.R. Martin<sup>1,2</sup>, G.S. Byrd<sup>5</sup>, J.R. Gilbert<sup>1,2</sup>, J.L. Haines<sup>4</sup>, G.W. Beecham<sup>1,2</sup>, M.A. Pericak-Vance<sup>1,2</sup>, A.J. Griswold<sup>1,2</sup>. 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL, USA; 2) Dr. John T Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL, USA; 3) Department of Public Health Sciences, University of Miami Miller School of Medicine, Miami, FL USA; 4) Institute for Computational Biology and Department of Population & Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH, USA; 5) North Carolina A&T State University, Greensboro, NC, USA.

Though genetic studies have implicated several biological processes in the pathogenesis of Alzheimer Disease (AD), little is known about the epigenetic mechanisms that regulate them. This hinders our ability to target these mechanisms for preventative and therapeutic effects. RNA editing, the post-transcriptional modification of individual bases, plays a vital role in neuronal development and immune regulation, and dysregulated RNA editing has been observed in cancer and neurological diseases. Our goal was to test whether RNA editing alters genes in potentially druggable biological pathways by pursuing the first transcriptome-wide study describing AD related changes of RNA editing in brain and blood. Whole transcriptome RNA sequencing was performed on temporal cortex samples from 39 AD cases and 9 cognitively normal individuals and on peripheral blood specimens from 121 AD cases and 120 cognitively normal individuals of non-Hispanic White ethnicity. We applied a bioinformatics and statistical pipeline utilizing REDIttools software, quality control filtering, and statistical analysis. This resulted in 89,540 high-quality editing events in brain and 44,985 in blood. Using a logistic regression model, 2,949 positions in 803 genes and 723 positions in 371 genes were differentially edited in brain and blood, respectively. Across both tissues, differentially edited genes were enriched for biological processes in key pathways related to AD pathogenesis including: immune regulation, endocytosis, protein modification, and amyloid precursor protein catabolism. The type-1 interferon, NF-kappa B, and MAP kinase signaling cascades were particularly enriched. Genes composing all three of these pathways are regulated by RNA editing, have been implicated in AD in molecular studies, and are targetable by pharmaceuticals. Some differentially edited sites within these genes, including *TBKBP1* and *KDM6B*, are predicted to result in nonsynonymous coding changes or disrupted miRNA binding sites, further supporting the functional relevance of dysregulated RNA editing on these pathways. RNA editing in AD shows dysregulation of targetable inflammatory pathways in both blood and brain. As such, RNA editing studies can help identify new targets for therapeutics, and editing signatures may serve as biomarkers for pathogenic processes in AD.

**DNA methylation analysis of cognitive decline and neuropathology.** A. Lu<sup>1</sup>, K. Nho<sup>2,3</sup>, A. Vasanthakumar<sup>4</sup>, J. Waring<sup>4</sup>, J. Wade Davis<sup>4</sup>, A. Saykin<sup>2,3,5</sup>, M. Levine<sup>6</sup>, S. Horvath<sup>1,7</sup>. 1) Human Genetics, UCLA, Los Angeles, CA; 2) Center for Neuroimaging, Department of Radiology and Imaging Sciences, Indiana University School of Medicine, Indianapolis, IN, USA; 3) Indiana Alzheimer Disease Center, Indiana University School of Medicine, Indianapolis, IN, USA; 4) AbbVie Inc., North Chicago, Illinois, USA; 5) Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA; 6) Department of Pathology, Yale School of Medicine, New Haven, CT, 06510, USA; 7) Biostatistics, School of Public Health, University of California Los Angeles, Los Angeles, USA.

Nearly 36.6 million people live with dementia. This number is expected to more than triple by 2050 according to World Health Organization. Despite significant progress, the molecular underpinnings of dementia remain poorly understood. A recent DNA methylation based biomarker of aging (known as DNAm age or epigenetic clock) has revealed a relationship between Alzheimer's disease (AD) related neuropathology and epigenetic aging rates in brain tissue but not yet in blood. Here we relate DNA methylation levels and DNAm age in blood to dementia related traits, using the Alzheimer's Disease Neuroimaging Initiative (ADNI) longitudinal cohort. Our study involved 332 individuals with mild cognitive impairment (MCI) and 218 controls. The mean age was 74 years at baseline and the mean follow-up period was 3.6 years. Our study focused on i) an imaging biomarker of cerebral glucose metabolism, FDG-PET, sensitive to dementia and ii) a rate of change in cognitive assessments based on the Mini-Mental State Examination (MMSE). We defined a measure of MMSE decline on the basis of a linear mixed model. Specifically, cognitive decline was defined as minus the estimated random slope effect with respect to MMSE on time. DNA methylation levels were measured on the Illumina EPIC array (~ 850k CpGs). Our epigenome-wide association study (EWAS) of MMSE decline (adjusted for age) identified two loci at a suggestive significance level of  $P < 10^{-6}$ . The top EWAS hit is within the *SORCS1* gene ( $P = 3.4E-6$ ). Interestingly, *SORCS1* is known to alter amyloid precursor protein processing. The second hit is near the *KCNH5* gene ( $P = 9.6E-6$ ), a member of voltage-gated K<sup>+</sup> channels implicated in epilepsy. Our epigenetic clock analysis of longitudinal changes of FDG-PET assessed the-pan tissue epigenetic clock by Horvath (353 CpGs), the blood based clock by Hannum (71 CpGs) and the estimator of DNAm PhenoAge by Levine (513 CpGs). Our growth curve analysis showed that FDG-PET was inversely related to all three clocks ( $=0.034$ ,  $=0.053$ , and  $=0.019$ ). A secondary analysis revealed that FDG-PET exhibited weak associations with age-adjusted DNAm based blood cell counts: a positive correlation with B cells ( $P = 0.039$ ) and a negative correlation with CD8<sup>+</sup> T cells composition ( $P = 0.042$ ). In summary, our DNA methylation studies in blood a) identify two loci for which methylation levels relate to cognitive decline, and b) demonstrate that epigenetic age acceleration relates to cerebral glucose metabolic changes.

**DNA hypomethylation in blood links *B3GALT4* ganglioside and *ZADH2* prostaglandin pathways to Alzheimer's disease.** A. Madrid<sup>1,2</sup>, K. Hogan<sup>3,4</sup>, L. Papale<sup>5</sup>, L. Clark<sup>4,5,6</sup>, S. Asthana<sup>4,6</sup>, S. Johnson<sup>4,5,6</sup>, R. Alisch<sup>1</sup>. 1) Department of Psychiatry, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA; 2) Neuroscience Training Program, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA; 3) Department of Anesthesiology, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA; 4) Wisconsin Alzheimer's Institute, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA; 5) Wisconsin Alzheimer's Disease Research Center, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA; 6) Geriatric Research Education and Clinical Center, William S. Middleton Memorial Veterans Hospital, Madison, WI, USA.

Alzheimer's disease (AD) is the most common neurodegenerative disease afflicting the elderly population. Late-onset AD (LOAD) is characterized by symptoms presenting after the age of 65 that include dementia and memory loss. While the etiology of LOAD remains largely unknown, evidence suggests that environmental influences increase disease risk, particularly through interactions with the epigenome. Recent epigenome-wide association studies (EWAS) using brain tissue report differential methylation in known and newly recognized LOAD genes, thereby underscoring the utility of EWAS in disclosing novel genes and pathways associated with LOAD pathogenesis. As an alternative to the study of donor brain tissues, investigation of DNA methylation in accessible peripheral tissues may provide an opportunity to improve clinical diagnosis and estimates of prognosis. To identify differentially methylated positions (DMPs) in blood that distinguish persons with and without LOAD, genomic DNA from the whole blood of 45 LOAD patients and 39 matched controls were interrogated using the Illumina HumanMethylationEPIC array platform, which detects DNA methylation levels at >850,000 sites spanning the genome. DMPs were observed at 477 loci corresponding to 106 genes. Remarkably, 17 of these DMPs were shared between six clinical markers of LOAD that were analyzed independently as continuous variables, comprising Rey Auditory Verbal Learning Test (RAVLT) scores, cerebrospinal fluid total tau (t-tau) and phosphorylated tau 181 (p-tau<sub>181</sub>) levels, and t-tau/Amyloid beta (AB<sub>1-42</sub> (AB<sub>42</sub>)), p-tau<sub>181</sub>/AB<sub>42</sub>, and AB<sub>42</sub>/AB<sub>1-40</sub> (AB<sub>40</sub>) ratios. In patients with LOAD, 12 of the 17 shared DMPs were hypomethylated in *B3GALT4* (Beta-1,3-galactosyltransferase 4), a gene previously associated with LOAD in the superior temporal gyrus of the brain. The remaining five shared DMPs were hypomethylated in *ZADH2* (Prostaglandin reductase 3), a novel LOAD-associated gene. Taken together, these data reinforce the use of blood as an accessible tissue of value in the identification of DMPs associated with dementia onset and progression. Our data lend further support to the role of enzymes in ganglioside and prostaglandin metabolism in the pathogenesis of Alzheimer's disease, and may provide novel diagnostic, prognostic, and modifiable therapeutic targets.

**1887W**

**Identification of genes regulated by H3K9 acetylation in brains of Alzheimer's disease patients: A ChIP-Seq approach.** D.A. Santana<sup>1</sup>, R.D. Puga<sup>2</sup>, T.C. Faria<sup>1</sup>, G. Turecki<sup>3</sup>, C.O. Gigeke<sup>4</sup>, M.A.C. Smith<sup>1</sup>, E.S. Chen<sup>1</sup>. 1) Genetics Division, Department of Morphology and Genetics, Universidade Federal de Sao Paulo (UNIFESP), Sao Paulo, SP, Brazil; 2) Department of Clinical Research, Hospital Israelita Albert Einstein, Sao Paulo, SP, Brazil; 3) Department of Psychiatry, Douglas Hospital Research Center, McGill University, Montreal, QC, Canada; 4) Department of Pathology, Universidade Federal de Sao Paulo (UNIFESP), Sao Paulo, SP, Brazil.

Alzheimer's disease (AD) is the most common neurodegenerative disease and the leading cause of irreversible dementia. Evidences suggest that epigenetic modifications, such as histone post-translational modifications, may increase the risk of AD. Thus, we aimed to identify genes regulated by H3K9 acetylation, an essential mark of transcriptional activation, in three brain regions – auditory cortex, hippocampus and cerebellum – of AD compared to control individuals. Samples underwent ChIP-Seq procedure and were pooled according to the region and the group for library preparation. Libraries were sequenced using Illumina HiSeq 2500 platform, in Rapid Run mode, producing single-ended reads. Quality control was evaluated using FastQC, and the alignment to reference genome (GRCh37/hg19) was performed using Bowtie2. Peak calling, differential analysis between groups, and identification of motifs in the output data were undertaken by HOMER software. Functional and gene network analysis were also performed using Gene Ontology (GO) and GIANT, respectively. ChIP-Seq analysis revealed that H3K9 acetylation was decreased in 17 genes, such as *ACHE* and *ADRA2A*, in AD compared to controls. Moreover, 71 genes, including *IREB2*, *RYR1*, *HMOX2*, *RORA*, *NRF1*, *ARSB* and *SAA1*, showed increased H3K9 acetylation levels in AD group. Gene network analysis demonstrated interactions among these genes and AD-associated genes (*APP*, *PSEN2* and *APOE*). Functional analysis revealed that most genes are involved in cellular process, cell part and catalytic activity. In AD group, motif discovery indicated the enrichment of the transcription factor *ERRα*, which is highly expressed in nervous system. In conclusion, we identified several differentially H3K9 acetylated genes in AD in comparison to controls, which could lead to abnormalities in the expression of such genes. Most identified genes were not previously described in AD. Therefore, our results indicate the importance of studying epigenetic modifications to better understand the pathophysiology of AD.

**Transcriptomic association analysis with Alzheimer's disease related traits in ROS/MAP, MSBB and Mayo Clinic cohorts.** C. Zhang, J. Hutz, A. Mitchell. Andover innovative medicines institute, Eisai Inc, Andover, MA.

Dementia, with Alzheimer's disease (AD) as the most common form, is currently affecting 36 million people worldwide and expect to affect 115 million by 2050 without effective therapeutic development. Large-scale RNA-seq analysis from human brain samples is a promising method for biomarker and drug target discovery, which is essential to the development of novel drugs for AD treatment and prevention. The Religious Orders Study and Memory and Aging Project (ROSMAP) study, the Mount Sinai Brain Bank (MSBB) study and the MayoRNAseq study are the three largest late onset AD cohorts with brain samples RNA-seq data linked to rich individual level clinical data in Accelerating Medicines Partnership - Alzheimer's Disease (AMP-AD) consortium. While there are publications associated with each individual study, it is not clear if the genes significantly associated with AD in one study can be replicated in other cohorts. Here, we performed association analysis with AD related traits using uniformly processed RNA-seq data from the three cohorts and found a list of protein coding and non-coding genes consistently associated with AD status, cognitive decline and neuritic plaques across all three cohorts. Some of the genes in this list, including *CCL4L2*, *GABRR2*, *CRH* and *VGF* are already being studied by the community for their neural or neuro-inflammation related functions, while others are not as well studied and can be new biomarkers or targets of interest. The newly discovered genes, including some long non-coding RNAs, *WISP1*, *APLNR*, *SIGLEC1*, *LTF*, *SERPINA5*, *SST* and *FREM3*, have broad range of functions in inflammation, cell signaling, cell proliferation and oxidative stress. We think this gene list can be complimentary to genes found in recent late onset AD genome wide association studies, where neuro-inflammatory genes became of high interest. We also highlight the importance for controlling covariates, such as RIN, batch effects, age, etc., in analysis of this scale.

**A suppressor screen in *Mecp2* mice implicates the DNA damage response in Rett syndrome pathology.** A. Enikanolaiye<sup>1</sup>, C.M. Buchovecky<sup>2</sup>, M.J. Justice<sup>1,2</sup>. 1) The Hospital for Sick Children, Toronto, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Canada; 3) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Rett syndrome (RTT) is an X-linked neuro-metabolic disorder caused by mutations in methyl-CpG binding protein 2 (*MECP2*). RTT is characterized by normal postnatal development, after which previously acquired motor and communicative skills are lost. Re-expression of *Mecp2* in symptomatic mutant mice rescues neurological defects and prolongs survival. This suggests that the disease may be improved or reversed by genetic or pharmacological intervention. To identify novel candidate pathways for such intervention, a dominant random mutagenesis screen for suppressors of RTT symptoms was carried out in a *Mecp2*-null mouse model of RTT. Genes that suppress the disease phenotype were isolated by whole exome sequencing and linkage mapping. Strikingly, multiple mutations in the DNA damage response (DDR), which repairs double-stranded breaks (DSBs) can contribute to the improvement of RTT-like symptoms in mice. Expression studies show that levels DDR and other DNA damage factors are perturbed in *Mecp2*-null mice brain and liver. In particular,  $\gamma$ H2AX, a marker of DSBs is upregulated in the brain and liver of *Mecp2*-null mice. *In vitro* assays that measure the frequency of DSB repair pathways, show that the rate of homologous recombination is upregulated in *Mecp2*-null mice. Because neurons are non-dividing cells, an ongoing question is why mutations in this pathway improve symptoms in mice. Unbiased genetics screens such as these can help uncover unexpected pathways that contribute to RTT pathophysiology and that can provide insight into therapies. DSB repair pathways may also prove to be important in other autism spectrum disorders as well.

**Placental DNA methylation at the interface of genetics and environment in the MARBLES prospective autism study.** Y. Zhu<sup>1</sup>, C. Mordaunt<sup>1</sup>, K. Dunaway<sup>1</sup>, D. Yasui<sup>1</sup>, R. Coulson<sup>1</sup>, P. Krakowiak<sup>1</sup>, B. Puschner<sup>1</sup>, Y. Lin<sup>2</sup>, R. Marathe<sup>1</sup>, T. Totah<sup>1</sup>, C. Walker<sup>1</sup>, S. Ozonoff<sup>3,6</sup>, I. Hertz-Picciotto<sup>2,6</sup>, F. Hormozdizadeh<sup>1</sup>, R. Schmidt<sup>6</sup>, J. LaSalle<sup>6,7</sup>. 1) Medical Microbiology and Immunology and Genome Center, University of California at Davis, Davis, CA; 2) Public Health Sciences, University of California at Davis, Davis, CA; 3) School of Veterinary Medicine, University of California at Davis, Davis, CA; 4) Obstetrics and Gynecology, University of California at Davis, Davis, CA; 5) Psychiatry and Behavioral Sciences, University of California at Davis, Davis, CA; 6) MIND Institute, Sacramento, University of California at Davis, Davis, CA; 7) Genome Center, University of California at Davis, Davis, CA.

DNA methylation acts at the interface of genetic and environmental risk and protective factors relevant for autism spectrum disorder (ASD). Placenta, a tissue normally discarded at birth, is a potentially rich source of DNA methylation patterns predictive of autism. The MARBLES (Markers of Autism Risk in Babies—Learning Early Signs) prospective cohort study enrolls pregnant mothers with at least one child with ASD. Mothers were interviewed about prenatal vitamin use and their blood was sampled at each trimester for environmental exposures, including persistent organic pollutants polychlorinated biphenyls (PCBs) and polybrominated diphenyls ethers (PBDEs). Placentas were collected for MARBLES births and stored frozen until diagnosis of ASD, typical development (TD), or non-typical development (NTD) in the child at age three. Whole genome bisulfite sequencing was performed on DNA isolated from 20 ASD and 21 TD male placentas. 352 differential methylated regions (DMRs) on 553 genes discriminated ASD from TD samples. Percent methylation over these DMRs showed strong positive association with autism severity scores but not other potential confounding variables. Placental ASD DMRs were significantly enriched in active transcription start sites and its flanking regions enriched in H3K4me1 and H3K4me2 from chromHMM chromatin state predictions, suggesting an impact on gene expression. Two placental ASD DMRs passed a family-wise error rate sample permutation test (adjusted  $p < 0.05$ ), at gene loci *IRS2* and *CYP2E1*. Both *IRS2* and *CYP2E1* loci replicated by an independent method of pyrosequencing ( $p = 0.014$  and  $p = 0.004$ ) and increased protein levels of *IRS2* in ASD were confirmed by Western blot. Methylation at *CYP2E1*, encoding a member of the cytochrome P450 superfamily, was primarily driven by genetic alterations (rs1536828). While percent methylation at *IRS2*, encoding insulin receptor substrate 2, was not significantly affected by genotype, multiple PCB and PBDE congeners showed significant associations with *IRS2* methylation, especially PCB 118 ( $p = 0.005$ ). *IRS2* methylation also significantly associated with prenatal vitamin intake ( $p = 0.012$ ). ASD diagnosis, *IRS2* genotype and PCB 118 level formed a significant three-way interaction on explaining *IRS2* methylation ( $p = 0.019$ ). This study identified epigenetic signatures of ASD risk in placenta that environmentally sensitive to prenatal vitamin, PCB, and PBDE exposures in pregnancies for ASD.

**Alcohol abuse associated allele specific expression and regulation in human brain tissue.** X. Rao<sup>1</sup>, H. Lin<sup>1</sup>, K. Hargreaves<sup>2</sup>, J. Ipe<sup>3</sup>, K. Thapa<sup>3</sup>, H. Gu<sup>3</sup>, M. Kapoor<sup>4</sup>, S. Farris<sup>4</sup>, T. Foroud<sup>4</sup>, A. Goate<sup>4</sup>, H. Edenberg<sup>1,3</sup>, R. Mayfield<sup>5</sup>, T. Skaar<sup>2</sup>, Y. Liu<sup>1</sup>. 1) Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 2) Division of Clinical Pharmacology, Department of Medicine, Indiana University School of Medicine, Indianapolis, IN; 3) Department of Biochemistry & Molecular Biology, Indiana University School of Medicine, Indianapolis, IN; 4) Ronald M. Loeb Center for Alzheimer's Disease, Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, New York; 5) Waggoner Center for Alcohol and Addiction Research, University of Texas at Austin, Austin, TX.

Alcohol abuse and alcoholism are significant public health problems. As a central nervous system depressant, high levels of alcohol intake over a long period of time may alter brain function to promote alcohol addiction and have extensive damaging effects on the brain. Understanding the molecular mechanism of how alcohol affects the brain will be very important to prevent alcohol abuse and to reverse the impact of heavy drinking on the brain. Animal models have been widely used to identify candidate mechanisms, which greatly advanced our knowledge of molecular basis of alcoholism. However, due to ethical considerations, there were very limited molecular evidence from human brain. Through collaboration between the Collaborative Studies on Genetics of Alcoholism (COGA) and Integrative Neuroscience Initiative on Alcoholism (INIA) Consortia, we obtained four regions of brain tissues of 60 human samples from NSW Brain Bank (Australia), of which 30 were heavy drinker and 30 were social/non-drinkers. By integrating deep RNA-seq data with GWAS array results, we identified 90 genes with differential allele-specific expression (ASE) in heavy drinkers, compared to social/non-drinker, in either of four brain regions, many of which have previously been implicated in neurological diseases. Because ASE provides an excellent model to study *cis*-regulatory mechanisms (both alleles are in the same cellular environment), single nucleotide variants (SNVs) in regulatory regions from GWAS array results were further examined, including upstream enhancer/promoter regions, gene bodies, 3'UTRs and downstream regions. Hundreds of SNVs were identified as highly potential *cis*-regulators based on their location in open chromatin regions, identification as expression quantitative trait loci (eQTLs) in GTEx, and prediction of altering transcription binding and miRNA binding sites. Using massively parallel reporter assays, we validated the regulatory role of several SNVs in 3'UTR and will further validate the functional SNVs in enhancer and promoter regions. Our findings will advance the understanding of alcohol abuse associated gene regulation in human brain and serve as a research framework for further study with expanded human brain tissues.

**Screening of drugs conferring an increase in miRNA that is deficient in Huntington's disease.** *H. Shimizu, E. Suzuki, M. Fukuoka, H. Hohjoh.* Department of Molecular Pharmacology, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Kodaira, Tokyo, Japan.

Huntington's disease (HD) is an inherited neurodegenerative disorder characterized by involuntary movement, cognitive decline and psychiatric symptoms, and is caused by mutant *Huntingtin (HTT)* genes carrying aberrantly expanded CAG triplet repeats that are translated to abnormal polyglutamine tracts. Mutant HTT proteins adversely affect biomolecules and genes including functional RNA genes such as microRNAs (miRNAs). Our previous study indicated that many miRNAs were markedly decreased in the brain of HD-model mice (R6/2 mice) relative to that of wild-type mice. Of such decreased miRNAs, *miR-132* was more prominent than other miRNAs. In addition, it had been reported to play important roles in neuronal maturation and functions. Based on the findings, we performed a challenging experiment, in which *miR-132* was supplied into R6/2 brains deficient the miRNA. The results indicated that *miR-132* supplementation brought about amelioration to motor functions and prolonged the lifespan of the treated R6/2 mice (Fukuoka et al., 2018). These findings led us to the possibility that recovery of the *miR-132* gene expression back to a normal level might produce symptomatic improvements as in *miR-132* supplementation. We attempted to search for biomolecules and chemical compounds that are capable of inducing the expression of endogenous *miR-132* gene. We constructed an *in vitro* assay system to search for such molecules. Because the expression of *miR-132* may be regulated by CREB transcription factor, and because the *miR-132* gene has a putative CREB binding site in its predicted promoter region, the luciferase reporter gene carrying a consensus CREB binding site was constructed and introduced together with a mutant *HTT* gene into SH-SY5Y cells, a human neuroblastoma cell line. The cells were subjected to exposure with various chemical compounds followed by a conventional luciferase reporter assay; and, molecules conferring enhancement of the expression of the reporter gene even under the presence of mutant HTT were selected. We screened approximately 1,200 chemical compounds and selected several candidates so far. *In vitro* and *in vivo* experiments using the candidates are currently under progress. We would like to discuss the assay system and the data related to the candidates in this meeting at San Diego.

**Leveraging brain cortex-derived molecular data to elucidate epigenetic drivers of neurological function and disease.** *C. Hatcher, T. Gaunt, T. Richardson.* MRC Integrative Epidemiology Unit, University of Bristol.

**Introduction:** We have performed extensive analyses to uncover regions of the genome where transcriptional and epigenetic mechanisms may play a role in the susceptibility of neurological traits and disease. **Methods:** This was undertaken by applying Bayesian multiple-trait colocalization (moloc) to assess the likelihood that genetic variants responsible for trait variation also influence intermediate molecular phenotypes. We harnessed high dimensional data concerning gene expression, DNA methylation and histone acetylation quantitative trait loci derived from prefrontal cortex tissue (available from the xQTLServe and ROSMAP resources). Summary statistics from genome-wide association studies (GWAS) on five neurological traits (Neuroticism, Schizophrenia, Educational Attainment, Insomnia and Alzheimer's disease) were obtained from large-scale consortia and the UK Biobank study. **Results:** There was evidence at 125 independent loci that genetic variants which influence these complex traits may be acting via changes in gene expression within brain tissue. Of these, 81 were also found to influence proximal DNA methylation and/or histone acetylation. These findings support previous evidence implicating DNA methylation as a transcriptional repressor, as we observed enrichment of an inverse relationship between DNA methylation and gene expression across these loci. Our results support previous findings implicating epigenetic factors in neurological trait susceptibility (such as at *KLC1* with schizophrenia), as well as uncovering evidence at dozens of novel loci not previously identified. For instance, variation at *MDGA1* has not previously been identified by GWAS, although our analysis provided evidence of colocalization between molecular phenotypes and insomnia risk at this locus (total posterior probability of association = 86%). This finding has recently been validated by a large-scale GWAS of insomnia (P-value =  $4.0 \times 10^{-13}$ ), suggesting that the other novel loci which colocalize with molecular phenotypes in our study are likely to be identified by GWAS as study sizes increase. **Conclusion:** We have identified evidence at dozens of loci that the same causal variant influencing complex traits is responsible for changes in epigenetic factors and gene expression. Integrating molecular data with GWAS can elucidate the biological mechanisms which influence traits, as well as help prioritise both known and novel candidate genes in disease.

**Human neuronal models of *CHD2*-associated epilepsy.** *K.J. Lamar<sup>a</sup>, A.M. Tidball<sup>b</sup>, J.M. Parent<sup>c</sup>, G.L. Carvill<sup>d</sup>.* 1) Ken and Ruth Davee Department of Neurology, Northwestern University Feinberg School of Medicine, Chicago, IL; 2) Department of Neurology, University of Michigan, Ann Arbor, MI, USA.

Pathogenic variants in *CHD2* are associated with developmental epileptic encephalopathy (DEE) in humans. The majority of these variants are frame-shifts or deletions and all are heterozygous, having arisen *de novo*, indicating that haploinsufficiency is the mode of pathogenesis. Chromodomain helicase DNA binding protein 2 (*CHD2*) is a chromatin remodeler that is associated with sites of active transcription. To better understand the role of *CHD2* in human DEE, we utilized the CRISPR/Cas9 system to create heterozygous disruptions of *CHD2* in human induced pluripotent stem cells (iPSCs). To examine the effect of *CHD2* disruption in neuronal development, we converted these iPSC lines into neuronal progenitor cells (NPCs) and performed RNA sequencing on *CHD2*<sup>-/-</sup> NPCs and isogenic wild-type (WT) controls. We found that *CHD2*<sup>-/-</sup> NPCs exhibited an upregulation of genes involved in neuronal differentiation and a downregulation of genes involved in proliferation. *CHD2* disruption in NPCs also lead to misregulation of other epilepsy genes. Basic fibroblast growth factor (bFGF) is a potent mitogen for NPCs and suppresses differentiation. In order to test for a possible proliferation defect in *CHD2*<sup>-/-</sup> NPCs, *CHD2*<sup>-/-</sup> and WT NPCs were grown with or without bFGF and labeled with BrdU for 30 minutes. When grown in the presence of bFGF, *CHD2*<sup>-/-</sup> NPCs did not have a significant difference in the percentage of BrdU+ cells compared to WT NPCs. However, when grown without bFGF for 3 days prior to BrdU labeling, the percentage of BrdU+ cells in *CHD2*<sup>-/-</sup> NPCs was significantly lower than that of WT NPCs, indicating that *CHD2*<sup>-/-</sup> cell lines have a proliferation defect at the neural progenitor stage and that bFGF may mask this phenotype. Overall, our results suggest that *CHD2* haploinsufficiency results in cell proliferation defect at the NPC stage which likely contributes to premature neuronal differentiation. In the future, we will examine expression changes in *CHD2*<sup>-/-</sup> and WT lines during neuronal differentiation. Moreover, we aim to identify *CHD2* targets and epigenetic changes during development. Ultimately, we seek to understand the mechanisms leading to gene expression changes when *CHD2* is disrupted and the role of *CHD2* in regulating other epilepsy genes. The role of chromatin remodeling and control of gene expression is largely unexplored in epilepsy, but it is a dynamic process with many therapeutic targets and presents a novel opportunity to develop new treatments for patients.

**Three-dimensional chromatin organization and gene regulation in human brain cells.** *M. Song<sup>1,2</sup>, X. Ren<sup>1</sup>, C. Wang<sup>4</sup>, S. Lu<sup>5</sup>, M. Traglia<sup>1</sup>, L. Maliskova<sup>1</sup>, I. Jones<sup>1</sup>, T. Tam<sup>1</sup>, J. Dixon<sup>6</sup>, L. Weiss<sup>1,7</sup>, J. Yao<sup>3</sup>, L. Gan<sup>4</sup>, Y. Shen<sup>1,2,3</sup>.* 1) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA, USA; 2) Pharmaceutical Sciences and Pharmacogenomics Graduate Program, University of California, San Francisco, San Francisco, CA, USA; 3) Department of Neurology, University of California, San Francisco, San Francisco, CA, USA; 4) Gladstone Institute for Neurological Disorders, San Francisco, CA, USA; 5) State Key Laboratory of Membrane Biology, Tsinghua-Peking Center for Life Sciences, School of Life Sciences, Tsinghua University, Beijing, China; 6) Salk Institute for Biological Studies, La Jolla, CA, USA; 7) Department of Psychiatry, University of California, San Francisco, San Francisco, CA, USA.

Mutations in gene regulatory elements have been associated with a wide range of neurological disorders. However, due to their inherent cell type specificity and difficulties in characterizing their regulatory targets, our ability to identify causal genetic variants has remained limited. To address these constraints, we perform integrative analysis of chromatin interactions (promoter capture Hi-C), open chromatin regions (ATAC-seq), and transcriptomes (RNA-seq) in three functionally distinct cell types associated with neurological disorders: iPSC-induced cortical excitatory neurons, hippocampal dentate gyrus (DG)-like neurons, and human primary fetal astrocytes. We identify tens of thousands of cell type-specific, long-range *cis* interactions between promoters and distal promoter-interacting regions (PIRs), enabling us to link regulatory elements to their target genes and identify putative pathways and genes that are dysregulated in disease. We perform validation of novel PIRs linked to neuronal function using CRISPR-Cas9 genome editing in human neurons. Finally, we demonstrate that physical chromatin interactions can mediate genetic interactions in autism spectrum disorder (ASD). Our study presents a catalog of regulatory interactions in the human brain and advances our understanding of how regulatory variants contribute to complex neurological disorders.

**1896W****Investigating cell type-specific promoter usage to uncover new biology:**

**Defining the role of SOX10 in myelination.** E. Fogarty<sup>1</sup>, A. Antonellis<sup>1,2</sup>. 1) Neuroscience Graduate Program, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

The variety of cellular identities in a multicellular organism is dependent on genomic complexity achieved partly by differential use of multiple transcription start sites (TSSs) at individual loci. TSS use can be regulated by cell type-specific transcription factors and defining these interactions provides insights into cell type-specific biology. Schwann cells and oligodendrocytes are the myelinating glia of the peripheral and central nervous systems, respectively. SOX10 is a transcription factor required for the development and maintenance of both cell types and SOX10 target genes include loci critical for myelination and genes implicated in demyelinating disease. We and others have described SOX10-responsive promoters at loci with multiple TSSs. We sought to leverage these features of SOX10 activity to uncover novel pathways and gene isoforms important for myelination. Toward this, we performed cap analysis gene expression (CAGE) on cultured Schwann (S16) cells and intersected these data with marks of SOX10 binding, active promoters, and open chromatin to identify 4,032 candidate SOX10-regulated promoter elements. Next, we used RNA-Seq to assay the expression of transcripts associated with these promoters in S16 cells ablated for SOX10 expression ( $\Delta$ SOX10) and found that 488 TSSs have reduced expression with loss of SOX10, while 362 TSSs have increased expression. Gene ontology analyses show that TSSs with reduced expression in  $\Delta$ SOX10 S16 cells reside at loci associated with pathways known to be SOX10-regulated including myelination and glial differentiation. Interestingly, these data also show an enrichment for terms not previously associated with SOX10: cell junctions, adhesion, and GTPase signaling. A target of interest is *FGD4*, a known demyelinating disease gene that encodes a GTPase exchange factor. Only one of three *FGD4* TSSs is utilized in Schwann cells and it is associated with a SOX10-regulated promoter element. Luciferase assays show that the promoter is active in S16 cells and deletion of a conserved SOX10 binding site reduces the activity to 25%. These findings support a model where loss of the protein specifically expressed from the SOX10-regulated TSS causes demyelinating disease. In sum, our data support the utility of leveraging cell type-specific transcription factors in defining TSS use genome-wide toward investigating isoform-specific gene function in a cell-type specific manner.

**1897T**

**Single cell analysis of Alzheimer's disease.** M. Kellis<sup>1,2</sup>, H. Mathys<sup>1,3</sup>, J. Davila-Velderrain<sup>1,3</sup>, S. Mohammad<sup>1,3</sup>, D. Bennett<sup>4</sup>, L.-H. Tsai<sup>1,2</sup>. 1) Massachusetts Institute of Technology, Cambridge MA 02139; 2) Picower Institute for Learning and Memory, Cambridge MA 02139; 3) Computer Science and Artificial Intelligence Lab, Cambridge MA 02139; 4) Department of Neurological Sciences, Rush Medical College, Rush Alzheimer's Disease Center, Chicago, Illinois 60612.

Alzheimer's disease (AD) is a devastating disorder characterized by cognitive decline and neuronal loss, whose complex etiology involves multiple brain cell types, but remains poorly characterized, due to the mostly-bulk-tissue-based analyses across disease cohorts. Here, we provide the first single-cell view of AD pathology across 48 individuals, including 24 AD and 24 non-AD individuals from the ROSMAP cohort, both male and female post-mortem samples, using 80,660 droplet-based single-nucleus transcriptomes. We clustered all cell jointly across individuals, resulting in 20 transcriptionally-distinct cell clusters capturing excitatory and inhibitory neurons, astrocytes, oligodendrocytes, microglial cells, and biologically-meaningful cellular subpopulations within them. We found systematic expression differences between AD and non-AD individuals, pinpointing specific candidate driver genes, including *LINGO1*, *SLC26A3*, and *RASGEF1B*, upregulated in all cell types, *APOE* upregulated in microglia only, *MT1E* upregulated in astrocytes, and *CRYAB* upregulated in oligodendrocytes. For microglia, up-regulated genes in AD were enriched in THE complement system, and down-regulated genes were enriched in insulin signaling. For astrocytes, AD-upregulated genes were enriched in cell-cell interactions and adhesion, and down-regulated genes were enriched in vesicular transport. For oligodendrocytes, AD-upregulated genes were enriched in translation and proteostasis, and down-regulated genes were enriched in metabolism. For excitatory neurons, AD-upregulated genes were enriched in calcium signaling, and down-regulated genes were enriched in immune pathways and metabolism. For inhibitory neurons, AD-upregulated genes were enriched in mTOR signaling, and down-regulated genes were enriched in glucose metabolism. Remarkably, two of the cellular subpopulations identified were only found in AD, indicated excitatory-neuron and oligodendrocyte cell states, involved in cognitive impairment, amyloid burden, and neuritic plaques. Surprisingly, early AD progression showed highly cell-type-specific transcriptional changes, and later-stage progression of AD showed common transcriptional changes across multiple cell types. Surprisingly, we found that cells isolated from women were overrepresented in both AD-associated cell states identified, consistent with the nearly 2-fold higher prevalence of AD in women, even accounting for age.

**1898F**

**The spliced lncRNA SNORD116HG is essential for the high order chromatin dynamics of the MAGEL2 and NDN locus over long distance.** S. Horike<sup>1</sup>, S. Akagi<sup>1</sup>, G. Okada<sup>1</sup>, D.H. Yasui<sup>2</sup>, J.M. LaSalle<sup>2</sup>, M. Meguro-Horike<sup>1</sup>: 1) Advanced Science Research Center, Kanazawa University, Kanazawa, Japan; 2) Department of Medical Microbiology and Immunology, UC Davis, USA.

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are distinct neurodevelopmental disorders that are caused by deletions of a differential parental origin of chromosome 15q11-q13. The PWS/AS imprinted gene cluster on 15q11-q13 spans 4Mb region that includes several protein-coding genes and multiple long non-coding RNAs (*SNORD116HG*, *IPW*, *SNORD115HG*) which are positively regulated by the PWS imprinting center (PWS-IC). Despite the fact that PWS-IC is known to be necessary for the coordinately controlled gene expression of 15q11-q13 imprinted locus, little is known concerning the mechanism by which it act and how it influence to the *MAGEL2* and *NDN* gene expression over long distance. In order to define the precise long-range gene regulation of 15q11-q13 by the imprinted lncRNAs, we have previously investigated the chromosomal architecture and dynamics by DNA-RNA FISH analyses. Our FISH analyses revealed that active paternal *MAGEL2* locus (*MAGEL2* expression is ON) was looping out from its chromosome territory, but inactive maternal locus (*MAGEL2* expression is OFF) was retained in the inside of its chromosome territory. Moreover, we found that the deletion of the PWS-IC causes the inactivation of the *MAGEL2* and *NDN* gene expression, and the re-localization of *MAGEL2* locus in the chromosome 15 territory. Therefore, we hypothesized that some of the imprinted lncRNAs such as *SNORD116HG*, *IPW*, *SNORD115HG* may be involved in the chromosomal architecture and dynamics of *MAGEL2* locus. In this study, we constructed three types of modified human chromosome 15( $\Delta$ *SNORD116* locus,  $\Delta$ *SNORD116* & *IPW* locus, and  $\Delta$ *SNORD116* & *IPW* & *SNORD115* locus) by CRISPR/Cas9 genome editing system in order to define which lncRNA is involved in this long-range regulation. Then, we found that the spliced lncRNA *SNORD116HG* is essential for appropriate expression of the *NDN* & *MAGEL2* genes over long distance. Moreover, we demonstrated that the *SNORD116HG* is co-localized with the *NDN* & *MAGEL2* genes locus by DNA-RNA FISH analyses. Therefore, we suggested that the *SNORD116HG* have a novel and essential role for the high order chromatin dynamics of the *NDN* & *MAGEL2* genes locus. These novel molecular insights into the high order chromatin dynamics should lead to the understanding of lncRNA roles in complex neurodevelopmental disorders.

**1899W**

**Hypermethylation of the FXN gene as a predictive biomarker of drug response for HDAC inhibitor treatment in Friedreich ataxia.** L.N. Rodden, K.M. Gilliam, Y.K. Chutake, S.I. Bidichandani. University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Transcriptional silencing caused by the expanded GAA triplet repeat mutation (GAA-TRE) in intron 1 of the *FXN* gene is the primary molecular defect in Friedreich ataxia (FRDA). Rationally-designed *FXN* reactivation strategies, including HDAC inhibitors, are currently being developed, therefore a clearer understanding of the mechanisms of *FXN* gene silencing and of potential determinants of effective gene reactivation are needed for these therapeutic modalities to succeed. We recently identified a new epigenetic silencing signal in FRDA involving hypermethylation of the *FXN* CpG island (CGI) shore. This was seen in disease-relevant tissues, such as the dorsal root ganglia, cerebellum and the heart, and in iPSC-derived FRDA neurons. Cell lines from FRDA patients with atypically low levels of DNA methylation showed higher efficacy of *FXN* gene reactivation via HDAC inhibition, and chemically-induced demethylation potentiated the gene reactivation ability of HDAC inhibition. A prospective study of people with FRDA, involving testing freshly isolated PBMCs for response to ex vivo HDAC inhibitor treatment and level of *FXN* CGI shore methylation indicated that lower CGI shore methylation correlates with superior response to HDAC inhibitor treatment in FRDA. This supports an epigenetic silencing model in FRDA, wherein DNA hypermethylation overlays repressive chromatin, serving as an *epigenetic lock* that impedes *FXN* gene reactivation. *FXN* CGI shore hypermethylation could serve as a predictive biomarker for drug response in FRDA.

**1900T****The correlation between the hydroxymethylome and the transcriptome.**

*D.W. Sant<sup>1</sup>, V. Camarena<sup>1</sup>, S. Mustafi<sup>1</sup>, T.C. Huff<sup>1</sup>, Z.M. Wilkes<sup>1</sup>, E.R. Martin<sup>1</sup>, G. Wang<sup>1,2,3</sup>.* 1) John P. Hussman Institute for Human Genomics, Human Genetics, Macdonald Foundation Department of Human Genetics, Human Genetics, University of Miami, Miami, FL; 2) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL; 3) Dr. Nasser Ibrahim Al-Rashid Orbital Vision Research Center; University of Miami Miller School of Medicine, Miami, FL.

Hydroxymethylcytosine (5hmC) is a unique epigenetic mark that has been shown to have bidirectional effects on transcription. Stimulation of the TET enzymes increases 5hmC globally and leads to monumental shifts in the transcriptome with both upregulated and downregulated transcripts. How 5hmC achieves this bidirectional effect is still not well understood. Levels of 5hmC in the genebody have previously been found to be positively correlated with transcription, but in the promoter it has been inconsistent between studies. To investigate the relationship between 5hmC and transcription, we performed 5-hydroxymethylcytosine DNA immunoprecipitation (hMeDIP-seq) and transcriptome sequencing (RNA-seq) on cells before and after stimulation of the TET enzymes: ARPE-19 cells were treated with ascorbate (vitamin C) and Schwann cells were treated with either ascorbate or cAMP. All three datasets showed massive shifts in both the hydroxymethylome and the transcriptome. Transcripts were divided into expression quartiles, and higher expression was found to be correlated with an increase in 5hmC in both the gene body and the promoter, but with a decrease in 5hmC at the transcription start site (TSS). When investigating 5hmC levels in nondifferentially expressed transcripts, it was not surprising that the stimulated samples across experiments had higher levels of 5hmC across the gene bodies and promoters, but the 5hmC at the TSS (500 bp region) was actually decreased in all stimulated samples. This increase in 5hmC at the promoters and gene bodies was even greater in the upregulated transcripts across all experiments, and an increase in 5hmC at the TSS was found in the upregulated transcripts in experiments involving ascorbate. Downregulated transcripts showed a greater decrease in RNA with a greater 5hmC increase in the TSS across all three experiments. Results of these experiments demonstrate that changes in 5hmC in the genomic regions of genes may be responsible for a large portion transcriptional changes observed after the activation of the TET enzymes, but is not sufficient to explain the majority of the change in transcription. Instead, it is likely that much of the transcriptional variation is mediated through changes in 5hmC at regulatory elements such as enhancer regions, through Polycomb-mediated silencing, or through inhibition of transcription factor binding.

**Background:** Parkinson's Disease (PD) is a common neurodegenerative disorder currently diagnosed through presentation of characteristic movement symptoms. Patients presenting with these symptoms have already undergone significant dopaminergic neuron cell loss. Earlier diagnosis, aided by molecular biomarkers specific to PD, would improve overall patient care. Epigenetics, which is modified by both environmental cues and disease pathophysiology, is emerging as an important component of neurodegenerative diseases, including PD. Alterations to the PD methylome have been reported in epigenome-wide association studies. However, studies have thus reported neither the extent to which methylation changes correlate with disease progression nor the degree to which they are modified by PD medications. **Methods:** We performed a longitudinal epigenome-wide DNA methylation study surveying 850,000 CpG sites in whole blood samples from 197 well-characterized PD patients and 199 control individuals at baseline and 2 years later, using the Infinium Methylation EPIC BeadChip arrays. **Findings:** We identified distinct patterns of methylation in PD cases versus controls at each time-point. Interestingly, specific methylation sites showed consistent changes regardless of sampling time, while others were changed either only at baseline, or only at follow-up, two years later. Additionally, we observed that levodopa and COMT-inhibitors impact DNA methylation, as PD patients that did not receive these drugs showed longitudinal changes in methylation in a larger number of sites. **Interpretation:** These results indicate that DNA methylation is dynamic in PD and changes over time during the progression of the disease. To the best of our knowledge this is the first longitudinal epigenome-wide methylation analysis for Parkinson's disease; and the first appraisal of the effects of dopamine replacement therapy on the blood methylome.

**1902W**

**A comprehensive approach to study the epigenome of monocytes in persons with Parkinson disease and matched healthy controls.** *J. Zhu, T. Carlile, D. Sangurdekar, KD. Nguyen, H. McLaughlin, C. Sun, MG. Weisz, O. Goldstein, A. Mirelman, JM. Cedarbaum, N. Giladi, A. Orr-Urtreger, MA. Penny, S. John, MD. Lalioti.* Biogen, 225 Binney Street, Cambridge, MA, 02142, US.

Understanding disease pathophysiology and progression paired with highly predictive biomarkers are crucial for finding effective treatments for complex diseases such as Parkinson's (PD). There is increasing evidence that chronic inflammation mediated by microglial cells, the resident immune cell in the brain, is a fundamental process contributing to the death of dopamine-producing neurons in PD. Because, brain tissue is inaccessible, monocytes from blood have been considered as an accessible proxy for microglia, and changes in their transcriptome have been described. The dynamics of the epigenome, including methylation and chromatin remodeling have profound effects on the transcriptome. The objective of this research is to perform a comprehensive study of the epigenome of monocytes from PD patients and healthy individuals to identify disease signature using gene expression (RNA-Seq), chromatin accessibility (ATAC-Seq), and methylation (MethylationEPIC BeadChip) assays. By contrasting chromatin accessibility and gene expression, we can obtain insights into non-coding regulatory elements implicated in the disease state. The pilot phase described here included 100 Ashkenazi Jewish individuals either manifesting or genetically at-risk for PD, or healthy controls. We inferred correlation between gene expression, chromatin accessibility and methylation across genes and at promoters. Positive within-subject correlation between gene expression and chromatin accessibility at promoter regions, including 1kb flanking the transcription start sites, was observed in 98% of individual samples. Looking across all the samples, we found that genes showing concordance between gene expression and chromatin accessibility (Spearman's correlation coefficients range from 0.2 to 0.6,  $p < 0.05$ ) are enriched in cell movement of mononuclear leukocytes related function ( $p < 0.001$ ) and associated with inflammatory response, neurological disease, skeletal and muscular disorders. These data are indicative of underlying environmental or pathological variability leading to differences in monocyte activation. In addition, approximately 1% of genes had significant correlation (FDR < 10%) between promoter methylation and gene expression across samples. We suggest that monocyte signature and the analysis pipelines developed as part of this study can be universally applied to other diseases where a change in the monocyte transcriptome and epigenome has been established or suspected.

