Novel Germline and Somatic Mutations of the MSH2 Gene in Hereditary Nonpolyposis Colorectal Cancer. *D.C. Ding[1,2], R.L. Huang[3], T.Y. Chu[1], K.S. Hwang[3]* 1) Dept of Obstetrics and Gynecology, Buddhist Tzu Chi General Hospital, Hualien, Taiwan, R.O.C; 2) Graduate Institute of Medical Science, Tzu Chi University, Haulien, Taiwan, R.O.C; 3) Dept of Obstetrics and Gynecology, Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan, R.O.C.

The non-epigenetic somatic second hits of the mismatch repair genes in hereditary nonpolyposis colorectal cancer (HNPCC) were not experimentally characterized before. We describe a HNPCC family in which the proband was found with synchronous cancers of endometrium, ureter, and bladder. A novel germline IVS 12 -2A>G splice acceptor site mutation of the MSH2 gene, 4 bases downstream to the known IVS12 -6T>C polymorphism site, was identified. The allelic specific second hits in different primary tumors were analyzed. In an in-situ transitional cell carcinoma, the wild type allele was lost by loss of heterozygosity (LOH), leaving a transcript skipping the exon 13. In the invasive endometrial carcinoma, LOH of the germline mutant allele occurred. This allowed the discovery of a somatic c.1637 delT mutation at exon 10 of the wild type allele. Replication error phenotype was evident in both of these two tumors. The novel splice acceptor site mutation underscores the importance of the canonical sequences around the splice acceptor site in RNA splicing. To our knowledge, this is the first discovery of a non-deletion somatic mutation of the wild type allele of the mismatch repair gene in HNPCC tumor.

Long QT, Syndactyly, Cardiac Defect, Joint Contractures and Stroke: Expanding the Clinical Spectrum of Timothy Syndrome, or a New Syndrome? *J. Gillis*[1,2], *G. Gross*[2], *D. Chitayat*[1,2] 1) Dept. of Medical Genetics, University of Toronto, Toronto, ON, Canada; 2) The Hospital for Sick Children, Toronto, ON, Canada.

Timothy Syndrome (TS) is a rare disorder characterized by cardiac arrhythmia, congenital heart disease, syndactyly, facial anomalies and neurologic sequelae including seizure, mental retardation, hypotonia and autism. Previous reports have shown that TS results from a de novo missense mutation in the $Ca_v1.2$ L-type calcium channel (CACNA1C) gene. Of the few cases reported, most present in the newborn period with no other known affected family members. Despite elucidation and characterization of the causative gene, the mode of inheritance remains elusive, and the prognosis is poor. We report a male newborn, born to a healthy, non-consanguinous couple, following an uncomplicated pregnancy and delivery, who presented with marked ventricular repolarization delay with several self-limited episodes of torsades des pointes and prolonged QTc interval on ECG. On clinical exam, he had wide fontanelles, split sutures and facial dysmorphism including: high forehead, frontal bossing, deep set eyes, micrognathia and fleshy low-set ears. Others features included short neck, sloped shoulders and syndactyly of the fingers and toes, ulnar deviation of the 2nd-5th fingers and dorsiflexion contractures of both hands and bilateral dorsiflexion of both feet. Subluxation of both hips was confirmed by ultrasound. He developed seizures, suffered an acute left hemispheric infarct and further episodes of arrhythmia. Rate control was achieved with beta-blocker. On early follow up, he demonstrates high intelligence and is advanced with his developmental milestones. There was no evidence of immune deficiency. Results of mutation analysis of the CACNA1C gene are pending. Collagen studies are being done to rule out concurrent connective tissue disease. Most of the findings in our patient are consistent with Timothy Syndrome. However, the contractures, facial dysmorphism and stroke have not yet been reported with this condition. This may be other manifestations not yet reported, or a new syndrome.

Molecular differences in breast tumors from African American and Caucasian women. *R.E. Ellsworth[1], J.A. Hooke[2], C.D. Shriver[2]* 1) Clinical Breast Care Project, Windber Research Inst, Windber, PA; 2) Clinical Breast Care Project, Walter Reed Army Medical Center, Washington, DC.

Breast carcinomas display different characteristics in African American women (AAW) compared to Caucasian women (CW), including earlier onset and less favorable clinical outcome. The less favorable prognosis in AAW has often been attributed to socioeconomic status, including access to quality-health care, however, these differences in outcome may also have a genetic contribution. To assess whether breast tumors from AAW differ at the molecular level from those from CW, a number of molecular markers, including ER, PR, HER2, Ki67, and p53 were examined in invasive tumor specimens from AAW (n=66) and CW (n=282) treated at Walter Reed Army Medical Center (WRAMC), an equal-access health care facility. When examined independently, breast tumors from AAW had significantly ($P<0.05$) higher frequencies of the following markers compared to those from CW: ER negative (46% vs. 20%) and PR negative (53% vs. 27%) negativity, and positive HER2 status (44% vs. 27%). AAW more frequently had the triple negative (ER-, PR- and HER2-) phenotype ($P<0.005$) than CW. Ki67 levels did not differ significantly between the two groups, however, differences in p53 status were significant, with 52% of tumors from AAW having positive p53 status compared to 30% of tumors from CW. Because 100% of the AAW patients with invasive breast cancer received regular screening mammograms, differences in tumor phenotype and outcome were likely not attributable to under utilization of early medical interventions. Together, these data suggest breast tumors in AAW differ at the molecular level from those in CW.

An infertile male with apparent 45,X turned out to have 45,X,der(Y)t(Y;13)(q11.1;q11),-13; Clinicopathologic and cytogenomics studies. *Y.X. Cui[1], X.Y. Xia[1], L.J. Pan[1], Y.H. Wang[1], J. Xu[2], Y.F. Huang[1]* 1) Department of Reproduction and Genetics, Jinling Hospital, Nanjing University School of Medicine, Nanjing, Jiangsu, China; 2) Cytogenetics Laboratory, London Health Sciences Centre and University of Western Ontario, Canada.

A 25-year-old Chinese man with a history of 3 years of infertility was diagnosed with azoospermia. His testes were slightly soft and marked small (8 ml, bilaterally vs.19.87.1 ml for a normal adult Chinese). He had normal male external genitalia, relative poor beard and slightly bilateral gynecomastia. His intelligence and development were normal. His serum testosterone was 7.9nmol/L by radioimmunoassay (vs. 9.4-37.0 nmol/L for a normal adult Chinese). His FSH, LH, estradiol, and prolactin concentrations were within normal ranges. Biopsy of the left testis showed the presence of only Sertoli cells and absence of germ cells in all seminiferous tubules examined. Initial routine cytogenetics of both lymphocytes and testicular fibroblasts suggested a karyotype of 45,X with a bit of uncertainty about the proximal regions of one chromosome 13. PCR using STSs including sY14 indicated the presence of SRY gene in the genome. FISH using probes wcp13, SRY, and X/Y CEP showed the presence of SRY and Y centromere in the questionable chromosome 13. The parents had a normal karyotype. The patient's karyotype was reinterpreted to be 45,X,der(Y)t(Y;13)(q11.1;q11),-13.ish der(Y)(SRY+, DYZ3+, wcp13+). This is an unbalanced karyotype with deletion of 13pter-q11 and Yq11-qter including the 3 azoopermia factor regions AZFa, b and c. PCR using 16 STSs in AZFa (interval 5C), AZFb(interval 5P-6A), and AZFc(interval 6D-6F) mapped the breakpoint to the interval 5B below sY82. DNA polymorphism analysis showed the chromosome X is of maternal origin. We propose that Y;13 recombination likely occurred during paternal meiosis. In literature, there are 9 cases of 45,X male with Y-acrocentrics (14, 15, 21, 22) translocation involving Yq11. To our knowledge, this is the first reported case with a 45,X,der(Y)t(Y;13) (q11.1;q11),-13, which will be useful for the phenotype/molecular karyotype correlation.