**Unsupervised clustering of spatially resolved single nucleus chromatin accessibility reveals cell-type and region specific transcriptional control in the mouse primary motor cortex.** *R. Fang<sup>1,2</sup>, S. Preiss<sup>3</sup>, X. Wang<sup>3</sup>, X. Hou<sup>3</sup>, J. Gu<sup>3</sup>, B. Chen<sup>1</sup>, J. Lucero<sup>4</sup>, M. Behrens<sup>4</sup>, E. Mukamel<sup>5</sup>, J. Ecker<sup>6</sup>, B. Ren<sup>1,2</sup>.* 1) Ludwig Institute for Cancer Research, La Jolla, CA, USA; 2) Bioinformatics and Systems Biology Graduate Program, University of California San Diego, La Jolla, CA, USA; 3) Center for Epigenomics, Department of Cellular and Molecular Medicine, University of California, San Diego, School of Medicine, La Jolla, CA, USA; 4) Salk Institute for Biological Studies, La Jolla, CA 92037, USA; 5) Department of Cognitive Science, University of California, San Diego, La Jolla, CA 92037, USA; 6) Howard Hughes Medical Institute, The Salk Institute for Biological Studies, La Jolla, CA, 92037, USA.

**Analysis of chromatin landscape across single cells can resolve heterogeneity and reveal cell-type specific regulatory programs in a complex tissue, but intrinsic sparsity of the data poses significant challenges in the data analysis. Here we introduce Snap, a R package that facilitates pre-processing, quality control, normalization, clustering and visualization of single-nucleus epigenomics data. Snap clusters cells based on chromatin variability in an unsupervised manner and identifies clusters through a highly robust consensus approach. Snap outperformed previous methods by rapidly identifying cell types while eliminating the experimental bias. As a part of BRAIN Initiative, we generated over 47,000 high-quality single-cell chromatin accessibility profiles from two areas of the primary motor cortex (MOp) of adult mouse brain with spatial resolution. Snap identified over 50 distinctive cell populations corresponding to different cellular functions in the MOp. Although the cell types are shared between different areas, excitatory neurons and oligodendrocyte are variable in a striking manner, suggesting regional specificity of transcriptional control. Finally, Snap successfully clusters multiple single-nucleus assays, providing a general framework for single-cell analysis and a possibility of integrative analysis of multi-omics data.**

**Epigenomic convergence of genetic and immune risk factors in autism brain.** A. Vogel Ciernia, B. Laufer, K. Dunaway, C. Mordaunt, R. Coulson, D. Yasui, J. LaSalle. University of California, Davis, Davis, CA.

Autism spectrum disorders (ASD) are characterized by impairments in social communication and increased repetitive behaviors. ASD etiology is complex, involving multiple genetic and environmental risks. Epigenetic modifications are poised at the interface between genes and environment and are predicted to reveal insight into the gene networks, cell types, and developmental timing of ASD etiology. Here, whole-genome bisulfite sequencing (WGBS) was used to examine DNA methylation in ASD and control frontal cortex samples. Systems biology approaches were leveraged to integrate methylation differences with relevant genomic datasets, revealing ASD-specific differentially methylated regions (DMRs) are significantly enriched for known neuronal and microglial regulatory elements, including cell-type-specific enhancers and transcription factor binding sites. ASD DMRs were also significantly enriched for known ASD genetic risk factors, including both common inherited and rare de novo variants. Weighted gene co-expression network analysis (WGCNA) revealed enrichment of ASD DMRs within developmental expression modules of brain and isolated microglia. Microglial modules identified dysregulated genes in maternal immune activation models of ASD. Weighted gene body co-methylation network analysis revealed a module characterized by hypomethylation of clustered protocadherin genes. Together, these results demonstrate an epigenomic signature of ASD in frontal cortex shared with known genetic and immune etiological risk. Epigenomic insights into cell types and gene pathways will aid in defining therapeutic targets and early biomarkers at the interface of genetic and environmental ASD risk factors.

**1905W**

**DNA methylation in the hippocampus contributes to anxious temperament in young primates.** R.S. Alisch<sup>1,2</sup>, L.A. Papale<sup>1,2</sup>, J.A. Oler<sup>1</sup>, A.S. Fox<sup>3,4</sup>, D.A. French<sup>1</sup>, P.H. Roseboom<sup>1</sup>, N.H. Kalin<sup>1</sup>, P. Chopra<sup>5</sup>. 1) Department of Psychiatry, University of Wisconsin, Madison, WI; 2) Department of Neurological Surgery, University of Wisconsin, Madison, WI; 3) Department of Psychology, University of California, Davis, CA; 4) California National Primate Research Center, University of California, Davis, CA; 5) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

Considerable evidence demonstrates that children with an anxious temperament (AT) are particularly sensitive to new social experiences, showing increased freezing behavior, decreased communications, and increased pituitary-adrenal and autonomic activity. However, despite substantial knowledge of these behavioral phenotypes, the molecular mechanisms governing them remain unclear; in part due to the difficulty in accessing human brain tissues for molecular analyses. Recently, we validated a nonhuman primate model of AT that demonstrates structural and functional similarities between rhesus monkeys and humans in the neural circuits mediating increased freezing, decreased vocalizations, and increased cortisol levels. We further identified that AT-related brain metabolism in the central nucleus of the amygdala (Ce) and the anterior hippocampus (aHIP) significantly differ in their heritability (aHIP > Ce), suggesting that these structures are differentially governed by genetic and environmental influences. Our initial studies of the Ce revealed AT-related differentially methylated loci linked to altered gene regulation. Here we built upon these findings and used whole genome bisulfite sequencing (WGBS) to examine an average of 25.3 million CpG dinucleotides in genomic DNA from the hippocampus of 71 monkeys (including 23 females) and found 645 differentially methylated regions (DMRs) associated with AT severity (permutation  $P$ -value < 0.01). Annotation of these DMRs to genomic structures revealed 515 genes that are enriched for neuronal ontological functions, such as synapse assembly and neuron development. Comparison of these genes to the genes previously found in the Ce revealed a significant overlap ( $P$ -value < 0.05), indicating that common AT-related epigenetic disruptions occur in these two brain structures. Finally, a significant overlap ( $P$ -value < 0.05) also was found between these differentially methylated genes from the monkey brain and AT-related differentially methylated genes reported in human blood, suggesting that blood may be an accessible tissue of value in the identification of differential methylation associated with the risk to develop trait-like anxiety. Thus, we have generated WGBS data on genomic DNA from the blood of these same 71 monkeys and analysis is underway to determine the utility of blood as a viable surrogate to brain tissue, providing novel diagnostic, prognostic, and modifiable therapeutic targets of human anxiety.

## 1906T

**Cell type specific methylome-wide studies in brain and blood implicate inflammation and neurodegenerative processes in major depressive disorder.** R.F. Chan<sup>1</sup>, A.A. Shabalin<sup>1</sup>, B. Dean<sup>2,3</sup>, M. Zhao<sup>1</sup>, G. van Grootheest<sup>4</sup>, B.W.J.H. Penninx<sup>5</sup>, G. Turecki<sup>5</sup>, K.A. Aberg<sup>1</sup>, E.J.C.G. van den Oord<sup>1</sup>. 1) Center for Biomarker Research and Precision Medicine, Virginia Commonwealth University, Richmond, VA, USA; 2) The Molecular Psychiatry Laboratory, The Florey Institute of Neuroscience and Mental Health, Parkville, Victoria, Australia; 3) Centre for Mental Health, Swinburne University of Technology, Hawthorne, Victoria, Australia; 4) Department of Psychiatry, Amsterdam Neuroscience, VU University Medical Center, GGZ inGeest, Amsterdam, The Netherlands; 5) Douglas Mental Health University Institute and McGill University, Montréal, Québec, Canada.

We sequenced the CpG methylome in three independent collections of human post-mortem brain samples (N=205) and blood samples (N=1,132) of controls and subjects with MDD. In addition to analyzing bulk tissue, we used cell type specific "reference" methylomes paired with a statistical deconvolution approach to conduct methylome-wide association studies (MWAS) in constituent populations of neurons/glia and granulocytes/T-cells/B-cells/monocytes. Cell type specific MWAS yielded case-control differences that were not readily detectable in heterogeneous bulk tissues. Using a round-robin rotation schedule, where two of the three brain collections were used to discover sites for replication in the third independent collection, top sites from the neuron/glia discovery MWASs consistently replicated as a group with enrichment P-values  $4.5 \times 10^{-4}$ / $3.9 \times 10^{-3}$ ,  $6.5 \times 10^{-4}$ / $9.8 \times 10^{-4}$ , and  $<1 \times 10^{-6}$ / $1.3 \times 10^{-3}$ . The top replicating finding in neurons was located within *TRIM1* (P-values = 0.0014/0.0025/0.007; combined =  $4.4 \times 10^{-6}$ ), a negative regulator of synaptic plasticity. Results for neurons (384 CpGs) were further overrepresented for pathways related to neuronal cell death and neurodegeneration. Top findings for glia (85 CpGs) were overrepresented for inflammatory pathways linked to MDD such as Toll-like receptor and cytokine signaling. Cell type specific analyses in blood identified 372 differentially methylated loci (FDR 0.1) in monocytes and 18 loci in T-cells. Top findings for monocytes, e.g. *ITPR2*, *SHANK2*, and *SLC1A1* (P-values =  $1.50 \times 10^{-9}$  to  $7.31 \times 10^{-7}$ ), were overrepresented for glutamatergic signaling pathways (that are both immunoregulatory and neuromodulatory) and enriched at SNPs associated with allergy, asthma, infection susceptibility, and neurodegenerative disorders. In supplementary analyses overlap was observed between brain and blood cell types. For example, a *SHANK2* CpG was implicated in neurons and monocytes with shared direction of effect in both (combined P-value =  $1.05 \times 10^{-6}$ ), suggesting that disease affects different tissues through like processes. In summary, epigenomic deconvolution analysis uncovered cell type specific methylation differences associated with MDD. Although individual findings were largely cell type specific, related biological processes were implicated across cell types and even across tissues. Thus, the involvement of inflammatory and neurotoxic processes in MDD are robust findings that impacts neurons, glia, and monocytes.

## 1907F

**Neural cell adhesion molecule 1 (NCAM-1) is associated to long-term memory in nematodes and humans.** P. Mastrandreas<sup>1</sup>, V. Vukojevic<sup>1,3</sup>, T. Elbert<sup>2</sup>, I.T. Kolassa<sup>4</sup>, V. Freytag<sup>1</sup>, F. Peter<sup>1</sup>, P. Demougin<sup>1</sup>, J.F. deQuervain<sup>2,3</sup>, A. Papassotiropoulos<sup>1,3</sup>, A. Stetak<sup>1,3</sup>. 1) University of Basel, Department of Psychology, Division of Molecular Neuroscience, Birmannsgasse 8, 4055 Basel, Switzerland; 2) University of Basel, Department of Psychology, Division of Cognitive Neuroscience, Birmannsgasse 8, 4055 Basel, Switzerland; 3) University of Basel, University Psychiatric Clinics, Wilhelm Klein-Strasse 27, 4055 Basel, Switzerland; 4) Clinical and Biological Psychology, Institute for Psychology and Education, University of Ulm, 89069 Ulm, Germany.

The neural cell adhesion molecule 1 (NCAM1) has been implicated in several brain-related biological processes, including neuronal migration, axonal branching, fasciculation, and synaptogenesis, with a pivotal role in synaptic plasticity. Here, using an interdisciplinary approach we investigated the evolutionary conserved role of neural cell adhesion molecule 1 (*ncam-1*) in learning and memory. We conducted a large-scale transcriptomic study examining the temporal expression profile of different genes during *C. elegans* long-term memory, and observed sustained changes in *ncam-1* expression up to 24 hours upon aversive olfactory conditioning. Loss of *ncam-1* function selectively impaired long-term memory in a negative but not in positive olfactory associative memory paradigm, without causing acquisition, sensory, motor or short-term memory deficits. Expression of the *C. elegans* or human NCAM1 in nematodes fully rescued loss of *C. elegans ncam-1* gene function. Tagging of NCAM-1 using CRISPR/Cas9 revealed that the protein expression occurs throughout the developmental life cycle of the worm. Additionally, confocal imaging of an established GLR-1::GFP line, revealed no defects in the post-synaptic structures of *ncam-1* (*lf*) worms, suggesting that the effects on aversive long-term memory can be attributed to deficits in the function of the protein and not due to developmental defects during synapse formation. Considering the conserved role of NCAM1 in higher complex organisms, we next expanded our *C. elegans* findings in human, using methylation data across three independent samples. In two samples of European descent, we showed a negative correlation between DNA methylation of the NCAM1 promoter and aversive memory (i.e., recognition of negative pictures). Moreover, in a population of genocide survivors of African descent, DNA methylation at an alternative promoter of the NCAM1 gene was inversely correlated with symptoms of posttraumatic stress disorder (PTSD), including traumatic aversive memory. Taken together, our results support a conserved role of NCAM1 in aversive associative memory from nematodes to humans and might, ultimately, prove to be helpful in elucidating novel therapies in the treatment of memory-related disorders.

**1908W**

**A comprehensive study of epigenetic signatures associated with PTSD in two independent African populations of severely traumatized individuals.** V. Vukojevic<sup>1,2,3</sup>, A. Milnik<sup>3,4</sup>, T. Elbert<sup>5</sup>, I. Tatjana Kolassa<sup>6</sup>, S. Wilker<sup>6</sup>, D. J.-F. de Quervain<sup>3,4,7</sup>, A. Papassotiropoulos<sup>1,2,3,4</sup>. 1) University of Basel, Department of Psychology, Division of Molecular Neuroscience, Birmannsgasse 8, 4055 Basel, Switzerland; 2) University of Basel, Department Biozentrum, Life Sciences Training Facility, Klingelbergstrasse 50/70, 4056 Basel, Switzerland; 3) Transfaculty Research Platform Molecular and Cognitive Neurosciences, University of Basel, CH-4055 Basel, Switzerland; 4) University of Basel, University Psychiatric Clinics, Wilhelm Klein-Strasse 27, 4055 Basel, Switzerland; 5) Clinical Psychology and Neuropsychology, University of Konstanz, D-78464 Konstanz, Germany; 6) Clinical & Biological Psychology, Institute of Psychology and Education, University of Ulm, D-89069 Ulm, Germany; 7) University of Basel, Department of Psychology, Division of Cognitive Neuroscience, Birmannsgasse 8, 4055 Basel, Switzerland.

Post-traumatic stress disorder (PTSD) is a chronic pathological response to life-threatening, i.e., traumatic experiences. Intrusive memories of such traumatic events, avoidance and hyperarousal are the core symptoms of the disorder. Furthermore, a complex interplay between genetic factors, epigenetic mechanisms and environment plays a significant role in the pathogenesis of PTSD. We have previously shown that DNA methylation of the glucocorticoid receptor gene (*NR3C1*) promoter is linked to aversive memories and PTSD risk in male survivors of the Rwandan genocide (N=152). Furthermore, DNA methylation at the same *NR3C1* promoter site was associated with picture recognition and differences in recognition-related brain activity in healthy young men (Vukojevic *et al*, 2014). In the current study, we extended our previous work to a genome-wide methylation analysis in a larger Rwandan sample (N=380) assessed with Illumina Human Methylation 450k array. Additionally, we have examined another population of traumatized individuals from Uganda (N=480) with the Illumina Human Methylation EPIC array. In both samples, we investigated the association between DNA methylation at *NR3C1*, aversive memories and PTSD risk. Next to reassessing our previous findings, we explored the shared epigenetic signatures of lifetime PTSD risk and symptomatology across two cohorts on the epigenome-wide level. Interestingly, the common genes were enriched in gene pathways related to immune response, regulation of steroid hormones and energy metabolism. The present study suggests the existence of global and gene-specific epigenetic mechanisms associated with PTSD. Observed epigenetic associations with PTSD risk and symptomatology support the observation that this mental disorder results in altered immunological, metabolic and neural regulations. Therefore, the findings of the proposed study may add to the understanding the mechanisms of PTSD and could thereby help to improve the development of targeted clinical interventions.

**1909T**

**Neuron and glia specific methylome-wide association studies of schizophrenia post-mortem brain samples identify unique loci not detected in bulk tissue.** K.A. Aberg<sup>1</sup>, R.F. Chan<sup>1</sup>, M. Zhao<sup>1</sup>, L.Y. Xie<sup>1</sup>, G. Turecki<sup>2</sup>, A.A. Shabalina<sup>1,3</sup>, B. Dean<sup>4,5</sup>, E.J.C.G. van den Oord<sup>1</sup>. 1) Center for Biomarker Research and Precision Medicine, Virginia Commonwealth University, Richmond, VA; 2) Douglas Mental Health University Institute and McGill University, Montréal, Québec, Canada; 3) Department of Psychiatry, University of Utah, Salt Lake City, UT, USA; 4) The Molecular Psychiatry Laboratory, Florey Institute of Neuroscience and Mental Health, Parkville, Victoria, Australia; 5) Centre for Mental Health, Swinburne University, Hawthorn, Victoria, Australia.

We used fluorescence-activated cell sorting to isolate NeuN+ (neurons) and the NeuN- (mainly glia) nuclear fractions from five post-mortem prefrontal cortex samples. For each of the isolated cell fractions DNA was extracted and a methylome-wide profile generated. Subsequently, the neuron and glia specific reference methylomes were used to estimate the proportions of neurons and glia in bulk brain (BA10) methylomes from 164 schizophrenia cases and 160 controls. Next, we used the RaMWAS software to perform a methylome-wide association study (MWAS) for schizophrenia for bulk, and applied a statistical deconvolution method where the estimated cell type proportions were used to perform cell type specific MWAS in neurons and glia separately. Results identified three genome-wide significant (q-value<0.1) loci in bulk and glia, and additional suggestive findings in all three MWASs. It should be noted that the cell type specific top findings were not present among the top bulk findings, supporting the notion that cell type specific effects cancel out in the bulk. The lambdas for the MWASs were 1.058/1.007/1.042 for bulk/glia/neurons, respectively. For each analysis we performed 1,000 MWASs after permuting case-control status. The average and the median lambdas from the permuted MWASs were 1.00 (95% confidence interval: 0.98-1.04) in all instances, suggesting the tests behaved as expected under the null hypothesis, and that the observed lambdas likely reflect true associations. Furthermore, to explore if many markers together contribute more to the disease association than any single marker individually we used a machine learning algorithm to combine associated sites into a single risk score. When screening the top 1,000 markers from the bulk MWAS, we detected a Pearson correlation of 0.26 ( $P=8.4 \times 10^{-7}$ ) between methylation-predicted and actual disease status. Thus, the variation in methylation levels of these markers explained 6.9% of the schizophrenia disease status. The explained variance did not further increase when additional markers were added, suggesting that the majority of independent effects are located among the top 1,000 MWAS findings. In conclusion, cell type specific MWAS identified associations not detectable in bulk analysis. These findings emphasizes the importance to further refine the reference panels so that relevant biological processes, occurring in unique subsets of cells, can be appropriately assayed.

**1910F**

**LCM-Seq: Single cell-type transcriptomic profiling in post-mortem brain of abused suicides.** D. Almeida<sup>1,2</sup>, G.G. Chen<sup>1</sup>, J.F. Theroux<sup>1</sup>, Z. Aouabed<sup>1</sup>, M.A. Davoli<sup>1</sup>, N. Mechawar<sup>3</sup>, G. Turecki<sup>1,3</sup>. 1) McGill Group for Suicide Studies, Montreal, Quebec, Canada; 2) Integrated Program in Neuroscience, McGill University, Montreal, QC, Canada; 3) Department of Psychiatry, McGill University, Montreal, QC, Canada.

**Background:** The transcriptome of a cell constitutes an essential piece of cellular identity and accounts for the multifaceted complexity and heterogeneity of cell types within the mammalian brain. Each discrete cellular population is differentially influenced by extrinsic signals from their local environments and neighbouring cells. Thus, while some studies have investigated transcriptomic alterations underlying the neurobiology of childhood maltreatment and suicide, the use of bulk-tissue homogenates have masked their ability to determine cell-type specific molecular dysfunctions. Here we employ a cell type specific investigation of transcriptomic alterations, in prefrontal layer V pyramidal neurons, associated specifically with a history of childhood abuse (CA). **Methods:** Laser captured microdissection (LCM) was used to isolate prefrontal (BA 10) layer V pyramidal neurons from post-mortem human brain. Subject groups included individuals who died by suicide with and without a history of severe CA and non-psychiatric controls. RNA sequencing libraries were constructed using the SMARTseq v4 kit, to generate full length cDNA libraries, followed by Illumina's Nextera XT DNA library preparation kit. The abused suicide and control groups were used for sequencing. Fifty libraries were sequenced on the HiSeq 4000 using PE 100bp sequencing at a depth of ~40M reads per subject. **Results:** We achieved a mapping efficiency of ~80% and captured a wide distribution of transcripts. Differential gene expression analysis revealed significant (FDR <0.10) dysregulation of a variety of protein coding transcripts in abused suicides compared to controls. Gene Set Enrichment Analysis (GSEA) showed significant enrichment of genes with high CpG density promoters in human brain. Weighted Gene Co-Expression Network Analysis (WGCNA) identified two modules associated specifically with CA. Gene ontology (GO) analysis on these modules revealed that they include genes involved in neuronal structure and signalling. **Conclusions:** By employing LCM followed by RNA sequencing we were able to uncover cell-type specific changes associated with a history of CA. Furthermore, these results open up an interesting avenue to explore whether cell-type specific epigenetic regulation, through DNA methylation, might explain our expression findings. .

**1911W**

**Ethnic and sex-specific induction of G-protein coupled receptor 15 expression in smokers.** A. Andersen, R. Philibert. Psychiatry, University of Iowa, Iowa City, IA.

Smoking is responsible for nearly half a million deaths annually in the United States, in part due to an increased risk of cardiovascular disease, diabetes, and chronic obstructive pulmonary disease. Each of these disease states is characterized by systemic inflammation, but the links between smoking and inflammation remain unclear. This may be because serological examinations of smoking-associated inflammation to date have failed to consider cell-based changes in immune functioning simultaneously. Incorporation of epigenetic methods into serological approaches may provide a method to systematically assess these variables. Recent work has demonstrated that demethylation of the CpG site cg19859270 reflects an increase in a specific T cell subtype expressing *G protein-coupled receptor 15* (GPR15), a chemokine receptor expressed primarily in the gut that has been linked with ulcerative colitis, a smoking-associated disease. Although the specific role of the GPR15 in the gut is not fully understood, increased homing of this T cell population to the gut may produce subtle changes in the gut microbiome that in turn promote inflammation. To translate this finding into a tool that can be employed systematically, our laboratory has developed a digital PCR assay for cg19859270 and validated it against flow cytometrically measured expression of GPR15 in a cohort of 62 young adults of mixed ethnicity with a high rate of smoking. GPR15 expression in CD3+/CD4+ cells was strongly associated with both cg19859270 methylation (R-squared = 0.216, P<0.001) and cumulative smoke exposure, as indicated by methylation of cg05575921 (R-squared = 0.443, P=2.19E-09), an established epigenetic biomarker for smoking. Multiple linear regression models including interactions between sex, ethnicity, cg05575921 methylation, and cg19859270 methylation produced significant improvements in predicting GPR15 expression (R-squared = 0.650, P = 3.32E-12). No correlation was found between GPR15 expression or smoke exposure and serum cytokine levels in this young cohort, suggesting that changes in GPR15 expression may precede the development of inflammation and complex medical illness in smokers. Going forward, the ability to robustly predict GPR15+ expression in a genetically contextual manner using digital PCR methods will allow for further explorations of the impact of this specific T cell population on inflammation and disease progression in older cohorts.

**DNA methylation profiles of monozygotic twins discordant for ADHD by Illumina MethylationEPIC BeadChip microarray.** T.V.M.M. Costa<sup>1,5</sup>, J.G. Damasceno<sup>1</sup>, F.A. Marchi<sup>2</sup>, F.A.R. Madia<sup>1</sup>, E.A. Zanardo<sup>1</sup>, G.M. Novo-Filho<sup>1</sup>, M.M. Montenegro<sup>1,3</sup>, A.T. Dias<sup>1</sup>, A.M. Nascimento<sup>1,3</sup>, M. Rocha<sup>1</sup>, C.A. Kim<sup>3</sup>, V. Schuch<sup>4</sup>, C.B. Mello<sup>4</sup>, M. Muszkat<sup>4</sup>, L.D. Kulikowski<sup>1,2</sup>. 1) Laboratório de Citogenômica, Departamento de Patologia, Faculdade de Medicina da USP, São Paulo, Brasil; 2) Laboratório NeoGene, AC Camargo Cancer Center, São Paulo, Brasil; 3) Laboratório de Citogenômica, Unidade de Genética, Departamento de Pediatria, Instituto da Criança, HC/FMUSP, São Paulo, Brasil; 4) Núcleo de Atendimento Neuropsicológico Infantil Interdisciplinar (NANI), Departamento de Psicobiologia da Escola Paulista de Medicina, UNIFESP, São Paulo, Brasil; 5) Instituto Federal de Educação, Ciência e Tecnologia do Maranhão (IFMA), Campus Barreirinhas, Barreirinhas, Brasil.

Attention deficit hyperactivity disorder (ADHD) is one of the most common neurobehavioral disorder diagnosed in childhood and is characterized by inadequate levels of hyperactivity/impulsivity and/or inattention. ADHD begins in childhood and affects around 5% of school children worldwide and, in most cases (50-80%), the disorder persists during adolescence and adulthood. Its high heritability (estimated at 76%) suggests that genetic factors strongly influence the etiology of ADHD. However, the genetic architecture of ADHD is not clear. Behavioral genetic studies have demonstrated that genetic influences play a role in the etiology of ADHD. In addition, some environmental factors are epidemiologically associated with ADHD. Therefore, it is very important to study whether epigenetic factors are related to the etiology of ADHD. Thus, performing the DNA methylation profiles of monozygotic twins are an important tool for studying the role of epigenetic factors in ADHD. Diagnosis was performed according to Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR). DNA was extracted from blood lymphocytes of one ADHD patient and his twin brother with neurotypical development (two boys, ages 12). Then, DNA methylation profiles were performed using Illumina MethylationEPIC BeadChip. Arrays data were treated and analyzed using specific packages in the R environment. We calculate the difference between the  $\beta$  values ( $\Delta\beta$ ) of all probes of both twins (with and without ADHD). Limma package was used to obtain significant probes considering  $p < 0.05$ . The probes were annotated according to the data provided by Illumina using the genome hg19 reference. We selected the probes with  $\Delta\beta > 0.1$  that were differentially methylated when comparing the patient with ADHD to the twin. Thus, our results suggest that DNA methylation profiles may present significant differences between monozygotic twins discordant for ADHD. Therefore, we emphasize the importance of investigating methylation profiles in more cases of ADHD discordant twins, in order to verify if, in fact, there are differences in the methylation between profiles and whether these differences are relevant for the development of ADHD.

**1913F**

**Neural-derived biomarkers for antidepressant response from plasma exosomes.** S. Saeedi<sup>1,2</sup>, C. Nagy<sup>2</sup>, J.F. Theroux<sup>2</sup>, M. Wakid<sup>2,3</sup>, N. Mechawar<sup>2,3</sup>, G. Turecki<sup>2,4</sup>. 1) Department of Human Genetics, McGill University, Montreal, QC, Canada; 2) McGill Group for Suicide Studies, Douglas Mental Health University Institute, Montreal, Quebec, Canada; 3) Integrated Program in Neuroscience, McGill University, Montreal, Quebec, Canada; 4) Department of Psychiatry, McGill University, Montreal, Quebec, Canada.

**Background:** Major depressive disorder (MDD) is a common psychiatric disorder affecting millions of people worldwide. The most common treatment for MDD is antidepressant drug therapy (ADT), with many options available for treatment. Decisions on treatment for MDD are up to the discretion of the physician, and are often highly subjective. Furthermore, 60% of patients do not respond to first trials with antidepressants. As a result, biomarker discovery has become a prominent aspect of ADT. However, the majority of the research in this field is limited to peripheral tissue, leaving questions concerning the relevance of these findings in the context of psychiatric disease. Exosomes may provide a solution to the disconnect between the source of material and disease. Given that exosomes can freely cross the blood brain barrier, neural-derived exosomes (NDE) found in plasma can provide information regarding central changes resulting from ADT response. MicroRNA (miRNA) represent exosomal cargo which are presumed to exert an influence on recipient cells. Differential miRNA profiles can potentially act as predictive biomarkers, and provide mechanistic insight into changes occurring as a result of ADT response. **Methods:** This pilot study uses plasma from 10 controls and 10 patients with MDD (5 ADT responders, and 5 non-responders). Exosomes were isolated using a size exclusion column from Izon Science (Christchurch, New Zealand). Each isolation was divided to produce a "whole exosome" fraction and an immunoprecipitated "(NDE)" fraction using neural marker L1CAM. Quantitation and size determination was done using Tunable Resistive Pulse Sensing (TRPS) on the qNano gold. RNA was extracted from L1CAM+ fraction and its depleted supernatant. Libraries were made following the 4N-small RNA-Seq (Galas) protocol and sequenced on the Illumina platform. **Results:** Results suggest that NDE exosomes are smaller than the full pool of exosomes. Also, exosomes from depressed patients (both responders and non-responders) are significantly smaller than controls in both full and neural enriched fractions. We have also identified a group of miRNAs that are highly enriched in NDE and that overlap with miRNAs present in brain. Differential analysis shows many hits for follow-up. **Conclusions:** Isolating NDE from plasma provides a valuable resource for biomarker discovery in MDD. Our ongoing work aims to provide a neural miRNA profile in MDD, and profiles of drug response and non-response.

**Genome-wide profiling of DNA methylome and transcriptome in peripheral blood monocytes for major depression: A monozygotic discordant twin study.** Y. Zhu<sup>1</sup>, E. Strachan<sup>2</sup>, E. Fowler<sup>2</sup>, T. Bacus<sup>3</sup>, P. Roy-Byrne<sup>2</sup>, J. Zhao<sup>1</sup>. 1) Department of Epidemiology, University of Florida, Gainesville, FL; 2) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 3) Department of Pediatrics, University of Washington, Seattle, WA.

Major depressive disorder (MDD) is one of the most prevalent mental disorders. Epigenetic factors play an important role in MDD, but the specific genes or genomic regions associated with MDD remain largely unknown. Here we report findings from a genome-wide profiling of DNA methylation using the Infinium MethylationEPIC BeadChip in peripheral blood monocytes from 79 monozygotic (MZ) discordant twin pairs. Gene expression was measured by RNA-seq in monocytes of the same twins. We identified 39 differentially methylated regions (DMRs) harboring putative genes associated with lifetime history of MDD. Integrative DNA methylome and transcriptome analysis revealed both negative and positive correlations between DNA methylation and gene expression, although there appears to be a trend that promoter DNA methylation is largely negatively correlated with gene expression. Network analysis revealed distinct modules enriched in signaling pathways related to neuron apoptosis, stress-activated protein kinase signaling, insulin regulation, and mTOR signaling. Together, our results revealed a critical role of altered DNA methylation in depression and identified novel genes and biological pathways underlying MDD pathogenesis. Moreover, our study highlights the utility of using peripheral blood epigenetic markers, and demonstrates that an MZ discordant co-twin control design could aid the discovery of novel DNA methylation signals, even in a relatively small sample size. If validated, the newly identified genes/pathways may serve as novel therapeutic targets for MDD and related disorders.

**Molecular changes that drive abnormal cortical development following mid-gestational Poly(I:C)-mediated maternal immune activation.** C.P. Canales<sup>1</sup>, M.L. Estes<sup>1</sup>, I. Zdilari<sup>1</sup>, L. Su-Feher<sup>1</sup>, S. Cameron<sup>1</sup>, J.P. Aboubechra<sup>1</sup>, R. Catta-Preta<sup>1</sup>, K. Lim<sup>1</sup>, T. Stradleigh<sup>1</sup>, D. Van Der List<sup>1</sup>, L. Haapanen<sup>2</sup>, K. Farrelly<sup>1</sup>, J. Van De Water<sup>2</sup>, A.K. McAllister<sup>1</sup>, A.S. Nord<sup>1</sup>. 1) Center for Neuroscience, University of California Davis, Davis, CA; 2) Div. of Rheumatology/Allergy and Clin. Immunology, University of California Davis, Davis, CA.

Maternal immune activation (MIA) has emerged as risk factor for neurodevelopmental disorders (NDDs), including autism and schizophrenia. MIA is among the strongest environmental risk factors and investigating the molecular mechanisms underlying pathology in offspring following MIA is crucial for understanding gene-environment interactions associated with neurodevelopmental disorders. Here, we applied transcriptional and epigenomic profiling to identify changes in fetal mouse cortex across a time course following mid-gestational MIA via maternal poly(I:C) injection at E12.5. To reduce variability in the experimental model, we established the effective dosage of Poly(I:C) to ensure induction of reproducible levels of MIA and disease-relevant changes in offspring. We then performed RNA-seq in cortical extracts from E12.5, E14.5 and E17.5 from MIA and control offspring and identified strong transient transcriptional signatures and developmental changes in fetal cortex. These changes included an initial acute signature that correlates with activation of genes associated with stress response pathways in the fetal brain, followed by alterations in proliferation, neuronal differentiation, astrogenesis, synaptogenesis and cortical lamination that emerged at E14.5 and peaked at E17.5. We also looked at epigenetic signatures at E14.5 by ChIP-seq analysis and found changes in histone modifications linking transcriptomic and epigenomic changes in fetal brain. To validate transcriptional signatures, we used immunohistochemistry at E17.5, examining several candidates identified by RNA-seq. Anatomical and protein expression changes in E17.5 cerebral cortex were concordant with signatures present in the RNA data, including reduced proliferative populations (i.e. Ki67, Pax6), altered cortical lamination patterns (Tbr1, Ctip2) and precocious astrogenesis (GFAP), with no evidence of previously reported cortical focal dysplasia (Satb2, Cux1). In summary, these transcriptomic signatures validated at the protein level provide novel insight into the molecular and developmental brain pathologies linking MIA and neurodevelopmental sequelae.

**1916F**

**Sex hormones regulate *SHANK* gene expression.** A. Eltokhi<sup>1,2</sup>, S. Berkel<sup>1</sup>, H. Fröhlich<sup>1</sup>, D. Gonzalez<sup>1</sup>, R. Rafiullah<sup>1</sup>, R. Sprengel<sup>2</sup>, G. Rappold<sup>1</sup>. 1) Institute of Human Genetics, Heidelberg, Germany; 2) Max Planck Institute for Medical Research, Heidelberg, Germany.

Autism spectrum disorders (ASD) have a higher prevalence in male individuals compared to females, with a ratio of affected boys compared to girls of 4 : 1 for ASD and 11 : 1 for Asperger syndrome. Mutations in the *SHANK* genes (comprising *SHANK1*, *SHANK2* and *SHANK3*), coding for postsynaptic scaffolding proteins, have been tightly associated with ASD. As early brain development is strongly influenced by sex hormones, we investigated the effect of dihydrotestosterone and 17 $\beta$ -estradiol on *SHANK* expression in the human neuroblastoma cell model, SH-SY5Y. Both sex hormones increased the expression of all three *SHANK* genes, which could be effectively blocked by androgen and estrogen receptor antagonists. In neuron-specific androgen receptor knock-out mice (ArNesCre), we found a nominal significant reduction of all *SHANK* genes at postnatal day 7.5 in the cortex. In the developing cortex of wild-type mice, a significant sex-differential expression was found for *Shank1* and *Shank3* at embryonic day 17.5 and for *Shank1* at postnatal day 1.5. This is of special interest as heterozygous *SHANK1* deletions showed a reduced penetrance in female individuals and only segregated in male carriers with high functioning autism. **Together, we could show that *SHANK* expression is influenced by sex hormones and is different between developing cortices of male and female mice, providing a possible mechanism underlying the sex bias in *SHANK*-associated ASD.**

**1917W**

**Parallel enhancer analysis in mouse brain to characterize regulatory variants in development and disease.** J.L. Haigh<sup>1</sup>, J. Lambert<sup>1</sup>, L. Su-Fehler<sup>1</sup>, K.J. Lim<sup>1</sup>, S.J. Morse<sup>1</sup>, I. Zdilar<sup>1</sup>, L.C. Byrne<sup>2</sup>, A.S. Nord<sup>1</sup>. 1) University of California, Davis, CA; 2) University of Pittsburgh, Pittsburgh, PA.

Enhancers are cis-regulatory elements with the capacity to promote gene expression. Enhancer activity is believed to underlie the differential expression patterns across neurodevelopment, between cell types, and in response to activity-dependent and neuroimmune signaling in the brain. Mapping the activity of enhancers with spatiotemporal and condition-dependent specificity will be critical to understanding gene regulatory networks and their role in human disease. Recent advances in massively parallel reporter assays (MPRAs) have enabled the functional characterization of enhancers via comparing RNA-based activity readout with genomic DNA delivery control. We implemented an MPRA strategy for in vivo delivery into the mouse brain. A pilot library of genomic enhancer candidate sequences containing common non-coding sequence variants associated with epilepsy and schizophrenia was developed. The enhancer library was delivered to neonatal mouse brain via adeno-associated virus (AAV), and genomic DNA and total RNA collected one week later at P7. Results from preliminary studies suggest this method is able to identify sequences capable of acting as enhancers in in vivo mouse brain based on transcriptional activity. We are currently validating the in vivo activity of individual disease-relevant enhancers by AAV delivery to the brain followed by immunohistochemistry and confocal microscopy to assess expression patterns in cerebral cortex. Having established the utility of the MPRA approach in vivo in brain, we are additionally testing this approach to assay allele-specific changes in enhancer activity linked with disease-associated sequence variation. These methods will allow rapid screening of libraries of DNA sequences for enhancer activity in vivo, with the potential to identify whether disease-associated variants contribute to altered gene expression with regional, temporal, and cell-type specificity in the brain. Such functional examination of enhancers will be critical toward understanding how non-coding sequence variation in human populations contributes to brain development and neurological and psychiatric disorders.

**1918T**

**Associations between KIBRA (*WWC1*) gene methylation and cognitive abilities in a childhood monozygotic twin difference design.** C.R. Lewis<sup>1,2</sup>, A. Henderson-Smith<sup>2</sup>, R.S. Breitenstein<sup>1</sup>, K. Lemery-Chalfant<sup>1</sup>, L.D. Doane<sup>1</sup>, M.J. Huettelman<sup>2</sup>. 1) TGen, Phoenix, AZ; 2) Arizona State University, Tempe, AZ.

Research suggests genetic variation drives individual differences in cognitive abilities. For example, 12 years ago others and we established an association between KIBRA gene (*WWC1*) variation and episodic memory in young, middle, and elderly aged participants (Papassotiropoulos et al., 2006; Schaper et al., 2008). However, research suggests environmental factors are also influencing complex phenotypes via the epigenome. We used a monozygotic (MZ) twin difference design to examine cotwin variation in *WWC1* methylation in relation to cotwin differences in a battery of cognitive functions. Comparing MZ twins allowed us to assess if environmentally driven differences in methylation affect phenotypes while controlling for genotype on methylation and performance. The sample included 48 MZ twin pairs (51% male; 50% Non-HispanicWhite, 15% Latinx, 8% AfricanAmerican, 4% AsianAmerican), mean age = 8.5 years, drawn from the Arizona Twin Project (Lemery-Chalfant et al., 2013). DNA methylation was quantified using the Infinium MethylationEPIC BeadChip. Executive attention and inhibition was assessed with the Flanker Task (Linear Integration Speed Accuracy Score [LISAS] for congruent and incongruent trials); short-term and working memory (STM and WM) with Digit Span (Total Forward and Backward); picture vocabulary, problem solving, and reading comprehension with the Woodcock Johnson. We extracted the first principal component from % methylation of 82 CpG sites near *WWC1* after removing all sites with a < .3 loading (45 sites remained; variance explained = 43.29%) for use in linear mixed models. Next, we computed MZ difference scores in % methylation and task performance for linear regression analysis. *WWC1* methylation was negatively associated with reading comprehension ( $b = -2.91$ ,  $p = 0.007$ ) and no other performance. MZ differences in *WWC1* methylation predicted executive attention performance (LISA Congruent:  $b = 0.367$ ,  $p = 0.022$ ) and no other performance. Our results indicate methylation levels of *WWC1* may influence reading comprehension, whereas environmentally driven methylation levels influence executive attention. Clearly, DNA methylation and complex cognitive functions employ an intricate relationship. As we unravel the distinction between environmentally and genetically driven methylation, we may be able to develop novel targetable interventions for neurodevelopmental, psychiatric, and neurodegenerative disorders that share a common cognitive dysfunction phenotype.

**1919F**

**An integrated genetic and epigenetic approach identified new candidate genetic loci for narcolepsy.** M. Shimada<sup>1,2</sup>, T. Miyagawa<sup>1,2</sup>, H. Toyoda<sup>2</sup>, K. Tokunaga<sup>2</sup>, M. Honda<sup>1,3</sup>. 1) Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Seiwa Hospital, Neuropsychiatric Research Institute, Tokyo, Japan.

Narcolepsy with cataplexy is a sleep disorder characterized by excessive daytime sleepiness and cataplexy. One proposed cause of narcolepsy is loss of hypocretin-producing cells in the lateral hypothalamus. Several genetic factors of narcolepsy including *HLA-DQB1\*06:02* have been identified, however, a detailed etiology still remains to be elucidated. Epigenetic modifications such as DNA methylation have recently been suggested to play a certain role in the pathogenesis of complex diseases. In this study, we first performed a microarray-based epigenome-wide association study (EWAS) of DNA methylation for narcolepsy using blood samples and examined differentially methylated positions (DMPs) linked to the disease. As a result, CpG sites with top associations were found to be significantly abundant in non-CpG islands ( $P = 7.32 \times 10^{-19}$ ) and more than 95% of such sites were hypomethylated in the narcolepsy patients. A pathway analysis identified that genes annotated to the top-ranked CpG sites had the functional relevance to hormone secretion and monocarboxylic acid metabolic processes. DMPs that showed an association with narcolepsy can be a cause of the disease, however, they also have the possibility to be a result of the disease. In order to search methylation loci which contribute to the development of the disease, we next conducted a new integrative approach of the EWAS and a genome-wide association study (GWAS) for narcolepsy. To achieve this, we utilized the concept of methylation quantitative trait loci (meQTL), i.e., methylation levels of meQTLs are related to genotypes of genetic variants. We searched meQTLs of which both methylation and genetic variant were associated with narcolepsy. We detected 19 meQTLs, all of which were *cis*-meQTLs located in the *CCR3* region. Further, now we are performing an EWAS using DNA samples extracted from lateral hypothalamus in the brain. We then examined whether the 100 top-ranked CpG sites found in the blood analysis also showed associations in the brain analysis. We found that associations of three CpG sites, including one annotated to *MAGEL2*, were consistent between blood and brain. *MAGEL2* is located in the region associated with Prader-Willi syndrome, which reportedly presents with symptoms of hypersomnia. Although future replication studies are necessary to confirm the results, the different levels of DNA methylation might have a certain role in the pathophysiology of narcolepsy.

**1920W**

**Positive and negative co-expression with *COMT* in four brain areas.** J.L. Dannemiller. Rice University, Houston, TX.

**Background:** The membrane-bound form of Catechol-O-Methyltransferase (MB-COMT) catabolizes catecholamines such as the neurotransmitter dopamine and is expressed most strongly in human Prefrontal Cortex. Variants of *COMT* (22q11.21) have been associated with various normal and abnormal cognitive phenotypes, but the literature is often conflicting on their effects. It is possible that some of the discrepancies in the literature arise because of differences in the genes co-expressed with *COMT*. **Methods:** Publicly available, post-mortem mRNA expression data (Illumina humanRef-8 v2.0 expression beadchip GPL6104) from four brain areas (Prefrontal Cortex, Cerebellum, Temporal Cortical Wall and Pons; hereafter PfCtx, CBell, TmCtx, Pons) in 138 subjects (GeneNetwork GN Accession: GN482, GEO Series: GSE15745) were used to determine characteristics of genes co-expressed with *COMT*. Bioconductor software for R (v3.5.0) was used as the primary analysis platform with gene as the data-analytic unit. The 500 genes (TOP500) whose expression levels were most strongly correlated (ranked by *p* value) with *COMT* expression were selected for further analysis in each brain area. A form of differential co-expression analysis was implemented by separating the TOP500 genes in each brain area into two sets: those with expression positively (*r*-pos) vs. negatively (*r*-neg) correlated with *COMT*. **Results:** 1) While the proportion of neg-*r* genes in the full sample was approximately 66% in all brain areas, this proportion flipped among the four sets of TOP500 genes. 2) When all length-6 motifs were examined in the promoter regions of these genes (-1000 to +600 bp from the TSS), the proportion of neg-*r* genes containing at least one instance of a given motif significantly exceeded the proportion of pos-*r* genes in 14 of 16 tests surviving *Bonferroni* correction. 3) The proportion of genes in PfCtx with at least one CpG island within 200 bp of the TSS differed significantly: 52% vs. 63% (neg-*r* vs. pos-*r*, respectively). 4) GO analysis (BP) produced a clear difference between the two sets of genes in PfCtx; 9 of the top 10 GO terms for the neg-*r* genes were related to "vesicle" processes. For pos-*r* genes, terms related to "catabolic" processes were enriched. **Implications:** The "vesicular" enrichment results could imply that when *COMT* is downregulated, some of the neg-*r* genes are upregulated possibly because of the increased demand for vesicular packaging of newly endocytic dopamine in presynaptic neurons.

**Small nucleolar RNAs in major depression and antidepressant response.**

R. Lin<sup>1</sup>, J.P. Lopez<sup>2</sup>, L.M. Fiori<sup>2</sup>, J.F. Theroux<sup>1</sup>, H. Peng<sup>1</sup>, C. Ernst<sup>1</sup>, C. Cruceanu<sup>1</sup>, R. Belzeaux<sup>1</sup>, CANBIND Working Group<sup>3</sup>, J. Foster<sup>2</sup>, S. Kennedy<sup>2</sup>, G. Turecki<sup>1</sup>. 1) McGill Group for Suicide Studies, Douglas Mental Health University Institute, McGill University, Montreal, Quebec, Canada; 2) Department of Psychiatry, University Health Network, University of Toronto, Toronto, Ontario, Canada; 3) The Canadian Biomarker Integration Network in Depression (www.canbind.ca).