Co-occurring asthma and externalizing symptoms: Genetic and environmental influences by child gender and reporter. *R.P. Goin-Kochel[1], J.L. Silberg[2], L.J. Eaves[2]* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Virginia Institute for Psychiatric & Behavioral Genetics, Virginia Commonwealth University, Richmond, VA.

Background and Purpose: Prior work has often detected a relationship between asthma and externalizing symptoms in children, and one study concluded that the association was based on a common genetic etiology. However, this work relied solely on parental report of childrens symptoms and did not have the statistical power to analyze data separately by child sex. The purpose of the current project, then, was to help clarify the nature of the relationship between these two phenotypes. **Methods**: We examined the relationship between asthma and externalizing symptoms among a population-based sample of adolescent twins (n = 1014) to assess the relative influence of both shared and trait-specific genetic and environmental influences. Maternal reports of asthma and both child and maternal reports of externalizing behaviors from the Virginia Twin Study of Adolescent Behavioral Development (VTSABD) were analyzed for boys and girls separately using structural equation modeling within the classic twin-study design. **Results**: Twin correlations were higher in MZ versus DZ twins for the two traits. For girls, the relationship between asthma and externalizing symptoms was best explained solely by additive-genetic factors, whereas for boys, this relationship was best accounted for by individual specific-environment effects. These findings were observed within both maternal and child reports, although parameter estimates differed between the two. **Conclusions**: Our results suggest different etiologies for co-occurring asthma and externalizing behaviors between the sexes. They further highlight the importance of considering gender differences, particularly in the context of adolescence, where different developmental trends may be at work, as has previously been reported for asthma. Future studies may elucidate which of these phenotypes presents first, potentially influencing the development of the second, by examining these data longitudinally, beginning at the earliest ages possible, when asthma is most acute.

Reciprocal Chromosomal Translocations, 47,XY, t(11;14) +der(14) t(11;14) (q25;q24.1), 46,XY,t(1;4) (q11-12;q11), 46,XY,t(6;9) (p21;q34) and 45,XY, der(13;15) (q10;q10). Four Mexican Pediatric Cases Report. *J. Aparicio[1,6], M. Barrientos[2], M.L. Hurtado[3], C. Gil[4,6], R. Ruiz[5], W. San Martin[4], C. Salinas[7]* 1) Dept Genetics,; 2) Endocrinology,; 3) Cytogenetics,; 4) Estomatology,; 5) Pediatrics, Hosp para el Nino Poblano, Puebla; 6) Estomatology, Benemerita Universidad Autonoma de Puebla, Mexico; 7) Estomatology and Genetics, univ of South Carolina, USA.

INTRODUCTIÓN. The reciprocal translocations should not be in relation to fenotipical malformations, since there should not be DNA alteration. however, fenotipical malformations, mental retardation and neoplasic proceses have been reported.CLINICAL CASES. Pacient 1: An adolescent male with a fibro-osseous lesion of the jaws, a non familiar gigantiform cementoma, radiologically and histopathologically, with a flat fascies and minor phenotypic alterations. A de novo reciprocal translocation between chromosomes 1 and 4. Pacient 2: A 9 years male with mental retardation, facial malformations, polidactilia, hypertricosis, small genitalia and obesity, with a translocation, 46,xy,t(6;9). both parents with a normal cariotype. Pacient 3: A newborn male with partial trisomy of chromosome 14 (14q24) and a translocation t(11;14), with , lobar neumony, hidrocele, septicemia, interauricular septal defect, cleft palate and a dismorfic phenotipe. Patient 4: A 10 years male, with oligodoncy and hyperkinesis with a 45,xy,der(13;15). Has an affected carrier mother 45,xx der(13;15). CONCLUSIONS. some chromosomal translocations has been reported as primary etiological factor for different kind of clinical malformations and celular neoplasias. t(1;4), t(6;9), t(11;14) and t(13,15) has been thought to be in relation to cell lymphoma, leukemia and other kind of neoplasias, originating from pre-immune b-cells in the mantle zone of the primary follicles in secondary lymphoid organs. in b-prolymphocytic leukaemia, in plasma cell leukaemia, and in chronic lymphocytic leukaemia, in multiple myeloma and also in immunosupresion events. it is important to study such chromosmal translocations in afected children in order to get an earlier treatment for a better quality of life.

Risck factors associated with a late Dental Exfolation in a small Mexican town with a High Consanguinity Degree. *S.A. Arias[1], J. Aparicio[1,2], G. Quintanar[1], M.A. Parra[1]* 1) Estomatology, Benemerita Universidad Autonoma de Puebla; 2) Genetics, Hospital para el Niño Poblano, Puebla, Mexico.

INTRODUCTION. The formation of human dentition begins as early as the 6th week in utero, during which, tooth buds of the primary (deciduous) teeth develop at 10 specific sites in the developing maxilla and mandible. Primary teeth begin to calcify at about 3 to 4 months in utero, and the enamel of all crowns is completed by 10 months after birth. Beneath the primary teeth, 20 permanent (succedaneous) teeth develop. As root development takes place in the permanent teeth underneath, this causes exfoliation of the primary teeth. Osteoclast formation is stimulated, which results in the resorption of the roots of the primary teeth and their subsequent loss. MATERIALS AND METHODS. Several families with late dental exfoliation and duplication (poliodoncy) was observed in a small Mexican Town. The families were estudied by performing radiological, metabolic, chromosomal studies and genetic pedigree to evaluated a mendelian inheritance on the population due to consanguinity. DISSCUSION. With the exfoliation of primary teeth and replacement by permanent teeth, the child enters a mixed-dentition stage. Permanent teeth erupt in the following sequence: lower central incisor and first molars at about age 6 to 7, followed by the upper central incisor and lateral incisors, the canines and premolars, second molars, and finally third molars during late teens up to the early twenties. Disorders of tooth eruption and positioning are common pediatric dental problems that present clinically as maloclusion or abnormal alignment of the dentition. Delayed eruption of all teeth is indicative of developmental delay, hormonal abnormalities, and nutritional or systemic disturbances Failure of eruption of single or small groups of teeth suggests local causes such as malpositioning of teeth, supernumerary (extra) teeth, retained primary teeth, or cysts. CONCLUSIONS. All genetic studies were normal in relation to late exfoliation, however some families had also chidren with albinism, where future studies will be also perfomed to find out the relation with consanguinity to provide genetic counseling.

Novel contiguous gene deletions and duplications in patients with developmental delay, mental retardation, and dysmorphology. *S. Aradhya[1], M. Manning[1,2], A.M. Cherry[1]* 1) Clinical cytogenetics, Stanford University, Stanford, CA; 2) Division of Medical Genetics, Stanford University, Stanford, CA.