**Background:** Major depressive disorder (MDD) is a prevalent global disorder treated primarily by antidepressants (AD). However, 30%-40% of subjects fail to respond after multiple attempts. Thus, discovering biomarkers for MDD and AD-response would greatly improve diagnostics and treatment. Small non-coding RNAs (sncRNAs) have recently been identified as feasible biomarkers associated with disease states, as they are stably circulated in peripheral blood and are involved in several post-transcriptional modification processes. I specifically profile small nucleolar RNAs (snoRNAs), since they have been disregarded in MDD pathology, leaving room for novel discoveries. To holistically evaluate snoRNAs as candidate biomarkers, I am using a unique combinatorial approach of profiling snoRNAs expression in both post-mortem human brain tissue and living human peripheral blood. **Methods:** Post-mortem brain tissue was collected from individuals who died by suicide during an MDD episode, and psychiatrically normal individuals who died suddenly. Peripheral blood was collected from 3 independent cohorts consisting of MDD subjects treated with AD for 8 weeks. Subjects were assessed for MDD severity using the Montgomery-Asberg Depression Rating Scale (MADRS) before treatment (Week 0) and afterwards (Week 8). Post-AD treatment subjects were separated into responders ( $\geq 50\%$  decrease in MADRS score; RES) or non-responders (nRES). Small RNA-sequencing was used to generate whole sncRNA-transcriptome expression data from post-mortem brain and peripheral blood. **Results:** SNORD90 and SNORD43 were found to be upregulated in AD-responders across time; this was replicated in all 3 cohorts. Next looking at our post-mortem brain samples, only SNORD90 was found to be differentially expressed between MDD-suicides and controls. All sequencing results have been validated via qPCR. Using in-silico analysis Neuregulin 3 (NRG3) has been identified as a potential target of SNORD90. This predicted SNORD90-NRG3 interaction will be interrogated via knock-down experiments in cell culture. **Conclusions:** To my knowledge, this is the first study focusing on snoRNAs in the context of MDD and AD-response. This novel information will not only further our understanding of MDD pathology, but has potential clinical impact as it also shows characteristics of a biomarker. Overall, my project has the potential of having a major impact on the diagnosis, treatment, and understanding of MDD.

## 1922F

**DNA methylation and three dimensional chromatin structure of the *IRXA* gene cluster in human cocaine dependence.**

K. Vaillancourt<sup>1,2</sup>, J. Yang<sup>1</sup>, G.G. Chen<sup>1</sup>, L. Fiori<sup>1</sup>, C. Ernst<sup>1,3</sup>, E. Calipari<sup>4</sup>, B. Labonté<sup>4</sup>, E. Nestler<sup>4</sup>, T. Fornes<sup>5</sup>, D.C. Mash<sup>6</sup>, G. Turecki<sup>1,2,3</sup>. 1) McGill Group for Suicide Studies, Douglas Hospital Research Center, Verdun, QC, Canada; 2) Integrated Program in Neuroscience, McGill University, Montreal, QC, Canada; 3) Department of Psychiatry, McGill University, Montreal, QC, Canada; 4) Icahn School of Medicine, Mount Sinai Hospital, New York, NY, USA; 5) Institute de Génétique Moléculaire de Montpellier, Montpellier, France; 6) Department of Neurology, University of Miami Miller School of Medicine, Miami, FL, USA.

**Background:** Multiple, interacting biological mechanisms are likely to contribute to the development and maintenance of cocaine use disorders. Epigenetic mechanisms are of particular interest as they may mediate the long-term effects of chronic cocaine abuse on brain cell functioning in addiction-related brain circuits. Although animal research has built a strong case for the role of DNA methylation and chromatin remodelling in cocaine dependence, little is known about the relationship between these phenomena in human patients.

**Methods:** We used reduced representation bisulfite sequencing (RRBS) to identify genome-wide differential methylation, in post mortem caudate nucleus and nucleus accumbens tissue, from 25 individuals with cocaine dependence and 25 drug-naïve controls. We validated and replicated our findings using targeted bisulfite sequencing, and used fluorescence activated nuclei sorting (FACS) to investigate cell-type specificity. We also used transcriptome sequencing, and chromatin conformation capture (3C) based techniques to explore the genomic regulation of the *IRXA* gene cluster. Our *in vitro* studies use immortalized fetal midbrain cells (RenCells) and dCas9-DNMT3a epigenome editing to investigate causal relationships between cocaine-related methylation changes and chromatin functioning at this locus. **Results:** We found altered methylation within two genes of the neurodevelopmental gene cluster, *IRXA*, in the caudate nucleus. We replicated our finding of decreased methylation within a cluster of 25 CpGs in the gene body of *IRX2* in an independent cohort, and found this effect to be specific to neuronal nuclei. In addition, cocaine dependence is associated with increased expression of the *IRX2* gene and altered co-expression of *IRX1* and *IRX2* transcripts. Moreover, we identified a large chromatin loop in human cells, which is related to *IRX2* methylation levels and is likely involved in *IRXA* regulation. **Conclusions:** Chronic cocaine dependence is associated with widespread alternations in DNA methylation in the human striatum, including decreased methylation within the gene body of *IRX2* in the caudate nucleus. This appears to be associated with dysregulated gene expression, and may be driven by altered chromatin looping. Further studies will continue to investigate the relationship between multiple epigenetic mechanisms in human cocaine use disorders.

## 1923W

**Co-expression patterns define epigenetic regulators associated with neurological dysfunction.**

L. Boukas<sup>1</sup>, J.M. Havrilla<sup>2,3,4</sup>, A.R. Quinlan<sup>2,3,4</sup>, H.T. Bjornsson<sup>1,5,6</sup>, K.D. Hansen<sup>1,7</sup>. 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Human Genetics, University of Utah, Salt Lake City, UT; 3) Department of Biomedical Informatics, University of Utah, Salt Lake City, UT; 4) USTAR Center for Genetic Discovery, University of Utah, Salt Lake City, UT; 5) Faculty of Medicine, University of Iceland; 6) Landspítali University Hospital, Reykjavik, Iceland; 7) Department of Biostatistics, Johns Hopkins School of Public Health, Baltimore, MD.

Coding variants in genes encoding for epigenetic regulators are an emerging cause of neurological dysfunction and cancer. However, a systematic effort to identify and prioritize disease candidates within the human epigenetic machinery (EM) has not been performed. Additionally, it is uncertain whether dysregulation of the normal chromatin state is the most likely cause of disease, as studies in model organisms have shown that the protein domains mediating the epigenetic function of these factors can at times be dispensable. Finally, it is unclear whether features exist that can distinguish between variation-intolerant and variation-tolerant EM genes, and between EM genes associated with neurological dysfunction versus cancer. Here, we first rigorously define a set of 295 human genes with a direct role in epigenetic regulation (writers, erasers, remodelers, readers). Using pLI as a metric, we find that the majority of EM genes are very intolerant to loss-of-function variation ( $p < 0.001$ , Odds Ratio = 7.7 for enrichment in the group of genes with pLI > 0.9), even when compared to the dosage sensitive class of transcription factors ( $p < 0.001$ , OR = 4.4 for enrichment in the pLI > 0.9 group). Using this strategy, we identify 103 novel EM disease candidates. We then perform a local, protein domain-specific mutational constraint analysis, and show that this intolerance to loss-of-function variation is driven by the protein domains encoding the epigenetic function ( $p = 0.009$ ), strongly suggesting that the disease phenotypes are in most cases caused by a perturbed chromatin state. To search for functional characteristics specific to dosage-sensitive EM genes, we construct tissue-specific co-expression networks, using large-scale RNA-seq data from the GTEx consortium. Unexpectedly, we describe 74 EM genes that are co-expressed in multiple tissues ( $p < 0.001$ ). This subset is almost exclusively populated by extremely variation-intolerant EM genes (72 of the 74 have a pLI > 0.9), and shows very high enrichment for a unique class of EM genes with dual enzymatic and reading function ( $p < 0.001$ , OR = 13.3). It is also enriched for genes associated with neurological dysfunction ( $p = 0.006$ , OR = 3.3), even when accounting for dosage sensitivity ( $p = 0.003$ , OR = 3), but not for cancer-associated EM genes ( $p = 0.41$ ). These findings prioritize disease candidate EM genes, and suggest that the co-expression itself may play a functional role in normal neurological homeostasis.

**1924T**

**Whole-genome bisulfite sequencing of Down syndrome cortex reveals regional DNA hypermethylation of active chromatin states and novel disorder insights.** *B.I. Laufer<sup>1</sup>, J.A. Gomez<sup>1</sup>, D.H. Yasui<sup>1</sup>, C.E. Mordaunt<sup>1</sup>, A.C. Vogel Ciernia<sup>1</sup>, H. Hwang<sup>1</sup>, J. Lu<sup>2</sup>, V.L. Sheen<sup>3</sup>, J.M. LaSalle<sup>4,5</sup>*. 1) Department of Medical Microbiology and Immunology, University of California, Davis, CA; 2) Department of Anatomy, China Medical University, Shenyang, China; 3) Department of Neurology, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA; 4) Genome Center, University of California, Davis, CA; 5) MIND Institute, University of California, Davis, CA.

Down Syndrome (DS) is the most common genetic cause of intellectual disability, resulting from trisomy of human chromosome 21 (HSA21). In addition to copy number and expression differences in HSA21 genes, genome-wide differences in DNA methylation have been observed in a variety of DS tissues and cells using reduced representation assays of individual CpGs. To obtain a more complete epigenomic profile of DS brain, whole-genome bisulfite sequencing (WGBS) of DS and matched control brains (male frontal cortex, BA9) was performed. Across the entire genome, 2047 significant (areaStat >20 or <-20) differentially methylated regions (DMRs) that distinguished DS from control brain were identified. A larger number of DS-specific DMRs were hypermethylated (1459) than hypomethylated (588). Notably, HSA21 showed the lowest abundance of autosomal DMRs as well as a uniquely even balance of hypermethylated and hypomethylated DMRs. The hypermethylated DMRs were significantly (FDR<0.05) enriched for active promoters and bivalent chromatin marked by H3K4me3, CpG islands and shores, and CTCF binding sites. Functionally, DMRs were significantly (FDR<0.05) associated with genes related to metabolism, neurodevelopment, transcription, and cell cycle. The DMRs also significantly ( $p=0.0003$ ) overlap with previously identified pan-tissue DS genes with differential methylation, which are primarily hypermethylated (24/25 genes). While predominantly novel, the DMRs identified from WGBS are significantly (FDR<0.05) enriched at the sequence level for CpG sites identified in previous DNA methylation analyses of 12 diverse DS adult and fetal cell-types/tissues. Integration of the DMRs with roadmap epigenomics histone modification data uncovered a brain specific profile of the hypomethylated, but not hypermethylated, DMRs. We hypothesize that the wide-scale DS hypermethylation is related to *DNMT3L*, which is located on HSA21, and its interactions with H3K4me3 and lamina associated domains, while the hypomethylated DMRs represent a tissue specific response to the hypermethylation. Currently, we are testing this hypothesis by utilizing DS and matched control fetal frontal cortex samples from both sexes and two transgenic human neuronal cell lines (LUHMES and SH-SY5Y) overexpressing *DNMT3L*. Overall, these results demonstrate that WGBS provides a more complete profiling of DNA methylation differences in DS that offers novel insights into genetic pathways that may be targeted by therapeutics.

**1925F**

**5-Aminolevulinic acid may ameliorate the cognitive function of patients of ATR-X syndrome.** *T. Wada<sup>1</sup>, S. Suzuki<sup>2</sup>, N. Shioda<sup>3</sup>*. 1) Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Department of Endocrinology and Metabolism, Fukuoka Children's Hospital, Fukuoka, Japan; 3) Department of Biofunctional Analysis Laboratory of Molecular Biology, Gifu Pharmaceutical University, Gifu, Japan.

**BACKGROUND;** ATR-X syndrome (OMIM #301040) is one of the X-linked intellectual disability syndromes caused by mutations of *ATRX* gene, encoding a chromatin remodeling protein, *ATRX*. We have no treatment for it up to now. It has been reported that *ATRX* protein targets tandem repeats, forming G-quadruplex (G4) structures, and regulates genes nearby. Recently we have published an article by Shioda N. in *Nature Medicine*, reporting that 5-Aminolevulinic acid (5-ALA) can be a potential therapeutic strategy to target G-quadruplexes and improve the cognitive function of ATR-X syndrome on the study of ATR-X model mice. This presentation is a case report of a boy of ATR-X syndrome, whose language ability improved with taking 5-ALA. **CASE;** The case is a 4-year-old boy, whose diagnosis of ATR-X syndrome was confirmed molecular genetically, c.7192 C>T [p.Gln2398\*] in *ATRX* gene. He showed typical clinical features of ATR-X syndrome with severe intellectual disability. At his age of 3 years and 4 months, he could not speak any meaningful words. He could only babble. His father gave 5-ALA to his son, hoping to improve his health for 9 months. At two month after starting taking 5-ALA at 5mg every day orally, he got several meaningful words, including "Ocha (referring to "tea" in English)", "Ka-san (Mom)", "Ji-chan (Grandpa)" and so on. After stopping taking 5-ALA for a month, he had lost his meaningful words. But he restarted taking 5-ALA at 30mg every day, and he could recover his language ability and acquired more new words, including "Tentei (teacher)", "Ko-ki (airplane)", "Ju-su (juice)", "Gyu-gyu (Milk)", and so on. He had to discontinue to take 5-ALA due to financial reasons, and he had lost his words again. No side effects were observed. **DISCUSSION;** This is the first case report suggesting that 5-ALA can ameliorate the cognitive function for ATR-X patients. 5-ALA is an endogenous non-protein amino acid, and is available commercially as an amino acid supplement in Japan. In general most patients of ATR-X patients cannot acquire any meaningful words, except some mild cases with a few specific variants in *ATRX* gene. This report can support our recent data that 5-ALA can ameliorate the cognitive function of ATR-X model mice. We are preparing to start the clinical trial study for administering 5-ALA to patients of ATR-X syndrome in order to confirm that 5-ALA is a good treatment for cognitive disability of ATR-X patients.

**1926W****MiRNAs involvement in the Fragile X-associated Disorders development.**

A.A. Dolskii, N.A. Lemskaya, D.V. Yudkin. State Research Center of Virology and Biotechnology VECTOR, Koltsovo, Russian Federation.

Fragile X-associated Disorders (FXD) include Fragile X-associated tremor/ataxia syndrome (FXTAS), Fragile X-associated Primary Ovarian Insufficiency (FXPOI) and Fragile X syndrome. All of them are related to the CGG repeat expansion in the 5'-UTR of *FMR1* gene and changing in synthesis of FMRP. The allele of the *FMR1* gene is called premutation, when the repeat expansion in the range of 55 to 200 triplets. Its frequency is 1:250 in women and 1:350 in men. In this case, expression of *FMR1* mRNA can be increased, but the amount of protein, usually decreases or stays at normal level. In this case, the FXTAS and FXPOI are developed. Fragile X syndrome emerges with the repeat expansion, more than 200 units and promoter region methylation (full mutation allele). It should be noted that the symptoms of full mutation and premutation alleles are different, indicating different mechanisms of pathogenesis in both cases. In the first case, this is the absence of the FMRP protein, whereas the pathogenesis mechanisms of the FXTAS and FXPOI is unclear. The alteration of the *FMR1* gene expression during repeat expansion indicates the possible miRNAs involvement in the development of this pathology. It is assumed that a decrease of FMRP protein in premutation is associated with RNA interference. Also, the *FMR1* gene activity can be influenced by miRNAs which arise from the GCC repeat in the *ASFMR1* transcript. The aim of this work is to study the of miRNAs involvement in the regulation of the *FMR1* gene expression in FXD. To achieve the goal, the level of 8 microRNAs was studied by Taq-man PCR in B-lymphocytes cell lines with different repeat size and different *FMR1* gene activity. Also, to study the possible effect of microRNAs containing the GCC repeat, the level of expression of *ASFMR1* was determined. An increase in some miRNAs expression in full mutation cell lines was shown, suggesting the possible involvement in the Fragile X syndrome pathogenesis. For other ones there was no correlation between their expression levels and the ratio of the expression values of the mRNA gene of the *FMR1* gene and the amount of the FMRP protein, which indicates that there is no participation in the FXD development. The work was supported by the Russian Science Foundation project 18-15-00099.

**1927T****(CGG)<sub>n</sub> repeat instability and active transcription in human tissue culture.**

I.V. Grishchenko, Y.V. Purvinsh, N.A. Lemskaya, D.V. Yudkin. State Research Center of Virology and Biotechnology VECTOR, Koltsovo, Russian Federation.

The expansion of repeats is a type of mutation, which is an increase of the repeats number in the hundreds of units. This phenomenon leads to a certain human genetic diseases, such as Huntington's disease, Fragile X syndrome. More than 30 diseases are caused by expansions of repeats dispersed throughout the human genome. Fragile X syndrome is the most common heritable intellectual disability associated with the repeat instability. It is caused by the expansion of (CGG)<sub>n</sub> repeat in the promoter region of the gene *FMR1*. The number of repeats in the normal ranges is from 5 to 54 units. With the repeat expansion in the range of 55 to 200 triplets, the allele of the *FMR1* gene is called premutation. Fragile X syndrome develops when the number of repeated triplets becomes over 200. Today the cause of this mutation is unknown. According to theory the expansion is due to the formation of alternative stable secondary DNA structures. At sites with these structures there is a failure of the repair and replication systems, which leads to an increase the size of the repeat. A feature of the *FMR1* gene promoter region is coding strand contains (CGG)<sub>n</sub> repeat, and the template strand contains CCG triplets. Thus, on the coding strand increased repeat form a G-quadruplex, and the ones on template strand form an i-motif. Since expansion take place in non-dividing cells like oocytes or neurons it can be assumed an expansion mechanism involves aberrant DNA repair, particularly transcription-coupled repair. Moreover, in the premutant alleles of the *FMR1* gene which rapidly accumulating the repeated units a dramatically increasing of the transcription level were observed. These findings indicate the possible involvement of active transcription in the of (CGG)<sub>n</sub> repeats expansion mechanism. The project aims to investigate (CGG)<sub>n</sub> repeat instability associated with the Fragile X syndrome during transcription in human tissue culture. Work was carried out on HEK293A culture cells, cultures of immortalized B-lymphocytes of patients and control cell lines. Recombinant plasmids with induced promoter TRE containing the premutant and normal alleles downstream of TRE were constructed. Further electroporation of immortalized B-lymphocytes and liposome transfection of HEK293A cells were carried out. In this study we investigated the effect of active transcription on the (CGG)<sub>n</sub> repeat length in the plasmid over time. The reported study was funded by Russian Science Foundation project 18-15-00099.

**FASD as an experimental model of an epigenetic neurodevelopmental disorder.** *B. Alberry<sup>1</sup>, E.J. Chater-Diehl<sup>2</sup>, B.I. Laufer<sup>3</sup>, S.M. Singh<sup>1</sup>.* 1) Biology, Western University, London, Ontario, Canada; 2) SickKids Research Institute, Program in Genetics and Genome Biology, Toronto Ontario, Canada; 3) Department of Medical Microbiology and Immunology, School of Medicine, University of California, Davis, CA.

Most neurodevelopmental disorders involve genes, environment and poorly understood epigenetic interactions that are multifaceted, dynamic and complex. Clarifying these interactions is critical but difficult, requiring a suitable model. We propose Fetal Alcohol Spectrum Disorder (FASD), a common neurodevelopmental disorder resulting from prenatal alcohol exposure modeled in C57BL/6J, is highly suited for this insight. Here we demonstrate that following continuous mild prenatal alcohol exposure in mice during neurodevelopment, mice have behavior phenotypes seen in FASD. Also, they have many life-long hippocampal molecular changes including genome-wide gene and microRNA expression (RNA-Seq), and DNA methylation (meDIP-Seq). The relationship between these features is not understood and may account for initiation as well as persistence of behavioral abnormalities in FASD. Interestingly, changes in DNA methylation in response to prenatal alcohol exposure in mice have also been demonstrated in buccal swabs from children with FASD. More importantly, postnatal manipulations or treatment paradigms potentially applicable to children can be applied and tested in young mice during development. In fact, it is possible to improve or worsen behavioral outcomes by favorable and unfavorable postnatal environments in mice subject to prenatal ethanol exposure, in this case early life stress via maternal separation. Additionally, behavioral outcomes are reflected in newly established molecular features in response to postnatal environment. Critical genes and pathways identified provide a foundation for the development of FASD diagnosis using DNA methylation and favorable interventions for children born with FASD. Finally, pathways and ontologies associated with these features implicate a role for epigenetic regulation of gene expression common in neurodevelopmental disorders.

**Common mitochondrial DNA variants implicated in variations in mitochondrial oxidative activity.** *N. Cai<sup>1,2</sup>, J. Stephenson<sup>2</sup>, E. Yonova-Doing<sup>3</sup>, M.J. Bondar<sup>2</sup>, B. Mirauta<sup>2</sup>, J. Danesh<sup>2</sup>, P. Chinnery<sup>4,5</sup>, J. Howson<sup>3</sup>, O. Stegle<sup>2</sup>, N. Soranzo<sup>1</sup>.* 1) Wellcome Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 2) European Bioinformatics Institute (EMBL-EBI), Wellcome Genome Campus, Cambridge, United Kingdom; 3) British Heart Foundation Cardiovascular Epidemiology Unit, Department of Public Health and Primary Care, University of Cambridge, Cambridge, United Kingdom; 4) MRC Mitochondrial Biology Unit, Cambridge Biomedical Campus, Cambridge, United Kingdom; 5) Department of Clinical Neurosciences, Cambridge Biomedical Campus, University of Cambridge, Cambridge, United Kingdom.

Mitochondrial DNA (mtDNA) codes for 13 proteins and 22 RNAs involved in the synthesis of key respiratory chain components, and hence an attractive candidate for the "missing heritability" in complex diseases through influencing metabolic activity. In this study, we examine the relationship between inherited mtDNA variations and 995 metabolites quantified from nearly 8,000 healthy blood donors in the INTERVAL study. Using high-resolution whole-exome (50x) and whole-genome (15x) sequencing, we are able to capture the near totality of mtDNA variation (of which 511 are high quality biallelic SNPs) and interrogate all potential causal SNPs. We show that sites defining common European haplogroups U and K are significantly associated ( $P < 10^{-14}$ ) with the levels of N-formylmethionine (fMet), the amino acid that initiates translation in the mitochondria, independent of nuclear variations and accounting for 1% of its heritability ( $h^2=18\%$ ). This finding implicates mtDNA variants in regulation of mitochondrial gene expression and, in turn, oxidative phosphorylation activity. We therefore investigated the functional impact on respiratory chain complexes associated with potentially causal SNPs by examining their effects on gene expression and protein levels in 44 human primary tissues from GTEx iPSCs from HipSci Consortiums. We find that MT1811G (16s rRNA), the top SNP associated with fMet affects protein levels of mtDNA encoded genes ( $p < 0.05$ ) in iPSCs. In addition, MT1189C (12s rRNA) shows the strongest and most consistent effects on expression of the mtDNA encoded genes across tissues, including significant negative associations with levels of ND3 transcripts (Complex I) in 7 tissues (5% FDR,  $p < 10^{-8}$ ), and positive effects on levels of COX3 transcripts (Complex IV) in 36 tissues. In contrast, we only detect enrichment of its effects on nuclear genes encoding subunits of respiratory complexes, in particular tissues such as heart left ventricle and several brain regions. This raises the possibility of cis-transcriptional control by mtDNA variants, with opposing effects on different complexes determining metabolic strategies, likely with tissue specific impacts. Our results, together with previous evidence that mtDNA variants have functional effects on oxidative phosphorylation, ATP levels, and generation of reactive oxygen species, shed light on potential new mechanisms where inherited mtDNA variation may influence oxidative, cellular and organismal phenotypes.

**Conserved roles for CHD7, the chromatin remodeler mutated in CHARGE syndrome, in transcriptional elongation of genes involved in neural, neural crest, and inner ear development.** E. Ritter<sup>1</sup>, H. Yao<sup>1</sup>, D.F. Hannum<sup>2</sup>, G.J. Sanchez<sup>3</sup>, E.D. Sperry<sup>3,4</sup>, A. Saiakhova<sup>5</sup>, D.R. Fuentes<sup>6</sup>, M.E. Bowen<sup>7</sup>, A.N. Niederriter-Shami<sup>3,4</sup>, J.M. Skidmore<sup>1</sup>, A. Srivastava<sup>3</sup>, L.D. Attardi<sup>7</sup>, T. Swigut<sup>6</sup>, J. Wysocka<sup>6,8,9</sup>, P.C. Scacheri<sup>5</sup>, D.M. Martin<sup>1,3,4</sup>. 1) Dept. of Pediatrics & Communicable Diseases, University of Michigan, Ann Arbor, MI; 2) Dept. of Biostatistics, University of Michigan, Ann Arbor, MI; 3) Dept. of Human Genetics, University of Michigan, Ann Arbor, MI; 4) Medical Scientist Training Program, University of Michigan, Ann Arbor, MI; 5) Dept. of Genetics, Case Western Reserve University, Cleveland, OH; 6) Dept. of Chemical and Systems Biology, Stanford University, Stanford, CA; 7) Dept. of Radiation and Cancer Biology, Stanford University, Stanford, CA; 8) Dept. of Developmental Biology, Stanford University, Stanford, CA; 9) Howard Hughes Medical Institute, Stanford University, Stanford, CA.

CHD7 is an ATP-dependent helicase that is critical for normal mammalian development. Heterozygous pathogenic variants in *CHD7* cause multiple organ system malformations and CHARGE syndrome, which includes ocular Coloboma, Heart defects, Atresia of the choanae, Retardation of growth and development, Genital hypoplasia and pubertal delay, and Ear abnormalities, including deafness and vestibular disorders. Central and peripheral nervous system impairment are common in CHARGE, yet the underlying mechanisms of CHD7 action in early neural and neural crest development are not well understood. *Chd7*<sup>ow/+</sup> mice exhibit dysplastic semicircular canals and mild mixed conductive-sensorineural hearing loss and are an excellent model for CHARGE syndrome. Reduced *Chd7* function in the ear disrupts expression of genes involved in developmental patterning and neurogenesis. Here we explored potential roles for CHD7 in global regulation of gene transcription in the nervous system, including differentiation of stem cells toward neural epithelial progenitors, neural crest cells, and inner ear tissues. We used mouse embryonic stem cells (ESCs) null for *Chd7* to study CHD7 in early neuronal development, during the transition of embryonic stem cells to neural epithelial progenitors (NEC), and found that loss of *Chd7* disrupts neuronal and glial differentiation without affecting proliferation or apoptosis. Transcriptome analysis via RNA-Seq on E10.5 and E12.5 otocysts from *Chd7*<sup>ow/+</sup> and *Chd7*<sup>ow/ow</sup> mutant mouse embryos showed a length-dependent effect of *Chd7* on gene transcription, with preferential effects on longer (>100 kb) genes. Notably, a similar length dependent effect was observed in heterozygous *CHD7* mutation-positive human induced pluripotent stem cells (iPSCs) differentiated into neural crest cells (NCCs) when compared to isogenic patient derived iPSCs in which the variant was corrected via CRISPR/Cas9 gene editing. We also observed that genes with high CHD7 occupancy display low RNA polymerase II (Pol II) pausing and higher RNAPII throughout the gene body. Collectively, our findings support roles for CHD7 in chromatin events that regulate transcriptional elongation. Interestingly, length-dependent gene dysregulation has been described for Rett syndrome, Autism Spectrum Disorder, and Fragile X syndrome, suggesting possible links between the molecular etiologies of these disorders and CHARGE syndrome.

Congenital microcoria (MCOR) is a rare autosomal-dominant disorder characterized by inability of the iris to dilate owing to absence of dilator pupillae muscle. In addition, the miotic iris is thin and displays abnormal stroma and iridocorneal angle. Iris thinning is consistent with transillumination of miotic irises and high sensitivity to light. In addition, consistent with abnormal iridocorneal angle development, glaucoma is frequently associated with this condition. Previously, we reported heterozygote 13q32.1 deletions as responsible for MCOR in six families. The deletions varied from 35 kbp to 80 kbp in size, but invariably encompassed or interrupted only two genes: *TGDS* encoding the TDP-glucose 4,6-dehydratase involved in Catel-Manzke syndrome and *GPR180* encoding the G protein-coupled receptor 180 which heterozygous loss-of-function caused iridocorneal angle dysgenesis but no microcoria, suggesting the contribution of 13q32.1 regulating elements in the full MCOR phenotype. We generated transgenic mouse lines harboring variable deletions of the syntenic region using CRISPR/Cas9 methodology. Homozygous animal were not viable. Heterozygous animals presented with minor iris dilation dysfunction but molecular analysis including RNAseq, qPCR and Western Blot disclosed strong ectopic expression of neighboring genes during iris development, suggesting that MCOR deletions modify the 13q32.1 regulatory landscape and the fate of some embryonic cells involved in iris formation.

**1932W**

**Induced pluripotent stem cell-derived retinal pigment epithelium is an effective model system to study regulatory genetic variation associated with age-related macular degeneration.** *E.N. Smith<sup>1</sup>, A. D'Antonio-Chronowska<sup>2</sup>, M. D'Antonio<sup>3</sup>, W.W. Greenwald<sup>2</sup>, V. Borja<sup>2</sup>, L. Aguiar<sup>2</sup>, J. Schmer<sup>2</sup>, H. Matsui<sup>2</sup>, S. Borooh<sup>4</sup>, R. Ayyagari<sup>4</sup>, K.A Frazer<sup>1,2</sup>.* 1) Pediatrics and Rady Children's Hospital, University of California, San Diego, La Jolla, CA; 2) Institute of Genomic Medicine, University of California San Diego, 9500 Gilman Dr, La Jolla, CA 92093, USA; 3) Bioinformatics and Systems Biology Graduate Program, University of California, San Diego, La Jolla, CA, USA; 4) Shiley Eye Institute, University of California San Diego, La Jolla, USA.

Over 1.6 million people ages 50 or older in the US have visual impairment resulting from age-related macular degeneration (AMD) – and current therapeutic options are quite limited. AMD has a well characterized genetic basis from GWAS, but little is known about the causal variants at associated loci. Induced pluripotent stem cell-derived retinal pigment epithelium (iPSC-RPE) are a highly promising system to functionally characterize the epigenetic and transcriptomic effects of these genetic variants as AMD pathogenesis involves progressive degeneration RPE cells. To overcome the challenges associated with directly obtaining primary RPE, we have begun the differentiation of iPSCs from the iPSCORE resource into iPSC-RPEs. Here we examine whether iPSC-RPEs are an effective model for studying and fine-mapping AMD associated genetic variation. We first differentiated iPSCs from 6 subjects and derived high-quality iPSC-RPEs displaying many morphological, molecular, and functional characteristics of naïve RPE including high ZO-1 and MITF staining. For all 6 iPSC-RPEs, as well as 1 fetal RPE sample, we generated RNA-seq and ATAC-seq. We then examined whether iPSC-RPEs showed similar gene expression profiles to fetal RPEs via principle component analysis (PCA) of the RNA-seq data, and observed clustering of the iPSC-RPEs with fetal RPE. Next, through functional enrichment analysis, we confirmed that the associated PCs were enriched for RPE associated functions, including sensory organ morphogenesis ( $P < 10^{-30}$ ) and retina development ( $P = 9.0 \times 10^{-10}$ ). We then analyzed the ATAC-seq data to determine if accessible chromatin peaks in iPSC-RPEs were: 1) reflective of RPE biology, 2) similar to adult RPE peaks, and 3) enriched for AMD GWAS loci. We observed motifs for important RPE TFs enriched in iPSC-RPE peak regions, including OTX2 ( $P < 10^{-2984}$ ), LHX2 ( $P < 10^{-518}$ ), and MITF ( $P < 10^{-215}$ ). Additionally, there was strong overlap between iPSC-RPE peak regions and peak regions from adult RPEs with and without AMD. Finally, we measured the enrichment for AMD GWAS association signal using FGWAS and found that both iPSC-RPE and fetal RPE peak regions had higher enrichment for AMD risk than adult RPE peak regions, suggesting that iPSC-RPE chromatin accessibility profiles could effectively prioritize regulatory AMD risk variants. Together, these findings support the use of iPSC-RPE as a model system to identify functional regulatory variants associated with AMD.

**1933T**

**ClinTAD: A tool for copy number variant interpretation in the context of topologically associated domains.** *J. Spector, A. Wiita.* University of California, San Francisco, San Francisco, CA.

Copy number variants (CNVs) have been associated with a variety of diseases in humans, including autism, intellectual disability, and congenital malformations. For this reason, the American College of Medical Genetics guidelines recommend genomic microarrays for CNVs as "first-tier" tests for the postnatal evaluation of individuals with these conditions. Current guidelines for interpreting CNVs mainly focus on examining genes within the CNV. However, emerging data suggests that alterations in one genomic region may affect gene expression distally via changes in regulatory elements. One important feature of chromatin architecture and gene regulation is topologically associated domains (TADs), with one recent study suggested that as many as 11.8% of pathogenic deletions may exert an effect through disruption of TADs (Ibn-Salem, et al., 2014). We developed ClinTAD, a browser-based tool that can be used to aid in determining the clinical significance of a CNV in the context of TADs. ClinTAD allows a user to input a chromosome number, coordinates, and phenotypic information as a Human Phenotype Ontology (HPO) ID number for either a single case or multiple cases. The single case view returns a visualization showing the CNV, TAD boundaries, and nearby genes, with genes that have phenotypic matches being highlighted. The multiple case view allows the user to enter information about multiple cases at once, and returns a text document with the HPO phenotype matches for each case. We include examples where ClinTAD could be of use in clinical practice, with a particular focus on CNVs of uncertain clinical significance. We specifically discuss three case vignettes where the CNV is predicted to disrupt TAD architecture and genes within the same or neighboring TAD may potentially relate to the patient phenotypes. Alterations in expression of these genes could potentially be used in a clinical interpretation, and these associations would not be suggested by examining genes with the CNV region alone. We anticipate that this decision support tool, freely available at [www.clintad.com](http://www.clintad.com), will be of widespread utility in clinical practice. We further suggest that it may be time to move beyond the current "CNV-region-only" perspective of array interpretation.

## 1934F

**Disrupted chondrocyte Sox9 expression underlies growth retardation in a mouse model of Kabuki syndrome.** J.A. Fahrner<sup>1,2</sup>, R.C. Riddle<sup>3</sup>, W.Y. Lin<sup>4</sup>, V.B. DeLeon<sup>5</sup>, S. Chopra<sup>6</sup>, S.E. Lad<sup>6</sup>, K.D. Hansen<sup>1,5</sup>, H.T. Bjornsson<sup>1,2,6,7</sup>. 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Pediatrics, Johns Hopkins University, Baltimore, MD; 3) Department of Orthopaedic Surgery, Johns Hopkins University, Baltimore, MD; 4) Department of Anthropology, University of Florida, Gainesville, FL; 5) Department of Biostatistics and Center for Computational Biology, Johns Hopkins University, Baltimore, MD; 6) Landspítali University Hospital, 101 Reykjavik, Iceland; 7) Faculty of Medicine, University of Iceland, Reykjavik, Iceland.

Mendelian disorders of the epigenetic machinery disrupt fundamental biological processes, most commonly neurological development and growth. One such disorder is Kabuki syndrome 1 (KS1), characterized by intellectual disability, postnatal growth retardation, and distinct dysmorphisms. KS1 is caused by de novo heterozygous loss of function mutations in *KMT2D*, encoding an epigenetic writer that methylates lysine 4 on histone H3 (H3K4me). Prior work demonstrated that a mouse model of KS1 (*Kmt2d*<sup>fl<sup>βgeo</sup></sup>) exhibits features of the human disorder, including neurological dysfunction, growth retardation, and facial flattening. Little is known, however, about the mechanistic basis of skeletal growth retardation and craniofacial development in KS1. Here we show that *Kmt2d*<sup>fl<sup>βgeo</sup></sup> mice indeed exhibit generalized growth retardation and flattening of the facial profile. High-resolution micro-computed tomography (micro-CT) revealed shortened, thinned long bones with decreased trabecular bone, and morphometric analysis showed ventral bowing of skulls in *Kmt2d*<sup>fl<sup>βgeo</sup></sup> mice. Furthermore, a unifying mechanism involving disrupted enchondral ossification at both sites is suggested by in vivo expansion of growth plates at these two distinct regions of skeletal growth. In vitro studies of stable ATDC5 chondrocyte cell lines harboring loss of function and hypomorphic mutations in *Kmt2d* (*Kmt2d*<sup>-/-</sup> and *Kmt2d*<sup>ΔR5551/-</sup>), revealed that upon induction of chondrogenesis both exhibited increased proliferation and precocious differentiation in a dose-dependent manner, further supporting the above mechanism. Explicitly, cartilage-specific Alcian blue staining and expression of markers of chondrocyte differentiation are increased in *Kmt2d*<sup>ΔR5551/-</sup> and *Kmt2d*<sup>-/-</sup> cells compared to *Kmt2d*<sup>+/+</sup> cells. We hypothesized a mechanism involving SOX9, which is known to induce chondrogenesis and inhibit osteogenesis. In fact, *Sox9* showed over 10-fold higher expression levels in *Kmt2d*<sup>-/-</sup> compared to *Kmt2d*<sup>+/+</sup> cells. SOX9-mediated enhanced chondrogenesis at the expense of osteogenesis provides a potentially novel and plausible explanation for the increased proliferation and precocious differentiation of chondrocytes whilst long bones are shortened with decreased bone formation. Further studies, including genome-wide transcriptome analyses, may determine the basis of *Sox9* dysregulation, implicate additional pathways, and suggest novel therapeutic strategies for growth retardation in KS1 and related disorders.

## 1935W

**Identification of putative epigenetically regulated key genes and pathways related to nonsyndromic cleft lip and palate using genome-wide DNA methylation analysis.** N.M. Saiyed<sup>1</sup>, S. Vishweswaraiah<sup>2</sup>, S.S. Chettiar<sup>3</sup>, S. Bakshi<sup>4</sup>, N.K. Jain<sup>3</sup>, U. Ratnamala<sup>4</sup>, U. Radhakrishna<sup>2</sup>. 1) Biotechnology, Nirma Institute of Science, Nirma University, Ahmedabad, Gujarat, India; 2) Department of Obstetrics and Gynecology, Oakland University William Beaumont School of Medicine, Royal Oak, MI, USA; 3) Department of zoology, School of sciences, Gujarat University, Ahmedabad-9, India; 4) Department of pharmacology, Creighton University, Omaha, NE.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is considered the most common, severe craniofacial disorder having both environmental and genetic etiologies. NSCL/P abnormalities are associated with increased morbidity and mortality in childhood, and adulthood. Progress has been made in elucidating the genetic mechanisms of familial NSCL/P; however, an increasing body of evidence implicates epigenetic processes as playing a role in adversely influencing orofacial development. To elucidate the epigenetic mechanism involved in the susceptibility and development of NSCL/P, genome-wide DNA methylation was performed on blood samples from 48 individuals including 24 cases with NSCL/P, and 24 controls. DNA methylation was examined using the Illumina *Infinium* MethylationEPIC array. Comparison of the methylation profiles between NSCL/P and controls revealed 636 differentially-methylated CpG loci associated with 672 unique genes that had at least 2.0-fold change in methylation (false discovery rate (FDR)  $p \leq 0.00001$ ) or  $p < 5 \times 10^{-8}$  with a receiver operating characteristic area under the curve (AUC)  $\geq 0.75$ . These genes included *COL4A1*, *COL4A2*, *TP63*, *TBX1*, *SUMO1*, *MSX1*, *HOXA2*, *PAX6*, *WNT6*, *NF2*, *NKX2-5*, *DLX5*, *ALX4*, *CLPTM1* etc., which have previously been reported to be associated with NSCL/P. *RPS6KA5/S6K1*, *DDAH2*, *IQGAP3*, *DAB2*, *ALDH9A1*, *KCNN1*, *GLIS3*, *CASP8AP2*, *BRD8*, *MLXIP*, *NIF3L1*, *ITGA3*, *ITGB4*, *WNT7B*, *PPP2R1B*, *DAPK3*, *RAD21*, *RPL23*, *STK36*, *DYRK1B*, *HAND1*, *ACTA1*, *TCF4*, *BACH2* and *RHOA* are the genes identified in the present study in significant association with NSCL/P. Pathway analyses indicated that alterations in the growth hormone, *Cdc42*, GABA receptor, P38 MAPK and protein kinase, axonal guidance, ephrin receptor, Wnt-B catenin, sonic hedgehog, BMP, JAK/Stat, endothelin-1, and epithelial adherens junction signaling pathways are associated with risk of NSCL/P. These results strongly supports proof-of-concept that NSCL/P is associated with differential DNA methylation in whole blood, which may have utility as biomarkers of NSCL/P risk.

**1936T****Therapeutic trial with an HDAC inhibitor in Rubinstein-Taybi syndrome.**

D. Lacombe<sup>1,2</sup>, M.P. Baudier<sup>1</sup>, E. Bestaven<sup>3</sup>, S. Fraisse<sup>1</sup>, E. Taupiac<sup>1</sup>, E. Grech<sup>1</sup>, I. Guillain<sup>1</sup>, P. Cazalet<sup>9</sup>, B. Arveiler<sup>1,2</sup>. 1) Medical Genetics, CHU Bordeaux; 2) INSERM U1211, Université de Bordeaux, Bordeaux, France; 3) Institut de Neurosciences Cognitives et Intégratives d'Aquitaine, Université de Bordeaux; 4) Direction de la recherche clinique, CHU Bordeaux; 5) Département d'Imagerie Médicale, CHU Bordeaux; 6) Service d'information médicale, USMR, CHU Bordeaux; 7) Service de Pharmacologie Médicale, CHU Bordeaux, Bordeaux, France.

The Rubinstein-Taybi syndrome (RTS) is a multiple congenital anomalies – intellectual deficiency syndrome characterized by growth retardation, microcephaly, characteristic facial features, and broad thumbs and first toes. RTS is genetically heterogeneous with mutations in the *CREBBP* or *EP300* genes encoding transcription cofactors involved in histone acetylation. RTS knock-out mouse studies showed an improvement of long-term memory using histone deacetyltransferase (HDAC) inhibitors or inhibitors of phosphodiesterase 4 (PDE4). This suggests therapeutic options for RTS. Among the identified HDAC inhibitors, sodium valproate has the marketing authorization for epilepsy and mood disorders and can go through the blood brain barrier. We conducted an exploratory phase 2 therapeutic trial («proof of concept»), with a primary endpoint to estimate the efficiency of sodium valproate after one year of treatment (30 mg/kg/d) on long term memory in RTS children. Secondary Outcomes included cognitive profiles, brain imaging, motor skills evaluation, and histone acetylation profile. It was a monocentric, double-blind, phase 2 trial, designed as a one-step Fleming with a control group, randomized 2:1 into two parallel groups. 41 RTS cases between ages 6 and 21 participated. Using subtests of neuropsychological battery test especially designed for memory evaluation (point location for CMS, and image recognition for RBMT), results were not significant between the treatment group and the placebo group for the primary outcome. The same essay with the RTS knock-out mouse is currently in process. However regarding motor skills for walking, it was noticed a slight decrease of cadence and an increase of the duration of the double step in the valproate group, showing an amelioration in the treatment group. Posturometry showed more oscillations in the placebo group during the task. This confirms the *CREBBP* and *EP300* roles in motor skill learning, and encourages to continue therapeutic approaches with HDAC (or PDE4) inhibitors in RTS. Grant references: PHRC 2011, Ministry of Health; French Rubinstein Taybi syndrome Fondation. .

**1937F****Investigation of the effect of allelic deletion of an enhancer element in the critical region of the 9p deletion syndrome using CRISPR/Cas9 and real-time quantitative PCR.** X. Hauge<sup>1</sup>, A. Gaede<sup>1</sup>, L. Manera<sup>1</sup>, D. Forteh-Ngochi<sup>1</sup>, J. Sloan<sup>2</sup>, K. Traver<sup>3</sup>. 1) Kennesaw State University, Kennesaw, GA; 2) EGL Eurofins Clinical Diagnostics, Tucker, GA; 3) Oncology Cytogenetics, Emory University School of Medicine, Atlanta, GA.

Deletions of the terminal region of the short arm of chromosome 9 are associated with trigonocephaly, dysmorphic facial features and mental retardation. The deletion of Cerberus 1 (*CER1*) gene located at 14.7 Mb from the 9p terminus has been postulated as the cause of trigonocephaly. However, several independent studies showed that patients with typical 9p deletion phenotype possess smaller than 12.4 Mb deletions. It raises the possibility that cis-regulatory elements for the *CER1* gene could be located in the first 12.4 Mb region of 9p. We have previously identified 8 conserved non coding sequences in the deletion breakpoint region between 10 Mb and 12.4 Mb of 9p. Of these, we found a strong enhancer element 5008 and a strong repressor 3362. Enhancer element 5008 showed a cell-type specific activity in a dual luciferase assay. It increased the luciferase activity 14 fold in a human mesenchymal progenitor cell line derived from H9 hESCs as compared to a 3.5-fold increase of the luciferase activity in the HEK293T cells. We also detected an increase in the *CER1* gene expression in the mesenchymal progenitor cell line after the treatment with osteogenic differentiating medium. We utilized *S. aureus* Cas9 and 4 guide RNAs to excise the enhancer element 5008. We created 4 different constructs with deletions ranging from 500 bp to 2000 bp, which correspond to the core sequence of enhancer element 5008 and the surrounding region. We established 3 different deletion clones from HEK293T cells. The pre-selected deletion breakpoint in the 12.4 Mb genomic region of 9p was verified for each clone by using Sanger sequencing. The effect of allelic deletion of the enhancer element 5008 on the *CER1* gene expression was investigated in each deleted clone using real-time quantitative PCR. The preliminary data showed that the expression of *CER1* gene was decreased in mesenchymal progenitor cells possessing a deletion of the enhancer element 5008. However, further study is needed to confirm the result.

## 1938W

**CHARGE Syndrome in a 22 year old patient of Bogota-Colombia: Report case with a c.5458C>T mutation of the gene encoding CHD7.** *D. Arteaga<sup>1</sup>, O. Beltran<sup>1,4</sup>, C. Restrepo<sup>2,3</sup>.* 1) Grupo de Biogenética & Bioderecho Facultad de Medicina de la Universidad Militar Nueva Granada, Bogotá D.C, Transversal 3ra. No 49-00; 2) Facultad de Medicina, Universidad del Rosario, Bogotá, Colombia, Calle 12C No. 6-25; 3) Genética Molecular de Colombia, Bogotá, Avenida carrera 68 #67F-16; 4) Departamento de genética Organización Internacional Colsanitas, Colombia, Bogota, Consultorio, Carrera 9 #103A-36.

CHARGE syndrome is a very rare genetic syndrome that results in a combination of multiple organ anomalies because of an epigenetic mutation given by the loss of function of the gene encoding the Chromodomain Helicase DNA binding protein 7 (CHD7). This protein is an ATP dependent chromatin remodeler and hence, it is essential for the chromatin modifications that customize the DNA information that is encoded dependent of the cell stage or in specific conditions. Recent evidence suggest the importance of epigenetic mechanism for the central nervous system development, and in this case, in multiple organ features like the iris, ears, genitals, heart, and bones. In patients with clinically typical CHARGE syndrome, the detection rate of this mutation is over 90%, but in patients suspected of having this syndrome the sequencing of CHD7 reveals a mutation in 32-41% of this patients. In 2004 another mutation arise as a cause of this syndrome in suspected cases, known as the SEMA3E, and there are other genetic alterations that can phenocopy this syndrome, like other chromosomal aberrations (like 22q11.2 deletion that involves the gene encoding T-box 1 – TBX1), teratogen exposure (like retinoic acid), or even maternal diabetes. The purpose of this article is to expose a clinical definite case of CHARGE syndrome in a 22 year old male patient in Bogotá, Colombia, the only son from healthy non-consanguineous parents, which meets three major diagnostic characteristics (VIII disfunction, outer ear malformation and choanal atresia) and four minor characteristics (genital hypoplasia, facial asymmetry, developmental delay and growth deficiency), and was study by molecular sequencing of CHD7 and SEMA3E in blood samples. The study results in a nonsense mutation c. 5458C>T of the gene encoding CHD7, confirming the diagnosis of CHARGE syndrome. .