Developmental delay is often seen in conjunction with mental retardation and dysmorphic features. This broad phenotype is observed in approximately 1-3% of children and is most often due to chromosomal abnormalities, although it is often difficult to recognize the specific genomic imbalance with conventional methods. We have studied a cohort of 20 patients with developmental delay in an effort to identify the underlying genetic causes. Some of these patients also had mental retardation and dysmorphic characteristics. Conventional cytogenetic analysis by karyotyping and sub-telomere fluorescence in situ hybridization (FISH) had previously yielded normal results for these patients. The Human Genome Project has encouraged the development of highly sensitive assays to detect quantitative changes in genetic material. Using whole genome microarrays, we identified eleven unique mutations of which nine were deletions and two were duplications. The mutations ranged in size from 280kb to 3 Mb. Virtually all of the patients also carried large-scale deletion and duplication polymorphisms, some of which were new. The mutations were confirmed by FISH and were shown to have occurred *de novo* in the respective families. All of the cytogenetic alterations found in our patients, with the exception of one, were large enough to encompass several genes, suggesting that diffuse phenotypes like developmental delay are due to contiguous aberrations in a significant fraction of these patients. Our results also underscore the strength of high-resolution genomic arrays in diagnosing cases of unknown genetic etiology. Eight of the eleven mutations have not been previously reported and represent novel genetic syndromes. Our findings add to an increasing number of genetic disorders caused by large-scale deletions or duplications. As genes in the respective mutation intervals are further studied, these new clinical entities will provide valuable insight into mechanisms that regulate prenatal and neonatal development.

Heterochromatin variations may cause changes in the quality of sperm. *A. Amiel[1,2], F. Sardos-Albertini[1], B. Bartoov[2], M.D. Fejgin[1,3]* 1) Genetics Institute, Meir medical center, Kfar-Saba, Israel; 2) Bar Ilan University; 3) Tel Aviv University.

Teratospermia is characterized by the presence of spermatozoa with abnormal morphology. It has been shown that infertile men with abnormal sperm parameters have an increased rate of sperm aneuploidy and that poor sperm morphology is associated with numerical chromosome abnormalities of the spermatozoa. In this study we evaluated the karyotype of 5 control healthy men, 10 men with teratospermia and 13 men with azoospermia. Also, the disomy rate of chromosomes 8,9,18, X and Y in sperm cells taken from the normal and teratospermic groups. Results: All teratospermic men and 8 of the azoospermic group showed a structural variation of 9qh + (46,xy,9qh+), compared to none in the controls. One patient with azoospermic was 47,xxy. The disomy rate of the group with teratospermia was significantly higher with all probes analyzed compared to control group ($p<0.001$). Our findings raise the possibility that the variation in the constitutive hetrochromomatin of some chromosome interfere in the meiosis process such as the exact pairing of the homologue chromosomes.

six years benefits of Deflazacort treatment for Mexican Pediatric patients with Duchenne muscular dystrophy. *R. Ruiz[1], J. Aparicio[2], A. Ortiz[3], M.A. Cubillo[4], F.E. Romero[5]* 1) pediatric Rheumatology; 2) Medical Genetics; 3) Orthopedics; 4) Rehabilitation; 5) Nutrition, Hospital para el niño Poblano, Puebla, Mexico.

INTRODUCTION. Duchenne muscular dystrophy (DMD) (also known as muscular dystrophy - Duchenne type) is an inherited disorder characterized by rapidly progressive muscle weakness beginning in the lower part of the body including pelvis later affecting all the body DMD is the most common form of muscular dystrophy It usually affects male patients, but in rare cases it can also be observed in female patients. It is considered an X-linked recessive inherited disease. A milder form of this disease is known as Becker Muscular dystrophy (BMD). In BMD, most of the symptoms are similar to Duchenne, but the onset is diefrent. MATERIAL AND METHODS. A group of 25 pediatric patients were diagnosed as Duchenne muscular dystrophy by enzimatic tests (CPK, DHL and Aldolasa), muscular biopsy and clinical syntoms includings Gowers sign. All of them were treated with deflazacort and their different clinical evolution among them was then analyzed. Weigth, size, arterial measure and glucose were monitored every three months for control CONCLUSIONS. DMD is named after the French neurologist Guillaume Benjamin Amand Duchenne (1806-1875), who first described the disease in the 1860s. One third of the cases are known to be caused by development of spontaneous mutations in the dystrophin gene. Boys with DMD develop weak muscles because the muscle fibers become distrophic, due to mutations in the dystrophin gene, which encodes a cell membrane protein in myocytes. Deflazacort dose concentration was used acording to clinical evolution, if muscular strenght decreased, the dose was used at 0.3mg/kg. This study shows that Deflazacort has an important impact on health, a better quality of life and few side effects were observed during the treatment among the patients. However, a near future study will be performed by comparing these results with a control group.

Knockdown of estrogen receptor alpha gene expression by siRNA in human breast cancer cell line. *M. El-Zawahri[1], Y. Luqmany[2], A. Al-Azmi[1]* 1) Dept Biological Sci, Fac Sci, Kuwait Univ,; 2) Det Pharmaceutical Chemistry, Fac Farmacy, Kuwait Univ, Kuwait.

The role of estrogen receptor alpha (ER) in breast cancer has been highlighted by numerous studies. Consequently, inhibition of ER is one of the major strategies for prevention and treatment of breast cancer. However, failure to overcome development of endocrine resistance, arising despite continued expression of tumor ER, limits this approach. The aim of this study is to establish a breast cancer cell line containing a permanent source of small interference RNA (siRNA) which specifically inhibits the production of ER protein, to produce a model system to investigate loss-of-function of ER. Three siRNA constructs (PI-III) targeting different sequences of human ER, and a scrambled sequence were cloned into the pRNA-U6.1/Neo GenScript vector. MCF7 breast cancer cells were transformed with 2 or 4ug of each plasmid (6 and 24h exposure), using lipofectamin or Xtreme reagent conjugates. Transformants were rescued by growth in G418 selection medium. ER mRNA levels were determined by Real Time RT-PCR of extracted RNA, and ER protein by Western blotting; normalization was achieved by simultaneous analysis of -actin. Presence of plasmid DNA in transformants was verified with primers targeting various regions of the vector. Stably transfected cells maintaining antibiotic resistance over several passages were established by continuous culture. Linearized anti-ER-siRNA construct PII most effectively down-regulated ER mRNA (as evidenced by Real-Time RT-PCR analysis) and protein in these cells as compared to G418 resistant transformants containing scrambled siRNA; complete knockdown was not observed. Whereas 4g produced more transformants, 24h exposure did not increase transformation efficiency. In conclusion, Our three anti-ER-siRNA vector constructs silenced its target mRNA specifically and we have successfully established a long term culture of MCF7 breast cancer cells that exhibit decreased expression of ER. This is hoped to provide a model system in which to study aspects of endocrine resistance. (Supported by Kuwait University Grant YS 01/04).

Genetic conversations - a bridge towards delivery of genetic services in medical subspecialties. *M. Cloutier[1], C. Shuman[2], R. Weksberg[2], D. Chitayat[2,4], F. Miller[3]* 1) Mol & Med Gen, U Toronto; 2) Clin & Metab Gen, SickKids, Toronto; 3) McMaster U, Hamilton; 4) Mount Sinai Hospital, Toronto.