Coffin-Siris and Nicolaides-Baraitser syndromes (CSS and NCBRS) are two Mendelian disorders caused by mutations in subunits of the BAF chromatin remodeling complex. We report overlapping peripheral DNA methylation signatures in individuals with various CSS subtypes (*ARID1B*, *SMARCB1*, and *SMARCA4*) and NCBRS (*SMARCA2*). We demonstrate that the degree of similarity in epi-signatures of some subtypes of CSS and NCBRS can be greater than that within CSS, indicating a link in the functional molecular basis of the two syndromes. We show that chromosome 6q25 microdeletion syndrome, harboring *ARID1B* deletions, also exhibits the same CSS/NCBRS methylation profile. Specificity of this epi-signature was confirmed across a wide range of neurodevelopmental conditions including other chromatin remodeling and epigenetic machinery disorders. We demonstrate that a machine-learning model trained on this profile can resolve ambiguous clinical cases, reclassify those with variants of unknown significance, and identify previously undiagnosed subjects through targeted population screening.

**1940F**

**Identification of a unique DNA methylation signature associated with Nicolaides-Baraitser syndrome.** R. Weksberg<sup>1,2</sup>, R. Ejaz<sup>1</sup>, E. Chater-Diehl<sup>2</sup>, S. Choufani<sup>2</sup>, C. Cytrynbaum<sup>1</sup>, D. Chitayat<sup>1,3</sup>. 1) Division of Clinical and Metabolic Genetics, Department of Paediatrics, The Hospital for Sick Children, Toronto, Canada; 2) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Canada; 3) The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynecology, Mt. Sinai Hospital, Toronto, Canada.

The critical role of epigenetic regulation in human development has recently emerged. Hundreds of epigenes modulate a complex interaction of layered epigenetic marks, including DNA methylation (DNAm). Pathogenic variants in many of these epigenes cause various neurodevelopmental disorders and have been shown to be associated with unique epigene-specific patterns of genome-wide DNAm. The SWI/SNF chromatin remodeling complex is a key developmental regulator of gene expression. Heterozygous pathogenic variants in *SMARCA2*, a component of the SWI/SNF complex, cause Nicolaides-Baraitser syndrome (NCBRS), characterized by facial dysmorphism, sparse hair, seizures and intellectual disability. Given the role of the SWI/SNF complex in transcriptional regulation, we hypothesized that individuals with NCBRS would have a unique DNAm signature that molecularly reflects *SMARCA2* loss of function and could contribute to the disorder's pathophysiology. DNA from whole-blood of two females and two males with NCBRS and pathogenic variants in *SMARCA2* were subjected to genome-wide DNAm analysis along with controls (n=25) using the Infinium MethylationEPIC Bead-Chip. Raw data were processed in the *Minfi* Bioconductor package, including background correction, Illumina normalization, and quality control. *Limma* regression with sex and age as covariates was used to identify differentially methylated CpG sites, and *bumphunter* to identify differentially methylated regions (DMRs). Gene Ontology analysis characterized genes overlapping DNAm changes. We found 1031 CpG sites with a false discovery rate (FDR) q-value < 0.05 and a beta (DNAm) value difference > 10% between NCBRS cases and controls. Two thirds of the DMRs were hypermethylated in NCBRS cases. DMRs were enriched in pathways pertaining to skin keratinization and elasticity, energy metabolism, histone acetylation and channelopathies, offering unique insight into the molecular changes underpinning NCBRS. Hypermethylated regions were enriched at genes involving transcriptional regulation. In this preliminary study, we identified a robust genome-wide DNAm signature for NCBRS. The results further our understanding of downstream target genes of *SMARCA2*. Identification of epigenetically driven biological pathways via the DNAm signature can be used for precision medicine by providing means of functionally classifying variants of unknown significance in this gene, and identifying novel therapeutic targets.

**Maternal effect variants in subcortical maternal complex members cause imprinting disorders.** T. Eggermann, L. Soellner, M. Begemann, I. Kurth, M. Elbracht. RWTH Aachen, Aachen, Germany.

The subcortical membrane complex (SCMC) comprises oocyte-derived proteins which are essential for the progression of the zygote and the early embryo. They are encoded by maternal effect genes as they are only expressed in the oocytes, highly abundant in early embryogenesis and then degraded without compensation by the embryonal genome. Though the precise physiological role of SCMC genes is unknown, animal models indicate their fundamental role in proper embryonal development. In humans, women carrying mutations in SCMC factors, i.e. KHDC3L, PADI6, TLE6 and NLRP7, are prone to reproductive failure, including complete hydatidiform moles and miscarriages. Additionally, maternal effect mutations in some of the SCMC genes are also associated with disturbed imprinting marks in their offspring. These aberrant imprints often affect numerous loci, resulting in a multilocus imprinting disturbance (MLID). MLID has firstly been reported in the imprinting disorders Beckwith-Wiedemann and Silver-Russell syndromes (BWS, SRS). Both diseases are molecularly heterogeneous, but in both the major epigenetic and genetic alterations affect the Imprinting Control Regions 1 (ICR1 in SRS) and ICR2 (in BWS) in 11p15. In BWS, loss of methylation (LOM) of the ICR2 is the major finding (~50% of patients), and in this group 25% of patients show a MLID. In SRS, 10% of the subgroup of ICR1 LOM (40% of SRS patients) exhibit MLID. In fact, the vesting majority of MLID carriers reported so far have been clinically ascertained either as BWS or SRS, but cases with unspecific phenotypes have also been identified. The pathomechanism behind MLID is unknown, but it has been postulated that in more than 50% of mother of MLID patients variants in SCMC genes (e.g. NLRP2, NLRP5, NLRP7, PADI6) are present. We will report on genetic, epigenetic and clinical data in 29 MLID families, including mutation data in SCMC genes, epigenotype-phenotype correlations in the patients and reproductive history of their mothers. Based on these data, we will emphasize the relevance to identify MLID carriers among imprinting disorder as the basis for personalized genetic and reproductive counseling.

**Utilizing dCas9 directed chromatin loop reorganization to unsilence the paternal *UBE3A* allele in LUHMES neuronal cell line.** O. Gutierrez Fugón<sup>1,2,4</sup>, D.H. Yasuji<sup>1</sup>, H. O'Geen<sup>2,3</sup>, D.J. Segal<sup>2,3,5</sup>, J.M. LaSalle<sup>1,2,5</sup>. 1) Department of Medical Microbiology and Immunology, University of California, Davis, CA; 2) Genome Center, University of California, Davis, CA; 3) Department of Biochemistry and Molecular Medicine, University of California, Davis, CA; 4) Integrative Genetics and Genomics, University of California, Davis, CA; 5) UC Davis MIND Institute, Davis, CA.

Angelman syndrome (AS) is a severe neurogenetic disorder caused by functional loss of the *UBE3A* gene. *UBE3A* encodes for ubiquitin-protein ligase E3A that is essential for synaptic development. This gene is biallelically expressed in non-neurons but in neurons it is imprinted on the paternal allele and is exclusively expressed from the maternal allele. Most AS cases are caused by a deletion of the maternal *UBE3A* resulting in no production of UBE3A in the brain of these patients. An antisense transcript of *UBE3A* (*UBE3A-ATS*) has been shown to be responsible for the silencing of the paternal allele. In neurons, transcription of *UBE3A-ATS* initiates at *SNRPN*, extends through *IPW* and continues through *UBE3A*, however in non-neurons it terminates near *IPW*. CTCF is a genomic insulator, which binds DNA in a methylation sensitive manner, to form chromatin loops that have been shown to regulate gene expression. A CTCF binding site is present near *IPW*, therefore we hypothesized that CTCF creates a chromatin loop at this locus in non-neurons that prevents the transcription of *UBE3A-ATS* past *IPW*. Furthermore, CTCF is evicted by DNA hypermethylation in neurons, allowing extension of the antisense transcript past *IPW*. As a neuronal model system, we tested Lund Human Mesencephalic (LUHMES) cells, originally derived from the ventral mesencephalon of an 8-week-old fetus. This cell line was engineered to selectively proliferate, allowing controlled neuronal differentiation. In LUHMES cells, we detected *UBE3A-ATS* by qRT-PCR following 7 days of neuronal differentiation but not in the undifferentiated proliferating state. The results demonstrate that these cells can model neuronal versus non-neuronal transcriptional patterns at *UBE3A*. In addition, DNA methylation analysis by pyrosequencing has demonstrated that the CTCF binding site at *IPW* is hypermethylated in neurons compared to non-neurons. In future planned experiments, to determine if a CTCF chromatin loop is sufficient to inhibit transcription of *UBE3A-ATS* past *IPW* in neurons, we will target a dCas9-CTCF chimeric protein to the *IPW* binding site. To determine if CTCF binding at *IPW* is necessary for the termination of *UBE3A-ATS* in non-neurons we will express a dCas9/DNA methyltransferase DNMT3A fusion protein in undifferentiated LUHMES cells. This research approach may provide insight into how chromatin looping regulates paternal *UBE3A* silencing in neurons and could lead to the development of epigenetic therapeutics for AS.

**Comparisons of chromosome-wide DNA methylation patterns between maternal and paternal UPD16 reveal evidence for additional imprinted regions.** K.V. Schulze<sup>1</sup>, P. Szafranski<sup>1</sup>, H. Lesmana<sup>2</sup>, R.J. Hopkin<sup>2</sup>, A. Hamvas<sup>3</sup>, J.A. Wambach<sup>4</sup>, C.M.B.C. Fonseca<sup>1</sup>, Q. Liu<sup>1</sup>, J. Karolak<sup>1</sup>, J.R. Lupski<sup>1,5,6</sup>, N.A. Hanchard<sup>1,6,7</sup>, P. Stankiewicz<sup>1</sup>. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, University of Cincinnati College of Medicine, Cincinnati, OH; 3) Pediatrics, Northwestern University Feinberg School of Medicine, Chicago, IL; 4) Division of Newborn Medicine, Edward Mallinckrodt Department of Pediatrics, Washington University School of Medicine, St. Louis, MO; 5) Dept. of Pediatrics, Baylor College of Medicine, Houston, TX; 6) Texas Children's Hospital, Houston, TX; 7) USDA/ARS/Children's Nutrition Research Center, Baylor College of Medicine, Houston, TX.

Trisomy 16 is the most frequent trisomy in pregnancy and is only viable with trisomic rescue, which in 1/3 cases results in maternal uniparental disomy (UPD(16)mat). In contrast to the very rare UPD(16)pat thought to be benign, UPD(16)mat can manifest with a range of congenital malformations, e.g. heart defects and pulmonary hypoplasia. Interestingly, similar anomalies have been observed in newborns with the lethal lung disease alveolar capillary dysplasia with misalignment of pulmonary veins (ACDMPV), caused by point mutations or CNV deletions involving the *FOXF1* locus at 16q24.1. Unlike point mutations, CNV deletions arise de novo exclusively on the maternal allele. Given the parental allelic bias in ACDMPV as well as the phenotypic differences between UPD(16)mat and -pat, we hypothesized that there may be additional imprinted or partially imprinted loci on chromosome 16q24.1 that mediate the influence of structural variants on the development of congenital malformations. Chromosome 16-targeted bisulfite sequencing, capturing >75% of CpG loci, was undertaken on paired peripheral blood samples with either UPD(16)mat, UPD(16)pat, and normal controls. Bioinformatic analyses revealed 18 regions with evidence of parent-of-origin biased DNA methylation ( $\geq 40\%$  methylation difference between UPD(16)mat and -pat with intermediate methylation in controls). We confirmed known imprinted loci near *ZNF597* and found evidence of maternal methylation at a CpG island close to *PRR25*, which is reported to be paternally expressed in lymphoblastoid cells. Methylation differences between maternal and paternal alleles were less pronounced in non-imprinted regions; however, we found evidence of hypomethylation in UPD(16)pat at *NARFL*, *PMM2*, and *WWOX* as well as partial imprinting at *CCPED1*, *MGRN1*, and an intergenic region on 16q24.1; the latter contained an additional 138 regions with modest evidence of parent-of-origin methylation biases. Bisulfite sequencing of UPD(16)mat fibroblasts, lung ACDMPV samples, and a lung control indicated that some parent-of-origin biased methylation patterns were consistent across tissues while others appeared tissue-specific. Given that only four of our 18 candidate regions are covered by the commonly used 450K methylation array, the high resolution of our approach allowed us to find evidence of new candidate imprinted loci on chromosome 16 that could contribute to the birth defects seen in UPD(16)mat and ACDMPV.

Development of the respiratory system is a complex and tightly controlled process. The canonical Hedgehog pathway acts as a critical piece in the lung development signaling puzzle. The inactivation of *Shh* and *Gli* genes in mice results in foregut malformations ranging from lung hypoplasia and abnormal tracheoesophageal septation to severe tracheal truncation patterns and complete lung agenesis. Malformations such as lung agenesis are rare events usually seen as sporadic cases and the molecular basis remains poorly understood. Here we describe three fetuses born to unrelated French parents with complete lung agenesis. The diagnosis was made by ultrasound. Fetal autopsy after termination of pregnancies at 26, 23 and 14 weeks revealed complete agenesis of both lungs in all three fetuses. Furthermore, two of them had moderate interdigital webbing. The male fetus had a micropenis, and in another the trachea was partially absent. We performed exome sequencing in two of them and found no convincing coding alteration. However, high resolution array-CGH revealed an approximately 659 Kb tri/tetraplication in all fetuses. Interestingly, the same structural variant was detected in the unaffected father, although in a mosaic state. The candidate CNV lies along *SHH* long-range regulatory domain and encompasses a specific enhancer, *MACS1*, driving the spatiotemporal expression of *SHH* in the airway epithelium. We speculate that *MACS1*, becomes disconnected from its gene through the formation of a new chromatin domain (neo-TAD) resulting in the ectopic activation of a neighboring gene, probably *MXN1*.

**1945T****The chromatin accessibility signature of aging in human blood leukocytes stems from CD8+ T cells.**

D. Ucar<sup>1</sup>, E. Marquez<sup>1</sup>, C. Chun<sup>1</sup>, R. Marches<sup>1</sup>, R. Rossi<sup>1</sup>, A. Uyar<sup>1</sup>, T. Wu<sup>1</sup>, J. George<sup>1</sup>, M. Stitzel<sup>1</sup>, K. Palucka<sup>1</sup>, G. Kuchel<sup>2</sup>, J. Banchemau<sup>1</sup>. 1) Jackson Laboratory, Farmington, CT; 2) University of Connecticut Health Center, Farmington, CT.

Aging is linked to deficiencies in immune responses and increased systemic inflammation. To unravel regulatory programs behind these changes, we applied systems immunology approaches and profiled chromatin accessibility and transcriptome in peripheral blood mononuclear cells (PBMCs), and purified monocytes, B and T cells. Analysis of samples from 77 young and elderly donors revealed a novel and robust aging signature in PBMCs with simultaneous systematic chromatin closing at promoters and enhancers associated with T cell signaling, and, a potentially stochastic, chromatin opening mostly found at quiescent and repressed sites. Combined analyses of chromatin accessibility and transcriptome uncovered immune molecules activated/inactivated with aging, and identified the silencing of *IL7R* gene and the *IL-7* signaling pathway genes as potential biomarkers. This signature is borne by memory CD8+ T cells, which exhibited an aging-related loss in binding of NF- $\kappa$ B and STAT factors. Thus, our study provides a unique and comprehensive approach to identify candidate biomarkers as well as mechanistic insights into aging associated immunodeficiency.

**Persistence of differential DNA methylation related to prenatal smoking exposure and the effects on later life health outcomes.** V. Karhunen<sup>1</sup>, P. Wiklund<sup>2</sup>, M. de Silva<sup>3</sup>, R. Richmond<sup>3,4</sup>, F. Rezwan<sup>5</sup>, M. Wielscher<sup>6</sup>, J. Holloway<sup>6</sup>, A. Rodriguez<sup>1,6</sup>, S. Sebert<sup>7</sup>, C. Relton<sup>3,4</sup>, M. Järvelin<sup>1,2,7,8</sup>. 1) Department of Epidemiology and Biostatistics, Imperial College London, London, United Kingdom; 2) Center for Life Course Health Research, University of Oulu, Oulu, Finland; 3) Medical Research Council Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom; 4) School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 5) Human Development & Health, Faculty of Medicine, University of Southampton, United Kingdom; 6) School of Psychology, University of Lincoln, Lincoln, United Kingdom; 7) Biocenter Oulu, University of Oulu, Finland; 8) Unit of Primary Care, Oulu University Hospital, Oulu, Finland.

Maternal smoking during pregnancy is known to alter DNA methylation in newborns. Many of these changes appear to persist throughout childhood and into adolescence but whether they endure into adulthood is unclear. Furthermore, whether changes in offspring DNA methylation mediate the effect of smoke exposure in utero on later life health outcomes is unknown. We assessed the association between exposure to maternal smoking in pregnancy and offspring blood DNA methylation in 2,821 individuals aged between 16 and 48 years from five prospective birth cohort studies. We concentrate on 6,073 CpG sites that has been previously reported as differentially methylated in cord blood of newborns exposed to maternal smoking in utero. We also used two-sample Mendelian randomisation to estimate the effect of maternal smoking related CpG sites on disease outcomes. We found evidence of association with exposure to maternal smoking for 70 differentially methylated CpG sites ( $P$  value  $< 1 \times 10^{-7}$ ) in 36 genomic regions in adolescents and adults. All of these CpG sites showed similar direction of effects to those reported in previous studies in newborns. We found a dose-dependent effect of smoking intensity during pregnancy on offspring DNA methylation levels. Sensitivity analyses implied that the associations were neither driven by offspring's own smoking nor confounded by paternal smoking behaviour, suggesting intra-uterine mechanisms. Longitudinal analysis showed no evidence for change in direction or magnitude of the associations, indicating sustained alteration in offspring DNA methylation related to intrauterine smoking exposure. Mendelian randomisation analyses provided evidence for a causal role of four maternal smoking related CpG sites on an increased risk of inflammatory bowel diseases or schizophrenia. Our findings indicate that maternal smoking during pregnancy has long-lasting effects on offspring DNA methylation and that some of these methylation changes may act as the mechanism between maternal smoking and later-life diseases in the exposed offspring.

**A decade of epigenetic change in aging twins: Genetic and environmental contributions to longitudinal DNA methylation.** C.A. Reynolds<sup>1</sup>, Q. Tan<sup>2</sup>, E. Munoz<sup>1</sup>, J. Jylhävä<sup>3</sup>, J. Hjelmborg<sup>3</sup>, L. Christiansen<sup>2</sup>, S. Hägg<sup>3</sup>, N.L. Pedersen<sup>3</sup>. 1) Psychology, University of California Riverside, Riverside, CA; 2) University of Southern Denmark, Odense, Denmark; 3) Karolinska Institutet, Stockholm, Sweden.

Epigenetic changes may result from the interplay of exposures and genetic influences and contribute to differences in aging outcomes. However, the etiologies contributing to stability and change in DNA methylation has been rarely examined longitudinally. We considered DNA methylation across a ten-year span in two samples of same-sex aging twins: the Swedish Adoption Twin Study of Aging (SATSA, N=53 pairs), and the Longitudinal Study of Aging Danish Twins (LSADT, N=43 pairs). The average age was 62.9 and 72.5 years (SD=7.2) at each wave in SATSA and 76.2 and 86.1 years (SD=1.8) in LSADT. Data processing of methylation probes from the Illumina HumanMethylation450 array included adjustments and normalizations for cell counts and batch effects, resulting in a joint analysis set of 359,399 probes. Biometrical analyses of M-values, adjusted for age, sex and country, were fitted. Bivariate ACE and ADE Cholesky models evaluated the degree to which additive genetic (A), dominance or non-additive genetic (D), common environmental (C), and unique non-shared environmental influences (E) contributed to variation and covariation in M-values within and across time. Scalar differences in variances were modeled for the two samples. Across sites, 58.5% showed significant cross-time associations indicative of stability via genetic and/or environmental mechanisms. At  $p < 1 \times 10^{-7}$ , 1.9% sites showed significant broad genetic (A, D) or familial effects (A, C) within or across time ( $df = 6$ ), and 10.4% met  $p < 1 \times 10^{-2}$ . Genetic ( $r_A$ ,  $r_D$ ) and shared environmental correlations ( $r_C$ ) were strong across time with median values of .99, .72, and .87, respectively, versus .16 for nonshared environmental influences ( $r_E$ ). Mean broad heritability estimates were higher at baseline ( $M1 = 23.8\%$ ) than a decade later ( $M2 = 18.0\%$ ). Broad heritability estimates varied by CpG location ( $p < 2.2 \times 10^{-16}$ ) with higher estimates, at both assessments, for open-sea and shores ( $M1 = 24.5\%$ ;  $M2 = 18.6\%$ ) versus islands ( $M1 = 22.6\%$ ;  $M2 = 17.2\%$ ) and shelves ( $M1 = 23.6\%$ ;  $M2 = 17.6\%$ ). Shared environmental contributions (C) tended to be modest ( $M1 = 5.7\%$ ;  $M2 = 5.4\%$ ). Overall, results suggest genetic contributions to DNA methylation tended to be small in effect size and lessen across 10 years but contributed to stability across time. Nonshared environmental influences largely explained the unique influences emergent across the decade suggesting person-specific experiences become more salient to DNA methylation in late life.

**Mitochondrial DNA copy number (mtDNA-CN) influences nuclear DNA methylation at CpGs associated with neuroactive ligand-receptor pathway interactions.** C.A. Castellani<sup>1</sup>, R.J. Longchamps<sup>1</sup>, J.A. Sumpter<sup>1</sup>, C.E. Newcomb<sup>1</sup>, J.A. Lane<sup>2</sup>, M.L. Grove<sup>3</sup>, J. Bressler<sup>4</sup>, J.A. Brody<sup>4</sup>, J.S. Floyd<sup>4</sup>, K.D. Taylor<sup>5</sup>, A. Tin<sup>6</sup>, J. Coresh<sup>6</sup>, J.S. Pankow<sup>7</sup>, M. Fornage<sup>8</sup>, E. Guallar<sup>8</sup>, B. O'Rourke<sup>8</sup>, N. Pankratz<sup>8</sup>, N. Sotoodehnia<sup>8</sup>, E. Boerwinkle<sup>8</sup>, D.E. Arking<sup>1,8</sup>. 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Laboratory Medicine and Pathology, University of Minnesota School of Medicine, Minneapolis, MN; 3) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX; 4) Cardiovascular Health Research Unit, Department of Medicine, University of Washington, Seattle, WA; 5) Institute for Translational Genomics and Population Sciences, Los Angeles BioMedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; 6) Department of Epidemiology and the Welch Center for Prevention, Epidemiology and Clinical Research, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 7) Division of Epidemiology & Community Health, School of Public Health, University of Minnesota, Minneapolis, MN; 8) Division of Cardiology, Johns Hopkins University School of Medicine, Baltimore, MD.

Mitochondrial DNA copy number (mtDNA-CN) has been associated with a variety of aging-related diseases, including all-cause mortality. The mechanism by which mtDNA-CN influences disease may be through regulation of nuclear gene expression via the modification of nDNA methylation. Supporting this, we report the cross-sectional association of mtDNA-CN and nDNA methylation as well as experimental evidence that modulating mtDNA-CN leads to changes in nDNA methylation and expression. nDNA methylation and mtDNA-CN were derived from DNA extracted from buffy coat for 1,567 African Americans (AA) and 940 European Americans (EA) from the Atherosclerosis Risk in Communities (ARIC) study. Twenty-three and fifteen independent CpGs reached epigenome-wide significance in ARIC AA and EA cohorts, respectively. Effect estimates for significant CpGs in ARIC AA and EA were strongly correlated ( $r=0.7$ ). In addition, five significant CpGs validated in an AA cohort ( $N=239$ ) from the Cardiovascular Health Study (CHS) ( $p<0.05$ ) and 19 of the 23 CpGs showed the expected direction of effect, however this was not the case for the CHS EA cohort ( $N=294$ ) where we were not able to validate any CpGs. Mendelian randomization using methylation QTLs for mtDNA-CN associated CpGs as the mediator demonstrated that nDNA methylation at these CpGs does not directly drive alterations in mtDNA-CN ( $\beta=0.001, p=0.83$ ) and there was no enrichment of p-values. In contrast, experimental modification of mtDNA-CN through knockout via CRISPR-Cas9 of *TFAM*, a regulator of mtDNA replication, demonstrated that modulation of mtDNA-CN drives changes in nDNA methylation and gene expression of specific CpGs/transcripts. Strikingly, the 'neuroactive ligand receptor interaction' KEGG pathway was found to be the top overrepresented pathway in the ARIC meta-analysis ( $p=1.56E-03$ ), as well as *TFAM* methylation ( $p=1.35E-04$ ) and expression ( $p=4.30E-04$ ) studies. These results show that changes in mtDNA-CN influence nDNA methylation at specific loci and lead to changes in gene expression of specific genes, including those acting in the 'neuroactive ligand receptor interaction' pathway and may lead to impacts on human health and disease via altered cell signaling.

**Biological aging is associated with stress and gene expression during pregnancy.** A.K. Knight, S. Resin, V. Kilaru, D. Cobb, E.J. Corwin, A.L. Dunlop, A.K. Smith. Emory University, Atlanta, GA., USA.

Stress, the environment, and health conditions can increase rates of biological aging. Biological aging can be measured based on combinations of CpG sites or RNA transcripts, which make up epigenetic and transcriptomic clocks, respectively. The difference between biological and chronological age is termed age acceleration. As pregnancy is a time of vast physiological changes and unique stressors, we would expect pregnancy to be reflected in measures of age acceleration. We leverage data from 255 women from the Emory University African American Microbiome in Pregnancy Cohort to determine whether age acceleration changes over pregnancy. Participants provided a blood sample for DNA methylation (HumanMethylation450 or MethylationEpic) and gene expression (HT-12) analyses, cytokine panels, and glucocorticoid resistance testing between 7-14 weeks and 24-32 weeks gestation. Overall, the methylation-based predictors ( $6 < r < .63$ ;  $p < 2e-16$ ) correlated more strongly with biological age than the transcriptomic predictor ( $r=.16$ ;  $p=5.6e-7$ ). Of the four biological age predictors tested (Horvath, Hannum, Levine, Peters), only the transcriptomic-based predictor was associated with changes over pregnancy ( $t=2.8$ ,  $p=.005$ ), likely reflecting the increased stability of DNA methylation as compared to gene expression. However, age acceleration calculated from all four prediction methods was associated with concentrations of at least one inflammatory cytokine and/or glucocorticoid resistance ( $p<.05$ ). Additionally, each of these measures of age acceleration was associated with gene expression (1231-9405 transcripts;  $FDR<.05$ ), with 332 transcripts associating with all four prediction methods ( $FDR<.05$ ). Thus, changes in age acceleration based on any method are likely to be biologically relevant. Each prediction method has unique strengths which must be considered in the design studies evaluating factors that contribute to or result from biological aging.

**Effects of miRNAs that are predominantly present in young mouse plasma on myogenic differentiation and muscle regeneration.** *M. Fukuoka<sup>1</sup>, N. Ito<sup>2</sup>, S. Takeda<sup>2</sup>, H. Hohjoh<sup>1</sup>.* 1) Department of Molecular Pharmacology, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Kodaira, Tokyo, Japan; 2) Department of Molecular Therapy, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Kodaira, Tokyo, Japan.

MicroRNAs (miRNAs) that are 21~23-nucleotide-long small non-coding RNAs function as mediators in gene silencing, and play essential roles in gene regulation by inhibiting translation of messenger RNAs (mRNAs) and by digestion of mRNAs. Recently miRNAs have been found in various body fluids including plasma/serum as well as inside cells, and a part of such miRNAs appear to be enclosed in extracellular vesicles such as exosomes and be associated with RNA-binding proteins, e.g., Argonaute2. Such cell-free (extracellular) miRNAs might be implicated in cell-cell communication and be capable of becoming useful biomarkers. Aging is characterized by a progressive loss of physiological integrity, in which functional declines in physiology such as a decrease in hearing, visual acuity, muscle strength and memory skills occur. To see such aging at a molecular level, we investigated plasma-circulating (cell-free) miRNAs prepared from young (6-week-old) and aged (2-year-old) C57BL6/J mice by expression profile analyses in this study. The results indicated that the level of myogenic miRNAs, which are involved in myogenic differentiation, was higher in the plasma of young mice than in that of aged mice. In addition, young mouse serum, but not aged serum, appeared to have the potential for inducing myogenic differentiation of mouse C2C12 cells (a myoblast cell line). We investigated the effects of the miRNAs increased in young mouse serum on myogenic differentiation using C2C12 cells: miRNAs of interest were introduced into C2C12 cells and the expression of the *Myogenin* and *Myh1* genes that were used as indicators for myogenic differentiation was examined. As a result, a certain miRNA appeared to have a strong induction for myogenic differentiation relative to other examined miRNAs, and might be associated with the increase in the level of miR-1, which plays a role in gene regulation during myogenic differentiation. We further examined the effects of the miRNA on muscle regeneration in injured mice and found that cross-sectional areas of regenerating muscle fibers enlarged in the presence of the miRNA mimics, suggesting that the miRNA might be capable of enhancing muscle regeneration. Our findings suggest that the miRNA may play an important role in gene regulation during myogenic differentiation, and may be related to muscle aging.

**Vegetarian diets, circulating miRNAs and healthspan in humans.** *T. Liu, C. Wang.* Center for Genomics, Loma Linda University, Loma Linda, CA.

**Abstract:** Diet has been shown to play an intricate role in modulating lifespan and aging process through nutrient sensing pathways/systems such as insulin/IGF, mTOR and Sirtuin gene family in animal studies. However, the mechanism of how these pathways are regulated by diet remains unclear in humans. Our recent studies suggested that lifetime diet-modulated epigenomic reprogramming (i.e., DNA methylation) be associated with healthspan while it is unknown if a lifetime vegetarian diet may alter the circulating miRNA expression which may regulate healthspan in humans. We hypothesize that long-term vegetarian diet modulates circulating miRNA expression which may affect the healthspan by regulating gene expression involved in nutrient sensing pathways/systems. We exploited a large (N = 96,000) and long-standing cohort, Adventist Health Study-2 (AHS-2), a well-characterized, group of participants with detailed clinical, dietary and health outcomes follow-up data over many years. The AHS-2 study found that a long-term vegetarian diet is a major determinant of both longevity and maintenance healthspan, but the underlying molecular mechanisms are largely unknown. We have collected plasma samples from the AHS-2 cohort for ~100 subjects with different dietary patterns (vegetarian vs non-vegetarian) and have performed miRNA deep sequencing for 33 subjects out of ~100 plasma samples so far. We identified 19 differentially expressed miRNAs between two dietary groups (2 fold-change plus,  $P \leq 0.05$ ), of which several miRNAs such as miR-320d, miR-664a and miR-203a are associated with lifespan regulation. We also found several miRNAs involved in cell senescence and tumor suppression pathways, i.e., miR-127, miR-22 and miR-140 etc., which were differentially expressed between vegetarians and non-vegetarians. Overall, our study showed that certain circulating miRNAs could serve as good candidate biomarkers for lifetime vegetarian diet-modulated healthspan and longevity in humans. .

**scaRNA1 levels alter pseudouridylation in spliceosomal RNA U2 affecting alternative mRNA splicing and development.** C.K. Nagasawa<sup>1</sup>, N. Kibiriyeva<sup>2</sup>, J. Marshall<sup>2</sup>, J.E. O'Brien Jr.<sup>2</sup>, D.C. Bittel<sup>1,2</sup>. 1) Kansas City University of Medicine and Biosciences, Kansas City, MO. 64106; 2) Children's Mercy Hospital, Kansas City, MO 64108.

Vertebrate embryonic development is complex and dynamically regulated, yet only partially understood. Over the last few years, there has been a growing interest in understanding the role that alternative mRNA splicing has in regulating developmental and pathological processes. Messenger RNA splicing is carried out by the spliceosome, a multimegadalton ribonucleoprotein complex composed of 5 snRNAs (small nuclear RNAs) and multiple proteins. Small noncoding cajal body-specific RNAs (scaRNAs) biochemically modify (i.e. pseudouridylation, methylation) snRNAs and is essential for proper spliceosomal function. Our previous research suggested that biochemical modification directed by scaRNAs altered mRNA splicing and significantly impacted development. One of those scaRNAs, scaRNA1, is responsible for pseudouridylating nucleotide U89 of the U2 snRNA. Pseudouridylated nucleotides are highly conserved across species and located in functionally important areas of the spliceosome, making it necessary for proper mRNA splicing. Here we present evidence that changes in expression of scaRNA1, either in vitro or in vivo, lead to changes in pseudouridylation accompanied by changes in mRNA splicing and altered development. These experiments provide evidence supporting a new model in the regulation of embryonic development that is unappreciated and needs further investigation.

**1953W**

**Gene-environment interactions in asthma: RV and the 17q locus.** B.A. Helling<sup>1</sup>, B. Laxman<sup>1</sup>, K. Luo<sup>1</sup>, Y.A. Bochkov<sup>2</sup>, J.E. Gern<sup>2</sup>, S.R. White<sup>1</sup>, C. Ober<sup>1</sup>. 1) Human Genetics, University of Chicago, Chicago, IL; 2) Pediatrics, University of Wisconsin Madison, Madison, Wisconsin.

Asthma is the most common chronic childhood illness in the United States. Although, GWAS have identified over 30 loci, these loci explain only a small proportion of asthma risk. This is due in part to the significant contribution of environmental factors and gene-environment interactions. For example, rhinovirus (RV)-associated wheezing in early life is predictive of asthma at school age, and this risk is modified by genotype at 17q12-21, the locus most significantly associated with asthma in GWAS. To identify novel pathways involved in asthma risk and specifically RV-associated asthma risk, we developed a cell culture model using primary bronchial epithelial cells (BECs) from donated lungs not used for transplant. BECs were selected from 9 asthmatic and 9 non-asthmatic individuals. BECs were treated with RV or vehicle for 24 hours and then processed for ATAC-seq to identify regions of open chromatin. ATAC-seq peak calls from each sample were pooled to create a 'peak library' and quality reads from each sample were mapped to this peak library. Total counts per peak were tabulated for each sample. After normalization and correction for relevant covariates, linear regression was used to identify differential chromatin accessibility (DC) between asthmatics and non-asthmatics or RV and vehicle treated samples. We identified 3,531 DCs associated with asthma and 4,821 associated with RV treatment genome-wide (FDR <0.05). At the 17q locus (chr17: 37850000 – 38150000), we identified 2 asthma-associated DCs, one in the transcriptional start site of *ERBB2* and one upstream of *GSDMA*. SNPs in both genes have been associated with asthma in GWAS. The DC upstream of *GSDMA* has predictive features of a transcriptional regulator including a CpG island and binding sites for POLR2A and CTCF in a lung epithelial cell line, A549 (ENCODE). In our BEC culture model, both asthma status and RV treatment had genome-wide effects on chromatin accessibility, and we identified two DCs at the asthma-associated 17q locus. We are currently analyzing RNA-seq data on these samples for integrative analyses of gene regulation in this cell model to ultimately identify novel pathways involved in asthma. This work was supported by P01 HL070831 and U19 AI095230. B.H. is supported on T32 HL007605.

**Tissue-specific RNA editing in diversity outbred mice.** A. Srivastava<sup>1</sup>, V.K. Sarsani<sup>1</sup>, D.A. Skelly<sup>1</sup>, D.M. Gatti<sup>1</sup>, K. Choi<sup>1</sup>, N. Raghupathy<sup>1</sup>, E.J. Chesler<sup>1</sup>, M.P. Keller<sup>2</sup>, A.D. Attie<sup>2</sup>, R. Korstanje<sup>1</sup>, G.A. Churchill<sup>1</sup>. 1) The Jackson Laboratory, Bar Harbor, ME, USA; 2) The University of Wisconsin, Madison, WI, USA.

RNA editing is defined as a co- or post-transcriptional change in the sequence of RNA transcripts that can lead to increased RNA and protein diversity. In mammals there are two types of RNA editing: A-to-I editing, which occurs by deamination of adenosine converting it to inosine, and C-to-U editing, which occurs by deamination of cytosine converting it to uracil. RNA editing typically alters only a fraction of the targeted transcripts that are present in a tissue. The fraction of edited transcripts can be influenced by polymorphisms or expression variation in the editing enzymes and by polymorphisms in the target RNA. Editing efficiency can also be tissue-specific and may be influenced by extrinsic factors including sex and age. We hypothesized that a better understanding of how genetic variation in editing enzymes and their RNA targets interact with the contexts of tissue, sex, and age will shed new light on RNA editing mechanisms. To understand the tissue-specific genetic architecture of RNA-editing, we obtained RNA-Seq data from liver, kidney, heart, brain, bone, and pancreatic islet tissues from Diversity Outbred (DO) mice, a genetically diverse multiparent mouse population. We identified RNA-editing sites using a bioinformatics workflow that accounts for known genetic variations in DO mice and minimizes false positive detection. We carried out genetic association mapping of the editing ratio as a quantitative trait and identified both common and tissue-specific features of RNA editing. We found that A-to-I editing ratios are controlled primarily by genetic variation in the target RNA whereas C-to-U editing ratios are primarily associated with a genetic variation at the *Apobec1* locus on mouse chromosome 6. We found significant levels of C-to-U editing only in liver, kidney and pancreatic tissues and observed a striking tissue-specific variation in allelic effects at the *Apobec1* locus. In addition, we found that C-to-U editing in kidney is strongly influenced by sex. A-to-I editing was present across all tissues with broad conservation in the target-specific editing ratios. Bone revealed a pattern of change with age that may be explained by age-related changes in the cellular composition of the marrow compartment. In summary, this study revealed distinct genetic architectures for C-to-U versus A-to-I RNA editing; a common pattern of genetic regulation is shared across most tissues but with tissue-specific influences of genotype, sex, and age.

**A first generation map of genome-wide methylation correlation suggests long-range genomic coordination and has implications for disease-mapping.** A. Jajoo, O. Hirschi, K. Schulze, Y. Guan, N. Hanchard. Baylor College of Medicine, Select a Country.

Genome-scale assessments of DNA methylation have been used to identify disease-contributing loci in variety of human diseases, cancers, and traits. These studies have largely focused upon identifying differences in methylation level between disease and non-disease states. Methylation sites in close proximity of each other are known to have sustainable correlation structures (CSs). These inter-relational CSs are described in the literature, but their consistency across individuals and tissues, genomic context, and relevance to disease have remained unexplored. Here, we develop a novel Image Clustering Method (ICM) that leverages image conversion and correlation matrices, to assess patterns of correlated CpG loci on the commonly used Illumina 450KBeadArray. We apply our method to 28 experimentally-derived and publically-available datasets, spanning 27 tissues and 11,000 individuals. We identify 207 clusters of contiguous correlation between adjacent sites that extend a median of 709 kb; these clusters are enriched for CpG island promoters ( $P < 0.01$ ), with between 30 and 50% being conserved across tissues. We also observe significant positive and negative correlation between contiguous clusters extending as far as 250kb. These non-contiguous clusters are bound within topology-associated domains (TADs) and suggest coordinated methylation between CpG promoters, particularly at gene-clusters, as well as between histone methylation marks and promoters. Finally, we identify significant differences in cluster correlation between diseased and non-disease states, including cancer, with disease-specific patterns of disruption.

**1956W****Understanding human puberty-associated genes using 3'UTR-seq of the mouse hypothalamus and pituitary gland during postnatal development.**

*H. Hou<sup>1,2</sup>, L. Uusküla-Reimand<sup>1,3</sup>, M. Hudson<sup>1,2</sup>, C. Chan<sup>1,2</sup>, D. Sokolowski<sup>1,2</sup>, A. Roy<sup>1</sup>, K.E. Yuki<sup>1</sup>, A. Goldenberg<sup>1,4</sup>, M. Palmert<sup>1,5</sup>, M. Wilson<sup>1,2</sup>.* 1) Genetics and Genome Biology Program, Sickkids Research Institute, Toronto, Canada; 2) Department of Molecular Genetics, University of Toronto, Canada; 3) Department of Gene Technology, Tallinn University of Technology, Tallinn, Estonia; 4) Department of Computer Science, University of Toronto, Canada; 5) Department of Paediatrics, Hospital for Sick Children and University of Toronto, Canada.

The timing of human puberty is highly variable, sexually dimorphic, and associated with adverse health outcomes. It is controlled by both genetics and environmental factors. Recent genome-wide association studies (GWAS) have identified more than 300 loci that are associated with age at menarche (AAM) in women or voice breaking in men. These GWAS studies provide valuable insights into the pathways involved in regulation of pubertal onset. However, little is known about the exact function of the majority of the GWAS loci and their associated genes. To explore the role of the increasing list of GWAS-implicated genes, it is critical to understand their expression patterns. We performed transcriptome-level gene expression profiling in male and female mouse hypothalamus and pituitary at five ages during pubertal development, using an automated 3'UTR-seq method. We showed that gene expression levels obtained using 3'UTR-seq correlate well with those obtained with qPCR, supporting that 3'UTR-seq is an efficient method for large-scale profiling. We identified large numbers of developmentally regulated genes, especially between postnatal days 12 and 22. The hypothalamus undergoes a greater level of gene expression change compared to the pituitary. On the other hand, while the hypothalamus transcriptome is largely similar between male and female mice, pituitary shows abundant sex-biased gene expression patterns, especially upon the onset of puberty. Pseudotime analysis supports that the observed sexual dimorphism in timing is not due to developmental delay in female vs. male mice, but divergence in gene expression between sexes. Using time-series analysis, we identified multiple co-expression gene clusters where functions of known genes could facilitate our understanding of candidate GWAS genes. Finally, we performed small RNA-seq in the same pituitary samples and discovered few sex-biased, but abundant developmentally regulated microRNAs, which potentially contribute to the regulation of GWAS-implicated genes. Transcriptome-level gene expression profiling during mouse pubertal development in a sex- and tissue-specific manner has provided valuable insights on the potential function of GWAS-implicated genes and pathways. Moreover, our study demonstrates that large-scale transcriptome profiling is a feasible and valuable post-GWAS candidate gene prioritization approach.

**1957T**

**A fast and streamlined method for methylome insights from various DNA samples.** *I. Andreou<sup>1</sup>, R. Samara<sup>2</sup>, B. Dugan<sup>2</sup>, S. Huebner<sup>1</sup>, C. Meerschiff<sup>1</sup>, A. Piotrowski<sup>1</sup>, E. Lader<sup>2</sup>.* 1) QIAGEN GmbH, Hilden, Germany; 2) QIAGEN Sciences Inc, Frederick, MD, USA.

Epigenetic changes play a crucial role in the regulation of important cellular processes such as gene expression and cellular differentiation, and were also identified as key factors in many various diseases. The methylation of cytosines in the genome, an important epigenetic regulatory mechanism, reduces the transcriptional activity of adjacent genes. Whole genome bisulfite sequencing (WGBS), combining bisulfite-mediated conversion of un-methylated cytosine to uracil and next generation sequencing (NGS), allows the genome-wide detection of 5-methylcytosine residues at unprecedented single-base resolution and thus enables the connection between gene activity and the precise localization of a DNA methylation mark. Clinically relevant specimens for next-generation sequencing can be difficult to come by, are limited in amount, or strongly fragmented. In order to safeguard and use samples as efficiently as possible, solutions that push the limits of input amounts and DNA integrity without sacrificing sensitivity and performance are needed. Here we present a fast and streamlined workflow for optimal bisulfite treatment, and NGS library construction, which overcomes these challenges. The combination of dedicated bisulfite conversion protocols using reagents of the EpiTect Fast Bisulfite Conversion Kit and the ultra-efficient DNA repair, end-polishing and adapter ligation chemistries of the QIAseq Methyl Library Kit allows fast and efficient bisulfite conversion and NGS library preparation to accurately interrogate the methylome starting from low input gDNA, ccfDNA, FFPE-DNA, or enriched CpG islands.

**COPD and IPF overlap GWAS SNP rs2076295 regulates desmoplakin expression.** *S. Bates, F. Du, B. Pham, C. Benway, F. Guo, W. Qiu, M. Cho, X. Zhou.* Brigham and Women's Hospital, Boston, MA.

Genome-wide association studies (GWAS) have identified overlapping loci between Chronic Obstructive Pulmonary Disease (COPD) and Idiopathic Pulmonary Fibrosis (IPF), including a strong co-localized expression quantitative trait locus (eQTL) with desmoplakin (*DSP*). *DSP* is a key component of the desmosome, a cell-cell adhesion structure that links desmosomal cadherins to the intermediate filament (IF) cytoskeleton. The desmosome is widely studied in the skin and heart where the tissues are often subjected to mechanical stress. However, little is known about the localization and function of *DSP* in lung diseases. Interestingly, the same top SNP for these two lung diseases, rs2076295, shows divergent effects, with the COPD risk allele protective for IPF and vice versa. To identify the functional variants in this locus and also address the function of *DSP* in the development of COPD and IPF, we utilized CRISPR/Cas9 based techniques to knockout and overexpress *DSP*, edit rs2076295 to homozygous genotypes of its major and minor allele and observe effects, and delete a 55 base pair area containing the variant. From these experiments, we demonstrated that the rs2076295 region and variant modulate *DSP* expression. Through RNA-seq analysis of the cell lines we generated, we have identified critical signaling pathways affected by *DSP* expression involved in pathogenesis of COPD and IPF. We further examined cellular phenotypes of CRISPR-edited cells and found key regulatory functions of *DSP* important for COPD and IPF development. These mechanistic studies illuminate shared but divergent pathways in COPD and IPF.

**1959W**

**Null findings in epigenome-wide association studies: Lack of power or lack of associations?** *T. Battram, T.R. Gaunt, N.J. Timpson, G. Hemani.* MRC Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom.