The advent of genomic medicine, with the increasing availability of genetic testing, poses major challenges for the delivery of genetic services. Primary care providers, medical specialists and nurses are becoming increasingly involved in the provision of genetic information and in the interpretation of genetic test results. The objective of this study was to gain insight into pediatric cardiologists and cardiac specialist nurses views on the provision of genetic services (genetic testing and genetic counseling) for their patient populations, both currently and for the future. Semi-structured interviews were conducted with non-genetics pediatric specialists in cardiology, including staff cardiologists, nurses and fellows. The qualitative analysis of the transcribed interviews was guided by a joint grounded-theory and hermeneutic approach and revealed the following key themes: 1. Genetics is an essential subtext to the provision of cardiac care; 2. A desire to share cardiogenetic care and integrate the role of genetic counselors in cardiology; 3. Genetic counseling or genetic conversations? Genetic conversations provide factual genetic information related to a patients condition. This differs from genetic counseling which, in addition to providing genetics education, allows for the contextualization of genetic information to help patients make decisions and adapt to the psychological, familial and social issues that stem from the risk or condition in the family. We propose a provisional theory of a genetic counseling continuum as a model to describe the types of genetic counseling activities that occur in non-genetics pediatric specialties. These results have implications for enhancing our understanding of the types of genetic counseling activities provided by non-genetics specialists and for policy formulation regarding the development of genetics programs in medical subspecialties. Recommendations are proposed for post-graduate training programs. This study informs the broader literature on the future shape and scope of genomic medicine in a pediatric setting.

Analysis of LOH effect on TCO gene within Iranian population with Familial Non- Medullary Thyroid Carcinoma. *H. Atashi Shirazi[1], M. Hedayati[1], A. Shafiee[2], M. Daneshpour[1], F. Azizi[1]* 1) Dept Genetics, EMRC of Shahid Beheshti University of Medical Science , Tehran,I.R.Iran; 2) Milad hospital, Tehran, I.R.Iran.

Introduction: Familial non-medullary thyroid carcinoma (FNMTC) is mostly sporadic and account for ~ %3-7; of thyroid cancers. Its inheritance is reported as autosomal dominant. Papillary and follicular thyroid carcinoma is two main variants of FNMTC. One of genes which involve in susceptibility to FNMTC is TCO (19p13.2). LOH studies have been used to identify sites harboring tumor suppressor genes involved in tumor initiation or progression. Aim:The aim of the study was to permit LOH analysis of TCO gene in Iranian FNMTC patients. Material & Methods: For LOH analysis, totally 56 papillary and follicular carcinoma subjects and their family selected. Peripheral blood genomic DNA was extracted from affected and non affected FNMTC subjects, according to standard salting out protocol and amplified using PCR technique. Finally LOH identified on acrylamide gel electrophoresis after staining. Results: Sixteen follicular and forty papillary carcinoma samples were analyzed. LOH observed at %5.4 of the follicular and % 17.9 of papillary carcinoma cases. Briefly, the obtained data related to analyzed microsatellite markers were: %10.7 D19S916, %12.5 D19S413, %41.1 D19S391, %1.8 D19S568 and %3.6 D19S865. LOH was absent in all normal samples. Papillary carcinomas displayed higher rate of LOH than follicular carcinoma. Discussion: This study data revealed that more than %20 of Iranian FNMTC showed LOH, and it is more frequent in papillary than follicular carcinoma. The predominant microsatellite marker in LOH searching related to D19S413. So probably there is difference in mechanisms controlling chromosomal stability in these two forms of papillary and follicular cancers.

The North Carolina - Louisiana Prostate Cancer Project (PCaP): Methods and design. *J. Bensen* Lineberger Cancer Ctr-North, Univ North Carolina, Chapel Hill, NC.

The North Carolina - Louisiana Prostate Cancer Project (PCaP) is a multidisciplinary population-based case-only study designed to investigate social, individual, and tumor-level causes of racial differences in prostate cancer (CaP) aggressiveness. PCaP includes nine projects; two are designed specifically to examine genetic variation in known hereditary CaP susceptibility genes and identify new genes associated with CaP aggressiveness. The PCaP population-based sample consists of incident CaP cases from North Carolina (NC) and Louisiana (LA) including 1,000 African Americans and 1,000 Caucasian Americans. Study nurses administer structured questionnaires and collect blood, adipose tissue, urine and toenail samples during an in-home visit. Clinical data are abstracted from medical records, diagnostic biopsies are reviewed and assayed, and tissue microarrays are constructed from prostatectomy samples. CaP aggressiveness is classified based on PSA, clinical stage and Gleason grade. Preliminary data was analyzed through August, 2005, by which time over 400 study visits were completed with 122 and 95 NC and 88 and 101 LA, African Americans and Caucasian Americans, respectively. Participation exceeded 70% at both sites through August, 2005 with an average time from diagnosis to study visit of 3 months. Of eligible participants interviewed, 98% consented to blood, urine and toenail donation, and 81% of African Americans and 91% of Caucasian Americans consented to donation of adipose tissue. Ninety-nine percent of patients provided consent for medical records retrieval and abstraction, and for tumor block retrieval and analysis. Preliminary data demonstrated between-and within-group differences in patient characteristics, screening and treatment by race and state. Preliminary data from this well-characterized cohort support the feasibility of this comprehensive study to help determine the focus of public health efforts, including those related to identification of genetic risk factors, to reduce racial disparities in CaP mortality. Supported by the Department of Defense Prostate Cancer Research Program.

Germline analysis of the ACVR1B gene as a candidate gene for ovarian failure. *H. Dixit[1], K.L. Rao[1], J. Nair[2], V.V. Padmalatha[1], M.K. Kanakavalli[1], M. Deenadayal[3], N. Gupta[4], B.N. Chakrabarty[4], L. Singh[1]* 1) Centre for Cellular and Molecular Biology, Hyderabad, Andhra Pradesh, India; 2) Vellore Institute of Technology, Vellore, Tamil Nadu, India; 3) Infertility Institute and Research Centre, Hyderabad, Andhra Pradesh, India; 4) Institute of Reproductive Medicine, Kolkata, West Bengal, India.

An amenorrhoea (>6 months) with elevated FSH levels before 40 years is defined as premature ovarian failure (POF). Elevation of FSH levels results in depletion of ovarian follicles. Activins up-regulate FSH production by activating its Type II and Type I receptors located on gonadotrophs. Activated Type I receptor (ACVR1B) sends intracellular signaling for FSH upregulation. The loss of function mutations in this gene cause carcinomas due to loss of growth inhibitory effect of activin. We hypothesize that gain of function mutations in this receptor gene may cause ovarian failure due to constitutive or increased FSH production. These mutations can result in either activin independent form of receptor or its increased sensitivity for activin binding. Case control study was performed by DNA sequencing analysis for coding regions (9 exons) of ACVR1B gene. A total of 196 ovarian failure cases including 133 POF cases, 63 pri. amenorrhoea (PA) cases and 200 control were recruited. All individuals were chromosomally normal and their recruitment followed strict medical norms. Sequence analysis of ACVR1B gene revealed 7 novel variants and 3 documented variants. Three novel missense variants c.392T>G, c.505T>G, c.581G>A were exclusively associated with patients while completely absent in controls. The c.392T>G (p.Iso131Ser) variant was revealed in 7/133 POF cases (p value=0.0015) and 4/63 PA cases (p value=0.003). The c.505T>G (p.Cys169Gly) was present in a POF patient. The c.581G>A (p.Gly194Glu) variant was present in 4/133 cases of POF (p value=0.025). Preliminary analysis showed gain of function nature of these variants. Frequency of an intronic variant c.332-155_332-154insA was higher in patients (12.2%) than controls (5%) (p value=0.012). This is first report presenting gain of function mutations in ACVR1B gene associated with ovarian failure.

Identification of Biological Markers in Amniotic Fluid of Trisomy 21 during Pregnancy by Proteomics. *D. Cha[1], K. Kim[2], C. Lee[1], S. Lee[1], J. Chang[1], K. Lee[1], J. Kim[1]* 1) Dept OB/GYN, Kangnam CHA Hosp, Seoul, Korea; 2) Dept molecular biology, KonKook Uni., Seoul, Korea.

Objectives : To identify the proteoms in amniotic fluid for the early detection of trisomy 21. **Methods** : Amniotic fluids from 3 patients (range 16-18 weeks) with Downs affected pregnancies were matched for gestational age and fetal sex with the amniotic fluid from 3 unaffected pregnancies. Total protein concentration was determined by the Bradford protein assay. Acetone-precipitated albumin/IgG-depleted/containing samples were separated on 4~20% gredient SDS-PAGE and the protein bands stained by coomassie blue. The amount of 25ug of protein was loaded in a lane of SDS-PAGE. The gel percentage was 4~20. After in-gel digestion, the sample was analyzed by LC-MS/MS. **Results** : Analyses were focused on regions corresponding to molecular masses between 6.5 and 250 kDa. 20 proteins were detected after albumin IgG depletion in the amniotic fluid of unaffected pregnancies. There were 22 proteins detected after albumin/IgG depletion in the amniotic fluid of trisomy 21. Proteomic profiling identified the differential expression of 11 proteins in the affected pregnancies. 4 proteins such as actin alpha 2 and serine proteinase inhibitor were increased and 7 proteins such as alpha-1-acid glycoprotein 2 precursor and prostaglandin D2 synthase were decreased in trisomy 21. **Conclusion** : Proteomics in the amniotic fluid is a valuable approach to develop new potential biological markers for the early screening of trisomy 21.

Hypertensives show downregulated expression of adrenoceptor genes in arterial tissue. *J.R. Dungan[1, 2], C. Yucha[3, 2], Y. Conley[4], J. Johnson[5], S. Kneipp[2], T. Langaee[5]* 1) Center for Aging, Duke Univ., Durham, NC; 2) Nursing, Univ. of Florida, Gainesville, FL; 3) Nursing, Univ. of Nevada-Las Vegas, Las Vegas, NV; 4) Nursing, Univ. of Pittsburgh, Pittsburgh, PA; 5) Center for Pharmacogenetics, Univ. of Florida, Gainesville, FL.

Objective: Differential expression of adrenoceptor genes has been implicated in the pathobiology of hypertension and may help explain some health disparities. This pilot study explored relative differences in $_{1A}$- and $_{2}$-adrenoceptor gene expression in human arterial tissue between people with and without hypertension. **Methods:** Relative levels of RNA of the investigated genes were measured in internal mammary artery tissue samples obtained from consented subjects who had coronary artery bypass surgery at local hospitals in Gainesville, FL. The extracted RNA was analyzed with Real-Time, reverse-transcription polymerase chain reaction. **Results:** The study included 41 subjects. Hypertensive subjects showed 3.92-and 2.05-fold reductions in $_{1A}$- and $_{2}$-adrenoceptor gene expression, respectively, compared to normotensives ($p < 0.05$).Comparing Caucasian hypertensives and normotensives produced over 4- and 5-fold reductions in hypertensives $_{1A}$- and $_{2}$-adrenoceptor gene expression ($p < 0.05$); however no significant differences were found between African American and Caucasian hypertensives. **Conclusions:** The downregulation of both investigated adrenoceptor genes in hypertensives suggests alterations at the level of transcription in the pathobiology of hypertension. To our knowledge, this is the first investigation exploring these particular genes and methods in *human* tissues, especially with regard to examining race. Interpretation of results is cautioned due to some limitations. Gene expression accounts for both genetic and environmental factors in disease. Translational research that involves gene expression is likely to benefit practitioners and patients in the future with personalized screening and management tools. This study was supported by NINR (#1F31NR009148-01), AHA (#01415124B, partial), & . Shands Hospital & the Malcom Randall Veterans Administration Medical Center also provided resource and facility support.

A *de novo* unbalanced t(7;13). *A. ABOURA[1], S. KANAFANI[2], AC. TABET[1], M. BENKHALIFA[3], E. PIPIRAS[1], B. BENZACKEN[1, 2], C. LEONARD[4], P. LANDRIEU[5], A. A one year old girl is addressed for a psycho-motor delay. Her parents are healthy and unrelated. Before birth, her first screening ultrasonography showed an increased nucal translucency. An amniocentesis, revealed a normal 46,XX prenatal karyotype. At birth, her clinical examination was normal. At 4 month old, a developmental delay appeared and increased at one year old, as revealed by the Denver test. A cranio-facial dysmorphia was noted with a wide forehead, long face, large nose, very small low implanted and in posterior rotation ears, heavy cheeks and a double chin. A high resolution karyotype showed one doubtful 13qter. CGH, then CGH array of 2600 clones were performed. The latter with a resolution of 1 Mb (Spectral Genomics), revealed a 7qter duplication and a 13qter deletion. A 2 colour painting WCP 7 and WCP 13 identified a reciprocal exchange between the terminal region of the long arms of one chromosome 7 and 13. A 2 colour subtelomeric probes 7 qter and 13 qter showed 1 fluorescent spot on 13qter, and 3 fluorescent spots of another colour on 7 qter. The karyotypes of the parents were normal. The proband has an unbalanced *de novo* karyotype: 46,XX.ish der(7)t(7;13)(qter+;qter-)(BACs+,BACs-),rev ish enh(7)(qter)dim(13)(qter). The microsatellites analysis for chromosomes 7 and 13 showed that the duplicated material on chromosome 7 is maternal whereas the deleted material on chromosome 13 is paternal. A set of BACs is hybridized to better explore the imbalance. We discuss the possible mechanisms of this rearrangement and the phenotype-genotype correlation.

Absence of the lysosomal enzyme Acid Sphingomyelinase protects against liver fibrosis following Bile Duct ligation. *C. Brown, J. Murray, A-M. D'Angona, J. Serriello, K. Karey, A. Vitsky, K. Sampath, L. Andrews, J. McPherson*
Pharmacology & Toxicology, Genzyme Corp, Framingham, MA.

The lysosomal enzyme, acid sphingomyelinase (ASM) is believed to play a role in apoptotic hepatic injury (Garcia-Ruiz et al. 2003). Indeed, ASM knockout mice are protected against liver damage elicited by TNF. Whether the protective effect of ASM is specific for this TNF biased liver injury model or extends to other acute models of liver disease such as Bile duct ligation (BDL) is currently unknown. With surgical ligation of the bile duct chronic hepatocellular apoptosis and inflammation results in additional markers of liver damage such as liver fibrosis and necrosis. We examined the role of ASM in the development of hepatic fibrosis by investigating whether the susceptibility to BDL-elicited liver fibrosis differs between ASM transgenic and wild type mice. Wild type mice (C57/Bl), heterozygotes with partial ASM levels or ASM Knockout mice (ASMKO) were subjected to Bile duct ligation or a sham surgical procedure. Seven days post surgery all excised livers were examined histologically for liver fibrosis and serum analysis performed to investigate potential alterations in liver function. Animals subjected to bile duct ligation demonstrated hepatomegaly and significant liver injury characterized by increased bile duct hyperplasia, extensive liver fibrosis, necrosis and inflammation. Sham surgery animals, where the abdomen was opened and liver manipulated, lacked these histological changes. Animals subjected to BDL had significantly elevated levels of serum gamma glutamyl transpeptidase, aspartate aminotransferase, bilirubin and cholesterol indicative of compromised liver function. Histologically liver fibrosis and bile duct hyperplasia were significantly improved in ASM KO and heterozygote mice compared to wild type mice however this was not reflected in serum markers, likely due to complication of liver function by the disease phenotype. In conclusion the absence of ASM appears to protect against fibrotic hepatic damage elicited by bile duct ligation however this protection while evaluable histologically did not appear to be reflected at the functional level.