For epigenome-wide association studies (EWAS) researchers have assumed DNA methylation explains some of the variance of their traits of interest. But interpretation of current and design of future studies cannot be made in an informed manner until it is known how much variation attributable to DNA methylation remains to be found. We estimated the proportion of variance related to DNA methylation at CpGs assayed by the 450k array ( $m^2_{450k}$ ) for 4847 phenotypes within the ALSPAC cohort ( $n = 941$ ), by producing DNA methylation-kinship matrices and using restricted maximum likelihood analysis implemented in LDAK. EWAS were performed on all 4847 traits and we found a relationship between number of differentially methylated probes (DMPs) identified at  $P < 1 \times 10^{-5}$  and  $m^2_{450k}$  ( $P = 3.4 \times 10^{-23}$ ). The ability for  $m^2_{450k}$  to predict the number of DMPs identified was assessed using receiver operating characteristic (ROC) curves. At low  $P$  value thresholds ( $P < 1 \times 10^{-7}$ )  $m^2_{450k}$  was no better than chance, but at higher  $P$  value thresholds (max threshold:  $P < 1 \times 10^{-3}$ ) the sensitivity and specificity increased dramatically. We then measured the proportion of total variance related ( $r^2$ ) to DMPs at varying  $P$  value thresholds ( $1 \times 10^{-4}$  –  $1 \times 10^{-7}$ ) amongst 11 traits in an independent cohort ( $n = 334$ ). As  $P$  value thresholds increased (more DMPs identified) the  $r^2$  increased. Both these findings provide evidence for a model whereby differential methylation at many CpG sites across the genome each contribute towards a small fraction of the overall association between DNA methylation and complex traits. This study explores the extent to which assayed DNA methylation variation could predict complex traits. This varied largely among traits - just among 125 metabolites measured the interquartile range = 16.3%. Unsurprisingly, it was found the greater the extent of prediction (higher  $m^2_{450k}$ ) the greater the likelihood of identifying DMPs in EWAS. This suggests that the relevance of studying differential methylation changes measured in blood varies largely, depending on the trait. It was found many DMPs contribute to the total  $m^2_{450k}$ , suggesting that for complex traits each CpG may be relevant and associate minimally with a phenotype. Thus, as for genome-wide association studies (GWAS), EWAS will have to increase sample sizes in hopes of discovering DMPs or alternatively produce accurate methods to group correlated sites.

**1960T**

**Up-regulation of SMN transcript is associated with a disease susceptibility in Weaver syndrome?** K. Hosoki<sup>1</sup>, E. Imagawa<sup>2</sup>, N. Matsumoto<sup>2</sup>, N. Okamoto<sup>1</sup>. 1) Department of Molecular Medicine, Osaka Women's and Children's Hospital Research Institute, Osaka, Japan; 2) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan.

Weaver syndrome (WS) is an overgrowth syndrome characterized by intellectual disability, limb anomalies, and abnormal muscle tone. WS is caused by a heterozygous mutation of *EZH2* gene, however, the pathogenesis in WS is still unclear. The *EZH2* is a member of polycomb repressive protein 2 (PRC2) associated with the regulation of gene transcription because of the function to mediate histone 3 lysine 27 trimethylation (H3K27me3). Recently, it is suggested that one of the transcriptional regulations with PRC2 is associated with long non-coding RNAs (lncRNAs), and there are a few reports that the transcription of disease-related genes is regulated by lncRNA-mediated recruitment of PRC2, however, this regulation mechanism is also unclear. Taken together, we herein evaluate the association between the gene transcription and PRC2 using *EZH2* mutant cells derived from a WS patient. In this study, we focused on lncRNA-related SMN transcript regulation as previously suggested. We used EBV-transformed lymphoblasts isolated from a WS patient with a heterozygous *EZH2* mutation with a decrease of H3K27me3 [Imagawa *et al.* Hum Mutat 2017]. We confirmed an increased expression level of *SMN1/SMN2* by RT-qPCR. We also detected the *SMN1/SMN2* overexpression when we performed *EZH2* knockdown using antisense oligonucleotides in HEK293 cells. Our results suggest that SMN transcriptional regulation is associated with PRC2 and/or H3K27me3, and may influence the pathogenesis in WS patients, considering that SMN deficiency leads to spinal muscular atrophy which is a severe neuromuscular disorder. In previous studies, the *SMN1* duplications were detected in amyotrophic lateral sclerosis (ALS), which is a progressive neurodegenerative disorder, and it is suggested that *SMN1* duplication is related the susceptibility of neuromuscular phenotype in ALS. The *SMN1* duplication in ALS is expected the increased expression level of *SMN1/SMN2*. Therefore, our results suggest that the up-regulation of SMN transcript is associated with the susceptibility of abnormal muscle tone in WS. We would like to examine detailed transcriptional regulation to understand the WS pathogenesis.

Germline mutations in epigenetic regulatory genes such as *DNMT3A* are commonly associated with overgrowth disorders, whereas somatic mutations are typically associated with malignancy. In order to elucidate the molecular effects of germline mutations in *DNMT3A*, we profiled genome-wide patterns of DNA methylation in *DNMT3A* p.(Arg771Gln) mutation carriers in a large sibship with Tatton-Brown-Rahman syndrome (TBRS), together with their mosaic father. We also profiled 15 other previously documented TBRS patients with distinct pathogenic *de novo DNMT3A* mutations. All TBRS patients displayed widespread reduction of DNA methylation at discrete sites across the genome, with significant overrepresentation at sites annotated to molecular pathways related to morphogenesis, development and differentiation, and pathways implicated in a predisposition to malignancy. Additionally, we performed a biological age measure using the DNA methylation age calculator. Individuals harbouring the *DNMT3A* p.(Arg771Gln) mutation, together with all other TBRS patients profiled, displayed significantly accelerated DNA methylation aging. Further to this, our profiling studies of another overgrowth disorder affecting the histone methyltransferase NSD1 (Sotos Syndrome) revealed similar accelerated epigenetic aging. Notably our studies of Kabuki syndrome, a disorder associated with poor growth resulting from pathogenic mutations affecting the *KMT2D* histone methyltransferase gene, revealed lower epigenetic age compared to their chronological age. Together, our findings provide important new insights into the role of aberrant epigenetic mechanisms and altered epigenetic aging in growth disorders such as TBRS, Sotos and Kabuki syndromes.

**Finding the missing heritability of complex disease: Optimization of the Assay for Transposase-Accessible Chromatin using Sequencing (ATAC-seq) for genome-wide examination studies.** L.R. Main<sup>1,2,3</sup>, K.L. Miskimen<sup>2,3</sup>, E.R. Chan<sup>2</sup>, H. Bai<sup>3,4</sup>, W.S. Bush<sup>2,3,4</sup>, J.L. Haines<sup>1,2,3</sup>. 1) Department of Genetics and Genome Sciences, Case Western Reserve University School of Medicine, Cleveland, Ohio 44106, USA; 2) Department of Population and Quantitative Health Sciences, Institute for Computational Biology, Case Western Reserve University School of Medicine, Cleveland, Ohio 44106, USA; 3) Institute for Computational Biology, Case Western Reserve University, Cleveland, Ohio 44106, USA; 4) Institute for Systems Biology and Bioinformatics, Case Western Reserve University, Cleveland, Ohio 44106, USA.

Although thousands of loci have been implicated in the inheritance of complex traits, in most cases a significant portion of the calculated heritability remains unexplained. One possible explanation for this missing heritability is the inheritance of epigenetic states. Studies in multiple model systems demonstrate that methylation states and histone modifications can be passed down to progeny, but these phenomena have been difficult to observe reproducibly in humans. Two significant hurdles in examining the phenomena are identifying an appropriate study population and applying a reproducible genome-wide epigenetic assay. To address the first hurdle, we can focus on an isolated founder population such as the Amish. The Amish present an ideal opportunity to study heritability because they have a relatively homogeneous environment, large and available multi-generational families, and their endogamy leads to reduced genetic variation. To address the second hurdle, we can examine chromatin accessibility using ATAC-Seq. Blood samples were obtained from an Amish nuclear family and were examined using ATAC-Seq to look at open chromatin structure. Because ATAC-Seq has been largely used to focus on specific segments of DNA, we first tested for genome-wide reproducibility. A large amount of variation was observed within this initial study, as low as 3.8% of called peaks were overlapping in technical replicates. Two more sets of experiments were then conducted to better understand the sources of the variability. The first experiment utilized multiple technical replicates of three unrelated individuals and another was performed on a synchronized cell line. We observed a high level of variability in all the ATAC-Seq experiments. Publicly available data showed similar variability to our results, with peak overlap ranging from 0.48-10.1%. This large range of variability demonstrates that ATAC-Seq is not highly reproducible with current bioinformatics techniques. Currently we are focused on optimizing the peak-calling step in the data analysis pipeline to improve the signal-to-noise ratio. Developing and refining a complete QC and analysis pipeline specifically for ATAC-Seq genome-wide analysis is important since there are very few standards on QC and downstream analysis of this method. Fully understanding the limitations of the ATAC-seq assay are critical as we begin to design studies that utilize ATAC-Seq data to examine genome-wide epigenetic inheritance in humans.

**1963T**

**Site-directed manipulation of DNA methylation in cells *In Vivo* and the effect on alternative splicing.** R. Shayevitch, D. Askayo, I. Keydar, G. Ast. Tel-Aviv University, Tel-Aviv, Israel.

Alternative splicing contributes to proteome diversity. As splicing occurs co-transcriptionally, epigenetic determinants such as DNA methylation likely play a part in regulation of alternative splicing. Previously, we have shown that DNA methylation marks exons and that a loss of DNA methylation alters splicing patterns in a genome-wide manner. To interrogate the influence of DNA methylation on splicing of individual genes, we developed a method to manipulate DNA methylation *in vivo* in a site-specific manner using the deactivated endonuclease Cas9 fused to enzymes that methylate or demethylate DNA. We used this system to directly change the DNA methylation pattern of selected exons and introns. We demonstrated that changes in the methylation pattern of alternatively spliced exons, but not constitutively spliced exons or introns, altered inclusion levels. This is the first direct demonstration that DNA methylation of exon-encoding regions is directly involved in regulation of alternative splicing.

**1964F**

**DNA methylome and whole transcriptome analyses identify genes potentially contributing to phenotypic differences in a set of monozygotic twins with Gaucher disease.** *N. Tayebi<sup>1</sup>, S. Hassan<sup>1</sup>, F. Donovan<sup>2</sup>, A. Elkahoulou<sup>2</sup>, M. Langeveld<sup>3</sup>, C. Hollak<sup>3</sup>, E. Sidransky<sup>1</sup>.* 1) NIH/ NHGRI/MGB, Bethesda, MD; 2) Cancer Genetics and Comparative Genomics core, NHGRI/NIH, Bethesda, MD; 3) Academic Medical Center, Amsterdam, The Netherlands.

Gaucher disease (GD) is an autosomal recessive disorder resulting from mutations in *GBA1*, encoding glucocerebrosidase, which leads to lysosomal accumulation of glucocerebroside. Vast phenotypic heterogeneity is observed among patients, even between monozygotic twins. Epigenetic marks such as DNA methylation may contribute to this variation. We previously described twin sisters with GD, confirmed to be monozygotic by DNA fingerprinting, who had divergent phenotypes. Mutational analysis revealed homozygosity for *GBA1* mutation N188S, c.670C>T. One sister exhibited splenomegaly, anemia and thrombocytopenia, severe bone pain, altered saccadic eye movements and complex seizures, while the second had no GD manifestations. We investigated whether epigenetic differences might underlie this phenotypic discrepancy, looking at methylation sites in the genomic DNA from each twin. Bisulfite- modification of DNA was used to discriminate between cytosine and methylated cytosine in DNA from peripheral blood. Treated DNAs were run on an Illumina HumanMethylation450 BeadChip. Data were analyzed using GenomeStudio. In the more affected twin, we identified five methylated and three demethylated genes at CpG islands (P-value= 0.01-0.001), and two differentially methylated genes in the enhancer region (P-value= 0.05-0.01). One demethylated gene, *CACNA1A*, encoding a neuronal alpha-1a subunit of a voltage dependent calcium channel, and one methylated gene, *MEST*, a member of the alpha/beta hydrolase superfamily, were validated by real time PCR using RNA extracted from both leukocytes and fibroblasts. Whole exome sequencing, performed to exclude somatic mosaicism, revealed no significant differences. A Clariom™ S transcriptome array, performed on RNA samples from the twins and three aged-matched female controls, confirmed the up- or down- regulation of genes identified on the methylation array. Differential expression of many other genes was seen, some related to *MEST* and *CACNA1A*. Both GeneMANIA pathway and Protein-Protein network (IMEX protein data base) analyses confirmed potential interactions between the proteins encoded by *GBA1*, *MEST*, *CACNA1A*, either directly or through intermediate proteins. Thus, epigenetic analyses can be used to help identify genes that influence disease manifestations and contribute to the complexity of genotype-phenotype relationships in Gaucher disease.

**1965W**

**1.1% of the global DNA is methylated in human amniotic fluid stem cells.**

*P. Upadhyaya<sup>1</sup>, I. Antonucci<sup>1,2</sup>, L. Stuppia<sup>1,2</sup>.* 1) Department of Psychological, Health and Territorial Sciences, Laboratory of Molecular Genetics, School of Medicine and Health Sciences; University of Chieti-Pescara, Chieti, Abruzzo, Italy; 2) Stem Tech Group, Center for Aging Studies (CESI); University of Chieti-Pescara, Chieti, Abruzzo, Italy.

Every phenotype of cell has their characteristic properties. These properties allow the cells to carry out their specific functions. The different lineages of the cells functionally do not match with each other. This difference is due to the different in gene expressions among the cells. It has been cleared till now that epigenetics largely controls the phenomenon by which control over the expression of genes takes place, without modifying the sequence of the DNA. There are several epigenetic mechanisms that come into play to determine the fate and behaviour of a cell. These mechanisms include DNA methylation, histones modification and regulation by micro RNA. In our research, we are focussed on quantification of methylated DNA (5-methylcytosine; 5-mC) within the total DNA of human amniotic fluid stem cells (hAFSCs), which contribute around 1% of the cell population in amniotic fluid and show multipotent characteristics with the ability to differentiate into cells of all three germ layers. The global DNA methylation quantification was performed on the nuclear DNA extracted from hAFSCs using MethylFlash Methylated DNA Quantification kit-Colorimetric (Epigenetek; USA) by following manufacturer's protocol. The kit uses optimised antibody and enhancer solutions to allow high specificity to 5-mC, with no cross-reactivity to unmethylated cytosine and no or negligible cross-reactivity to hydroxymethylcytosine. Our results found consistent 5-mC in all the five hAFSC lines. The mean 5-mC was found to be  $1.11 \pm 0.03$  %. Statistical analysis showed the data to be significant (two-tailed P value= < 0.0001, coefficient of variation = 2.83%). Interestingly, our results also suggest that difference in passage number does not change the amount of 5-mC, which implies that the methylation remains almost equal among the cells with the different number of cell divisions. In conclusion, global DNA methylation quantification may be used as the marker to identify the lineage and functional ability of any cell type. More research is necessary to quantify the global methylation of the DNA in all the human normal and cancerous cell types to identify epigenetic differences in normal and pathological cell types.

**1966T****Incorporate measurement errors in epigenome-wide association studies.**

W. Guan<sup>1</sup>, Y. Bai<sup>1</sup>, J.S. Pankow<sup>1</sup>, E.W. Demerath<sup>1</sup>, J. Bressler<sup>2</sup>, M.L. Grove<sup>2</sup>, M. Fornage<sup>2</sup>. 1) University of Minnesota, Minneapolis, MN; 2) The University of Texas Health Science Center at Houston, Houston, TX 77030.

Genome-wide DNA methylation measures are now routinely used to investigate their association with various outcomes of interest. Inherent to the array-based DNA methylation measures, e.g., Illumina HumanMethylation450 (HM450) or Infinium MethylationEPIC chips, is the associated technical variation of non-biological interest. One example of such variation is the bead-to-bead variation due to the use of multiple beads on HM450 or EPIC arrays. These technical variations can be viewed as measurement errors, and are commonly ignored in downstream association analysis. We have proposed a novel statistical framework to take into account of these measurement errors. Specifically, we used a mixed effects model to quantify the measurement error, and developed an expectation-maximization (EM) algorithm to estimate the model parameters. We applied our proposed method to the Atherosclerosis Risk in Communities (ARIC) methylation data ( $n = 2,843$ ; HM450 array) in an epigenome-wide association study of smoking status, after accounting for the bead-to-bead variation. We identified 14 additional CpG sites associated with smoking, at sites with high technical variation (intraclass correlation coefficient  $< 0.4$ ). We expect that our new method can improve statistical power of association tests and accuracy of parameter estimates in future epigenome-wide association studies (EWASs) using methylation arrays.

**1967F****Estimating cell type abundance in GTEx enables insights into cellular mechanisms and origins of eQTLs.**

F. Aguet<sup>1</sup>, S. Kim-Hellmuth<sup>2</sup>, M. Oliva<sup>3</sup>, M. Muñoz-Aguirre<sup>4</sup>, J. Quan<sup>5</sup>, V. Wucher<sup>5</sup>, H.S. Xi<sup>5</sup>, B.E. Stranger<sup>3</sup>, T. Lappalainen<sup>2</sup>, R. Guigó<sup>4</sup>, K.G. Ardlie<sup>1</sup>, GTEx Consortium. 1) Broad Institute, Cambridge, MA; 2) New York Genome Center, NY, NY; 3) U Chicago, Chicago, IL; 4) CRG, Barcelona, Spain; 5) Pfizer Inc, Cambridge, MA.

The Genotype-Tissue Expression (GTEx) project has identified expression quantitative trait loci (cis-eQTLs) for the majority of genes across a range of human tissues. However, the interpretation of these eQTLs has been limited by the complex cell type composition of GTEx tissue samples. Here, we applied gene expression-based deconvolution approaches to estimate the cellular composition of GTEx tissues, based on gene expression profiles of 17,382 RNA-seq samples from 838 individuals across 49 tissues (v8 data release). We found that highly abundant cell types were robustly estimated across multiple methods and were consistent with cell types expected to be present in different tissues. Cell type composition explained a large part of inter-individual variation in gene expression, and provided insights into cellular events associated to pathological changes in GTEx individuals. To demonstrate that computationally inferred cell type abundances can be used as proxies to identify cell-specific eQTLs, we used neutrophil estimates from GTEx whole blood RNA-seq data (670 individuals) to identify cell type-interacting eQTLs (i-eQTLs). We found 1258 genome-wide significant (FDR 5%) i-eQTLs interacting with neutrophil abundance; these showed good replication of eQTLs identified in purified neutrophils. Notably, 14% of neutrophil i-eQTLs had a nominal whole blood cis-eQTL p-value  $> 0.05$ , implying that a significant fraction of cell type-specific eQTLs is undetectable when studying heterogeneous bulk tissue expression. Finally, colocalization analysis of neutrophil i-eQTLs with multiple immune-related diseases not only pinpointed the cellular origin of known whole blood eQTLs, but identified novel colocalized loci that were masked in bulk tissue. Taken together, our results emphasize the importance of identifying genetic effects on gene expression at the cellular level, and demonstrate that cell type-specific effects can be uncovered in bulk tissues by integrating increasingly available single-cell and cell type-specific transcriptomic data. The GTEx tissues provide a unique opportunity to expand this approach to immune and stromal cell types in tissues where cell-specific eQTLs have not yet been characterized.

**1968W**

**Validation of causal variants underlying eQTLs in LCLs and iPSCs by CRISPR/Cas9 genome editing.** *KA. Barr<sup>1</sup>, Y. Gilad<sup>2</sup>.* 1) Section of Genetic Medicine, University of Chicago, Chicago, IL, USA; 2) Department of Human Genetics, University of Chicago, Chicago, IL, USA.

Expression quantitative trait loci (eQTLs) connect natural variation to functional changes in gene expression and provide an essential link between genotype and disease risk. To date, hundreds of thousands of eQTLs have been identified in diverse human tissues. In the majority of cases, linkage disequilibrium precludes the identification of the true causal variant underlying these eQTLs. While fine mapping, hierarchical models and reporter assays have been used to prioritize variants, these methods cannot prove causality. It is now possible to directly assess the consequence of individual variants using precise genome editing. Currently, only a handful of causal variants have been confirmed with these methods. To address this need, we are directly testing the effects of several genetic variants underlying tissue-specific eQTLs. These eQTLs are active in either lymphoblastoid cell lines or induced pluripotent stem cells. Each variant is likely to be causal according to a Bayesian hierarchical model that incorporates chromatin state and transcription factor footprints. Using CRISPR/Cas9 and template-directed genome repair, we are generating cell lines that differ at only the variants in question. We will then assess the consequences of these variants on gene expression using qPCR. These results will provide validation and serve as a benchmark for past and future eQTL studies. In addition, we expect that the identification of causal variants will open the door to future inquiries on molecular mechanisms that underlie differences in gene expression between individuals and tissues types.

**1969T**

**Validation of cis-regulatory transcript variants using fine-mapping and CRISPR/Cas9 genome editing.** *M. Brandt<sup>1,2</sup>, F. Hormozdiazari<sup>3,4</sup>, A. Vasileva<sup>1,2</sup>, T. Lappalainen<sup>1,2</sup>.* 1) Department of Systems Biology, Columbia University, New York, NY; 2) New York Genome Center, New York, NY; 3) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute of Massachusetts Institute of Technology (MIT) and Harvard, Cambridge, MA.

Expression quantitative trait loci (eQTL) studies in humans have identified thousands of common genetic variants associated with gene expression levels. However, due to linkage disequilibrium, the true causal variants and therefore the molecular mechanisms remain mostly unknown. Furthermore, functional effects of rare variants are often challenging to detect in population studies. In this study, we have developed a scalable CRISPR-based assay for experimental assessment of regulatory effects of genetic variants in transcribed regions. We have applied this method to rare protein-truncating variants and eQTLs from the GTEx project. First, we utilized CRISPR/Cas9 to introduce nine rare stop-gained SNPs from GTEx into human cells. These variants are expected to trigger nonsense mediated decay, resulting in a reduction in transcripts which contain the alternative variant. We transfected Cas9-inducible 293T cells with gRNAs and single stranded homologous templates specific to each variant. After editing, we extracted mRNA and gDNA from the pool of edited cells and performed targeted sequencing. A difference in the representation of the edited variant in gDNA versus mRNA confirms its effect on transcript abundance. Compared with matched controls, the stop-gained variants show a significant allele-specific reduction in transcript abundance ( $p = 7.8e-3$ ). This demonstrates our ability to detect the effects of causal regulatory variants on gene expression, which can be applied in the future to testing whether rare variants of interest trigger nonsense-mediated decay. Next, we applied the same method and principles to validate common eQTLs found in the general population. Starting with 15,219 fibroblast eGenes from 483 individuals in the GTEx v8 data, we selected 189 eGenes for experimental validation of the causal variant. We focused on genes with good statistical fine-mapping, demonstrated as a CAVIAR fine-mapping posterior probability of greater than 0.8 for at least one SNP inside the transcript. Additionally, genes were selected for relatively high effect size and gene expression in HEK293 cells. The putative causal variants from these eGenes are being experimentally tested, followed by analysis of statistical fine-mapping accuracy and regulatory annotation overlap of causal variants. Altogether, our method allows scalable experimental confirmation of putative causal regulatory variants, and improved interpretation of regulatory variation in humans.

**1970F**

**Human cytomegalovirus UL23 protein regulates transcription of interferon- $\gamma$ -stimulated genes.** H. Li<sup>1</sup>, L. Feng<sup>1</sup>, C. Foo<sup>1</sup>, S. Wu<sup>1</sup>, Y. Ran<sup>1</sup>, X. Yang<sup>1</sup>, T. Zhou<sup>1</sup>, Z. Deng<sup>1,2</sup>. 1) Dept. of Biotechnology, Jinan University, Guangzhou, Guangdong, China; 2) Keck School of Medicine, University of Southern California, Los Angeles, CA.

Human cytomegalovirus (CMV), a member of the human herpesvirus family, is a common opportunistic virus causing severe ailments and deaths in people with immature or compromised immune systems. HCMV expresses viral proteins to modulate the host immune responses at every step of its life cycle, which play a crucial role in viral pathogenesis. Interferons (IFNs) are part of the innate immune response to viral infections and confer potent antiviral effects. These cytokines also have important roles in immune-surveillance for malignant cells. Interferon- $\gamma$  (IFN- $\gamma$ ) responses are vital for a host to combat infections of many human viruses including human herpesviruses. Upon treatment of IFN- $\gamma$ , transcription of many genes responsible for IFN- $\gamma$  immune responses is activated primarily by the signal transducer and activator of transcription (STAT) proteins such as STAT1 protein. UL23 is a virion protein found in the tegument and is expressed in the cytoplasm in HCMV-infected cells. However, UL23 is dispensable for viral replication in cultured cells and little is currently known about its function. In this study, we observed (a) UL23 significantly reduced levels of STAT1 in the nuclei, the sites where these proteins act to induce transcription of IFN- $\gamma$  stimulated genes, and (b) decreased levels of the induction of the transcription of IFN- $\gamma$  stimulated genes. UL23-deficient HCMV mutants induced higher transcription of IFN- $\gamma$  stimulated genes and exhibited lower titers than parental and control revertant viruses expressing functional UL23 in IFN- $\gamma$  treated cells. Our results highlight the roles of UL23 in facilitating viral immune escape from IFN- $\gamma$  responses and enhancing viral resistance to IFN antiviral effects.

**1971W**

**Novel regulators of *CFTR* gene expression in airway epithelial cells.** M. NandyMazumdar, S. Yin, M. Mutolo, S-H. Leir, A. Harris. Department of Genetics and Genome Sciences, Case Western Reserve University School of Medicine, Cleveland, OH.

The cystic fibrosis transmembrane regulator (*CFTR*) gene is subject to complex regulation by multiple mechanisms including the recruitment of both activating and repressive transcription factors (TFs), which coordinate cell-type-specific chromatin looping at the locus. Within a topologically associated domain (TAD), multiple *cis*-elements regulate *CFTR* gene expression by looping to the promoter and/or to sites of CTCF occupancy at the TAD boundaries. Though lung disease is key feature of Cystic Fibrosis (CF), *CFTR* expression in the airway is substantially lower than in the pancreas or the intestine. Moreover, although the TAD boundaries are conserved among diverse cell-types; different cell lineages utilize specific regulatory elements for optimal gene expression. Our previous work established several airway-specific DNase hypersensitive sites (DHS) which encompass enhancers. Of these, 2 major enhancers identified at the -35 and -44 kb DHS with respect to the promoter, may serve important regulatory roles; thereby maintaining the required cell-type selective *CFTR* expression profiles. In addition to cell-specificity; these enhancers demonstrated cooperativity and binding of several important TFs including Interferon regulatory factors 1 and 2 (IRF1, IRF2) and nuclear factor (erythroid-derived 2)-like 2 (Nrf2) at the -35 and -44 kb sites respectively. In order to determine their function, we used CRISPR/Cas9 technology to delete these sites in the 16HBE14o human bronchial epithelial cell line. Here we successfully excised these 2 airway-specific enhancers from multiple cell clones. Interestingly, the enhancer-deleted clones demonstrated almost complete loss of *CFTR* expression as measured by RT-qPCR assays, suggesting that these *cis*-regulatory elements may be critical in airway *CFTR* transcription. Moreover, we are examining the impact of loss of each element on higher order locus architecture by 4C-seq. Concurrently new candidate transcription factors that activate *CFTR* expression in airway epithelial cells were identified in an siRNA screen targeting 1500 TFs and chromatin modifying factors. Current experiments are combining ChIP-seq with RNA-seq following TF depletion for candidate factors, to determine direct and indirect mechanisms of *CFTR* regulation. These data will also enhance our understanding of the transcriptional networks in human airway epithelial cells, which are pivotal to several common lung diseases. .

**1972T**

**Regulatory role of chromosome 11p13 in cystic fibrosis lung disease severity.** H. Swahn, K-M. Lamar, J. Sabith Ebron, S. Yin, M. NandyMazumdar, S-H. Leir, A. Harris. Department of Genetics and Genome Sciences, Case Western Reserve University School of Medicine, Cleveland, OH.

Mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene cannot fully explain lung disease phenotype in cystic fibrosis (CF). Previous genome-wide association studies identified genomic regions associating with CF lung disease severity; among these the highest p-value single nucleotide polymorphisms mapped to an intergenic region at chromosome 11p13. This interval lies between the E74-like factor 5 (*ELF5*) and Ets-homologous factor (*EHF*) genes, and Apaf-1 interacting protein (*APIP*) gene. *ELF5* is thought to confer asthma susceptibility in certain populations, and *EHF* regulates response to injury and inflammation in the lung. *APIP* is a methionine salvage enzyme involved in apoptosis. Our goal is to determine the functional significance of this region, which is predicted to be regulatory. Our previous work established that the 11p13 modifier region contains specific sites of open and active chromatin and encompasses airway selective *cis*-regulatory elements. Two of these elements, DHS11.2516 and 11.2521, encompass enhancers of the *ELF5* and *EHF* promoters, but not *APIP*. Furthermore, we showed that 11p13 is contained within a topologically associated domain (TAD), and the *APIP* promoter lies outside of this TAD. Our results focus attention on the likely role of *ELF5* and/or *EHF* in modifying CF lung disease severity. We hypothesize that these epithelial selective genes are regulated by *cis*-elements found at 11p13, and that dysregulation of these genes contributes to CF lung disease severity. Here we used CRISPR/Cas9 technology to remove the two enhancer elements from the endogenous region in airway epithelial cells. We found that deletion of 11.2516 increased expression of several genes at 11p13 and altered locus architecture, but deletion of 11.2521 had no apparent impact. Moreover, we are using nuclease dead Cas9 (dCas9) fused either to VP64, p65 and Rta, or to KRAB and SID, to activate or repress, respectively, promoters and *cis*-regulatory elements across 11p13 in human airway epithelial cells. These experiments will connect critical *cis*-regulatory elements with the individual genes at 11p13 and may reveal the molecular mechanism underlying the role of this region in modifying lung disease severity. Key processes such as epithelial cell barrier function, migration, proliferation and apoptosis will be assayed. These data will show how non-coding variants at 11p13 impact CF lung pathology.

**1973F**

**Epigenetic marks at major histocompatibility complex affect male fertility.** S. Sarkar, S. Rajender. Endocrinology Division, CSIR-Central Drug Research Institute, Sector 10, Jankipuram Extension, Sitapur Road, Lucknow, Uttar Pradesh 226031.

Human leucocyte antigens are membranous glycoproteins playing salient role in immune recognition and response. The expression pattern of HLA class antigens is dubious in nature. However, quite a number of studies have reported the expression of HLA class molecules. Trophoblastic *HLA-C* gene variants have been shown to be associated with preeclampsia in African and European women. Maternal *HLA-C* genetic variants are also seen to have effect on high fetal and maternal mortality and morbidity. HLA class 1 molecules were found to be expressed in spermatozoa of infertile patients but showed no significant difference against fertile groups. On the other hand, it was found that mRNA levels of *HLA-G* in normal spermatocytes were significantly higher than the testicular samples with only Sertoli cells and/or spermatogonia, which suggests its involvement in spermatogenesis. A study observed that the predisposition to antisperm antigen can increase the levels of some HLA class1 antigen in vasectomized men. A whole genome epigenetic study on adolescent chemotherapy patients causing infertility also showed differential methylation pattern in *HLA-C* gene. We investigated differential methylation regions present in different classes of *HLA* in patients with different sperm count in order to correlate epigenetic patterns with sperm production ability. To achieve this objective, our experimental method included isolation of sperm DNA from individuals of various sperm count groups followed by Infinium 450K DNA methylation array. Among these groups we have identified six different classes of *HLA* genes to be differentially methylated. *HLA* class I genes showed higher level of methylation in oligospermic group as compared to normospermics, suggesting the potential role of these genes in spermatogenesis. Similar methylation pattern was also seen in DNA from PBMCs. Out of all immune response gene only *HLA-DRB1* showed disparate methylation pattern in oligospermics (bvalue=0.345) than normal men (bvalue=0.679). This DNA methylation pattern suggests an important role of these immune responsive genes in sperm production. These observations opened a valuable insight into the cause of infertility which directs the focus to select best sperm for fertilization success. However, more epigenetically focused experimental designs are warranted to draw conclusive insights and theories about the role of immune response genes and reproductive health.

**1974W****Epigenetics of cyanogenic toxicity of dietary origin: The model of konzo.**

K. Kocher<sup>1,2</sup>, M. Bramble<sup>1,2</sup>, N. Vashist<sup>1,2</sup>, S. Bhattacharya<sup>1,2</sup>, K. Panchapakesan<sup>1,2</sup>, S. Knoblach<sup>1,2</sup>, D. Tshala-Katumbay<sup>3,4</sup>, E. Vilain<sup>1,2</sup>. 1) The George Washington University, Washington, DC; 2) Children's National Research Institute, Washington, DC; 3) Oregon Health & Science University, Portland, OR; 4) University of Kinshasa, Kinshasa, DRC.

The consumption of poorly processed cyanogenic bitter cassava, a vital staple in the diet of over 600 million people around the globe, is associated with konzo, an irreversible, non-progressive motor neuron disease. Dietary cyanide toxicity results in a considerable burden on Public Health in sub-Saharan Africa, affecting up to 5% of the population in certain regions, with numerous individuals affected with chronic motor and cognitive disabilities. Yet the underlying biological mechanisms of this toxicity remain poorly understood. While certain risk factors such as malnutrition and young age are associated with konzo onset, there has been no comprehensive mechanistic approaches to understanding the etiology or susceptibility factors associated with konzo. Not all individuals who consume cyanogenic cassava develop konzo, suggesting that certain epigenetic factors may be associated with disease onset. We hypothesize that the exposure to cyanogenic factors present in the cassava result in durable epigenetic changes affecting long term neurologic development. To test this hypothesis, we investigated the global DNA methylation differences associated with konzo-affected youth in comparison to age-matched healthy controls from the same outbreak zones of the Democratic Republic of Congo. We noted that there were approximately 60,000 differentially methylated regions among the genomes of konzo-affected youth and healthy controls, many of which are enriched for biological processes of interest in the context of konzo etiology, including metabolic and neurological pathways that may be influenced by cyanogenic cassava consumption. Additional investigation of transcriptomic level changes that are involved with the susceptibility to and pathobiology of konzo through dietary cyanogen exposure is underway. Understanding the genomic and epigenomic landscape of konzo will provide invaluable insights into dietary cyanogen metabolism, and will have a high impact from a global health perspective, as the metabolism and associated neurodegenerative and cognitive effects of dietary cyanogen could affect millions of individuals around the world.

**1975T****Integrative genomic analysis of microRNA transcriptional responses to malaria infection.**

A. Diawara<sup>1</sup>, M.M. Dieng<sup>1</sup>, V. Manikandan<sup>1</sup>, H. Tamin El Jarkass<sup>1</sup>, R. Eteer<sup>1</sup>, A.B. Tiono<sup>2</sup>, S.B. Sirima<sup>2</sup>, I. Soulama<sup>2</sup>, Y. Idaghdour<sup>1</sup>. 1) New York University, Abu Dhabi, United Arab Emirates; 2) Centre National de Recherche et Formation sur le Paludisme, Ouagadougou, Burkina Faso.

Joint analysis of clinical phenotypes, genotypic and gene expression data emerged as a promising approach to map complex diseases. We used this approach to address the sources of variability of global miRNA gene expression in 121 whole blood samples collected from West African children sampled before and during *Plasmodium falciparum* infection and after treatment. Genome-wide expression profiling revealed 95 miRNAs responsive to infection and 72 miRNAs associated with parasite load. Cross-correlation of infection-responsive miRNAs with host total RNA from the same individuals pinpoints miRNAs and target mRNAs involved in key immune response pathways. Furthermore, using whole-genome sequencing data we have conducted a genome scan for miRNA eQTLs and identified genetic variants associated with infection-responsive miRNAs and discovered several cases of genotype-by-infection interactions. The novel insight gained from this study elucidates the roles of miRNA and regulatory variation as mediators of host response to malaria infection and highlights the power of systems genetics approaches in infectious disease. .

**Regulatory network of transcription factors determining CYP3A4 expression: Identified with mathematical modeling and CRISPR-mediated genome editing.** D. Wang<sup>1,4</sup>, R. Lu<sup>2</sup>, G. Rempala<sup>3</sup>, W. Sadee<sup>4</sup>. 1) Department of Pharmacotherapy and Translational Research, College of Pharmacy, University of Florida, PO Box 100486, 1345 Center Drive MSB PG-05B, Gainesville, FL32610; 2) Department of Clinical Sciences, Bioinformatics Core Facility, University of Texas Southwestern Medical Center, Dallas, Texas 75235; 3) Mathematical Bioscience Institute, The Ohio State University, Columbus, OH43210; 4) Center for Pharmacogenomics, Department of Cancer Biology and Genetics, The Ohio State University, Columbus, OH43210.

CYP3A4 is the predominant drug metabolizing enzyme in the liver. CYP3A4 expression and enzyme activity displays large inter-person variability with unknown causes, substantially affecting individual drug exposure and therapeutic outcomes. The expression of CYP3A4 is controlled by several liver enriched transcription factors (TFs), but how these TFs interact with each other to regulate CYP3A4 expression remains unknown. We hypothesize that several key TFs are critical to CYP3A4 expression through a regulatory network with nonlinear, dynamic, and hierarchical interactions. To resolve this complex interactive system, we use existing liver gene expression microarray data (GSE9588) and a novel mathematical modeling approach, global sensitivity analysis or Sobol indices (SI). This approach successfully converges on a network of TFs critical to CYP3A4 expression and identified interacting TF pairs, triplets and quadruplets. Some of the key factors are known, while others are novel as CYP3A4 regulators. ESR1 emerges as the key TF with the strongest main effects and the most frequently included interacting partner. Consistent with this result, CRISPR-mediated gene knockout or siRNA/shRNA gene knockdown of *ESR1* decreased CYP3A4 expression, while CRISPR-mediated transcriptional activation of *ESR1* increased CYP3A4 expression. Moreover, ESR1 also regulate the expression of other TFs known to regulate CYP3A4 expression. These results validate ESR1 playing critical roles in CYP3A4 expression. As the role of ESR1 was detectable in both male and female livers and no estrogen was added, the results demonstrate a role for unliganded ESR1 in CYP3A4 expression, consistent with the known transcriptional role of unliganded ESR1 in other cells.

**Characterization of the nuclear and cytosolic transcriptomes in human brain tissue reveals new insights into the subcellular distribution of RNA transcripts.** L. Feuk<sup>1,2</sup>, A. Zaghool<sup>1,2</sup>, A. Niazi<sup>1,2</sup>, A.K. Björklund<sup>3</sup>, J. Orzechowski Westholm<sup>4</sup>, A. Ameer<sup>1,2</sup>. 1) Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden; 2) Science for Life Laboratory in Uppsala, Uppsala University, Sweden; 3) Department of Cell and Molecular Biology, National Bioinformatics Infrastructure Sweden, Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 4) Department of Biochemistry and Biophysics, National Bioinformatics Infrastructure Sweden, Science for Life Laboratory, Stockholm University, Stockholm, Sweden.

Transcriptome analysis has mainly relied on analyzing RNA sequencing data from whole cells, overlooking the impact of subcellular RNA localization and its influence on our understanding of gene function, and interpretation of gene expression patterns in cells. Here, we performed the first comprehensive analysis of cytosolic and nuclear transcriptomes in human fetal and adult brain samples. We show significant differences in RNA expression for protein-coding and lncRNA genes between cytosol and nucleus. Transcripts displaying differential subcellular localization belong to particular functional categories and display tissue-specific localization patterns. We also show that transcripts encoding the nuclear-encoded mitochondrial proteins are significantly enriched in the cytosol compared to the rest of protein-coding genes. Further investigation of the reliability of using the cytosol or the nucleus for differential gene expression analysis in single cell experiments as a proxy for whole transcriptome indicates important differences in results depending on the cellular compartment used for analysis. These differences were manifested at the level of transcript category and number of differentially expressed genes. Our data provides the first resource of RNA subcellular localization of RNA in human brain and highlight the influence of using the cytosol and the nucleus in interpreting and comparing results from single cell studies.

**The accessible chromatin landscape of the hippocampus at single-cell resolution.** K.A. Torkenczy<sup>1</sup>, J. Sinnamoni<sup>2</sup>, M. Linhoff<sup>3</sup>, S. Vitak<sup>4</sup>, H. Pliner<sup>5</sup>, C. Trapnell<sup>3</sup>, F. Steemer<sup>4</sup>, G. Mandel<sup>3</sup>, A.C. Adey<sup>1,5</sup>. 1) Molecular and Medical Genetics, Oregon Health and Science University, Portland, OR; 2) Vollum Institute for Neuroscience, Portland, OR, USA; 3) University of Washington, Department of Genome Sciences, Seattle, WA, USA; 4) Illumina, Inc., San Diego, CA, USA; 5) Knight Cardiovascular Institute, Portland, OR, USA.

The hippocampus is a major component of the vertebrate brain. It is made up of anatomically and functionally distinct regions composed of multiple cell types that play a critical role in the formation and retrieval of episodic and spatial memory. However, the complex nature of this brain region poses a challenge in its accurate characterization. Cell type specific differences are lost due to the averaging of properties of cells comprising the tissue. Single-cell studies address this problem by identifying individual cells based on their relative occupied place in the landscape laid out by types and cell states within the assessed tissue. Recent single-cell transcriptional profiling in the hippocampus has demonstrated this by recapitulating cell types previously defined based on morphology. While RNA profiling provides valuable information on transcript abundance, it misses other regulatory factors that define the epigenetic state of cells, such as enhancers. There are up to an order more of such highly tissue and cell-type specific regulatory elements than transcripts in a cell. Single-cell Combinatorial Indexed Assay-for-Transposase-Accessible-Chromatin (sci-ATAC-seq) allows for the accurate description of the single-cell regulatory landscape through the mapping of promoter and enhancer accessibility and the identification of putative cell-state specific DNA binding transcription factor proteins. We applied sci-ATAC-seq to produce 2,346 high-quality single-cell chromatin accessibility maps with a mean unique read count per cell of 29,201 from both fresh and frozen hippocampi; observing little difference between the preparations. Using this dataset, we identified eight distinct major clusters of cells representing both neuronal and non-neuronal cell types and characterized the driving regulatory factors and differentially accessible loci that define each cluster. We then applied a recently described co-accessibility framework to identify co-regulated elements, which produced 487,156 links in a cell-type specific context, including 146,818 distal-promoter peak associations. Lastly, we carried out an additional sci-ATAC-seq preparation from cultured hippocampal neurons (899 high-quality cells, 43,532 mean unique reads) and revealed substantial alterations to their epigenetic landscape when compared with primary tissue.

**1979F**

**WBSCR22: A genetic basis for lateralization of the magnocellular visual system?** D.L. Mills<sup>1</sup>, L. Dai<sup>2</sup>, J.R. Korenberg<sup>2</sup>. 1) School of Psychology, Bangor University, Bangor, Wales, United Kingdom, United Kingdom; 2) The Brain Institute Department of Pediatrics University of Utah 36 South Wasatch Drive, SMBB 4205 Salt Lake City, UT 84112-5001.

Investigating the role of genes in cognition and brain activity is of considerable interest across disciplines. However, correlational approaches can present a variety of methodological problems including false-positives. Here we propose a basic multi-level model for approaching genetic studies of human cognition. Research in Williams syndrome (WS), a neurodevelopmental disorder caused by a deletion of approximately 25 genes on chromosome 7, has identified a small set of candidate genes associated with specific social and cognitive functions. Recent findings suggest specific genes are linked with socio-cognitive brain activity as indexed by event-related potentials (ERPs) via cases with full and partial deletions in the WS region. Many neurodevelopmental disorders, including WS, are associated with selective vulnerabilities in magnocellular/dorsal stream visual processing. The role of specific genes in this process are examined in four lines of converging evidence using WS as a model. Study 1 examined differential neural activation of the magnocellular and parvocellular pathways as indexed by event-related potentials (ERPs) in a large sample of adults with the full deletion for WS, including FKBP6 through GTF2IRD1. The results suggested that individuals with WS have increased sensitivity of the left and decreases sensitivity to the right hemisphere to direction of motion, whereas activation of the parvocellular pathway did not differ from controls. Study 2 examined the role of specific genes, in ERP amplitudes to direction of motion in individuals with smaller WS deletions. The results suggested that sparing of genes from WBSCR22 and left towards FKBP6 were associated with typical ERP right hemisphere asymmetries to direction of motion. Study 3 correlated gene expression and methylation with ERP amplitudes linked to lateralization of magnocellular activity in individuals with the full deletion for WS using gene expression and methylation techniques. The results showed that expression and methylation of WBSCR22 were correlated with the right hemisphere ERP asymmetry to direction of motion. Study 4 examined expression of WBSCR22 in the visual cortex in the non-human primate brain. Taken together the findings showed converging evidence across levels that WBSCR22 is linked with lateralization of function for the magnocellular pathway. This is the first study to link specific genes with activation of separate pathways in visual stream processing.

**Genetic effects on promoter usage are highly context-specific and contribute to complex traits.** *K. Alasoo<sup>1,2</sup>, J. Rodrigues<sup>2</sup>, J. Danesh<sup>2,3,4,5</sup>, D.F. Freitag<sup>2,3,4</sup>, D.S. Paul<sup>2,3,4</sup>, D.J. Gaffney<sup>2</sup>*. 1) Institute of Computer Science, University of Tartu, Tartu, Estonia; 2) Wellcome Sanger Institute, Wellcome Genome Campus, Hinxton, Cambridge CB10 1SA, UK; 3) BHF Cardiovascular Epidemiology Unit, Department of Public Health and Primary Care, University of Cambridge, Cambridge CB1 8RN, UK; 4) British Heart Foundation Centre of Excellence, Division of Cardiovascular Medicine, Addenbrooke's Hospital, Cambridge CB2 0QQ, UK; 5) National Institute for Health Research Blood and Transplant Unit (NIHR BTRU) in Donor Health and Genomics, Department of Public Health and Primary Care, University of Cambridge, Cambridge CB1 8RN, UK.

Genetic variants regulating RNA splicing and transcript usage have been implicated in both common and rare diseases. However, identifying specific transcriptional effects of these variants remains challenging, partly because reference transcriptomes are incomplete and contain many truncated transcripts that lack annotated 3' or 5' ends. We developed a novel analytical approach to overcome these limitations by stratifying transcript annotations into three separate components: promoters, internal exons and 3' ends. We apply our method to genotype and RNA-seq data from human macrophages exposed to a range of inflammatory stimuli (IFN $\gamma$ , Salmonella, IFN $\gamma$  + Salmonella) and a metabolic stimulus (acetylated LDL), obtained from up to 84 individuals. We found that over half of the quantitative trait loci (QTLs) colocalising with complex traits were identified only at the transcript level with no detectable effect on total gene expression. Furthermore, 55% of the transcript-level associations regulated either promoter or 3' end usage, many of which are missed by methods that only quantify exon-exon junctions. Finally, we demonstrate that promoter-usage QTLs have distinct genetic architecture and are 50% more likely to be context-specific than alternatively spliced internal exons. In summary, we highlight how different RNA-seq quantification approaches capture distinct aspects of transcription and that characterizing the full spectrum of transcriptional consequences of genetic variation requires a combination of analytical strategies.

## 1981T

**Accurate prediction of chromatin conformation status using deep neural network model.** *H. Uryu<sup>1</sup>, K. Hata<sup>2</sup>*. 1) Medical Genome Center, National Center for Child Health and Development, Japan, Tokyo, Tokyo, Japan; 2) Department of Maternal, Fetal Biology, National Center for Child Health and Development, Japan, Tokyo, Tokyo, Japan.

Chromatin conformations in nuclei play an important role in regulating gene expression, and many reports have demonstrated that disruptions of these three-dimensional (3D) structures lead to disease status. Recent advances of high-throughput sequencing have enabled it to display 3D proximities among each genomic locus on the chromatin contact matrix using Hi-C analysis method. However, large-scale computational resources are indispensable in current protocols of Hi-C analysis for high-resolution contact map, and the repeatability of those contact matrix are still uncertain in the current practical procedures. In addition, it is difficult to understand the mechanism of chromatin conformation disruptions that lead to disease status. For understanding the conformation of chromatin 3D structures, we established deep neural network models to predict the existence of chromatin looping with the data set derived from a human lymphoblastoid cell line GM12878. For supervised learning of neural network model, we prepared the combination of genomic loci tagged as chromatin-loop-positive (N = 8526) using HiCCUPs protocol as previously reported (Rao et al 2014), and also prepared randomly selected genomic loci combinations other than positively-tagged loci as chromatin-loop-negative (N = 131365). The established model displayed its high accuracy (96.25%), sensitivity (99.35%), and specificity (95.22%). The AUC of the model was 0.997 against a test data set. These results suggest that our established deep neural network model is an effective method for analyzing chromatin 3D structures substituted for Hi-C analysis.

**1982F****X chromosome aneuploidy alters the epigenetic landscape and gene expression genome-wide.**

*G.N. Filippova<sup>1</sup>, J.B. Berletch<sup>1</sup>, W. Ma<sup>2</sup>, G. Bonora<sup>2</sup>, X. Chen<sup>4</sup>, H. Hrnčir<sup>3</sup>, D.L. VanDyke<sup>5</sup>, A.P. Arnold<sup>4</sup>, X. Deng<sup>1</sup>, C.M. Distèche<sup>1</sup>.* 1) Department of Pathology, University of Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Department of Statistics, University of California, Riverside, CA; 4) Department of Integrative Biology & Physiology, University of California, Los Angeles, CA; 5) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Two major problems in studying sex chromosome aneuploidy (Klinefelter, XXX and Turner syndromes) in human are: (1) there is considerable variability in the background genotype of individuals, and (2) relevant cell types are often inaccessible. To address these issues we derived human iPSC lines from individuals with sex chromosome aneuploidy and constructed pairs of isogenic lines with a different number of X chromosomes. These cells were differentiated into neuronal cells and cardiomyocytes to address cognitive deficits and heart defects in sex chromosome aneuploidy. In parallel, frontal cortex, cerebellum, heart and spleen tissue samples from mice with sex chromosome aneuploidy on the same strain background were collected. DNA methylation and transcriptome studies showed significant differences in autosomal CpG methylation and gene expression in cells and tissues with a different number of X chromosomes. Notably, human primary cells with a specific type of X aneuploidy (XXY, XXX, or X) clustered in terms of differentially methylated regions on autosomes, with significant alterations in the DNA methylation landscape being maintained after reprogramming to iPSCs. These results indicate that having an abnormal number of sex chromosomes influences the epigenetic landscape across the genome. We also found dysregulated autosomal genes in mouse tissues with sex chromosome aneuploidy. Interestingly, brain consistently showed fewer dysregulated genes compared to heart and spleen across the different types of aneuploidy, suggesting genome-wide effects of X aneuploidy in a tissue/cell-type specific manner.

**1983W****Characterization of large familial copy number variation in regions of low gene density and chromatin accessibility.**

*W.A. Khan<sup>1,2</sup>, R. Singh<sup>1,2</sup>, Y. Mito<sup>1,2</sup>, L. Shi<sup>1,2</sup>, L. Edlmann<sup>1,2</sup>, S.A. Scott<sup>1,2</sup>.* 1) Sema4, a Mount Sinai venture, Stamford, CT; 2) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

It is estimated that ~5-10% of the human genome contains structural copy number variants (CNVs), yet only aberrations that are large and/or rare typically lead to syndromic disorders. The majority of CNVs are small (<500 kb), common, intergenic, and inherited. Interestingly, some large euchromatic CNVs do not result in a penetrant clinical phenotype; however, it is currently unclear how these large aberrations are tolerated and if this is related to gene density and/or other chromatin packaging factors. To determine if large inherited CNVs in otherwise healthy individuals are distinct from pathogenic structural aberrations with respect to content and accessibility, deidentified clinical chromosomal microarray (CMA) data was interrogated from over 11,000 patients tested in a clinical cytogenomics laboratory. All identified CNVs that were 1.5-10 Mb were assessed, which revealed 90 large CNVs in the cohort. Of these, 70 were either coincident with known syndromic regions, a recurrent benign pericentromeric variant, or were transmitted to the proband as the consequence of a balanced structural rearrangement. The remaining 20 CNVs ranged in size from 1.5-10.4 Mb, were not implicated in any recurrent syndrome, and were typically inherited and classified as variants of uncertain significance – likely benign. Additionally, they were distributed over fourteen chromosomes and did not exhibit any parent of origin bias. Chromatin accessibility as determined by deoxyribonuclease I hypersensitivity (DNase HS) from the ENCODE project and CpG dinucleotide content were compared between these 20 CNVs and 20 well-characterized pathogenic syndromic CNVs (2.4-9.9 Mb) as defined by ClinGen. Notably, normalized DNase HS cluster scores, morbid gene content, and CpG island number and length were an order of magnitude greater in the pathogenic CNVs compared to the inherited likely benign CNVs ( $F=21.7$ ,  $p<0.0001$ ). The inherited CNVs also broadly corresponded to GC poor isochores at an 850 haploid band length. Taken together, these results indicate that CNV gene density is a better predictor of clinical significance than CNV size. In addition to informing on CNV interpretation, these data also suggest that a paucity of morbid genes and a closed chromatin environment permits certain regions of the genome to tolerate a change in copy number, which likely influences their population frequencies by allowing transmission in subsequent meioses.

**1984T**

**Using humanized mouse models to understand the role of human accelerated regions in human evolution.** *E.V. Dutrow<sup>1</sup>, D. Emera<sup>1</sup>, S. Uebbing<sup>1</sup>, T.P. Nottoli<sup>2</sup>, J.P. Noonan<sup>1,3</sup>*. 1) Department of Genetics, Yale School of Medicine, New Haven, CT; 2) Department of Comparative Medicine, Yale School of Medicine, New Haven, CT; 3) Kavli Institute for Neuroscience, Yale School of Medicine, New Haven, CT.

The evolution of uniquely human morphology required genetic changes that altered embryonic development. Human Accelerated Regions (HARs), which include conserved developmental regulatory elements whose sequences have substantially diverged in human, are prime candidates for driving human-specific developmental modifications. Several HARs have been shown to encode developmental enhancers with human-specific patterns of activity using transgenic reporter assays or direct comparisons of enhancer activity in human and nonhuman tissues using epigenetic marks. However, the potential human-specific biological functions of HARs have not yet been examined using genetic models. To address this question, we used genome editing to generate a humanized mouse model for the most prominent HAR experimentally studied to date, *HACNS1*. In transgenic reporter assays, *HACNS1* shows increased activity in the developing limb and pharyngeal arch compared to its nonhuman primate orthologs, and it shows increased levels of epigenetic marks associated with active enhancers in the human limb. The human-specific *in vivo* functions of *HACNS1* remain unknown; however, humanized mouse models provide a novel tool for deciphering the function of *HACNS1* in a living system. We precisely replaced the orthologous 1.2kb region of the mouse genome with *HACNS1*. In this mouse model, we find that *HACNS1* recapitulates its human-specific increase in enhancer activity observed in the developing human limb. *HACNS1* also shows increased activity in the mouse pharyngeal arch. To establish the human-specificity of *HACNS1* activity in our genetic model, we generated a second mouse model for the chimpanzee ortholog of *HACNS1*. The chimpanzee ortholog showed consistently weaker activity in both limb and pharyngeal arch compared to *HACNS1*. Furthermore, we find that *HACNS1* drives increased expression of a critical developmental transcription factor, *Gbx2*, in embryonic limb and pharyngeal arch. We are carrying out both molecular and tissue-level functional characterization of development in humanized mouse tissues to identify phenotypic correlates of human biological traits. Our results show that HARs can directly alter gene expression in genetic models, establishing humanized mice as a platform for experimental studies of human evolution.

**1985F**

**Evaluation of a targeted custom capture bisulfite sequencing approach.** *D. Daley<sup>1</sup>, R. Munthali<sup>1</sup>, A. Eslami<sup>1</sup>, M. Wan<sup>1</sup>, A. Sandford<sup>1</sup>, K. Oros<sup>2</sup>, C. Greenwood<sup>2,3</sup>*. 1) Medicine, University of British Columbia, Vancouver, BC, Canada; 2) Lady Davis Institute for Medical Research, Montreal, Quebec, Canada; 3) Departments of Oncology, Epidemiology, Biostatistics & Occupational Health, and Human Genetics, McGill University, Quebec Canada.

CpG methylation can be modified by environmental exposures, such as smoking and medication. Differential methylation of CpG sites likely contributes to the etiology of many common complex diseases. As such, there is an increased interest in evaluating CpG methylation and conducting epigenome-wide association studies. CpG methylation can be assessed using a variety of methods including whole genome bisulfite sequencing which can be prohibitively expensive, pyrosequencing of small regions, or the relatively inexpensive, and commonly utilized chip based approaches such as Illumina's 27K, 450K and Epic arrays. While cost effective, there are significant limitations of the array based approaches including the limited number CpG sites that can be assessed and the number of CpG sites that demonstrate variable methylation. An emerging alternative to array based approaches, targeted capture bisulfite sequencing can offer several advantages including greater number CpGs that can be assessed, greater percentage of CpG sites with variable methylation, joint sequencing of both SNPs and CpG sites facilitates evaluation of both haplotype and SNP effects. We recently piloted the Illumina TruSeq Methyl Capture Epic bisulfite sequencing approach using 48 samples selected from asthma studies. We compared the library content (TruSeq) to Illumina's arrays (27K, 450K and Epic). We found that the majority of CpG sites on the arrays (27K (100%), 450K (98%) and Epic (97.5%)) overlapped with the targeted capture library. However, the proportion of CpG sites with variable methylation is considerably higher 50% TruSeq vs. 9% 450K. A full analysis of the pilot of 48 samples is currently underway but our initial findings suggest that bisulfite targeted capture sequencing offers a cost effective alternative to whole genome bisulfite sequencing.

Embryogenesis requires epigenetic information that allows each cell to respond appropriately to developmental cues. The state and accessibility of chromatin are core components of a cell's epigenome, modulating the function of the underlying genome sequence. However, a comprehensive survey of chromatin dynamics during mammalian embryogenesis has been lacking except for very early stages. We will report unpublished results of a systematic effort by the ENCODE consortium to profile histone modifications and chromatin accessibility in a diverse panel of mouse tissues at 8 time points from 10.5 days post conception until birth. In total we performed 1,128 ChIP-seq assays and 132 ATAC-seq assays across 72 distinct tissue-stages. We will highlight results of several integrative analyses that we think will be of particular interest to human geneticists: First, we find strong enrichment of human trait-associated SNPs ("GWAS SNPs") in the orthologs of mouse fetal cis-regulatory elements (cREs). Many of these enrichments are tissue-dependent, linking traits to specific fetal tissues and cREs therein. In forebrain where we have single-cell ATAC-seq data, we further map disease enrichments to specific cell types within the tissue. Second, we leveraged the breadth of our data to generate genome-wide predictions of cRE target genes. We find that cREs linked to Mendelian disease genes (as cataloged by OMIM) are significantly more likely to harbor GWAS SNPs, highlighting the potential of non-coding variation at Mendelian disease genes to contribute risk for non-mendelian phenotypes. Third, we find that Transcription Factor (TF) genes underlying Mendelian disease are strongly and significantly overrepresented among targets of Polycomb-mediated repression during development (comprising 66% of all Mendelian disease TFs). These results point to incomplete or failed repression as a potential disease mechanism for further exploration. Beyond these highlights, we will describe a multi-tiered compendium of functional annotations for the mouse genome including chromatin state maps, an extensive catalog of cREs with dynamic developmental activity, and a collection of 150 in vivo transgenic reporter assays that reveal a quantitative relationship between epigenomic signals and validation rate. Given the uniquely critical role of the mouse as a model system in biomedical research, we believe that these resources and findings will be of high interest to the human genetics community..

**1987T**

**Collecting roadmap and ENCODE data into reference epigenomes.** J.A. Hilton, ENCODE Data Coordination Center. Genetics, Stanford University, Palo Alto, CA.

The Encyclopedia of DNA elements (ENCODE) project has produced data from more than 9,000 experiments using a variety of techniques to study the structure, regulation, and transcription profiles of human and mouse genomes. The data from these experiments first pass through the ENCODE Data Coordination Center (DCC) for basic validation and meta-data standardization before they are openly available at the ENCODE site (<https://www.encodeproject.org/>). The ENCODE portal also hosts data from external projects, including the NIH Roadmap Epigenomics Mapping Consortium. In order to align with the existing structure of the ENCODE portal, Roadmap experimental metadata were carefully curated, and raw data were collected from production labs and public repositories. The import of these experiments allows for Roadmap data to be searched, downloaded, and analyzed alongside ENCODE data. Furthermore, the ENCODE DCC has processed Roadmap data using the uniform processing pipelines designed by the ENCODE consortium. This provides high-quality and consistent data with cross-project compatibility. One of the aims of the Roadmap project was to provide to the scientific community a set of reference epigenomes for human cells and tissues. Using data produced from the Roadmap project, 111 reference epigenomes were assembled, plus an additional 16 reference epigenomes from ENCODE data, each of which have been modeled on the ENCODE portal. The ENCODE DCC has also curated data produced by the ENCODE consortium to compile reference epigenomes for human and mouse biosamples, following guidelines set forth by the International Human Epigenome Consortium. These reference epigenomes, combined with the open access to ENCODE's uniform processing pipeline code, provide the framework for ease of comparison and integration within future studies from the scientific community..

**Rare genetic variation at transcription factor binding site modulates local DNA methylation profiles.** A. Martin Trujillo<sup>1</sup>, N. Patel<sup>1</sup>, F. Richter<sup>1</sup>, B. Jadhav<sup>1</sup>, P. Garg<sup>1</sup>, B.D. Gelb<sup>1,2</sup>, A.J. Sharp<sup>1,3</sup>. 1) Department of Genetics & Genomic Sciences and The Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Pediatrics, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Graduate School of Biomedical Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Background: DNA methylation is an important epigenetic regulator, playing a critical role in many cellular processes such as transcriptional regulation, X-chromosome inactivation, genomic imprinting or maintenance of genome stability. Although DNA methylation has been extensively characterized, the mechanism by which this epigenetic mark is targeted to specific regions in the genome remains unclear. Interestingly, recent studies have revealed that local DNA methylation profiles might be dictated by *cis*-regulatory DNA sequences so called methylation-determining regions, which activity relies on DNA-binding factors. In agreement with this finding, we have recently shown that disruption of CTCF-binding sites by rare single nucleotide variants (SNVs) can underlie *cis*-linked DNA methylation changes in patients with congenital anomalies (PMID: 29802345). These data raise the hypothesis that rare genetic variation at regulatory sequences, such as transcription factor binding sites (TFBS), might contribute to local DNA methylation patterning and represent a global mechanism of genome regulation. Results: To investigate the association of rare SNVs within TFBS with altered DNA methylation, we analyzed genome-wide DNA methylation profiles (Illumina 850k), SNVs derived from whole genome sequencing data from 247 unrelated individuals, and 133 active TFBS motifs derived from ENCODE ChIP-Seq data. We observed an enrichment for local outlier DNA methylation values in individuals carrying rare variants at TFBS when compared to non-carriers. Interestingly, this enrichment is greater for rare variants at TFBS than those outside these motifs, highlighting the role of regulatory sequences on modulating proximal DNA methylation profiles. Furthermore, greater difference in position weight matrix scores between alternate and reference alleles is associated with larger methylation changes at nearby CpG sites. This finding suggests that rare SNPs at TFBS might negatively influence the TF-DNA binding that can lead to an altered local DNA methylation profile. Conclusions: Our findings provide firstly, insights into the effect of rare variation at TFBS on shaping local DNA methylation affecting genome regulation and secondly, a rationale to incorporate DNA methylation data to interpret the functional role of rare variants.

**An atlas of epigenetic signatures across the human phenome associated with polygenic burden of disease.** T.G. Richardson, M. Suderman, T.R. Gaunt, G. Davey Smith, C.L. Relton. MRC Integrative Epidemiology Unit (IEU), Population Health Sciences Institute, University of Bristol, Bristol, United Kingdom.

DNA methylation holds considerable potential as a biomarker for disease diagnosis and prognosis. However, to date epigenome-wide association studies (EWAS) have been confined to a small proportion of complex traits across the human phenome. Polygenic risk scores (PRS) derived from large populations can provide a feasible alternative to help elucidate and prioritise CpG sites which may be implicated in disease based on genetic liability. Such findings can be utilised in conjunction with PRS to improve prediction of later life disease susceptibility. We curated PRS for 212 complex traits from large-scale consortia and the UK Biobank study. Using blood-derived data from the Accessible Resource for Integrated Epigenomics Studies (ARIES) project, we conducted EWAS analyses at 5 different stages across the life course (birth, childhood, adolescence, pregnancy and middle age) for each PRS. In total, 916 associations survived conventional EWAS corrections ( $P < 1.0 \times 10^{-07}$ ) across all time points (at 375 unique CpG sites with 115 complex traits). These associations between genetic liability for a given trait and DNA methylation may indicate that this CpG site is mechanistically involved in disease pathogenesis. For example, concerning cardiovascular disease, *SORT1/CELSR2* methylation was associated with the polygenic burden of coronary heart disease and high cholesterol, whereas DNA methylation at *LIPA* was associated with risk of myocardial infarction. There were also associations detected at loci previously linked with cancer susceptibility, such as *MSMB* methylation and risk of prostate cancer. Despite using methylation data derived from blood, we identified associations where expression data from GTEx implicates genes that appear to be expressed predominantly in other tissue types. For example, there were several associations with neurological traits where CpG-mapped genes appear to be expressed specifically in brain tissue. These included associations between *LINGO1* and *DOC2A* methylation with facets of neuroticism, as well as between *LHFPL3* methylation and a measure of general cognition. These findings support the utility of whole blood as a proxy for tagging epigenetic signatures in tissue types which may be more pertinent to the disease of interest. We have developed a web application to disseminate our findings to the scientific community. This resource should prove valuable for future studies undertaking in-depth evaluations of epigenetic mechanisms in disease.

**Exposure to polybrominated biphenyl (PBB) associates with DNA methylation differences across the genome.** S.W. Curtis<sup>1</sup>, V. Kilaru<sup>2</sup>, D.O. Cobb<sup>2</sup>, M.L. Terrell<sup>3</sup>, C.J. Marsit<sup>4</sup>, M. Marcus<sup>3,4,5</sup>, K.N. Conneely<sup>6</sup>, A.K. Smith<sup>2,7</sup>. 1) Genetics and Molecular Biology, Emory University, Atlanta, GA; 2) Department of Gynecology and Obstetrics, School of Medicine, Emory University, Atlanta, GA; 3) Department of Epidemiology, Rollins School of Public Health, Emory University, Atlanta, GA; 4) Department of Environmental Health, Rollins School of Public Health, Emory University, Atlanta, GA; 5) Department of Pediatrics, School of Medicine, Emory University, Atlanta, GA; 6) Department of Human Genetics, School of Medicine, Emory University, Atlanta, GA; 7) Department of Psychiatry and Behavioral Sciences, School of Medicine, Emory University, Atlanta, GA.

In 1973, approximately 6.5 million Michigan residents were exposed to an industrial mixture of polybrominated biphenyl (PBB), an endocrine-disrupting compound, when it was added to farm animal feed during a factory accident. Highly exposed individuals and their children have numerous health problems, including genitourinary conditions, spontaneous abortions, and early puberty, though the underlying mechanism behind these health problems remains unknown. Other endocrine-disrupting compounds have been linked to epigenetic differences, but no epigenetic studies have been done for PBB. In this study, DNA from the blood of individuals with PBB exposure was interrogated with the MethylationEPIC BeadChip (N = 659). Associations between each of the ~850,000 CpG sites and current, serum PBB levels were tested with a linear regression that controlled for age, sex, and cell type proportions. After multiple test correction (FDR <0.05), 1758 CpG sites associated with total PBB levels. These CpGs were not enriched in any particular biological pathway, but were enriched in enhancer and insulator regions, and depleted in regions near the transcription start site or in CpG islands ( $p < 0.05$ ). In order to better understand the function of the enhancers that were enriched, PBB-associated CpGs were also interrogated for transcription factor binding sites, correlations with hormones, and links to gene expression. They were also more likely to be in ARNT and ESR2 transcription factor binding sites ( $p = 2.32e-29$  and  $p = 1.01e-18$ , respectively), and there was significant overlap between CpGs associated with PBB and CpGs associated with estrogen ( $p < 2.2e-16$ ). PBB-associated CpGs were also enriched for CpGs known to be associated with gene expression in blood (eQTMs) ( $p < 0.05$ ). These eQTMs were associated with the expression of genes that were enriched for pathways related to immune function and endocrine-related autoimmune disease (FDR <0.05) and the signal from PBB correlated with the methylation signal from low-grade inflammation ( $R = 0.34$ ,  $p$ -value =  $4.82e-07$ ). Taken together, these results indicate that exposure to PBB is associated with differences in epigenetic marks that suggest that it is acting similarly to estrogen and is associated with dysregulated immune system pathways.

**Trans-eQTL analysis informs tissue-specific regulation of gene expression.** A. Battle<sup>1</sup>, B. Jo<sup>2</sup>, A. Saha<sup>1</sup>, B.J. Strober<sup>1</sup>, A. He<sup>1</sup>, P. Parsana<sup>1</sup>, B.E. Engelhardt<sup>2</sup>, The GTEx Consortium. 1) Johns Hopkins University, Baltimore, MD; 2) Princeton University, Princeton, NJ.

Recent work suggests that regulation of gene expression by distal genetic loci across the genome contributes substantially to the heritability of both gene expression and complex human traits. These distal effects on gene expression can be captured by analysis of trans-eQTLs (distal expression quantitative trait loci) and are thought to act through complex cellular networks specific to particular tissues and cell types. Identifying trans-eQTLs in human data has been challenging due to power, tissue cell-type heterogeneity, confounding factors, and tissue-specificity. We have identified over 400 trans-eQTLs across 30 tissues in the latest (v8) release of the Genotype Tissue Expression (GTEx) project data, which includes 838 postmortem donors with whole genome and RNA sequencing of 17,382 samples. We present analysis of statistical methods along with functional characterization of trans-eQTLs using this large multi-tissue cohort. Statistical considerations for trans-eQTL detection include improving power, filtering rampant false positive associations, detecting regulatory hotspots, and assessing the false discovery rate at multiple levels including genomic loci and target genes. Functionally, while trans-eQTL variants overlap greatly with cis-eQTL variants, they display some notable differences. As we and others have previously found, we show that trans-eQTLs are more tissue-specific than cis-eQTLs, often only displaying strong effects in just a single tissue and independently replicating only in data for matched tissues. We evaluate the enrichment of trans-eQTLs in regulatory elements, protein-coding regions, and near transcription factors, and investigate tissue-specific regulatory mechanisms including overlap with regulatory networks. These results provide the broadest characterization to date of trans-eQTLs across human tissues, essential to understanding tissue-specific gene regulation and effects of genetic variation that propagate through cellular networks to affect complex phenotypes with tissue-specific origins.

**Fine-mapping regulatory variants across 49 tissues.** *A. Brown<sup>1</sup>, F. Hormozdiari<sup>2</sup>, F. Aguet<sup>3</sup>, E.T. Dermitzakis<sup>1</sup>, X. Wen<sup>3</sup>, the GTEx consortium.* 1) Department of Genetic Medicine and Development, University of Geneva, Geneva, Switzerland; 2) The Broad Institute of Massachusetts Institute of Technology and Harvard University, Cambridge, Massachusetts 02142, USA; 3) Department of Biostatistics, University of Michigan, Ann Arbor, Michigan 48109, USA.

Identification of causal regulatory variants can substantially enhance our understanding of the mechanisms of gene expression and the links between expression and disease. The latest GTEx data provided RNA-seq and WGS from 838 individuals across 49 tissues. We applied 3 published fine-mapping methods to these data: CaVEMaN, CAVIAR and dap-g. We find 68,948 high confidence causal variants ( $P > 0.8$ ), with a median number of 6 variants in a 95% credible set. Fine-mapping approaches can also find independent eQTLs, accounting for multiple testing. We find 7.2% (kidney-cortex) to 45% (nerve-tibial) of eGenes have  $>1$  eQTL, with differences explained by sample size ( $\rho = 0.95$ ). We used these results to derive properties of regulatory variants; these could be used, e.g., for developing personalised genome interpretation methods to predict deleterious variants solely from genomic context. We annotated eQTLs to 715 ChIP-seq peaks and 54 transcription factors motifs, greatest enrichment is in peaks for a mark of active promoters (H3K4me3 peaks contain 16.5% of regulatory variants, a 372 fold enrichment (FE)). Motifs show more enrichment (up to 1,100FE), but explain a far smaller proportion of regulatory variation (0.3%). We also explored using combinations of annotations to predict causal regulatory variants, to produce more tailored inference on specific variants. Assigning priors to variants, 32% of variants have unique prior weight due to unique genomic context. Using these priors we see a significant increase in lead variant causal probability ( $P < 1e-316$ , median  $P = 0.41$  vs  $0.27$ ). In 58% of cases we find a different variant to be causal than when considering only statistical information; these new variants had a slightly higher replication rate in a new dataset (88.1% vs 87.6%). We used the fine-mapping results in whole blood to look for colocalization with GWAS hits for 4 lipid traits. We find 36 out of 148 GWAS hits colocalize with eQTLs ( $P > 50\%$ ), explaining 21 new GWAS hits compared to the previous GTEx release. This demonstrates the improvement due to the new release, with 332 new samples and genotypes from WGS. We show here that leveraging molecular phenotype associations, annotations and posterior probabilities can bring benefits to diverse sets of analyses. These include looking at properties of regulatory variants, assessing allelic heterogeneity, and exploring the relationship with GWAS signals, moving us towards the goal of personalized non-coding genome interpretation.

**1993T**

**Tissue-variability of eQTL effects and the role of transcription factors.** *E.D. Flynn<sup>1,2</sup>, S.E. Castel<sup>1,2</sup>, P. Mohammadi<sup>1,2,3,4</sup>, T. Lappalainen<sup>1,2,4</sup>, GTEx Consortium.* 1) Department of Systems Biology, Columbia University, New York, NY; 2) New York Genome Center, New York, NY; 3) The Scripps Translational Science Institute, The Scripps Research Institute, La Jolla, CA; 4) Shared last author.

The GTEx Consortium has identified thousands of local expression quantitative trait loci (*cis*-eQTLs) in the human population that affect gene expression in multiple tissues. Over a third of GTEx eQTLs are active across all or almost all surveyed tissues and may have different effect sizes in different tissues, but the molecular mechanisms of this cross-tissue variability of eQTL effect size are poorly understood. Since eQTLs are enriched in transcription factor binding sites (TFBS), we developed a model of eQTL effect size as a function of transcription factor (TF) activity levels across tissues – low (absence of TF binding) or high (saturation of TF binding) tissue TF level results in reduced eQTL tissue effect size, with maximum eQTL effect at mid-range TF levels. We investigated mechanisms of tissue-variability of eQTL effect size (allelic fold change) in the GTEx v8 data release, which includes 838 individuals' whole genome sequences and their RNA-seq data from a total of 15,201 samples across 49 tissues. We first examined the correlation of eGene expression with eQTL absolute effect size across tissues and identified 3,477 expression-correlated eQTLs (Spearman corr., 5% FDR,  $N = 26,499$ ), with 60% positive and 40% negative correlations. This result shows that expression level and genetic regulatory effects are not independent phenomena, and we found that the expression-correlated eQTLs have distinct genetics, gene features, and functional annotations. Importantly, they are enriched for TFBS overlap compared to non-correlated eQTLs, and a portion of these TFBS-overlapping eQTLs are also correlated with the relevant TF gene expression level across tissues. This indicates that TF activity levels may indeed modify eQTL effects across tissues, and it allows identification of upstream molecular drivers of eQTL activity. We proceeded to find several examples of eQTLs that co-localize with GWAS signals, directly disrupt TFBS, and correlate with TF levels across tissues, thus pinpointing the likely causal variant and the direct molecular regulator of disease associations. Our results provide a basis for identifying regulatory mechanisms of eQTL activity and for understanding eQTL effect size variability across tissues in the context of TF activity. This has major implications for future work investigating context-specific mechanisms of GWAS loci and their effects on human phenotype and disease.

Tuomilehto<sup>5,7,8,9</sup>, H.A. Koistinen<sup>6,10,11</sup>, F.S. Collins<sup>2</sup>, M. Boehnke<sup>4</sup>, S.C. Parke<sup>1,5</sup>, L.J. Scott<sup>4</sup>. 1) Department of Computational Medicine & Bioinformatics, University of Michigan, Ann Arbor, Michigan, United States of America; 2) National Human Genome Research Institute, National Institutes of Health, Bethesda, United States of America; 3) European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Genome Campus, Hinxton, Cambridgeshire, United Kingdom; 4) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, Michigan, United States of America; 5) Department of Human Genetics, University of Michigan, Ann Arbor, Michigan, United States of America; 6) Department of Public Health Solutions, National Institute for Health and Welfare, Helsinki, Finland; 7) Department of Neurosciences and Preventive Medicine, Danube University Krems, Krems, Austria; 8) Diabetes Research Group, King Abdulaziz University, Jeddah, Saudi Arabia; 9) Dasman Diabetes Institute, Dasman, Kuwait; 10) Department of Medicine and Abdominal Center: Endocrinology, University of Helsinki and Helsinki University Central Hospital, Haartmaninkatu 4, Helsinki, Finland; 11) Minerva Foundation Institute for Medical Research, Biomedicum 2U, Tukholmankatu 8, Helsinki, Finland.

Skeletal muscle represents ~40% of lean body weight and constitutes the largest organ. Many diseases affect skeletal muscle and differences in gene expression may cause or be caused by disease states. Genetic variants that affect RNA expression levels are called expression quantitative trait loci (eQTL). To date, most studies have focused on *cis*-eQTLs, which affect expression of nearby genes; fewer studies have examined *trans*-eQTLs, which affect expression of distal genes. Here we identify skeletal muscle *trans*-eQTLs from 301 FUSION (Finland-United States Investigation of NIDDM Genetics) study participants and 491 GTEx (Genotype-Tissue Expression project) V7 donors. We performed inter-chromosomal *trans*-eQTL analysis for protein-coding and lincRNA genes within each study for SNPs with minor allele count >10 (7.1M SNPs in FUSION, 9.2M in GTEx) imputed using the Haplotype Reference Consortium panel. We used an additive genetic model to test for the association of inverse normalized gene expression with imputed autosomal allele count, adjusting for potential known and latent confounders. Using an approximate Bonferroni-corrected threshold ( $5 \times 10^{-8}$  divided by the number of tested genes), we identified 4 *trans*-eGenes (genes whose expression levels are significantly associated with a genetic variant) out of 15906 genes in FUSION and 3 *trans*-eGenes out of 16216 genes in GTEx. Of 9 genes identified in the GTEx V6p publication (10% genome-wide FDR), in FUSION we replicated SNP-gene pairs in 4 genes ( $p < 8 \times 10^{-5}$ ); of the remaining genes, 4 genes had SNP-gene pairs  $p > .05$ , and 1 gene was not tested in FUSION (SNP not imputed). As an initial analysis, we performed a sample size-based meta-analysis of 245M variant-gene pairs with  $p$ -values  $< 0.05$  in both FUSION and GTEx and identified 21 *trans*-eGenes ( $p \leq 3 \times 10^{-12}$ ) out of 15348 genes. Within these, we identified *trans*-eQTL signals for *DYNLL1* ( $p = 4.0 \times 10^{-14}$ , Chr 12) and *DYNLL2* ( $p = 1.4 \times 10^{-16}$ , Chr 17) that both overlapped a *cis*-eQTL signal for the transcription factor *ATMIN*. *ATMIN* has been shown to influence the expression of *DYNLL1*. We calculated enrichment for the lead *trans*-eQTLs in genomic regions with different classes of skeletal muscle chromatin states and found significant enrichment in the active transcription start site state ( $p = 0.0012$ , fold-enrichment 3.8). These findings will help increase our understanding of cross-chromosomal regulation of genetic expression by genetic variation in skeletal muscle.

## 1995W

**Conserved DNA methylation helps drive tissue-specific gene expression differences across primates.** L.E. Blake<sup>1</sup>, J. Roux<sup>1,2</sup>, I. Hernando-Herraez<sup>3</sup>, N.E. Banovich<sup>1,4</sup>, R. Garcia Perez<sup>3</sup>, C. Joyce Hsiao<sup>5</sup>, C. Chavarria<sup>1</sup>, T. Marques-Bonet<sup>6</sup>, Y. Gilad<sup>1,5</sup>. 1) Department of Human Genetics, University of Chicago, IL; 2) Department of Biomedicine, University of Basel, Basel, Switzerland; 3) Institute of Evolutionary Biology, Universitat Pompeu Fabra, Barcelona, Spain; 4) Integrated Cancer Genomics Division, Translational Genomics Research Institute, Phoenix, AZ; 5) Department of Medicine, University of Chicago, Chicago, IL.

Gene regulatory changes are hypothesized to play an important role in primate adaptive evolution and human disease. Previous work has identified tissue-specific gene expression patterns that are conserved across primates, suggesting that these patterns are important for tissue-specific functions. However, we still know remarkably little about the mechanisms driving the conserved tissue-specific gene expression profiles. Therefore, we chose to assess the contribution of one epigenetic mechanism, DNA methylation, to primate regulatory evolution across multiple tissues. We collected RNA and DNA from 4 tissues (heart, kidney, liver and lung) from each of our 4 human, chimpanzee and rhesus macaque individuals. We then interrogated the CpG methylation status genome-wide with whole-genome bisulfite sequencing and collected gene expression profiles using RNA-sequencing. Consistent with previous studies, we found that tissue-specific differentially expressed (DE) genes in our dataset were highly conserved. Furthermore, we observed that tissue-specific differentially methylated regions (T-DMRs) are also conserved across the three species. Ultimately, we are interested in identifying DNA methylation differences that drive interspecies and intertissue gene expression differences in primates. To this end, we estimated that at least 14% of interspecies gene expression differences across primates in a given tissue can be explained, at least in part, by DNA methylation differences. DNA methylation differences could contribute to a similar percentage (11-22%) of gene expression differences across tissues in these species. Finally, we discovered that conserved DNA methylation significantly contributes to 10-30% of genes with tissue-specific gene expression. Overall, this work identifies DNA methylation differences that may underlie species-specific traits and tissue-specific functions. .

**1996T**

**Gene circuitry mapping is a powerful tool for identification of drug-gable targets and appropriate chemistries for therapeutically relevant outcomes.** *D. Bumcrot, E. Cohick, Y. Liu, O. Chung, C. Smith, J. Weinstein, B. Schwartz, G. Whissell, A. Sehgal, C. O'Donnell, A. Sigova, I. Grossman.* Camp4 Therapeutics, Cambridge, MA.

**Background:** A wide range of under-served diseases could be therapeutically addressed by increasing or decreasing the expression of specific genes. This includes rare disorders caused by loss- or gain-of-function mutations, as well as common diseases with well validated genetic modifiers. Genetic studies of human disease, including GWAS, are increasing the number of well supported associations between diseases and specific genes, thus presenting opportunities for therapeutic intervention. We have built a gene circuitry mapping platform that discovers novel connections between signaling pathways that control transcription and the regulation of specific disease-associated genes. **Hypothesis:** Our goal is to utilize this platform across primary human cells derived from a range of tissues to develop testable therapeutic hypotheses for a broad spectrum of diseases. To test the validity of the platform we selected a well-characterized disease gene, *PCSK9*, and elucidated the control circuitry, relevant druggable nodes and existing chemistries that affect it at clinically meaningful levels. **Methods:** We have generated a gene circuitry map for primary human hepatocytes through the application of functional genomics techniques. These include RNA-seq profiles in response to more than 300 different experimental conditions and ChIP-seq profiles measuring the binding of approximately 60 DNA binding proteins and chromatin marks. Together with the results of DNA-DNA interaction assays (including HiChIP) these data inform an algorithmic approach to decoding hepatocyte gene regulatory circuitry. This enables prediction of novel mechanisms for modulating genes of interest via signaling pathway nodes; many of which are targets of approved drugs. As an example, we mapped the transcriptional control of the metabolic disease-associated gene, *PCSK9*. **Results:** The map correctly identifies known mechanisms regulating *PCSK9*, such as elevation in response to statin treatment, but importantly also predicts pathways that heretofore have not been linked to its transcriptional regulation. Follow-up testing validates our predictions and proposes novel approaches for therapeutic intervention. **Conclusions:** The Gene Circuitry platform yields readily testable predictions for druggable targets, often with existing clinical-stage chemistries. In this way, it can provide a significant head start to drug development programs for a wide range of diseases.

**1997F**

**Mapping gene regulatory dynamics during cardiomyocyte differentiation at single cell resolution.** *R. Elorbany<sup>1,2</sup>, R. Dohn<sup>2</sup>, K. Rhodes<sup>3</sup>, H. Eckart<sup>4</sup>, A. Selewa<sup>5</sup>, S. Pott<sup>3,4</sup>, A. Basu<sup>4,6</sup>, Y. Gilad<sup>3,4</sup>.* 1) Interdisciplinary Scientist Training Program, University of Chicago, Chicago, IL; 2) Committee on Genetics, Genomics, and Systems Biology, University of Chicago, Chicago, IL; 3) Department of Human Genetics, University of Chicago, Chicago, IL; 4) Department of Medicine, University of Chicago, Chicago, IL; 5) The Graduate Program in Biophysical Sciences, University of Chicago, Chicago, IL; 6) Center for Nanoscale Materials, Argonne National Laboratory.

Characterizing the impact of genetic variation on gene expression is essential for understanding human development and disease. As cells differentiate over time, the regulation of gene expression must also change dynamically. In this study, we aim to detect genetic variants associated with the change in gene expression over time, which we term “dynamic QTLs.” Dynamic QTLs can provide insight into the temporal patterns of gene regulation, and how these dynamic processes vary between individuals. However, during differentiation, the composition of cell types in a sample is heterogeneous and may also differ between individuals. To determine whether observed variation in gene expression is due to differences in gene regulation or in cell composition, we investigate gene expression over time at single cell resolution. Using the Drop-seq platform, we collected single cell RNA-seq data at 5 time points during differentiation from human induced pluripotent stem cells (iPSCs) to cardiomyocytes in 10 individuals. The 5 time points used in this study were chosen to be representative of broad developmental stages from iPSC to cardiomyocyte, as determined by bulk gene expression data from cells collected daily during the differentiation. Using single cell expression data, we can characterize the cell composition of each sample at each time point. Cells in the same differentiation stage can be directly compared between individuals for QTL mapping. We expect to identify QTLs associated with inter-individual differences in gene expression, both at each time point independently (static QTLs) and across the entire timecourse (dynamic QTLs). Our single-cell expression data will allow us to investigate variation between individuals in both cell composition and gene regulation over time. Thus far, we have collected single cell RNA-seq data using Drop-seq on two individuals at five time points during differentiation. By the final stage of our cardiomyocyte differentiation, gene expression profiles of single cells show clustering into distinct cell populations. In preliminary analysis, we can identify genes most significantly associated with distinct cell populations at each time point, including cardiac-specific gene *TNNT2* which increases in expression in a particular cell population over time. As such, we have confidence in our ability to investigate gene expression within a heterogeneous sample of cells as they transition between cell states during differentiation.

**1998W****Hi-C-based characterization of the landscape of physically interacting regions and interaction mechanisms across six human cell lines using HIPPIE2.**

*P.P. Kuksa<sup>1</sup>, A. Amlie-Wolf<sup>1,2</sup>, Y.-C. Hwang<sup>3</sup>, B.D. Gregory<sup>4</sup>, L.-S. Wang<sup>1,2</sup>.* 1) Penn Neurodegeneration Genomics Center, Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA; 2) Genomics and Computational Biology Graduate Group, University of Pennsylvania Perelman School of Medicine; 3) DNAnexus, Inc., Mountain View, California, USA; 4) Department of Biology, University of Pennsylvania, Philadelphia, PA.

Most regulatory chromatin interactions are mediated by various transcription factors (TFs) and involve physically-interacting regions (PIRs) that are regulatory elements such as enhancers, insulators, or promoters. To map these interactions across cell lines, we developed a novel approach, HIPPIE2. HIPPIE2 accepts raw Hi-C reads as input and provides extensive characterization of (1) PIRs and their potential regulatory roles using epigenomic annotations, (2) high-confidence PIR-PIR interactions, and (3) mediating TF complexes based on binding motifs and ChIP-seq experiments. Unlike standard genome binning approaches with fixed-sized bins at 10K-1Mbp resolution, HIPPIE2 calls physical locations of PIRs with better precision and higher resolution by using restriction enzyme cutting sites and strand orientations in the ligation step of the Hi-C protocol. We applied HIPPIE2 to in situ Hi-C datasets across 6 human cell lines (GM12878, IMR90, K562, HMEC, HUVEC, and NHEK; Rao et al, 2014) with matched functional genomics datasets from ENCODE and Roadmap. HIPPIE2 detected 1,042,738 unique PIRs genome-wide across cell lines, with an average length of 1,005bps and high reproducibility (92.3% shared PIRs in GM12878 replicates). We discovered PIRs are enriched for epigenetic marks (H3K27ac 2.18x and H3K4me1 1.96x), suggesting active regulatory roles. With respect to cell-type specificity, on average 32.8% of PIRs were shared between cell lines. HIPPIE2 identified 2.8M significant (Fit-Hi-C) intrachromosomal PIR-to-PIR interactions. PIR-PIR interactions were enriched for TF binding with experimental evidence of TF binding from ChIP-seq in 27.2% of interactions. 50,608 PIR-PIR interactions were between enhancers and promoters based on genomic and epigenomic annotations of PIRs. These enhancer-promoter interactions were mediated by 45 distinct TFs (41 in enhancers and 40 in promoters) obtained from overrepresented TF-TF pairs. 35 TFs were enriched in >1 cell lines and 10 were cell line-specific. Several of these factors are known to be involved in DNA looping and long-distance regulation (e.g., *YY1*, *SP1*, *CTCF*, *MYC*, *NR4A1*, *MEF2*, *PAX5*). Our analysis demonstrated HIPPIE2 identifies PIRs, TFs, and interactions with excellent sensitivity and specificity thanks to its high resolution and reproducibility of PIR detection. HIPPIE2 (<https://bitbucket.com/wanglab-upenn/HIPPIE2>) is useful for studying genome-wide regulatory mechanisms and how TF binding mediates these interactions.

**1999T****High resolution genetic mapping of causal regulatory interactions in the human genome.** *N. Kumasaka, A. Knights, D. Gaffney.* Wellcome Sanger Institute, Cambridge, United Kingdom.

Physical interaction of distal regulatory elements in three-dimensional space poses a challenge for studies of common disease because noncoding risk variants may be substantial distances from the genes they regulate. Experimental methods to capture these interactions, such as chromosome conformation capture (CCC), usually cannot assign causal direction of effect between regulatory elements, an important component of disease fine-mapping. Here, we developed a Bayesian hierarchical approach that models causal interactions between regions of open chromatin using two-stage least squares. We applied our model to a novel ATAC-seq data from 100 individuals mapping over 15,000 high confidence causal interactions. Strikingly, the majority (>60%) of interactions we detected were over distances of <20Kb, a range where CCC-based methods perform poorly. For a fraction of loci, we identify a single variant that alters accessibility across multiple peaks, and experimentally validate one, the BLK/FAM167A locus associated with risk for multiple autoimmune disorders, using CRISPR engineering. Our study highlights how association genetics of chromatin state provides a powerful complement to CCC-methods to map regulatory variants to genes.

**Characterizing the genetic basis for variation in m<sup>6</sup>A methylation.** K. Luo<sup>1</sup>, Z. Zhang<sup>2,3,4,5</sup>, M. Qiao<sup>6</sup>, X. He<sup>1</sup>, M. Stephens<sup>1,7</sup>, C. He<sup>2,3,4,5</sup>. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Chemistry, University of Chicago, Chicago, IL; 3) Department of Biochemistry and Molecular Biology, University of Chicago, Chicago, IL; 4) Institute for Biophysical Dynamics, University of Chicago, Chicago, IL; 5) Howard Hughes Medical Institute, University of Chicago, Chicago, IL; 6) School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX; 7) Department of Statistics, University of Chicago, Chicago, IL.

There has been great progress over the past few years in linking genetic variation to molecular phenotypes by mapping QTLs across the gene regulatory cascade from DNA to RNA and protein. Recent breakthroughs in transcriptome-wide profiling of N<sup>6</sup>-methyladenosine (m<sup>6</sup>A), the most abundant internal modification in eukaryotic mRNA, has opened a new frontier in gene regulation. This reversible RNA methylation affects almost every stage of mRNA metabolism, from processing to translation and decay. However, the mechanistic role that genetic variants have in guiding m<sup>6</sup>A changes and the functional interactions between m<sup>6</sup>A and other layers of gene regulation are still largely unknown. To understand the genetic basis for inter-individual variation in m<sup>6</sup>A methylation, we measured m<sup>6</sup>A methylation using m<sup>6</sup>A-seq in 60 Yoruba lymphoblastoid cell lines (LCLs), for which genotypes are available and multiple other molecular phenotypes have been extensively characterized. We identified genetic variants that are associated with m<sup>6</sup>A methylation level (m<sup>6</sup>A-QTLs). We observed that m<sup>6</sup>A-QTLs are strongly enriched within binding sites of many important RNA-binding proteins and also active chromatin features. To dissect the causal relationships between m<sup>6</sup>A and other molecular phenotypes in the cascade of gene regulation, we integrated m<sup>6</sup>A-QTLs with other layers of molecular QTLs in LCLs identified in earlier studies (such as transcription rate, translation, and protein). Our integrative analysis uncovered interesting yet complex relationships between m<sup>6</sup>A methylation and other layers of gene regulation. Finally, we discovered significant enrichment of m<sup>6</sup>A-QTLs for GWAS traits, which may suggest novel mechanisms for complex diseases at the RNA methylation level.

**Genetic loci associated with inter-individual variation in alternative polyadenylation and PolII pausing provide new insight into the gene regulatory code.** B.E. Mittleman<sup>1</sup>, K. Patterson<sup>2</sup>, S. Warland<sup>2</sup>, S. Pott<sup>2,3</sup>, Y. Gilad<sup>1,2,3</sup>, Y.I. Li<sup>2</sup>. 1) Genetics, Genomics and Systems biology, University of Chicago, Chicago, IL; 2) Genetic Medicine, University of Chicago, Chicago, IL; 3) Human Genetics, University of Chicago, Chicago IL.