Identification and replication of GATA2 polymorphisms associated with familial early onset coronary artery disease. *J.J. Connelly[1], C. Haynes[1], L. Wang[1], S.H. Shah[1,2], J.E. Cox[1], D. Crosslin[1], A.B. Hale[1], T. Wang[1], S. Nelson[1], D.C. Crossman[3], C.B. Granger[1], J.L. Haines[4], C.J.H. Jones[5], J.M. Vance[1], P.J. Goldschmidt-Clermont[6], W.E. Kraus[2], E.R. Hauser[1], S.G. Gregory[1]* 1) Department of Medicine and Center for Human Genetics, Duke University, Durham, NC; 2) Department of Medicine and Division of Cardiology, Duke University, Durham, NC; 3) University of Sheffield, Sheffield, United Kingdom; 4) Vanderbilt University, Nashville, TN; 5) University of Wales College of Medicine, Cardiff, United Kingdom; 6) Miller School of Medicine, University of Miami, Miami, FL.

The transcription factor GATA2 plays an essential role in the establishment and maintenance of adult hematopoiesis. It is expressed in hematopoietic stem cells, as well as the cells that make up the aortic vasculature, namely aortic endothelial cells and smooth muscle cells. We have shown that GATA2 expression is predictive of location within the thoracic aorta; location is suggested to be a surrogate for disease susceptibility. The GATA2 gene maps beneath the Chromosome 3q linkage peak from our GENECARD early onset coronary artery disease study. Given these observations, we investigated the relationship of several known and novel polymorphisms within GATA2 with coronary artery disease. We identified five SNPs that were significantly associated with early onset coronary artery disease in our family based sample set (GENECARD). These results were validated by identifying significant association of two of these SNPs in an independent case-control sample set that was phenotypically similar to the GENECARD families. These observations identify GATA2 as a novel coronary artery disease susceptibility gene and suggest that the study of this transcription factor and its downstream targets may uncover a regulatory network important for coronary artery disease inheritance.

A Score Test for Linkage Analysis of Ordinal Traits Based on IBD Sharing. *R. Feng*[1], *H. Zhang*[2] 1) Biostatistics, University of Alabama at Birmingham, Birmingham, AL; 2) Biostatistics, Yale University, New Haven, CT.

Statistical methods for linkage analysis are well established for both quantitative and binary traits. However, numerous diseases including cancer and mental illness are rated on discrete, ordinal scales, and the genetic heritabilities and/or candidate genes for many of the diseases have been documented. Recently, a latent variable model has been developed to analyze pedigree data with ordinal traits from which increased power of detecting linkage is revealed when the ordinal, rather than dichotomized, traits are fully used. The challenge with the latent variable model is that the likelihood is usually very complicated and as a result, the computation is intensive and sometimes prohibitive. We derived a score statistic based on the identity by decent (IBD) sharing information within pedigrees, which greatly alleviates the computation burden. Using the new test statistic, the latent variable model for ordinal traits can test linkage for large pedigrees while adjusting for non-genetic covariates. Using simulation studies, we examined the asymptotic distribution of the test statistic and the power of our proposed test under various genetic models. We then applied our method for the Collaborative Study on the Genetics of Alcoholism (COGA) and performed a genome scan to map susceptibility genes for alcohol dependence. We found strong linkage signals on chromosomes 4, 13 and 18.

Double male syndrome with Tetralogy of Fallot , report of the second case. *M. AL-Atwi[1], H. Al-Girim[1], W. Eyaid[2], I. Amir[3]* 1) pediatrics Department, King AbdulAziz Hospital, AlAhsa, Eastern, Saudi Arabia; 2) pediatrics Department, King Fahad Hospital, Riyadh,central, Saudi Arabia; 3) Cytogentics Department, King Fahad Hospital, Riyadh,central, Saudi Arabia.

The patient was a product of full term uneventful pregnancy presented at age of 8 weeks with ten days history of cyanotic spells his clinical examination was unremarkable except for a loud systolic murmur with normal hearts sounds and normal femoral pulses bilaterally. He has normal penis with bilaterally descends testis. His echocardiography was compatible with Tetralogy of Fallot (TOF). The patient was referred to our cardiac center where he was operated for TOF repair. Because of his congenital heart disease a chromosomal analysis was done which revealed the presence of an extra chromosome X as well an extra chromosome Y in all the 20 analyzed cells giving 48,XXYY chromosomal constitution . Chromosome number 22 was also investigated by the fluorescence in situ hybridization technique (FISH) which showed no evidence of abnormality involving the critical region of DiGeorge syndrome on chromosome 22q . The combination of 48,XXYY with TOF was first reported in 1995 by Meschede et al . Our report and others suggest that congenital heart disease may occur in the 48,XXYY syndrome more frequently than currently appreciated.

Genomic DNA isolated from semen better diagnostic and prognostic marker of AZF status. *R. Dada[1], R. Kumar[1], R. Kumar[2], K. Kucheria[1]* 1) Dept Anatomy, All India Inst Medical Sci, New Delhi, India; 2) Dept Urology, All India Inst Medical Sci, New Delhi, India.

Deletions of Azoospermia factor (AZF)genes on Yq are pathogenetically involved in male infertility. AZFgene consists of 3 non overlapping loci AZFa,AZFb and AZFc and these are involved in germ cell development and differentiation. The aim of this study was to establish if AZF status of DNA isolated from blood reflects the Yq microdeletions status of DNA isolated from germ cells which are of different embryonic origin. Seventy five infertile males with idiopathic oligozoospermia were included in this study. Cytogenetic and semen analysis was done in each case. Testicular Fine Needle aspiration Cytology was collected whenever possible. Of the 75 cases, 5 cases were identified as Klinefelter mosaics, 1 cases had D/D group robertsonian translocation. In cytogenetically normal cases (n=69) microdeletion analysis was done) from DNA isolated from blood and semen using STS-PCR approach using primers sY84, sY86 (AZFa); sY127, sY134 (AZFb); sY254, sY255 (AZFc. The STS was considered as absent after 3 amplification failures. Of the 69 cases 2 cases showed deletion of at least one of the AZF loci from blood DNA and 5 cases showed deletion from semen DNA. The DNA isolated from blood had AZFc deletions which were also detected in semen DNA and both these cases had depressed spermatogenesis on testicular cytopathology. The semen DNA in addition showed 1 case with AZFb and 2 cases with large deletions spanning AZFb and AZFc loci. Two cases with AZFb and AZFc had hypospermatogenesis and the cases with AZFb deletion had maturation arrest. As majority of infertile couples opt for Assisted Reproduction, genetic analysis is a must in these cases. Till date majority of centers offer microdeletions status from DNA isolated from blood. However this study clearly highlights the need to do Yq microdeletions analysis from semen DNA in all infertile couples as this is a better diagnostic and prognostic marker than Yq screening from genomic DNA isolated from blood.

Low-income Americans understandings of the relationship of genes and behavior in producing health outcomes.
C. Condit, M. Gronnvoll, J. Landau, C. Groscurth, T. Harris, L. Shen, L. Wright Speech Communication, Univ Georgia, Athens, GA.