Characterizing the effects of genetic variation on gene regulation can shed light on the mechanisms that underlie inter-individual differences in complex traits and disease. While there has been immense progress in our ability to identify the effects of genetic variants on gene expression and splicing, we still have a poor understanding of many regulatory steps, including active transcription and polyadenylation. To begin addressing this gap, we assayed inter-individual variation in two post transcription initiation regulatory steps, polymerase II pausing and polyadenylation site usage. We obtained high quality Native elongation transcript sequencing (NET-seq) data to detect strand-specific polymerase II density along gene bodies at base-pair resolution. As expected, NET-seq reads are enriched at promoter proximal regions and at exon-intron boundaries. These data allow us to detect native elongating transcription-QTLs (NetQTLs) associated with polymerase II pausing. We also use these data to examine the alternative splicing kinetic coupling model, namely, the hypothesis that internal pol II pausing reduces splice site competition leading to increased exon inclusion. In turn, we use 3' sequencing data collected in the same LCLs to detect polyadenylation QTLs (apaQTLs) associated with alternative polyadenylation site usage. We collected these data for whole cell and nuclear specific mRNAs to detect short-lived transcripts prior to nuclear export. We can thus test the role of alternative polyadenylation usage on mRNA localization and export. Finally, by integrating both data types from this study, we ask whether Pol II pausing can be used to explain inter-individual variation in alternative polyadenylation usage.

**Detection and replication of rare variant driven gene expression outliers via joint modeling of total and allele-specific expression.** *B. van de Geijn<sup>1</sup>, G. McVicker<sup>2</sup>, J.D. Blischak<sup>3</sup>, Y. Gilad<sup>3</sup>, A.L. Price<sup>1</sup>*. 1) Harvard T.H. Chan School of Public Health, Boston, MA; 2) Salk Institute for Biological Studies, La Jolla, CA; 3) University of Chicago, Chicago, IL.

Non-coding genetic variants can lead to large changes in gene expression and may underly instances of genetic disease. Indeed, a recent study found that individuals with outlier expression ( $|z\text{-score}| > 2$ ) for a given gene often harbor a rare variant nearby (Li et al. Nature 2017); however, it is challenging to determine whether a particular outlier is genetically driven by a rare variant. We developed a rigorous statistical method to identify rare variant driven outliers by jointly modeling total and allele-specific expression, leveraging a previous method for identifying quantitative trait loci (WASP: van de Geijn, McVicker et al. Nature Methods 2015). Total expression for each individual is directly modeled as count data, taking into account gene- and individual-level overdispersion as well as technical effects on expression measurements; this boosts power to detect outliers over methods that require normalization. Similarly, we modeled allele specific expression directly as read counts while taking into account overdispersion and technical effects. We distinguish between four possible scenarios based on model likelihood. The first is no-effect, where the individual being tested has total expression similar to the others and no allelic imbalance. The second, which we are most interested in, is cis effect, where an individual has outlier total expression and allelic imbalance. The third and fourth are trans or monoallelic effects where there either outlier expression or allelic imbalance, but not both. To evaluate our method, we analyzed RNA-seq data from lymphoblastoid cell lines of 30 Yoruba trios. We expect any heritable outlier in one of the parents to also occur in the child half of the time. At 5% FDR, we identified 15 parent-gene pairs with evidence of a cis effect (likelihood ratio test for cis vs. no-effect model and higher likelihood for the cis model vs. trans or monoallelic models). Of these, 11 were overexpressed (median 20x change in expression) and 4 were underexpressed (median 1/10x change). 5 of the 15 genes were also outlier genes in the corresponding children. We also identified 7 parent-gene pairs that would have been labeled as outliers based on total expression, but that showed stronger evidence of trans or monoallelic effects and were thus not labeled as outliers by our method. None of these replicated in the corresponding children. Our findings highlight the need for an outlier model that can specifically identify cis effects.

**Conserved enhancer domains reflect gene pathogenicity and evolutionary buffering of expression.** *X. Wang<sup>1,2</sup>, D.B. Goldstein<sup>1,2</sup>*. 1) Columbia University, New York, NY; 2) Institute of Genomic Medicine, New York, NY.

Non-coding transcriptional regulatory elements are critical for controlling the precise spatiotemporal expression of genes. We used maps of enhancer activity across human tissues to define a genome-wide "enhancer domain score" that represents the number of nucleotides implicated in regulating the expression of a human gene. We demonstrate that the number of conserved bases in enhancers linked to a gene is reflective of disease pathogenicity, and provides information independent of and complementary to commonly-used metrics including pLI and RVIS. The enhancer domain score can also predict the specific affected tissues for developmental disease genes. Additionally, genes with large conserved enhancer domains are depleted for *cis*-acting genetic variants that disrupt gene expression. Finally, we show that the cumulative burden of rare genetic variation in enhancers is associated with gene expression differences, and that genes with large enhancer domains are buffered against these disruptive effects. Our results demonstrate that dosage-sensitive disease genes have evolved robustness to the disruptive effects of genetic variation by expanding their transcriptional regulatory domains. This resolves a puzzle in the genetic literature on why disease genes are depleted for *cis*-eQTLs and establishes a framework for the identification of non-coding regulatory variation with phenotypic consequences. .

**Methylation quantitative trait loci in CD4<sup>+</sup>T lymphocytes, monocytes, and neutrophils in Japanese individuals.** S. Komaki<sup>1</sup>, Y. Shiwa<sup>1</sup>, R. Furukawa<sup>1</sup>, T. Hachiya<sup>1</sup>, H. Ohmomo<sup>1</sup>, Y. Sutoh<sup>1</sup>, R. Otomo<sup>1</sup>, M. Satoh<sup>1</sup>, J. Hitomi<sup>2</sup>, K. Sobue<sup>2</sup>, M. Sasaki<sup>2</sup>, A. Shimizu<sup>1</sup>. 1) Division of Biomedical Information Analysis, Iwate Tohoku Medical Megabank Organization, Iwate Medical University, Yahaba, Iwate, Japan; 2) Iwate Tohoku Medical Megabank Organization, Iwate Medical University, Yahaba, Iwate, Japan.

Purpose DNA methylation (DNAm) centrally regulates gene expression; inter-individual variations of DNAm are associated with various human traits. Numerous trait-associated single-nucleotide polymorphisms (SNPs) identified via genome-wide association studies (GWAS) are not located in coding regions and mechanisms underlying the effects of genomic variations on traits remain unclear; DNAm may cause this effect. This study aimed to reveal how genomic variations affect DNAm via methylation quantitative trait locus (mQTL) analysis. Methods We used CD4<sup>+</sup> T lymphocytes (CD4T; n = 102), monocytes (n = 102), and neutrophils (n = 94) isolated from peripheral blood by fluorescence-activated cell sorting with >95 % purities. DNAm profile at ~24 million CpGs and genotypic data of ~9 million SNPs were obtained from each cell type. Based on these datasets, we conducted cis-mQTL analysis with cis-proximity defined as a distance < 1 Mbp. False discovery ratio for multiple testing correction was applied with a significance threshold q-value ≤ 0.05. We further investigated the enrichment of the mQTLs among cardiovascular/immunological disease-associated SNPs listed in the PheGenI database. Results & Discussion Among >3 billion SNP-CpG pairs, mQTL analysis revealed 115,390,389 SNP-CpG associations (mQTLs). mQTL number was largest in neutrophils, followed by CD4T and monocytes. Cell type-specific mQTLs accounted for >50% of all detected mQTLs. Among 5997 cardiovascular disease-associated SNPs and 3887 immunological disease-associated SNPs, 71% and 55%, respectively, were associated with DNAm level (mQTL), of which 35% were cell type-specific mQTLs. Hence, numerous phenotype-altering SNPs are accompanied by changes in DNAm. Expression quantitative trait methylation analysis is needed to understand how genomic variation affects gene expression through changes in DNAm. Moreover, the association between genomic variations and DNAm levels was highly cell type-specific, thereby potentially contributing to specific functions of each cell type. We have published the resulting mQTL data on iMETHYL, a genome browser (<http://imethyl.iwate-megabank.org>). This is the first cell type-specific and comprehensive multi-omic genome browser that provides QTL-related information, which will greatly contribute to understanding the biological consequences of genomic variation in terms of phenotypic variation.

**Penalized functional regression method for across-platform imputation of methylation levels.** G. Li<sup>1</sup>, L. Raffield<sup>2</sup>, M. Logue<sup>3,4</sup>, M.W. Miller<sup>2,4</sup>, Y. Li<sup>2,5,6</sup>.

1) Dept. of Statistics and Operations Research, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Dept. of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) National Center for PTSD at VA Boston Healthcare System; 4) Dept. of Psychiatry, Boston University School of Medicine; 5) Dept. of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 6) Dept. of Computer Science, University of North Carolina at Chapel Hill, Chapel Hill, NC.

DNA methylation of cytosine residues at CpG dinucleotides is one of the most extensively studied epigenetic marks. CpG site methylation is involved in not only normal development but also risk and progression to many diseases. With the advancement of powerful technologies such as DNA methylation microarrays and bisulfite sequencing techniques, geneticists are able to profile DNA methylation at increasingly higher resolution. However, different DNA methylation profiling platforms employ different designs with varying resolutions, which hinders joint analysis of methylation data. Thus, we proposed a penalized functional regression (PFR) model to impute missing-by-design methylation levels. We have previously demonstrated the power of our PFR approach: it improved imputation accuracy when imputing the Illumina HumanMethylation450 (HM450) BeadChip from the HumanMethylation27 (HM27) BeadChip, compared with alternative methods. In this study, we further extend our method to impute from HM450 to 850,000 methylation sites on the recently released HumanMethylationEPIC BeadChip. We compared our PFR model with state-of-the-art methods including lasso, elastic net regression and machine learning based methods. We applied our PFR model to 144 samples measured both by HM450 and EPIC. Among the most challenging 3,000 CpG sites with the largest variations, 1036 probes exceeding a threshold of 0.25 for our under-dispersion statistic (a measure of estimated imputation quality) achieved a prediction accuracy > 75.1% when dichotomizing the DNA methylation level with a cutoff of 0.5; with a more stringent threshold of 0.5, 530 probes passing quality control had accuracy 80.0%. In addition, we found data harmonization across platforms before applying PFR model crucial: our non-parametric regression-based harmonization approach further improved quality by 1% with the more stringent 0.8 threshold. Our results validate that, by incorporating the nonlocal information in functional terms, the PFR model is a convenient and efficient imputation tool. The imputed methylation values can be used to boost power for discovery in subsequent epigenome-wide association studies (EWAS).

## 2006F

**Exploring the longitudinal association between loneliness and methylation of genes associated with the Conserved Transcriptional Response to Adversity (CTRA).** D. Phillips<sup>1</sup>, Y. Wang<sup>2</sup>, N.L. Pedersen<sup>2</sup>, S. Hagg<sup>2</sup>, C.A. Reynolds<sup>1</sup>. 1) University of California, Riverside, Riverside, CA; 2) Karolinska Institutet, Stockholm, Sweden.

Perceived loneliness is a potentially modifiable factor linked with a wide range of adverse physical, cognitive, and mental health outcomes. While the mechanisms of these associations remain largely unknown, prior work has shown altered gene expression in blood leukocytes of chronically lonely (vs. non-lonely) individuals, with increased expression of genes associated with inflammation and reduced expression of genes associated with fighting viral infections in lonely compared to non-lonely persons, an expressional pattern which has been referred to as a *conserved transcriptional response to adversity* (CTRA) and has been linked with other circumstances involving objective and perceived stress. Despite these observations, the relation between loneliness and DNA methylation remains unexplored in published work. To address this gap, we assessed the longitudinal association between loneliness and methylation at 1,586 CpG sites associated with 105 CTRA genes in up to 375 twins from the Swedish Adoption Twin Study of Aging (SATSA) across up to 18 years. Partial correlations adjusting for age, sex, and number of longitudinal assessments were calculated between baseline loneliness levels ( $Base_{Lonely}$ ), longitudinal means ( $M_{Lonely}$ ), and variability ( $SD_{Lonely}$ ), with longitudinal patterns of methylation ( $M_{CpG}$ ,  $SD_{CpG}$ ) at each site. Partial correlations exceeded an absolute effect size of .1 or higher for 504 of 1,586 sites (32%) across 4 sets of comparisons of  $Base_{Lonely}$  with  $M_{CpG}$  and  $SD_{CpG}$ ,  $M_{Lonely}$  with  $M_{CpG}$ , and  $SD_{Lonely}$  with  $SD_{CpG}$ .  $Base_{Lonely}$  was associated with  $M_{CpG}$  at 149 sites at .1 or higher ( $r_s$  range = -.20 to .18), and with  $SD_{CpG}$  at 200 sites ( $r_s$  range = -.24 to .21).  $M_{Lonely}$  was associated with  $M_{CpG}$  at 177 sites ( $r_s$  range = -.20 to .20).  $SD_{Lonely}$  was associated with  $SD_{CpG}$  at 162 sites ( $r_s$  range = -.19 to .22). Some of the CpGs flagged suggest an enrichment of sites within particular genes. For example, 48 of 147 CpG sites near or within the *SLC12A7* gene suggested loneliness may correlate differentially with methylation levels and variability across time; among these, baseline loneliness correlated with higher  $M_{CpG}$  at 18 of 20 sites, and negatively with  $SD_{CpG}$  at 17 of 20 sites. These findings indicate that longitudinal growth analyses are warranted to explore the link between feelings of loneliness and level and change in methylation at these sites.

**Identification of rare genetic variants contributing to tissue-specific patterns of extreme expression.** N.M. Ferraro<sup>1</sup>, J.R. Davis<sup>2</sup>, E.K. Tsang<sup>1</sup>, X. Li<sup>3</sup>, M. Gloudemans<sup>1</sup>, A.J. Scott<sup>4</sup>, I.M. Hall<sup>4</sup>, A. Battle<sup>5</sup>, S.B. Montgomery<sup>2,3</sup>, GTEx Consortium. 1) Biomedical Informatics Program, Stanford University, Stanford, CA; 2) Genetics Department, Stanford University, Stanford, CA; 3) Pathology Department, Stanford University, Stanford, CA; 4) McDonnell Genome Institute, Washington University School of Medicine, St. Louis, MO; 5) Department of Computer Science, Johns Hopkins University, Baltimore, MD.

While numerous genetic association studies have associated common variants with human traits, the specific molecular consequences of rare variation are often unknown or difficult to predict, despite their implications in both rare and common disease. Recent work has shown that some rare variants induce large changes in gene expression across many human tissues. However, for other variants, effects are likely to manifest differently in distinct tissues. To identify such effects, we have developed a method to discover gene expression outliers that directly accounts for patterns of correlation of expression levels across tissues, and can therefore detect tissue-specific changes. We applied this method in a dataset of gene expression data of 550 individuals and 23 tissues, with a median of 12 tissues available per individual, from the Genotype-Tissue Expression project. Outliers discovered by our correlation-aware method, like the primarily distinct set of outliers discovered via standard methods, are significantly enriched for nearby rare variation, including SNPs, indels, and structural variants ( $p < 2e-16$ ). Further, nearby rare variants identified in both methods are enriched in highly conserved regions of the genome and are predicted to be consequential via fitCons and CADD scores. However, unlike existing approaches, our correlation-aware approach is able to discover outliers that manifest in a single tissue. These tissue-specific outliers are significantly enriched ( $p=0.008$ ) for nearby rare variants located in matched-tissue specific enhancer regions, and are depleted for rare variants in enhancer regions specific to other tissues ( $p=4.35e-10$ ), indicating that rare variants in tissue-specific enhancers may be driving the extreme expression observed in that tissue. Our results provide a new avenue to study rare variant biology in tissue-specific contexts. In doing so, we improve the discovery of functional rare variants with tissue-specific effects, which can provide novel insights into genome interpretation and genetic disease risk.

**2008T****High-throughput untranslated region engineering and screening.** *J. Cao*<sup>1,2</sup>, *E. Novoa*<sup>2,3</sup>, *Z. Zhang*<sup>2,3</sup>, *M. Kellis*<sup>2,3</sup>, *T. Lu*<sup>1,3</sup>.

Gene therapy holds the promise of treating the diseases that cannot be treated using traditional small molecule or protein drugs. The *in vivo* drug expression levels depend highly on the genetic elements near the coding region. In this work, we developed a comprehensive strategy to identify novel 5' untranslated region (5' UTR) sequences that can enhance protein expression from the human cytomegalovirus (CMV) promoter in human muscle cells. We first designed a library of 12,000 5' UTR sequences based on genomic searches and *in silico* computation, then designed a novel recombinase-based screening strategy to screen the library in mammalian cells. In addition, we developed next-generation sequencing (NGS) analysis pipelines that allow investigating the correlations between the 5'UTR sequences and protein expression levels. We identified two 5' UTR candidates that can improve protein expression by greater than 40% in human rhabdomyosarcoma (RD) cells, which outperformed the commonly used introns. We envision these synthetic UTRs can be used to enhance *in vivo* drug productivity for DNA vaccines and mRNA therapeutics.

Skeletal muscle biology is important in multiple human diseases including obesity and diabetes. These and many other diseases exhibit differences between sexes. Identifying genes that are differentially expressed by sex in human skeletal muscle will enhance our understanding of biological differences in this disease relevant tissue. To quantify gene expression levels, we performed strand-specific mRNA-seq on 301 vastus lateralis biopsies from Finnish individuals with a range of glucose tolerances as part of the FUSION (Finland-United States Investigation of NIDDM Genetics) study. We tested for differential gene expression by sex using a linear mixed model with random effects adjusting for technical covariates, batch, age, BMI, and estimates of muscle fiber type proportions. Out of 21,743 tested genes, we found 9,512 genes, including 9,117 on autosomal chromosomes, to be significantly differentially expressed by sex (false discovery rate=0.05). 2,923 genes show higher expression in males while 6,589 genes show higher expression in females. The majority of signals were unaffected by adjusting for muscle fiber type estimates. GRTP1 Antisense RNA 1 transcript had higher expression in males and showed the most significant differential expression by sex (p-value=2.1x10<sup>-6</sup>) of autosomal genes. Gene set enrichment testing, performed using RNA-Enrich, revealed that mitochondria-related genes from the nuclear genome had higher expression in males. Our results show a high degree of sex-biased gene expression in skeletal muscle tissue, indicating significant differences in gene regulation or cell type composition by sex. Further analyses are needed to study the possible relationships between the differences in expression levels and their biological impact on health and disease.

**Variance QTL mapping in human induced pluripotent stem cells.** A.K. Sarkar<sup>1</sup>, P.Y. Tung<sup>1</sup>, J.D. Blischak<sup>1,2</sup>, J. Hsiao<sup>1</sup>, Y.I. Li<sup>1,3</sup>, M. Stephens<sup>1,4</sup>, Y. Gilad<sup>1,3</sup>. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Committee on Genetics, Genomics, and Systems Biology, University of Chicago, Chicago, Illinois, USA; 3) Department of Medicine, University of Chicago, Chicago, Illinois, USA; 4) Department of Statistics, University of Chicago, Chicago, Illinois, USA.

Advances in single cell sequencing have revealed that the variance of gene expression across cells is a complex trait which could provide a previously unconsidered regulatory mechanism to explain human development and disease. However, previous studies of gene expression variance have been limited to yeast, or to carefully chosen gene pathways in humans. Here, we take an unbiased, genome-wide approach to identify variance quantitative trait loci (vQTLs). We reprogrammed 53 Yoruba lymphoblastoid cell lines into induced pluripotent stem cells and generated RNA-Seq data for median 95 cells per individual and total 5,447 single cells. We find 279 eQTLs (FDR 10%), of which 83% replicate in matched bulk RNA-Seq data, and 148 vQTLs (FDR 10%). We find that the vast majority of vQTLs replicate as eQTLs, suggesting they can be explained away by mean effects. We demonstrate the current study is underpowered to directly find dispersion effects, or variance effects which are independent of mean effects, and estimate at least 500 cells per individual (condition) would be required to have 80% power to find a two-fold change in dispersion. Overall, our results do not rule out the existence of genetic effects on dispersion, and will guide the design of future studies.

**2011T**

**Multi-tissue analysis of mitochondrial post-transcriptional methylation.** A.T. Ali<sup>1</sup>, K. Small<sup>2</sup>, A. Hodgkinson<sup>1</sup>. 1) Department of Medical and Molecular Genetics, School of Basic and Medical Biosciences, King's College London, London, United Kingdom; 2) Department of Twin Research and Epidemiology, School of Life Course Sciences, King's College London, London, United Kingdom.

The mitochondrial genome is transcribed as poly-cistronic strands that are subsequently cleaved and processed by nuclear encoded proteins to release mature mitochondrial RNA products. Post-transcriptional processes therefore play a crucial role in regulating the expression of the mitochondrial genome, and in particular, variable methylation of mitochondrial RNA can lead to changes in transcript abundance and protein levels, ultimately impacting mitochondrial function. Here, we characterise variation in mitochondrial post-transcriptional methylation levels at functionally important positions in the mitochondrial genome across a total of 11,552 samples from 39 tissue/cell types. Using genome-wide association studies, we replicate previously found associations between missense mutations in nuclear encoded mitochondrial genes (*MRPP3*, *SLC25A26* and *MTPAP*) and mitochondrial RNA methylation levels across multiple tissue types, and we additionally identify 4 novel independent associations at genome-wide significance ( $P < 5 \times 10^{-8}$ ). Newly identified genetic variants are predicted to be functional or show evidence of significantly ( $P < 0.05$ ) mediating RNA methylation levels through the expression of nearby nuclear-encoded mitochondrial genes. Finally, these nuclear loci co-locate with genetic variants associated with complex disease, suggesting that mitochondrial post-transcriptional methylation may be involved in disease progression.

**Organs and tissues are complex structures composed of millions of cells of diverse morphology and function. Tissue transcriptomes, thus, represent the average behaviour of genes across a highly heterogeneous collection of primary cells. How the transcriptional profiles of each of these cell types relate to the profiles of tissues and organs is still poorly understood. Here we have monitored by RNA-Seq the transcriptome of multiple human primary cells from multiple tissues. We found that their transcriptional profiles cluster into a few broad cell types: endothelial, epithelial, mesenchymal, neuronal and blood cells. The clustering is recapitulated using independent transcriptomic and epigenomic data. The influence of tissue of origin contributes very little (<4%) to the transcriptomes of primary cells. We identified about 3000 genes specific to these three cell types. These include a core set of transcription factors (TFs), showing strong co-expression patterns, and thus likely candidates to drive cell type specificity. Cell type specific genes are enriched for motifs of TFs specific to the same cell type. Cell type specific genes are mostly a vertebrate innovation, appearing early in the evolution of this lineage, with epithelial specific genes being the most evolutionary dynamic. We employed a method to estimate the proportion of cells from each type in a given tissue from gene expression values in that tissue in the GTEx collection of tissue transcriptomes. We found that, although we characterized a very limited number of primary cells from a limited number of tissues, the basic cell types capture a large proportion (>70%) of cellular composition of many human tissues. Through the analysis of the GTEx catalog of histological images and associated annotations, we show that our inferred cellular composition precisely defines tissue type and captures morphological heterogeneity in the samples. We identified changes in the cell type composition occurring with age and sex in a few tissues. We found that departures from the normal cellular composition of tissues correlate with histological phenotypes associated to diseases. Alterations of the cellular composition are particularly relevant in cancer, where they can be even associated to different stages of disease progression. The collection of primary cells transcriptomes produced here is a unique resource to understand tissue biology, serving as interface between tissue and single cell transcriptomics.**

**2013W**

**Investigation of human elements regulating escape from X-chromosome inactivation in mouse models.** S. Peeters<sup>1</sup>, A. Korecki<sup>1,2</sup>, E. Simpson<sup>1,2</sup>, C. Brown<sup>1</sup>. 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, BC, Canada.

X-chromosome inactivation (XCI) epigenetically silences one X chromosome in every cell in female mammals; however, approximately 12–20% of genes escape from XCI in humans and continue to be expressed from both the active and inactive X chromosomes. Only 3–7% of X-linked genes escape in mouse, and tend to be distributed as singletons while human escape genes often cluster in larger domains, suggesting both promoter-centric and regional mechanisms of escape. We have recently shown that despite known species differences between escape gene number and distribution on the X chromosome, human escape genes *RPS4X* and *CITED1* retain their ability to be expressed from the inactive X chromosome in multiple tissues of a transgenic mouse model. The recognition of human elements necessary for escape from XCI in mouse provides a tractable system to assess additional human genes for intrinsic escape ability, and characterize the critical regions responsible for continued expression from an inactive X. As the *RPS4X* construct used above included an entire escape domain bounded by genes subject to inactivation, we next targeted the human escape gene *KDM5C*, which is part of a larger domain of escape not included in its construct. In this case, the well-characterized escape gene became silenced, supporting a need for more distal elements to retain expression in a heterochromatic environment. To validate these results, as well as further explore promoter-centric versus regional models for escape, we are targeting additional constructs to the same X-linked docking site in mouse embryonic stem cells and analyzing expression and promoter DNA methylation for evidence of escape following differentiation and XCI. Expression of genes escaping from XCI may contribute to the phenotypes of X aneuploidies as well as influence male and female susceptibility to disease. As X-chromosome reactivation is being examined therapeutically for some X-linked disease, understanding of how X-linked gene regulatory mechanisms work may provide insights into utilization of such therapeutic approaches.

**2014T**

**Male-female subject-specific XCI-adjusted differential gene expression reveals changes in active-X expression of escape genes.** *R. Sauteraud, D. Liu.* Biostatistics, Penn State University, Hershey, PA.

X chromosome inactivation (XCI) mechanism randomly silences one female X (Xi) and only expresses the alleles on the active X (Xa). ~10% of the X-linked genes escape XCI and express both copies of alleles and it is estimated that ~30% of the X-linked genes may escape in a subset of individuals, but remain silenced in others. Often used to assess X-chromosome inactivation (XCI) status of X-linked genes and gain insight into the mechanisms of inactivation and escape, Male-female differential gene expression analysis (DGEA) suffers from the major drawback that it only allows gene level calls and does not account for variable escape between individuals. DGEA is further complicated by the changes in the level of expression of the Xi in escape genes at the subject level. Using our recently developed RNA-Seq based subject-specific XCI inference method to assess Xa/Xi expression in 217 samples of the GEUVADIS project, we adjusted the expression levels to compare expression of the female Xa with males. While the XCI field is usually concerned with the study of the Xi and assumes that the Xa remains largely unaffected, we show that there are significant male-female differences in the active copy of X that may be affected by subject-specific levels of escape. Our results indicate that X-linked escape genes with no Y homologs are up-regulated in females, even after adjusting for Xi expression. We further investigated the role of inter-individual differences on tissue-specific escape and showed that along with the previously reported limited tissue-specificity of XCI, there are differences at the subject level that need to be accounted for when comparing expression levels. XCI-adjusted DGEA could shed some light into the mechanism of escape from inactivation and our XCI-inference allows to circumvent the usual limitations of differential expression by implementing additional subject-level information.

**2015F**

**Comparative analysis of the effects of sex chromosome dosage changes in Turner syndrome and Klinefelter syndrome on local and global gene expression.** *X. Zhang<sup>1,2</sup>, D. Hong<sup>1</sup>, S. Ma<sup>3</sup>, A. Stankov<sup>1</sup>, S. Shrestha<sup>1</sup>, J. Hallmayer<sup>1</sup>, W. Wong<sup>3</sup>, A. Reiss<sup>1</sup>, A. Urban<sup>1,2</sup>.* 1) Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Palo Alto, CA; 2) Department of Genetics, Stanford University School of Medicine, Palo Alto, CA; 3) Department of Statistics, Stanford University, Palo Alto, CA.

**Background:** In both Turner syndrome (TS; XO) and Klinefelter syndrome (KS; XXY) copy number aberrations of the X chromosome lead to various developmental symptoms. To date there has not been a comprehensive and directly comparative analysis of TS vs. KS regarding the molecular effects of these sex chromosome dosage changes, on the expression levels of the genes on chromosome X as well as for genes on the autosomes, and of transcriptome-wide network effects. **Methods:** We analyzed gene expression patterns with RNA-Seq and DNA methylation patterns with the CpGiant assay, in blood from 55 clinically well-characterized individuals (13 TS, 14 KS, 13 male controls, 14 female controls). The data from TS patients were analyzed vs. the female controls and the data from KS patients were analyzed vs. the male controls, followed by comparative analyses between KS and TS of differentially expressed genes (DEGs), of transcriptome network effects, and of patterns of DNA methylation. **Results:** On chromosome X we detected 67 DEGs in TS and 42 DEGs in KS. DEGs were enriched on the short arm of chromosome X in both TS and KS. Genome-wide, there are 974 DEGs in TS and 172 DEGs in KS. Interestingly, there is a 'core-group' of differentially expressed genes, where 81 genes are differentially expressed in both TS and KS. These 81 shared DEGs are located on autosomes (50 DEGs) as well as on chromosome X (31 DEGs). Strikingly, all of these 81 core-group DEGs change their levels of expression into opposite directions in TS vs. KS. Weighted correlation network analysis (WGCNA) shows significant co-expression of DEGs on the X chromosome and on the autosomes in both TS and KS, indicating that there are ripple effects of the changes in X chromosome dosage that extend to the autosomes. Broad hypomethylation of the X chromosome is observed in TS whereas hypermethylation of chromosome X is present in KS. Both hypomethylated and hypermethylated regions are present on the autosomes in both TS and KS. **Conclusions:** We carried out direct comparative analysis on the molecular level in TS vs. KS. Multiple DEGs on chromosome X were identified, as well as a large number of DEGs transcriptome-wide. The discovery of shared core-genes indicates the existence of common molecular mechanisms in both TS and KS for transmitting the gene dosage changes to the transcriptome. The findings regarding positional effects and reciprocal DNA methylation patterns on chromosome X further underscore this possibility.

**2016W**

**Gene therapy prevents hepatic tumor development in glycogen storage disease type Ia mice at the tumor-developing stage.** *J.H. Cho<sup>1</sup>, Y.M. Lee<sup>1,3</sup>, M.F. Starost<sup>1</sup>, B.C. Mansfield<sup>1,2</sup>, J.Y. Chou<sup>1</sup>.* 1) NIH, Bethesda, MD; 2) Foundation Fighting Blindness, Columbia, MD; 3) University of Connecticut School of Medicine, Farmington, Connecticut.

Hepatocellular adenoma/carcinoma (HCA/HCC) is a severe long-term complication of glycogen storage disease type Ia (GSD-Ia) caused by a deficiency in glucose-6-phosphatase- $\alpha$  (G6Pase- $\alpha$  or G6PC), a key enzyme in gluconeogenesis. Using liver-specific *G6pc*-knockout (*L-G6pc*<sup>-/-</sup>) mice, we have shown that hepatic G6Pase- $\alpha$  deficiency leads to metabolic reprogramming and defective autophagy, both contribute to tumorigenesis. Here, we show that from pre-tumor to tumor-developing stages, the livers of *L-G6pc*<sup>-/-</sup> mice displayed metabolic abnormalities and autophagy impairment along with elevated accumulation of p62, a specific autophagy substrate critical for tumorigenesis. Treating tumor-free and tumor-bearing *L-G6pc*<sup>-/-</sup> mice at the tumor-developing stage with rAAV-G6PC, a G6PC-expressing recombinant adeno-associated virus (rAAV) vector led to restoration of hepatic G6Pase- $\alpha$  expression and prevention of de novo HCA/HCC development. However, rAAV-G6PC-mediated gene transfer could not abrogate the pre-existing HCA/HCC nor restore G6Pase- $\alpha$  expression in these tumors. Significantly, the expression of 11  $\beta$ -hydroxysteroid dehydrogenase type-1 that mediates local glucocorticoid activation is down-regulated in HCA/HCC lesions, leading to impaired glucocorticoid signaling critical for activation of gluconeogenesis. This suggests local glucocorticoid action downregulation may prevent restoration of G6Pase- $\alpha$  expression in HCA/HCC lesions of rAAV-G6PC-treated *L-G6pc*<sup>-/-</sup> mice. Examining the tumor lesions in untreated and rAAV-G6PC-treated *L-G6pc*<sup>-/-</sup> mice showed that in addition to continued p62 accumulation, two tumor promoting pathways, nuclear factor erythroid 2-related factor 2 (Nrf2) and mammalian target of rapamycin (mTOR) signaling were activated. In summary, rAAV-G6PC-mediated gene transfer prevented HCA/HCC development but failed to abrogate the pre-existing tumors that were characterized by the lack of G6Pase- $\alpha$  expression, accumulation of p62, and activation of Nrf2 and mTOR signaling.

**2017T**

***Clec16a* knock out mice suffer excessive weight loss, a process mediated through dysregulated lipophagy and rescued using a JAK/STAT inhibitor.** *R. Pandey<sup>1</sup>, H. Heather<sup>1</sup>, B. Strenkowski<sup>1</sup>, M. Bakay<sup>1</sup>, H. Hakonarson<sup>1,2</sup>.* 1) Children's Hospital Of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, the Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

*CLEC16A* is implicated in multiple autoimmune diseases. *CLEC16A*'s genomic location next to the suppressor of cytokine signaling 1 (SOCS1) gene and role in modulating mitophagy led us to hypothesize that *CLEC16A* exerts its effect on a wide variety of immune cells through modulation of SOCS expression and regulation of cytokine signaling, suggesting that perturbations in the molecular link between *CLEC16A*, mitophagy, lipophagy, and SOCS1 may underlie inflammatory and autoimmune disorders. Consequently, we generated *Clec16a* inducible KO mice to examine the mechanism underlying altered *CLEC16A* expression and autoimmune susceptibility. Our results demonstrate that *Clec16a* KO mice exhibit metabolic disturbances resulting in severe weight loss which is accompanied by a reduction in white adipose tissue and enhanced inflammatory response and energy wasting despite increased food intake. In addition, our ubiquitous *Clec16a* KO mice exhibited dysregulated mitophagy and lipophagy as well as altered cytokine/chemokine profile, thereby contributing to the immune dysregulation and risk of autoimmunity associated with specific *CLEC16A* variants. Indeed, treatment of *Clec16a* KO mice with the pan-JAK/STAT inhibitor, Tofacitinib, partially rescues the pathological lipodystrophic phenotype and improves survival. Taken together, loss of function variants in *CLEC16A* that are associated with decreased *CLEC16A* levels may contribute to autoimmunity through dysregulated mitophagy and lipophagy, while drugs modulating lipolysis or the JAK/STAT pathway reverse the process and may be effective in treating and preventing autoimmunity in individuals with risk associated *CLEC16A* variants. Our study underscores for the first time, critical association of *CLEC16A* with lipid metabolism and unravels the therapeutic potential of the combination of mitophagy and JAK/STAT inhibitors in a myriad of autoimmune diseases and may unveil new directions in treatment interventions of obesity.

**2018F**

**A novel role for a long noncoding RNA in airway differentiation during allergic asthma.** G.J. Kwon<sup>1,2</sup>, M. Yurieva<sup>1</sup>, A. Williams<sup>1,2</sup>. 1) The Jackson Laboratory for Genomic Medicine, Farmington, CT; 2) Department of Genetics and Genome Sciences, University of Connecticut Health, Farmington, CT.

Allergic asthma is characterized by airway hyperresponsiveness to a type 2 adaptive immune response. Immune cells release type 2 cytokines, such as IL-4 and IL-13, which drive airway inflammation. Airway epithelial cells are essential in orchestrating this immune response and undergo distinct morphological changes following type 2 cytokine exposure. However, the molecular pathways regulating these alterations are not fully understood. Long noncoding RNAs (lncRNAs) are defined as non-protein-coding transcripts longer than 200 nucleotides with an increasingly diverse set of functions and are generally more cell-specific than protein-coding transcripts. Despite evidence of their function in regulating the immune response, few lncRNAs have been functionally identified in airway epithelial cells, leading us to speculate their potential role in airway immunity. We cultured primary human bronchial epithelial cells under air-liquid interface (ALI) conditions and performed RNA sequencing from eight individual donors following IL-13 stimulation. The most significantly induced lncRNA was *WFDC21P*, a lncRNA reported to modulate STAT3 dephosphorylation in dendritic cells, but whose function is unknown in airway epithelium. *WFDC21P* is cytoplasmic, highly expressed relative to previously identified lncRNAs in the airway and displays tissue specificity. IL-13 is a critical mediator of differentiation in airway epithelial cells, and we hypothesized *WFDC21P* may mediate differentiation via regulating STAT phosphorylation, similar to dendritic cells. Knockdown via short-hairpin-mediated RNA of *WFDC21P* in an immortalized bronchial epithelial cell line resulted in increased STAT3 signaling, contrary to its effect in dendritic cells. Furthermore, knockdown of *WFDC21P* in primary human bronchial epithelial cells under ALI conditions resulted in morphological disturbances and defective cilia development, as shown by an absence of beating cilia in culture via time lapse and lack of *FOXJ1* expression via quantitative PCR. Our studies reveal a novel role for *WFDC21P* in airway epithelium and type 2 immunity. Current functional studies are underway to further define the effects of *WFDC21P* on the morphology of airway epithelium, in addition to downstream pathways affected by loss of *WFDC21P* following IL-13 exposure via RNA-sequencing. Future studies to understand *WFDC21P*'s mechanism of action will include identifying interacting partners via RNA pulldown followed by mass spectrometry.

**Loss of Cdk5rap3 impairs liver regeneration after partial hepatectomy.** Y. Jia, S. Yang, H. Wang, R. Yang, Y. Huang. Institute of Basic Medical Sciences, Peking Union Medical College, Beijing, China.

Liver regeneration can be induced by hepatic damage, such as partial hepatectomy (PH). Patients with terminal liver failure would be prone to high mortality due to impaired regenerative process. Liver regeneration after PH induced the endoplasmic reticulum stress (ER stress) in remnant hepatocytes. Cdk5rap3, also known as C53 and Lzap, exerts the role in regulating cell cycle, proliferation, apoptosis and adherence/invasion. It was also reported as a potential tumor suppressor. Our previous work demonstrated that Cdk5rap3 plays an important role in mammalian liver development and maintaining endoplasmic reticulum homeostasis. Here, we investigated its function in liver regeneration. Cdk5rap3 liver-specific knockout mice (Cdk5rap3<sup>liver<sup>tm</sup>md</sup> : Alb-Cre, designated as CKO hereafter) were subjected to standard two-thirds partial hepatectomy (PH). We found that Cdk5rap3 deficiency reduced hepatocyte proliferation, induced lipid accumulation, impaired glycogen synthesis, decreased PCNA, PHH3, BrdU-positive cells in the livers of mice after PH. Moreover, the blood glucose was significantly lower in CKO mice compared to WT mice after PH. In regenerating livers, Cdk5rap3 deficiency aggravated ER stress by upregulation of phosphorylation of PERK and Chop expression. Taken together, Cdk5rap3 deficiency impairs liver regeneration, and it might be a possible therapeutic target for patients with terminal liver failure.

Acinar dysplasia (AcDys) is an extremely rare neonatal lethal lung hypoplasia characterized by diffuse maldevelopment of respiratory bronchioles, alveolar ducts, and alveoli with unclear molecular etiology. In a newborn with AcDys, we reported a *de novo* missense variant in *TBX4* (PMID:27374786), known to be involved in lung branching morphogenesis in mice and associated with childhood onset pulmonary hypertension (PMID:23592887) and ischiocoxopodopatellar syndrome (OMIM147891). In addition, a homozygous missense variant in *FGFR2* was described in a patient with AcDys and ectrodactyly (PMID:27323706). Using SNP and CGH arrays, Sanger sequencing, WES, WGS, and reporter assays, we analyzed 25 AcDys and 28 non-AcDys samples. In unrelated patients with AcDys, we identified one novel heterozygous *de novo* missense variant in *TBX4*, five *de novo* recurrent 2.2 Mb CNV deletions at 17q23.1q23.2 and one overlapping *de novo* deletion of 2.12 Mb at 17q23.2q23.3, all including *TBX4*. Additionally, in two AcDys sibs, WGS analyses revealed an 8.6 kb deletion spanning two *TBX4* exons, inherited from their healthy mother. No coding variants in *TBX4* were identified by WES on the second allele in these patients. Intriguingly, the recurrent 17q23.1q23.2 deletion has been reported in patients with heart and limb abnormalities without the AcDys features (OMIM613355). Importantly, WGS of the second allele revealed the presence of at least one non-coding variant in each AcDys patient with structural or sequence variant involving *TBX4* that are absent in non-AcDys patients with 17q23.1q23.2 deletion and showed a statistically significant enrichment of non-coding variants within and upstream to *TBX4* that overlap putative regulatory elements. In four other patients with lung hypoplasia and AcDys features, we identified heterozygous variants involving *FGF10*, known to be functionally interacting with *TBX4* during lung development: two sequence variants (nonsense and frameshift) in *FGF10* and in two family members, 2.5 Mb non-recurrent CNV deletion at 5p12 encompassing *FGF10*. The occurrence of the *TBX4* or *FGF10* rare coding pathogenic variants on one allele in concomitance with the putative hypomorphic non-coding common variants within the regulatory elements on the other allele, suggests a complex autosomal recessive inheritance in patients with AcDys and support the previously proposed role of *TBX4*-*FGF10*-*FGFR2* signaling pathway in human lung organogenesis. (NIH-R01HL137203).

## 2021F

**Long read assay of *DMD* mRNA reveals isoform heterogeneity in normal and Duchenne muscle.** R.T. Wang<sup>1,2</sup>, F. Barthelemy<sup>2,3</sup>, E. Tseng<sup>4</sup>, K. Eng<sup>4</sup>, P. Babayan<sup>4</sup>, M.C. Miceli<sup>5</sup>, S.F. Nelson<sup>1,2,5</sup>. 1) Human Genetics, University of California Los Angeles, Los Angeles, CA; 2) Center for Duchenne Muscular Dystrophy, University of California Los Angeles, Los Angeles, CA; 3) Department of Microbiology, Immunology, and Molecular Genetics, David Geffen School of Medicine and College of Letters and Sciences, University of California, Los Angeles, Los Angeles, CA; 4) Pacific Biosciences, Inc. Menlo Park, CA; 5) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA.

The *DMD* gene is one of the largest and most complex genes in the human genome. It encompasses 2.3Mb (0.1%) of the genome and its 11.3kb long mRNA encodes the essential structural protein dystrophin. Defects in *DMD* give rise to Duchenne muscular dystrophy, a X-linked progressive muscle wasting disease with an incidence of approximately 1 in 3500 male births. Dystrophin is encoded by 79 exons of the *DMD* transcript and consists of an N-terminal actin binding domain, 24 spectrin-like repeats, a cysteine-rich domain and a C-terminal domain. Despite much study into the structure and composition of the *DMD* transcript, its isoforms have been difficult to elucidate due to its enormous length and large number of exons. Using PacBio Iso-Seq technology, we performed long read, single molecule sequencing of cDNA generated from healthy human myoblasts. Transcript lengths ranged from 0.14-11.3kb. We found evidence of extensive isoform heterogeneity with over 300 unique transcripts identified. The primary differentiation between isoforms was their differential exon inclusion and exclusion. The canonical muscle-specific 79-exon isoform was most prevalent, but several novel abundant isoforms excluded nearly all spectrin repeats regions. Exons 71 and 78, which both code for the C-terminal region of dystrophin, were commonly spliced out in multiple isoforms. Isoform diversity was approximately 75% lower in the dystrophic sample from a patient with a deletion in exons 3-23. Overall, long read sequencing identified a large number of novel *DMD* isoforms in wild type and dystrophic human muscle. These results provide a reference of known *DMD* transcripts for use in the development of splice modulating therapies currently in development for Duchenne as well as helping understand the role of dystrophin in muscle biology.

**2022W**

**Somatic activating mutations in *MAP2K1* cause melorheostosis.** J.C. Marini<sup>1</sup>, H. Kang<sup>1</sup>, S. Jha<sup>1</sup>, Z. Deng<sup>2</sup>, N. Fratzl-Zelman<sup>3</sup>, W.A. Cabral<sup>1</sup>, A. Iovic<sup>2</sup>, F. Meylan<sup>2</sup>, E.P. Hanson<sup>2</sup>, E. Lange<sup>2</sup>, J. Katz<sup>2</sup>, P. Roschger<sup>2</sup>, K. Klaushofer<sup>2</sup>, E.W. Cowen<sup>2</sup>, R.M. Siegel<sup>2</sup>, T. Bhattacharyya<sup>2</sup>. 1) National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD; 2) National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, MD; 3) Ludwig Boltzmann Institute of Osteology at the Hanusch Hospital of WGKK, and AUVA Trauma Center Meidling, 1st Medical Department Hanusch Hospital, Vienna, Austria.

Melorheostosis is a benign bone overgrowth condition, with “dripping candle wax” appearance on X-rays. Because melorheostosis occurs sporadically, somatic mutations were hypothesized. We investigated bone tissue with paired biopsies of affected and contralateral unaffected bone of 15 melorheostosis patients. The bone samples were utilized for DNA extraction, osteoblast cultures and histology. Using WES and ddPCR, we identified somatic mutations in *MAP2K1*, encoding the kinase MEK1, in affected, but not unaffected, bone of 8 melorheostosis patients. The variant allele frequency ranged from 3-34%. We found no genomic mutations in *LEMD3* or MAPK-related genes that would support a two-hit mechanism. Mosaicism was shown by immunohistochemistry of p-ERK1/2 in bone tissue and two populations of cultured osteoblasts with distinct p-ERK1/2 levels on flow cytometry. All MEK1 mutations occur in two adjacent residues (p.Q56 and p.K57) in the Negative Regulatory Domain, and produce normal levels of mutant transcripts and protein, supporting an activating mechanism. Osteoblasts from affected bone displayed increased MEK1-ERK1/2 signaling and faster proliferation than cells from unaffected bone. The histology of melorheostotic bone featured parallel layers of lamellar bone on the surface, followed by intense remodeling in the interior of the lesions, with increased osteoblasts and osteoclasts. The elevated osteoclast number reflected the increased RANKL/OPG ratio in affected osteoblasts, stimulating osteoclast development. Also, BMP2-stimulated mineralization was significantly suppressed in cultured affected osteoblasts, explaining the 50-fold increase in unmineralized bone matrix (osteoid per bone surface) seen in the interior of the bone lesions, and reduced osteoblast *RUNX2*, *COL1A1* and *ALPL* expression. Melorheostosis provides the first demonstration that the *MAP2K1* oncogene is important to human bone formation. Interestingly, germline mutations in the catalytic core of *MAP2K1* and the negative regulatory domain of *MAP2K1* and *MAP2K2* were identified in Cardio-Facio-Cutaneous syndrome (CFC). CFC and other RASopathies are associated with variable cardiac, facial and neurodevelopmental defects, but not with bone overgrowth. Somatic *MAP2K1* mutations found in melorheostotic osteoblasts and extracranial arteriovenous malformations apparently have consequences distinct from germline mutations. We conclude that outcomes of *MAP2K1* mutations depend on tissue and timing.

**2023T**

**Regulation of *RUNX2* gene during evolution: Functional implications in nonsyndromic craniosynostosis patients.** W. Lattanzi<sup>1</sup>, M. Barba<sup>1</sup>, L. Di Pietro<sup>1</sup>, P. Frassanito<sup>2</sup>, G. Tamburrini<sup>2</sup>, C. Prampolini<sup>3</sup>, M. Baranzini<sup>3</sup>, V. Orticelli<sup>3</sup>, S.A. Boyadjev<sup>4</sup>, O. Parolini<sup>5</sup>, A. Benitez-Burraco<sup>5</sup>, A. Arcovito<sup>5</sup>. 1) Università Cattolica del Sacro Cuore, Roma, Italy; 2) Pediatric Neurosurgery Unit, Fondazione Policlinico Universitario Agostino Gemelli, Rome, Italy; 3) Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento, CA; 4) Dept. of Spanish, Linguistics, and Theory of Literature, Faculty of Philology, Universidad de Sevilla, Sevilla, Spain; 5) Institute of Biochemistry and Clinical Biochemistry, Università Cattolica del Sacro Cuore, Rome, Italy.

Runt related transcription factor 2 (*RUNX2*) encodes the master transcription factor in bone development. Most *RUNX2* mutations described in the literature result in loss-of-function, which causes cleidocranial dysplasia, whereas increased gene dosage is associated with craniosynostosis. *RUNX2* affects indeed skull ossification and is thought to be involved in the different skull morphology of anatomically-modern humans (AMH) compared with extinct species. The aim of our study was to comparatively characterize the genomic structure of *RUNX2* in AMH and extinct hominins, and to infer putative functional correlations for human skull morphogenesis, using nonsyndromic craniosynostosis (NCS) as a disease model. *RUNX2* sequences from extinct hominins (Neanderthal and Denisova) and AMH genomes were compared, and their functional consequences were predicted *in silico*. The expression of *RUNX2* isoforms and of miRNAs binding to the 3'UTRs of the gene, were then analyzed in NCS suture tissues and cells. The affinity of selected miRNAs to specifically interact with the binding site on *RUNX2* mRNA has been evaluated by SPR-based analysis with the Biacore™ X100 biosensor. *RUNX2* counts 11 splice variants, alternatively transcribed from two promoters, and featuring two alternative 3'UTRs. *In silico* analysis allowed detecting all nt changes between AMH and Neanderthal/Denisova, within noncoding regulatory sequences, and predicting the effect of the 3'UTRs sequence changes on miRNA binding. Gene expression analysis of miRNAs and *RUNX2* splice variants during *in vitro* osteogenic differentiation of suture-derived cells highlighted that miRNAs expression was modulated during the ossification process and correlated with *RUNX2* expression. Particularly the isoform containing the second 3'UTR was apparently stabilized by miRNAs binding. SPR-based biomolecular interaction analysis validated the interaction between selected miRNAs and their *RUNX2* mRNA binding site. Our data suggest that *RUNX2* genomic evolution may have affected regulatory sequence of the gene, affecting a specific splice isoform. Changes at the 3'UTR of the AMH gene modified the epigenetic regulation of *RUNX2*, by altering the binding of selected miRNAs and influencing the expression of bone-specific genes plausibly involved in the evolution of skull shape and volume.

**2024F**

**The role for ribosome biogenesis in disorders of craniofacial development.** *K.E.N. Watt<sup>1</sup>, K. Terrazas<sup>1</sup>, S. Shannon<sup>1</sup>, A. Achilleos<sup>1</sup>, P.A. Trainor<sup>1,2</sup>*. 1) Stowers Institute for Medical Research, Kansas City, MO; 2) Department of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS.

The synthesis of ribosomes is an essential and ubiquitous process for cell survival, growth, and proliferation; however, disruptions in this process result in a group of disorders termed ribosomopathies which display tissue-specific phenotypes. Two examples of ribosomopathies are Acrofacial Dysostosis, Cincinnati Type (AFDCin) and Treacher Collins syndrome (TCS), which exhibit similar facial dysmorphism. AFDCin is also distinguished by various limb anomalies. Pathogenic variants in the RNA Polymerase I (PolI) subunit *POLR1A* are associated with AFDCin, while pathogenic variants in PolI subunits *POLR1C* and *POLR1D*, as well as PolI-associated factor *TCOF1*, underlie the pathogenesis of TCS. Previous studies in zebrafish and mouse models have shown that alterations in these genes result in reduced rDNA transcription, a rate-limiting step of ribosome biogenesis. This leads to both increased cell death and reduced proliferation particularly of neural crest cells, which give rise to the majority of craniofacial cartilage and bone, resulting in cranioskeletal anomalies. In order to fully understand the function of ribosome biogenesis in neural crest cell and skeletal biology, we have conditionally deleted *Polr1a*, *Polr1c*, and *Tcof1* in neural crest cells or at specific times during embryogenesis. These mouse models have revealed that PolI subunits are essential for embryonic survival beyond the blastocyst stage and that there is a specific requirement for PolI genes and associated factors within the neural crest for craniofacial development and embryo survival past mid-gestation. Furthermore, temporal excision of these genes indicates that different tissues may have different threshold requirements for ribosome biogenesis, as some tissues, including cartilage and bone, are more specifically perturbed upon removal of PolI genes. In conclusion, these mouse models provide new information on the role of PolI specifically in neural crest cell and skeletal development. This is important for understanding the role for ribosome biogenesis during normal craniofacial development, and will help in identifying mechanisms underlying the pathogenesis and possible prevention of craniofacial anomalies arising from perturbations in ribosome biogenesis.

**ER-stress involvement in the pathogenic mechanism of Spinocerebellar Ataxia 38 (SCA38).** *E. Di Gregorio<sup>1</sup>, M. Marta<sup>2</sup>, M. Manes<sup>3</sup>, E. Hoxha<sup>4</sup>, C. Costanzi<sup>5</sup>, D. Tripathy<sup>6</sup>, S. Cavalieri<sup>7</sup>, E. Giorgio<sup>8</sup>, C. Mancini<sup>8</sup>, E. Pozzi<sup>8</sup>, E. Riberi<sup>8</sup>, E. Chierto<sup>8</sup>, N. Mitro<sup>8</sup>, D. Caruso<sup>8</sup>, M. Basso<sup>8</sup>, M. Sallèse<sup>8</sup>, F. Tempia<sup>8</sup>, B. Borroni<sup>8</sup>, A. Brusco<sup>1,2</sup>*. 1) Medical Genetics Unit, Città della Salute e della Scienza University Hospital, Turin, Italy; 2) Department of Medical Sciences, University of Turin, Turin, Italy; 3) Neurology Unit, Department of Clinical and Experimental Sciences, University of Brescia, Brescia, Italy; 4) Neuroscience Institute Cavalieri Ottolenghi, Orbassano, Italy; 5) Centre for Integrative Biology, University of Trento, Trento, Italy; 6) University of Turin, Department of Public Health and Pediatrics, Turin, Italy; 7) Department of Pharmacological and Biomolecular Sciences, University of Milan, Milan, Italy; 8) Department of Medical, Oral and Biotechnological Sciences, University G. D'Annunzio, Chieti, Italy.

*ELOVL5* gene is associated with autosomal dominant Spinocerebellar Ataxia 38 (SCA38, MIM#611805), a rare adult-onset cerebellar neurodegeneration. This gene encodes for an elongase, an enzyme localized in the endoplasmic reticulum (ER) where it is involved in the synthesis of a subset of polyunsaturated fatty acids. We explored pathogenic mechanism of SCA38, studying aberrant ELOVL5-p.Gly230Val protein. We demonstrated a subcellular mislocalization in perinuclear area of aberrant protein in different cellular models. Based on these, we hypothesized p.Gly230Val-ELOVL5 is a misfolded protein able to activate the cellular unfolded protein response (UPR). Supporting that idea, we showed a significant increase of ELOVL5 protein in SCA38 fibroblasts after a treatment with the proteasome inhibitor MG-132. In COS7 cells stably expressing p.Gly230Val ELOVL5 we demonstrated the activation of ER-stress response by a significant increase of UPR markers CHOP, ATF-4 and XBP1 and an alteration of ER homeostasis by a slow-down protein transport from ER to the Golgi. Moreover, the use of the chemical chaperone PBA, acting on unfolded p.Gly230Val-ELOVL5 in COS7 cells, led to a physiological ER relocalization of the protein. To determine whether the activation of UPR was associated with neuronal degeneration, we measured cell viability of primary cortical neurons overexpressing wild type or aberrant ELOVL5 and we demonstrated a slightly increased of cells death in p.Gly230Val ELOVL5 neurons. In conclusion, our results support a role for altered ER-stress response in SCA38 pathogenesis, suggesting chemical chaperones might be useful in the treatment.

**Sacs R272C missense homozygous mice develop a milder ataxia phenotype than knock-out mice.** R. Lariviere<sup>1</sup>, N. Sgarioto<sup>1</sup>, B. Toscano Marquez<sup>2</sup>, R. Gaudet<sup>3</sup>, K. Choquet<sup>3</sup>, R.A. McKinney<sup>4</sup>, A.J. Watt<sup>2</sup>, B. Brais<sup>1</sup>. 1) Department of Neurology and Neurosurgery, McGill University, Montreal Neurological Institute, Montreal, Qc, Canada; 2) Department of Biology, McGill University, Montreal, Qc, Canada; 3) Department of Human Genetics, McGill University, Montreal Neurological Institute, Montreal, Qc, Canada; 4) Department of Pharmacology and Therapeutics, McGill University, Montreal, Qc, Canada.

Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS [MIM 270550]) is an early-onset neurodegenerative disorder caused by mutations in the SACS gene. Over 200 SACS mutations worldwide have now been identified. Most mutations lead to a complete loss of saccin, a large 520 kD protein, although some missense mutations are associated with low levels of saccin expression. We previously showed that *Sacs* knock-out mice demonstrate early-onset ataxic phenotype with neurofilament bundling in many neuronal populations. To determine if preservation of some mutated saccin protein resulted in the same cellular and behavioral alterations, we generated mice expressing the R272C missense mutation, a homozygous mutation found in some affected patients. *Sacs*<sup>R272C</sup> mice express 21% of wild-type brain saccin and display similar abnormalities to *Sacs* knock-out mice: they have reduced Purkinje cell firing rate, exhibit somatodendritic neurofilament bundles in neurons, and develop a similar, but milder ataxic phenotype. These results support the hypothesis that low levels of saccin, even if mutated, mitigates the severity of the clinical phenotype.

**2027F**

**Characterization of *STUB1* in zebrafish: Development of a new knock-out model to study neurodegeneration.** Y. Pakdaman<sup>1,2</sup>, S. Johansson<sup>1,2</sup>, I. Aukrust<sup>1,2</sup>, P.M. Knappskog<sup>1,2</sup>, S. Ellingsen<sup>3</sup>. 1) Clinical Science Dept, University of Bergen, Bergen, Norway; 2) Medical Genetics Dept, University of Bergen, Bergen, Norway; 3) Biology Dept, University of Bergen, Bergen, Norway.

Spinocerebellar ataxia-16 (SCAR16) is an autosomal recessive neurodegeneration disorder that develops due to deficiencies in *STUB1* gene encoding the ubiquitin E3 ligase and dimeric co-chaperone CHIP. There is limited knowledge regarding the pathogenic role of mutant CHIP *in vivo* and mechanisms underlying SCAR16. In this project, we aim to study the zebrafish *STUB1* orthologue (*stub1*) by CRISPR/Cas9 mediated knock-out of the *stub1* gene. Single guide RNAs (sgRNAs) targeting a 20 nucleotide-sequence in the last exon of *stub1* gene were constructed and injected together with Cas9 proteins into the 1-cell stage of fertilized wild type zebrafish embryos. High resolution melting (HRM) and MluI-restriction digest of the target sites were used to calculate the frequency of somatic mutations after injection. All injected eggs showed a relatively high frequency of modifications at the *stub1* locus (33-100%) at 48 hours post injection (hpi). Sequencing data showed a wide range of insertions and deletions (indels) within the targeted locus. Analysis of F1 siblings was performed to investigate the frequency of germ-line transmission of *stub1* mutations. One founder showed 100% mutation frequency of offspring and was used to produce F1 heterozygous carriers for the *stub1* mutation with 7nt deletions at position 10800 in the *stub1* gene. F1 siblings from the selected founder were raised and identified carriers of the *stub1* mutation were mated in order to obtain homozygous offspring. So far, we have not detected major differences in viability and morphology of carriers compared to the wild-type, however, further studies are required in order to investigate neurobehavioral and physiological consequences of CHIP deficiency in these fishes. Our findings provide the first evidence of customizing CRISPR/Cas9 system to induce modifications and very likely knock out of the *stub1* gene in zebrafish and contribute to establishing a new animal model for studying *STUB1*-related ataxia disease. Future work will focus on phenotypic analysis of homozygous F2 fish. The homozygous fish will be analyzed for the main phenotypes found in humans with mutation in *STUB1* such as ataxia, movement abnormalities and atrophy of different regions of the brain.

**2028W**

**High throughput screen (HTS) using ARSACS fibroblast cytoskeletal bundling assay.** N. Sgarioto<sup>1</sup>, R. Lariviere<sup>1</sup>, J.P. Chapple<sup>2</sup>, B. Brais<sup>1</sup>. 1) Neurology and Neurosurgery, McGill University, Montreal Neurological Institute Montreal, Quebec, Canada; 2) William Harvey Research Institute, Barts and the London School of Medicine, Queen Mary University of London, London, United Kingdom.

Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) is a Quebec founder disease caused by mutations in the SACS gene. Our data show that the cytoskeletal defects first observed in *Sacs*<sup>-/-</sup> mice and patient brains, are also found in cultured fibroblasts derived from ARSACS patient skin biopsies (HDF). In both primary and immortalized HDF, vimentin intermediate filaments form in the great majority of cells perinuclear bundles. To search for therapeutic molecules we developed a cellular model for high throughput screen (HTS) by expressing a fluorescent-tagged vimentin protein in patient HDFs. Using high-resolution confocal plate reader, we are in the process of screening 20 000 molecules. Our first HTS of 2 000 FDA-approved drugs has uncovered 8 active compounds that had the potential to reverse the ARSACS cytoskeletal phenotype. Validation on 6 different patients HDF carrying 4 different mutations as well as a CRISPR/Cas9 SACS knockout line is under way. The identification of compounds that may influence cytoskeletal bundling formation serve as proof of concept that further HTS screens using this model make uncover therapeutic molecules for ARSACS.

**2029T**

**Disruption of *Tmem30a* results in cerebellar ataxia and degeneration of Purkinje cells.** X. Zhu<sup>1,2</sup>, Y. Yang<sup>2</sup>. 1) Sichuan Academy of Medical Sciences and Sichuan People's Hospital, Chengdu, Sichuan, China; 2) School of Medicine, University of Electronic Science and Technology of China, Chengdu, Sichuan, China.

Mutations in phosphatidylserine (PS) flippase *ATP8A2* cause cerebellar atrophy, mental retardation and disequilibrium syndrome. The proper transport and function of *ATP8A2* require a  $\beta$ -subunit transmembrane protein 30A (TME-M30A). However, the roles of *TMEM30A* in the central nervous system remain elusive. To investigate the role of *Tmem30a* in the cerebellum, we developed a *Tmem30a* Purkinje cell (PC)-specific knockout (KO) mouse model. The *Tmem30a* KO mice displayed early-onset ataxia and progressive PC death. Deficiency in *Tmem30a* led to an increased expression of Glial fibrillary acidic protein (GFAP) and astrogliosis in regions with PC loss. Elevated C/EBP homologous protein (CHOP) and BiP expression levels indicated the presence of endoplasmic reticulum (ER) stress in the PCs prior to visible cell loss. The TUNEL analysis suggested that apoptotic cell death occurred in the cerebellum. Our data demonstrate that loss of *Tmem30a* in PCs results in protein folding and transport defects, a substantial decrease in dendritic spine density, increased astrogliosis and PC death. Altogether, our data demonstrate the essential role of *Tmem30a* in the cerebellum.

**2030F**

**Neuroprotective efficacy of *Bacopa monnieri* (Bramhi) extract: Molecular approach in Parkinson's disease models: *In vivo* and *in vitro* study.** B. Singh<sup>1,2</sup>, S. Pandey<sup>1</sup>, R. Verma<sup>2</sup>, A.A. Mahdi<sup>3</sup>. 1) Biochemistry, King George's Medical University, Lucknow, India; 2) Neurology, King George's Medical University, Lucknow; 3) Era University, Lucknow.

Parkinson's disease is a second most common neurodegenerative disease, with the selective death of dopaminergic neurons and motor impairment. The disease has no absolute cure yet; all the therapeutic strategies involve prescription of dopamine agonist drugs which turn ineffective after prolonged use. We previously reported the propensity of *Bacopa monnieri* (BM) extract against oxidative stress markers and neurogenic parameters at a molecular level in the brain of MPTP treated mice. In this study, we tested the hypothesis whether pretreatment or post-treatment of BM could provide better neuroprotection against rotenone-induced neuroinflammation under *in vitro* and *in-vivo* conditions in the different region of brain tissues. BM exhibited multiple free radical scavenging and anti-inflammatory capacity *in-vitro* study. Pretreatment of neuroblastoma SH-SY5Y cells with BM not only abrogated the generation of inflammation but also offered significant marked protection against rotenone mediated cytotoxicity as compared to post-treatment. These findings were further validated employing rotenone rat model through *in-vivo* study. BM pretreatment completely abolished rotenone-induced inflammatory response in the different region of brain substantia nigra, striatum, hippocampus as compared to standard control treatment L-dopa. We determined the degree of oxidative stress induction, redox status, enzymatic antioxidants and dopamine function in various brain regions of PD rat model provided with BM for one month followed by rotenone challenge (2mg/kg body weight) subcutaneous last four weeks via RT-PCR analysis. BM prophylaxis completely prevented rotenone-induced oxidative dysfunctions and inflammation. Interestingly, BM prophylaxis also prevented the aggregation of alpha-synuclein. Collectively these findings provide evidence on the significant prophylactic neuroprotective efficacy of BM in *in-vitro* as well as *in-vivo* study. Based on these data, it is hypothesized that BM can serve as a useful adjuvant in protecting the brain against oxidative-mediated neurodegenerative disorders.

**2031W**

**Neurobehavioral issues in the phenotypic spectrum of variations in OTX2.** A. Kumar, G. Mainali, M. Yelton, G. Raymond. Penn State Milton S Hershey Medical Center, Hershey, PA.

**Introduction:** The majority of pathogenic variants in the OTX2 gene have been reported in the patients with ocular malformation, pituitary dysfunction with growth hormone deficiency and rarely patients with neurological issues such as developmental delay, learning disabilities, behavioral problems or seizure. We describe a 7-year-old boy with varied neurological presentation found to have two variants in OTX2 which may be related to his phenotype. **Case Presentation:** The proband initially presented at 5 years of age for evaluation of periodic dystonia and ataxia. His birth history and family history was largely unknown as he was adopted but he had complex medical history including developmental delay, failure to thrive, tremors, hypotonia, recurrent vomiting, OSA, periodic dystonia and ataxia. On examination he was short, developmentally delayed with autistic features, dysarthric, appeared anxious with perseveration, hypotonia, titubation, unsteadiness and tremors. MRI of his brain showed thinning of splenium of the corpus callosum, hypoplasia of pituitary gland with ectopic posterior pituitary and a Dandy-Walker variant with prominent fourth ventricle and cisterna magna. 16 gene dystonia panel was negative. Whole exome sequencing showed two variants in OTX2 in cis, p.L61R and p.R69W. He is presently doing well on oxcarbazepine and lamotrigine for dystonia and behavioral issues. **Discussion:** The OTX2 gene, a bicoid-type homeodomain gene, is implicated in the development of brain, eye, and the pituitary. Most of the patients reported have ocular abnormalities most commonly anophthalmia-microphthalmia, short stature due to growth failure from pituitary dysfunction and other neurological abnormalities. Our patient had no eye abnormality but he had pituitary hypoplasia and multiple neurological problems including hypotonia, dystonia, ataxia which has not been reported in the literature. His WES showed two cis-variants in OTX2 p.L61R and p.R69W, that is possibly related to his phenotype. These variants have not previously been reported but are predicted to have a detrimental effect. We are reporting a single individual with intellectual disability, autism, and paroxysmal movement disorder potentially expanding the phenotype seen in variations in OTX2.

**Functional modeling of NMIHBA-causing PRUNE1 variants reveals a requirement for its exopolyphosphatase activity.** *H. Nistala<sup>1</sup>, J. Dronzek<sup>1</sup>, S. Rajamani<sup>2</sup>, S. Nuwayhid<sup>2</sup>, D. Delgado<sup>2</sup>, E. Burke<sup>3</sup>, C. Gonzaga-Jauregi<sup>1</sup>, M. Franklin<sup>2</sup>, C. Schoenherr<sup>1,2</sup>, P. Sarangapani<sup>2</sup>, M.C. Malicdan<sup>3</sup>, J.R. Lupski<sup>1</sup>, W.K. Chung<sup>2</sup>, A.N. Economides<sup>1,2</sup>.* 1) Regeneron Genetics Center, Tarrytown, NY; 2) Regeneron Pharmaceuticals Inc., Tarrytown, NY; 3) Undiagnosed Diseases Program Translational Laboratory, NHGRI, National Institutes of Health, Bethesda, MD; 4) Department of Human Genetics, Baylor College of Medicine, Houston, TX; 5) Columbia University Irving Medical Center, New York NY.

Neurodevelopmental disorder with microcephaly, hypotonia, and variable brain anomalies (NMIHBA, OMIM# 617481) is an autosomal recessive disorder caused by variants in the prune exopolyphosphatase 1 gene (*PRUNE1*). NMIHBA is a debilitating neurodevelopmental and neurodegenerative disorder characterized by global developmental delay and intellectual disability. Microcephaly, progressive cortical atrophy, cerebellar hypoplasia and delayed myelination are neurological hallmarks of affected individuals. In this report, we provide clinical description of two patients harboring compound heterozygous variants c.G383A (p.Arg128Gln), c.G520T (p.Gly174\*) in *PRUNE1*. Furthermore, we demonstrate biochemically that missense variants within the conserved N-terminal aspartic acid-histidine-histidine (DHH) motif result in the destabilization of protein structure and consequent loss of exopolyphosphatase activity, leading to *PRUNE1* loss-of-function. Lastly, we demonstrate that loss of *Prune1* results in embryonic lethality in mouse secondary to structural brain malformations. Taken together, these studies provide a molecular definition of the pathogenesis underlying NMIHBA while underscoring the critical role of *PRUNE1* exopolyphosphatase activity in neurodevelopment.

**2033F**

**CEDNIK syndrome, a rare neuro-cutaneous disorder.** *H.K. Tiwana, G.V. Raymond, A. Johri, A. Kumar.* Penn State Milton S. Hershey Medical Center, Hershey, PA.

Introduction: CEDNIK (cerebral dysgenesis, neuropathy, ichthyosis and keratoderma) syndrome is a rare autosomal recessive neuro-cutaneous disorder characterized by mutation in Synaptosomal-associated protein 29 (*SNAP29*) gene. We present a patient with alteration in *SNAP29* and present the clinical, radiographic, and discuss the role of *SNAP29* in development. Case Presentation: A 26-month old male born to non-consanguineous parents without any prenatal complications, had severe retrognathia at birth requiring G-tube placement and mandibular enhancement procedure. He had severe developmental delay with inability to sit, no speech development, severe cognitive issues and seizures developed at 9 months. Examination showed bilateral epicanthic folds with mid-facial hypoplasia, generalized ichthyosis and diffuse hypotonia. MRI showed multiple brain malformations including partial agenesis of corpus callosum and diffuse polymicrogyria. A sequencing panel showed two mutations, a homozygous pathogenic frame shifts sequence change in the *SNAP29* gene, associated with the CEDNIK syndrome. He has continued to have profound developmental delay and at 2 years is functioning in the 4-6 month range. CONCLUSION: Our patient's DNA analysis of *SNAP29* gene demonstrated a homozygous one base pair duplication in exon 2, c.354dup. This pathogenic sequence change results in an amino acid frameshift and creates a premature stop codon 14 amino acids downstream of the mutation, p.Leu119Alafs\*15. This pathogenic change is predicted to result in an abnormal transcript, causing truncated *SNAP29* protein with abnormal function. SNAP proteins are t-SNARE proteins that function in intracellular vesicle fusion. *SNAP29* has been determined to bind to a broad range of syntaxin fusion proteins and is involved in a number of intracellular transport steps and would impact a variety of neuroectodermal tissues. Recent study suggest that SNAP has additional role as a negative modulator of neurotransmitter release by slowing the recycling of the SNARE-associated fusion machinery and synaptic vesicle turnover. This may be related to the severe neurologic al manifestations shown by patients with CEDNIK syndrome.

## 2034W

**CSF1R allelic and biallelic loss-of-function lead to microglia loss in adult and respectively their complete absence in congenital brain disease.** T.J. van Ham<sup>1</sup>, N. Oosterhof<sup>1</sup>, I.J. Chang<sup>2</sup>, L.E. Kuil<sup>1</sup>, D. Jensen<sup>3</sup>, R. Daza<sup>1</sup>, L. Astle<sup>5</sup>, H. van der Linde<sup>1</sup>, C. Latimer<sup>6</sup>, D. Keene<sup>6</sup>, E. Loter<sup>7</sup>, W.F.J. van IJcken<sup>8</sup>, J.A.A. Demmers<sup>9</sup>, J.C. van Swieten<sup>10,11</sup>, M.H.G. Verheijen<sup>12</sup>, R.F. Hevner<sup>1,6</sup>, J.T. Bennett<sup>2,3,7</sup>. 1) Clinical Genetics, Erasmus University Medical Center, Rotterdam, Netherlands; 2) Department of Pediatrics, Division of Genetic Medicine, University of Washington School of Medicine, Seattle, WA, USA; 3) Center for Developmental Biology and Regenerative Medicine, Seattle Children's Research Institute, Seattle, WA, USA; 4) Center for Integrative Brain Research, Seattle Children's Research Institute, Seattle, WA, USA; 5) Department of Laboratory and Pathology, Alaska Native Tribal Health Consortium, Anchorage, AK, USA; 6) Department of Pathology, University of Washington School of Medicine, Seattle WA USA; 7) Department of Laboratories, Seattle Children's Hospital, Seattle, WA, USA; 8) Center for Biomics, Erasmus Medical Center, Rotterdam, the Netherlands; 9) Proteomics Center, Erasmus University Medical Center, Rotterdam, the Netherlands; 10) Department of Neurology, Erasmus Medical Center, Rotterdam, the Netherlands; 11) Department of Clinical Genetics, VU Medical Center, Amsterdam, the Netherlands; 12) Department of Molecular and Cellular Neurobiology, CNCR, Amsterdam Neuroscience, VU University, Amsterdam, the Netherlands.

Haploinsufficiency of *CSF1R*, a key regulator of microglia, brain resident macrophages, causes adult onset leukoencephalopathy with axonal spheroids (ALSP). ALSP is a rapidly progressive disorder and is considered a microgliopathy, as it is thought that microglial dysfunction is the primary cause. Apart from phagocytosis, microglia functions in the human brain are poorly understood and it is unknown how *CSF1R* variants affect microglia and lead to disease. Here, we report the first neuropathological description of an infant whose brain contained almost no microglia, caused by homozygous pathogenic variants in *CSF1R*. This patient had structural brain anomalies, including agenesis of the corpus callosum (ACC). Neuropathology revealed calcifications, loss of white matter and axonal spheroids, which are also characteristic for ALSP. To investigate underlying mechanisms, we generated zebrafish deficient in both *CSF1R* homologs (*csf1<sup>pm</sup>*). We found that, in *csf1<sup>pm</sup>* zebrafish, microglia were almost absent, but also that haploinsufficiency caused aberrant microglia density and local loss of microglia. We also observed lower microglia numbers and even widespread microglia depletion in post mortem brain tissue of ALSP patients, suggesting loss of microglia may contribute to ALSP pathogenesis. To investigate the consequences of a lack of microglia, we performed brain proteome analysis in control and *csf1<sup>pm</sup>* brain, which identified *Cux1a* as a highly downregulated protein in *csf1<sup>pm</sup>* brain. *CUX1* is expressed in, and regulates, neurons forming the corpus callosum in mice and we found that *CUX1*-expressing neurons were reduced in the *CSF1R* homozygous infant. This suggests that there is a conserved, possibly trophic role of microglia affecting *CUX1*-neurons. As white matter diseases caused by variants in other genes, e.g. *TREM2* and *TYROBP*, are also considered to be microgliopathies, this implies that microglia have essential roles in human white matter. Phenotypic similarities between *CSF1R* haploinsufficiency and biallelic loss-of-function variants, imply that related mechanisms, likely functional loss of microglia, cause severe abnormalities in the embryonic and adult brain. This suggests that having too few microglia is severely detrimental to the adult and developing human brain.

## 2035T

**Loss of function mutations in *EPHB4* are responsible for vein of Galen aneurysmal malformation.** A. Vivanti<sup>1</sup>, A. Ozanne<sup>2</sup>, C. Grondin<sup>1</sup>, G. Saliou<sup>3</sup>, L. Quevarec<sup>1</sup>, H. Maurey<sup>4</sup>, P. Aubourg<sup>4</sup>, A. Benachè<sup>5</sup>, M. Gutè<sup>6</sup>, I. Gutè<sup>6</sup>, J. Martinovic<sup>7</sup>, M.V. Senatè<sup>8</sup>, M. Tawkè<sup>9</sup>, J. Melki<sup>1</sup>. 1) UMR-1169 and University Paris Sud, Inserm, Le Kremlin Bicêtre, Ile de France, France; 2) Department of Neuroradiology, Assistance publique des Hôpitaux de Paris, Hôpital Bicêtre, Le Kremlin-Bicêtre, 94276, France; 3) Department of Diagnostic and Interventional Radiology, Centre Hospitalier Universitaire Vaudois, Lausanne University Hospital, Lausanne, CH-1011, Suisse; 4) Department of Paediatric Neurology, Hôpital Bicêtre, Assistance publique des Hôpitaux de Paris, Le Kremlin-Bicêtre, 94276, France; 5) Department of Obstetrics and Gynecology, Hôpital Antoine-Béclère, Assistance publique des Hôpitaux de Paris, 92140, Clamart, France; 6) CNAG-CRG, Centre for Genomic Regulation, Barcelona Institute of Science and Technology, 08028, Barcelona, Spain; 7) Unit of Fetal Pathology, Hôpital Antoine-Béclère, Assistance publique des Hôpitaux de Paris, 92140, Clamart, France; 8) Department of Obstetrics and Gynecology, Hôpital Bicêtre, Assistance Publique des Hôpitaux de Paris, Le Kremlin-Bicêtre, 94276, France; 9) INSERM UMR-1195, University Paris Sud, Le Kremlin-Bicêtre, 94276, France.

Vein of Galen aneurysmal malformation (VGAM) is one of the most common fetal brain vascular malformations. This results from the persistence of the embryonic prosencephalic vein of Markowski and may lead to congestive heart failure and pulmonary hypertension in neonates, macrocrania, ventriculomegaly, seizures, mental retardation, haemorrhage or venous ischaemia. Clinically, VGAM cases appear to be sporadic. We conducted whole exome sequencing in 19 unrelated VGAM patients and screened candidate gene in a cohort of 32 additional patients using either targeted exome or Sanger sequencing. In a cohort of 51 VGAM patients, we found 5 affected individuals with heterozygous mutations in *EPHB4* including *de novo* frameshift (p.His191Alafs\*32) or inherited deleterious splice or missense mutations predicted to be pathogenic by *in silico* tools. Knockdown of *EPHB4* in zebrafish embryos leads to specific anomalies of dorsal cranial vessels including dorsal longitudinal vein, the ortholog of the median prosencephalic vein, the embryonic precursor of the vein of Galen. This model allowed to demonstrate *EPHB4* loss of function mutations in VGAM by the ability to rescue the brain vascular defect in knockdown zebrafish co-injected with wild type but not truncated *EPHB4* mimicking the p.His191Alafs mutation. Our data showed that in both species, loss of function mutations of *EPHB4* result in specific and similar brain vascular development anomalies (Vivanti et al. 2018). Recently, *EPHB4* germline mutations have been reported in non-immune hydrops fetalis and in cutaneous capillary malformation–arteriovenous malformation. Here, we show that *EPHB4* mutations are also responsible for VGAM indicating that heterozygous germline mutations of *EPHB4* result in a large clinical spectrum. The identification of *EPHB4* pathogenic mutation in patients presenting capillary malformation or VGAM should lead to careful follow up of pregnancy of carriers for early detection of VGAM in order to propose optimal neonatal care. Endovascular embolization indeed greatly improved the prognosis of VGAM patients.

**Neuron-specific activation of a patient mutation reveals the prominent role of forebrain excitatory neurons in *SCN8A* epileptic encephalopathy.** J.L. Wagnon<sup>1</sup>, R.K.A. Bunton-Stashyshyn<sup>1</sup>, A. Faulkner<sup>1</sup>, E.R. Wengert<sup>2</sup>, P. Wagley<sup>3</sup>, Y. Yuan<sup>4</sup>, K. Bhatia<sup>5</sup>, J.M. Jones<sup>1</sup>, L.L. Isom<sup>1</sup>, J.M. Parent<sup>5</sup>, H.P. Goodkin<sup>2</sup>, M.K. Patel<sup>1</sup>, M.H. Meisler<sup>1,5</sup>. 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Anesthesiology, University of Virginia, Charlottesville, VA; 3) Neurology, University of Virginia Health System, Charlottesville, VA; 4) Pharmacology, University of Michigan, Ann Arbor, MI; 5) Neurology, University of Michigan, Ann Arbor, MI.

*De novo* mutations of the sodium channel gene *SCN8A* cause severe epileptic encephalopathy with early seizure onset, developmental delay, movement disorders, and elevated risk of sudden death. A previously described knock-in mouse model carrying the patient mutation p.Asn1768Asp (N1768D) recapitulated the seizures and sudden death characteristic of the disorder. To define the contributions of specific neuronal populations to the seizure phenotype, we generated a conditional allele of *Scn8a* that can be activated by Cre recombinase. We chose the recurrent *de novo* mutation p.Arg1872Trp (R1872W), which has been seen in 14 unrelated individuals with severe *SCN8A* encephalopathy. We used TALENs and a targeting vector to insert two copies of the final *Scn8a* exon 26 into the endogenous locus. The upstream copy of exon 26 is flanked by loxP sites and encodes wildtype Arg1872. Upon exposure to CRE, the upstream copy is removed and expression of the downstream exon containing the R1872W mutation is activated. We crossed mice with the conditional *Scn8a* allele with mice expressing Ella-Cre to generate heterozygous mice with global, constitutive expression of R1872W. We also used Nestin-Cre (pan-neural), Emx1-Cre (excitatory neurons), and Gad2-Cre (inhibitory neurons) to evaluate contributions of neuronal subpopulations to *SCN8A* encephalopathy. We evaluated age of seizure onset, survival, video-EEG, and neuronal firing in brain slice recordings. Global activation of R1872W with Ella-cre resulted in seizure onset at 2 weeks of age followed by death within 24 hours, often immediately after the first seizure. Brain slice recordings revealed sustained spontaneous firing in cortex and hippocampus indicative of extreme neuronal hyperexcitability. Pan-neural activation by Nestin-Cre also resulted in early seizure onset and sudden death. Activation of R1872W in excitatory neurons by Emx1-Cre was sufficient to cause seizures and sudden death, with onset between 3 weeks and 2 months of age. In contrast, activation of R1872W in inhibitory neurons with Gad2-Cre did not induce seizures, neurological dysfunction or abnormal EEG. These findings provide insight into the pathogenic mechanism of gain-of-function mutations of *SCN8A*. The work underscores the differences between *SCN8A* encephalopathy and Dravet Syndrome caused by haploinsufficiency of *SCN1A* in inhibitory neurons. Our observations identify excitatory neurons as critical targets for therapeutic intervention.

Rett syndrome (RTT) is an X linked neurodevelopmental disorder that predominantly occurs in females. RTT, caused by mutations in the *MECP2* gene encoding the MeCP2-e1 and MeCP2-e2 isoforms, is diagnosed within the first 24-36 months of life and presents early as loss of speech, mobility, and purposeful hand movements followed by breathing abnormalities, seizures and gastrointestinal symptoms in later disease stages. To model the RTT disease process and identify potential treatments we have recapitulated an *MECP2* mutation from a RTT patient in a mouse model. This model establishes that loss of the MeCP2-e1 isoform and not the MeCP2-e2 isoform underlies the RTT phenotype as *Mecp2-e1*<sup>-/-</sup> deficient mice have severe motor and behavioral deficits and die by 30 weeks of age. For the current studies we have expanded behavioral and motor characterization of *Mecp2-e1*<sup>-/-</sup> females and *Mecp2-e1*<sup>-/-</sup> males by performing repeated analysis of motor tasks using rotarod, beam walking and gait assays throughout the disease process up to 18 weeks of age. *Mecp2-e1*<sup>-/-</sup> females and *Mecp2-e1*<sup>-/-</sup> males have significant increases (p<0.05) in hind limb clasping while *Mecp2-e1*<sup>-/-</sup> females show increased beam walking times (p<0.05), along with reduced latency to fall in rotarod and altered gait (p<0.05). In an independent cohort of early disease stage *Mecp2-e1* deficient animals, metabolism, sleep, and total activity was determined using Comprehensive Lab Animal Monitoring System analysis, while body composition was assayed by Dual-energy X-ray Absorptiometry and untargeted liver lipid profiling was performed by mass spectrometric analysis. *Mecp2-e1*<sup>-/-</sup> mice show a significant elevation of respiratory exchange rate (p=0.0368), significant reductions in energy intake (p=0.0174) and activity (p=0.023) along with reduced sleep (p=0.0085) and elevated percent body fat (p=0.0096). Analyses of *Mecp2-e1*<sup>-/-</sup> females revealed significantly elevated body fat content (p=0.0183) along with elevated liver cholesterol esters 204 and 181 and triglycerides 502, 568 and 589. The identification of early metabolic alterations, body composition changes and sleep defects in *Mecp2-e1*<sup>-/-</sup> male mice along with body composition and motor defects in *Mecp2-e1*<sup>-/-</sup> females suggests novel mechanisms underlying disease progression in RTT model mice. Identification of these early phenotypic effects may lead to development of potential RTT translatable therapies.

**Role of the DUF1220 protein domain in neurogenesis.** *E.A. Werren*<sup>1,2</sup>, *A.W. Bigham*<sup>2</sup>, *S.L. Bielas*<sup>1</sup>. 1) Human Genetics, University of Michigan, Ann Arbor, MI, USA; 2) Anthropology, University of Michigan, Ann Arbor, MI, USA.

Recurrent, reciprocal genomic disorders resulting from segmental duplications in humans are a major cause of disease and a source for highly plastic genomic regions subject to human-lineage specific evolution. The DUF1220 (Olduvai) protein domain has undergone a significant expansion in copy number in the human lineage. This protein domain is encoded by the neuroblastoma breakpoint family (*NBPF*) genes, located primarily on chromosome 1 and enriched in the 1q21 region. DUF1220 can be sub-classified into six clades – three of which are conserved across primates, and three are human-lineage specific (HLS). Interestingly, in *NBPF* genes located within the 1q21 region, the three DUF1220 HLS domains have undergone extreme amplification. Mutations in 1q21 have been linked to several neurodevelopmental disorders with clinical features including microcephaly, macrocephaly, and autism spectrum disorder. Recent studies have shown that increased copy number of the DUF1220 domain is associated with increased proliferation in human neural stem cells. Likewise, peak DUF1220 expression in early- to mid-fetal brain tissues during development, overlapping with periods of cortical neurogenesis. However, the precise molecular mechanism behind the domain's effect on neural proliferation is unknown. We detect NBPF in neural progenitor cells (NPCs) differentiated from H9 embryonic stem cells. NBPF co-localizes with vesicles and the cleavage furrow at the late stages of cytokinesis, consistent with cell biology described as the molecular basis of primary microcephaly. We will test the hypothesis that the type of DUF1220 expansion and the domain clade contribute to early human brain development using 3D cerebral organoids differentiated from human embryonic stem cells.

**Gabapentin therapy: Improvement in neurologic and behavioral phenotype of patient with *GABRB2* and *CHAMP1* dual diagnosis.** *A. Basunia*<sup>1</sup>, *M. Byler*<sup>1</sup>, *N. Havernick*<sup>2</sup>, *J.A. Bassetti*<sup>3</sup>, *H. Cui*<sup>4</sup>, *C. Eng*<sup>5</sup>, *RR. Lebel*<sup>1</sup>. 1) Section of Medical Genetics, SUNY Upstate Medical University, Syracuse, NY; 2) Department of Neurology, SUNY Upstate Medical University, Syracuse, NY; 3) Department of Pediatrics, Weill Cornell Medicine, New York, NY; 4) School of Information, University of Arizona, Tucson, Az; 5) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Our female patient was born to a non-consanguineous 28 year old Caucasian father and a 26 year primigravida Caucasian mother at 40 weeks gestation following pregnancy complicated by bleeding in the late second trimester. There were no suspected teratogen exposures and family history revealed no intellectual disability or genetic disorders. She developed severely adverse phenotype including developmental delays, dysmorphic features and hypotonia at 2 months and partial complex seizures at 12 months. Whole-exome analysis revealed a pathogenic *de novo* *CHAMP1* frameshift mutation (c.1876\_1877del; p.S626fs) as the underlying cause. Levetiracetam was used with beneficial effects. The *GABRB2* mutation (c.236T>C; p.M79T) was discovered upon revisiting the database, and Gabapentin was then added to the regimen. Soon thereafter, it was apparent that in addition to excellent seizure control the patient was also demonstrating improved global neurologic function.  $GABA_A$  receptors are multi-subunit inhibitory chloride channels of the central nervous system. Mutations in  $GABA_A$  genes, such as *GABRB2*, have all been associated with epilepsy and/or developmental delays. The M79T *GABRB2* variant is found in the N-terminal extracellular domain associated with GABA binding, particularly in allosteric changes. Thus, the variant may reduce functionality of  $GABA_A$  receptor by hampering fast synaptic inhibition and decreasing the threshold for seizure. Gabapentin modulates the activity of GABA biosynthesis enzymes, increasing GABA concentration in the postsynaptic cleft and thus the probability of GABA -  $GABA_A$  receptor interactions. A comparative analysis of the response to various anti-epileptic drugs (AEDs) in children with pathogenic *GABRB2* mutations was subsequently performed. While response to AED combination therapies varied markedly even within recurrent *de novo* mutations, Gabapentin was efficacious in alleviating motor symptoms in a 4 year old male patient multifocal seizures and dystonic movements. Until the genomic era, the treatment of seizures in neonates and children was strictly empiric and based on pharmacokinetics, adverse effects and potential drug-drug interactions. Targeting underlying molecular mutations identified through genomic analysis should be therapeutically effective for management of such patients.

**Using zebrafish as a tool to model patient mutations of *KCNB1* and its role in epilepsy.** M.Y. Dennis<sup>1</sup>, A. Colón-Rodríguez<sup>1</sup>, K. Burbach<sup>1</sup>, E. Ferino<sup>1</sup>, M. Bader<sup>1</sup>, P. Lein<sup>2</sup>, L. Jao<sup>3</sup>. 1) Genome Center, MIND Institute, and Department of Biochemistry & Molecular Medicine, University of California, Davis, CA; 2) Department of Molecular Biosciences, University of California, Davis, CA; 3) Department of Cell Biology and Human Anatomy, University of California, Davis, CA.

Genetic factors responsible for complex neurological disorders, including epilepsy, are not fully understood. *De novo* mutations in *KCNB1* encoding K.2.1 voltage gated potassium channel have been identified in patients with sporadic infantile epilepsy. Nearly all variants identified are missense making their pathogenicity uncertain. *Kcnb1* homozygous null mice exhibit neuronal hyperexcitability, sensitivity to convulsant-induced seizures, defects in spatial learning and motor activity, and anxiety-like behavior. A recent study examining *kcnb1* null mutants in zebrafish resulted in a reduced ventricular system and gain of function caused hydrocephalus; however, additional phenotypic and neuronal alterations were not examined. Zebrafish are a compelling organism to model neurodevelopmental disorders due to their considerable orthology of genes (~70%) and synaptic function with humans. The relative ease to gene edit and produce great numbers of offspring allow for higher-throughput experiments compared with mouse. Using gene editing, we produced knockout alleles of *kcnb1* and performed subsequent morphological and behavioral analyses in zebrafish larvae. Our results show no significant differences between mutant zebrafish carrying one (heterozygote) or two (homozygous) null alleles compared to wildtype fish in body or head size. However, there was a significant increase in activity (distance moved) between heterozygous and homozygous fish in the presence of PTZ, a GABA<sub>A</sub> antagonist, recapitulating phenotypes observed previously in *Kcnb1* null mice. Considering the majority of patient mutations are amino-acid substitutions, efforts to introduce missense variants at evolutionarily conserved sites using gene editing are ongoing. The results of this study will lay the groundwork to: (1) identify neurodevelopmental alterations of *kcnb1* mutations in zebrafish; and (2) develop tools that we will continue to use as we move forward to characterize unknown disease-related mutations in a higher-throughput manner.

**PCDH19 regulation of neural progenitor cell differentiation suggests asynchrony of neurogenesis as a mechanism contributing to PCDH19 Girls Clustering Epilepsy.** L.A. Jolly<sup>1,2</sup>, C.C. Homan<sup>1,2</sup>, S. Pederson<sup>1</sup>, T. To<sup>1</sup>, C. Tan<sup>1</sup>, S. Piltz<sup>1,3</sup>, M. Corbett<sup>1,2</sup>, E. Wolvetang<sup>4</sup>, P. Thomas<sup>1,3</sup>, J. Gecz<sup>1,2,3</sup>. 1) University of Adelaide, Adelaide, South Australia, Australia; 2) Robinson Research Institute, Adelaide, South Australia, Australia; 3) South Australian Health and Medical Research Institute, Adelaide South Australia, Australia; 4) Australian Institute for Bioengineering and Nanotechnology, The University of Queensland, Queensland, Australia.

PCDH19-Girls Clustering Epilepsy (PCDH19-GCE) is a female restricted childhood epileptic encephalopathy characterised by a spectrum of neurodevelopmental problems. PCDH19-GCE is caused by heterozygous loss-of-function mutations in the X-chromosome gene, *Protocadherin 19* (*PCDH19*) encoding a cell-cell adhesion molecule. Intriguingly, hemizygous males are generally unaffected. As *PCDH19* is subjected to random X-inactivation, heterozygous females are comprised of a mosaic of cells expressing either the normal or mutant allele, which is thought to drive pathology. In alignment, males displaying somatic mosaicism of *PCDH19* mutations also present with the disorder. Despite being the second most prevalent monogenic cause of epilepsy, little is known about the role of PCDH19 in brain development. Here we show that PCDH19 is highly expressed in human neural stem and progenitor cells (NSPCs) and investigate its function *in vitro* in these cells of both mouse and human origin. Transcriptomic analysis of mouse NSPCs lacking *Pcdh19* revealed changes to genes involved in regulation of neuronal differentiation, and we subsequently show that loss of *Pcdh19* causes increased NSPC neurogenesis. We reprogrammed human fibroblast cells harbouring a pathogenic *PCDH19* mutation into human induced pluripotent stem cells (hiPSC) and employed neural differentiation of these to extend our studies into human NSPCs. As in mouse, loss of PCDH19 function caused increased neurogenesis, and furthermore, we show this is associated with a loss of human NSPC apical-basal polarity. Overall our data suggests a conserved role for *PCDH19* in regulating mammalian cortical neurogenesis and has implications for the pathogenesis of PCDH19-GCE. We propose that the difference in timing or 'heterochrony' of neuronal cell production originating from PCDH19 wildtype and mutant NSPCs within the same individual contributes to downstream disruption to neuronal network formation, predisposing the individual to network dysfunction and epileptic activity.