To assess the understandings held by low income African Americans and Whites in the U.S. of the relationships of genes and environment in producing human health outcomes, 40 in-depth interviews were conducted. Results suggest most participants encode genes and health behaviors in separate verbal neural networks linked solely through the concept of health outcomes, rather than having models that integrate the two verbal neural networks. Activation of the genetics track leads to a deterministic discourse about health causation, but this does not generally lead to fatalistic beliefs, because participants shift readily to the behaviors track to imagine effective health prevention activities. In addition, a large sub-group harbors an additive model of the relationship between genes and environment. This model imagines risk-conferring alleles as placing individuals on a higher platform, so that health behaviors are useful in lowering risk levels. This model may provide the basis for integrating conceptions of genetics into health campaigns focused on prevention. Although no participants clearly articulate a multiplicative or interactive model of the relationship between genes and environment, a widely shared model of how heart disease occurs may provide the platform for introducing that model. Barriers include understandings of genes as equivalent to having a disease (after the model of viruses) and a belief that behavior-induced damage cannot be erased by behaviors.

Prioritary indications for prenatal karyotyping in developing countries: a study in Brazil. *R. Gus[1,2], M.T.V Sanseverino[1,2], J.A.A Magalhaes[2], R. Giugliani[1]* 1) Genetics Dept, Hosp Clinicas Porto Alegre, Porto Alegre, RS, Brazil; 2) Fetal Medicine Group, Obstetrician Dept.

In the last decades the study of fetal chromosomes became a very important tool for prenatal diagnosis. In developing countries, like Brazil, this test is not widely offered, specially because abortion due to fetal disease is not legally allowed. The purpose of this study was to describe the Fetal Medicine Group experience in Brazil, trying to give priorities to the indications for such exam. Despite prenatal diagnosis is very limited here, we have been providing this test free of charge to at-risk pregnancies since 1989. In a genetic counseling session, the risks, methods and approaches were explained to the family. Accordingly to each situation, the best procedure was indicated. CVS and AF were mainly obtained for cell culture. The cultures remained at the CO2 incubator with Amniomax medium for few days, and then harvested and G-banded for chromosome analysis. From 1989 to 2005, 874 fetal karyotypes were performed and abnormal results were found in 69 (7,8%) cases. The three most frequent indications were: advanced maternal age, fetal malformation detected at ultrasound, and previous child with Down syndrome. Despite advanced maternal age was the most frequent indication for prenatal diagnosis (233 cases and 10 abnormal karyotypes), the majority of the aberrant karyotypes was found in the group where the indication was a severe fetal malformation detected at ultrasound (21.5% of 167 cases). On the other hand, although the history of a previous child with Down syndrome was a frequent indication (123 cases), we did not find any positive case on the prenatal analysis performed in this group. This means that, for this last indication, the risk of complications due to the procedure (0,5%)was greater than the risk of recurrence of Down syndrome, in our sample. Considering the limitations to offer prenatal tests in our conditions, we propose that the indication of prenatal diagnosis for couples who had a previous child with Down syndrome should be reconsidered, and higher priority given to the pregnancies where a malformation is detected on the ultrasound scan.

A statistical approach to predict the presence of a *CHD7* mutation in patients with suspected CHARGE syndrome. *J.P. Ferraro[1], M.S. Williams[2], C.M.A. van Ravenswaaij[3], L.H. Hoefsloot[3], M.C.J. Jongmans[3], M.A. Hefner[4], S.R. Lalani[5], S.D. Fernbach[5], A.A. Safiullah[5], J.W. Belmont[6]* 1) Department of Medical Informatics, Intermountain Healthcare, Salt Lake City, UT; 2) Clinical Genetics Institute Intermountain Healthcare Salt Lake City, UT; 3) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 4) Division of Medical Genetics, Department of Pediatrics, Saint Louis University School of Medicine, St. Louis, MO; 5) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 6) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

The purpose of this study is to apply statistical models to determine the predictive accuracy of the various CHARGE syndrome diagnostic criteria, singly and in combination, for finding a mutation in the *CHD7* gene in patients with the clinical diagnosis of CHARGE syndrome.

Clinical information from 196 patients who underwent *CHD7* mutation analysis was obtained from the two testing centers. Twenty clinical characteristics were identified, as well as gender and mutation status. Several statistical approaches including binomial logistic regression, step-wise regression and Bayesian model averaging were used to identify the best combination of characteristics to predict *CHD7* positive status. In addition, the individual power of the characteristics to predict a *CHD7* positive-mutation was also calculated.

Analysis of the individual factors lead to some surprising findings. Neither choanal atresia, long recognized as an important feature of CHARGE syndrome, nor characteristic CHARGE ear were found to be a significant predictor of presence of a mutation in *CHD7*. The single feature with the best overall predictive performance was pituitary dysfunction. Three features; coloboma, temporal bone anomaly and cranial nerve dysfunction singly and in combination had very high predictive power for presence of a mutation. Additional combinatorial analyses as well as methods to approximate missing data will be modeled and presented.

Inductive screening of -thalassemia in a large consanguineous Pakistani family. *S.M. Baig[1,2], M. Amin-Ud-Din[3], H. Hassan[1], A. Azhar[1], J.M. Baig[1], M. Aslam[1], J.A. Qureshi[1], T. Zaman[1]* 1) Human Molecular Genetics Laboratory, National Institute for Biotechnology and Genetic Engineering (NIBGE), Faisalabad, Pakistan; 2) Molecular Biology Laboratory, Nuclear Medicine Oncology and Radiotherapy Institute (NORI), Islamabad, Pakistan; 3) Human Genetic Research Society, Biology Department, Government College, D.G. Khan, Pakistan.

Pakistan has one of the highest numbers of children with transfusion dependent thalassemia in the world due to high frequency of the gene, consanguineous marriages, high birth rate, and large population size. In this report, we present retrospective inductive screening of a large consanguineous Pakistani family for -thalassemia gene, a strategy for identification and counseling carriers of hemoglobinopathies in developing countries for prevention of the disorders caused by recessively inherited genes. In this family with an index case, 27 members were screened for -thalassemia and 12 (44.4%) were found to carry the mutant gene, a very high carrier rate as compared to just over 5% gene frequency of -thalassemia in the general population of Pakistan. Screening was carried out in the available living members of the index families by measuring the Hb A2 and red cell indices using automated Hb electrophoresis system and hematology analyzer. Amplification refractory mutation system (ARMS-PCR) was used to identify the specific -thalassemia mutation. This report emphasizes the need of mandatory screening of families with index case in particular to identify the carriers for disease prevention through genetic counseling and prenatal diagnosis program. This approach is more practical, feasible and cost effective as compared to population screening.

Islet-specific glucose-6-phosphate catalytic subunit-related protein (IGRP) is a candidate gene for plasma glucose. *D. Fradin[1], F. Letourneur[2], P. Bougneres[3]* 1) INSERM U561, Paris, France; 2) ICGM, Paris, France; 3) INSERM U561 and Department of Pediatric Endocrinology, Paris, France.

Plasma glucose (PG) is at the center of energetic metabolism in humans, and is implicated as a nutrient in multiple physiological processes at the cell and organ level. PG is highly regulated in order to be maintained in narrow limits, in contrast with other fuels such as free fatty acids, ketone bodies or amino-acids, whose range of physiological variation is very wide. There is however an individual variability of glucose level, which depends on genetic and environmental factors. Higher PG level within the normal range is an independent risk factor for type 2 diabetes among young men. We have tested a common variant of IGRP (Islet-specific Glucose-6-phosphatase catalytic subunit-Related Protein) as a potential candidate gene of glucose homeostasis. IGRP is located in the endoplasmic reticulum (ER) and expressed exclusively in pancreatic islets. This enzyme catalyzes the conversion of glucose-6-phosphate (G-6-P) to glucose. An association study analyzing the Val219Leu variant of IGRP was conducted in 638 obese Caucasian juveniles with glycaemia. We found that the Val219Leu variant of IGRP was significantly associated with PG levels. Obese children who were Val219 homo- or heterozygotes had significantly greater plasma glucose concentrations at 30, 60, 90 and 120 min following oral glucose ingestion (7.66mM 0.06, 6.91mM 0.08, 6.4mM 0.06, 5.96mM 0.05 respectively) than subjects with the Leu/Leu genotype (7.13mM 0.11, $p=1.10^{-4}$; 6.46mM 0.13, p=0.011 ; 5.91mM 0.11, $p=7.10^{-4}$; 5.72mM 0.08, p=0.038). These findings suggest that IGRP influence the individual variability of glucose homeostasis. Because the physiological role of IGRP has been established by only one paper (Petrolonis et al. 2004), these results should await for replication and functional characterization of the gene and of its variant.

Detection of known and novel human syndromes by high-density oligonucleotide array comparative genomic hybridization (HOaCGH). *Y.S. Fan, D. Barbouth, P. Jayakar, H. Zhu, S. Sacharow, L.J. Elsas* The Dr. John T. Macdonald Foundation Center for Medical Genetics, University of Miami Miller School of Medicine, Miami, FL.

Genomic imbalance is a major cause of morphological and developmental disorders. Fluorescent in situ hybridization (FISH) has been used for diagnosis of some of the over 40 known dysmorphic syndromes and 3% of idiopathic mental retardation associated with subtelomeric rearrangements. Microarray-based comparative genomic hybridization (aCGH) has shown large-scale DNA copy number variations in the human genome. BAC clone-based arrays targeting to the known microdeletion syndromes and the 41 subtelomeric regions (TaCGH) have been used as a diagnostic tool for clinical cases. We have assessed the clinical utility of three platforms of aCGH: a targeted array (TaCGH), a BAC-clone based array for the whole genome with a ~1M interval (BaCGH) and a high-density oligonucleotide array containing 44,000 probes representing over 30,000 mapped human genes (HOaCGH). Using HOaCGH, we have precisely determined the size and gene involvement of two cases with known microdeletion syndromes (Miller-Deiker; DiGeorge) and fully characterized a new neocentric supernumerary marker chromosome derived from Xp22.3pter. While the number of cases in our study is rapidly growing, we have at this time compared the results of TaCGH and HOaCGH on 32 new patients with developmental delay and dysmorphic features. We have identified a 1p36.3 deletion and 4 novel microdeletions: del(15q11.2q11.2)(0.3Mb, 7 genes), del(15)(q24.1q24.2) (3.04Mb, 56 genes), del(19p13.1p13.2)(3.46 Mb, 101 genes), del(21)(q21.3qq22.12)(6.18Mb, 99 genes). We also identified a 7.47 Mb duplication at Xp11.22p11.23(107 genes). Thus, clinically relevant large genomic alterations have been revealed in 6 out of 32 patients (19%) and 5 of them (83%)are not in the regions targeted by TaCGH. Our study suggests that high density whole genome array CGH is a powerful diagnostic tool for unexplained developmental disorders and further molecular studies of these disorders will lead to new genomic mechanisms of disease.

Chiari type I malformation: phenotypic definition by MRI and significant linkage to 15q21.3 and 9q22.31 with a high-density SNP genomic screen. *A.L. Boyles[1], D.S. Enterline[1], P.H. Hammock[1], D.G. Siegel[1], S.H. Slifer[1], L. Mehltretter[1], J.R. Gilbert[1], D. Hu-Lince[2], D. Stephan[2], B.J. Iskandar[3], T.M. George[1], T.H. Milhorat[4], M.C. Speer[1]* 1) Duke University Medical Center, Durham, NC; 2) Translational Genomics, Phoenix, AZ; 3) University of Wisconsin-Madison Medical School, Madison, WI; 4) The Chiari Institute, Great Neck, NY.

Chiari type I malformation (CMI) is clinically characterized by herniation of the tonsils of the cerebellum below the foramen magnum into the top of the spinal column. CMI presents with myriad of neurological symptoms, including chronic and often unremitting pain, and increases the risk of syringomyelia. Although the etiology is unknown, a small posterior fossa (PF) volume relative to total cranial volume is widely thought to cause the herniation. MRIs from 114 affected individuals and their family members were used to evaluate correlations between 10 cranial morphologies and heritabilities were estimated in a subset of 99 MRIs from 32 families. Support for the small PF theory was provided by the correlations between PF delineating structures and high heritability of PF volume (0.955, p=0.003), thereby confirming evidence for a genetic factor in this condition, supporting previous reports of familial clustering.

A genome wide linkage screen with a 10k SNP chip in 23 families with 71 CMI patients identified two significantly linked regions. At 15q21.1-22.3 two-point LOD scores maximized at 3.3 identifying a 13cM region with multipoint scores LOD scores over 1. This region contains a biologically plausible CMI gene, fibrillin-11. Mutations in this gene are the major cause of Marfan syndrome and it is also linked to Shprintzen-Goldberg syndrome which can include CMI in the phenotype. On chromosome 9 multipoint LOD scores maximized at 3.05 highlighting a 40cM region (9q21.33-33.1) with LOD scores over 1 containing an 8.5cM region with multipoint LOD scores over 2. This linkage evidence further confirms a genetic component to CMI and warrants further exploration with fine mapping and investigation of plausible candidate genes.

The potential of Mad1 and Menin in breast cancer therapeutics. *L. Andrews, T.E. Mott, S.M.O. Phipps, J.B. Berletch, T.O. Tollefsbol* Biology, Univ Alabama at Birmingham, Birmingham, AL.

Expression of the catalytic subunit of telomerase, hTERT, is closely linked with the bypass of cell cycle checkpoints in normal and malignant cells. The purpose of this study is to investigate the effects of tumor suppressors, Mad1 and Menin, in inhibiting the expression of telomerase in breast cancer cells. We have introduced Mad1 and Menin in a Tet-responsive vector into estrogen receptor positive and negative breast cancer cell lines. TRAP assays, soft agar analysis of tumorigenicity, mRNA expression of hTERT, growth curve studies, and immunoblotting analyses were performed. The results have confirmed that introduction of these tumor suppressors is sufficient to inhibit telomerase activity, decrease proliferative potential, reduce anchorage independence, and alter epigenetic regulatory and cell cycle checkpoint mechanisms, thereby reducing the carcinogenic phenotype of these cells. Information gained in these investigations could have great potential in the development of therapies for breast cancer.

An interphase fluorescence in situ hybridization (FISH) assay for the detection of 3q26.2/EVI1 rearrangements in myeloid malignancies. *D. Bobadilla[1], E. Enriquez[1], G. Alvarez[1], P. Gaytan[1], D. Smith[2], M.L. Slovak[1]* 1) Cytogenetics, City of Hope National Med Ctr, Duarte, CA; 2) Biostatistics, City of Hope National Med Ctr, Duarte, CA.

Chromosome rearrangements involving band 3q26.2 are associated with an unfavorable prognosis and a highly aggressive subgroup of myeloid malignancies. These apparently balanced rearrangements result in ectopic EVI1 and/or MDS1/EVI1 expression and may be difficult to detect in poor quality metaphases. In this report, we describe the development of a dual-color FISH assay for the detection of 3q26.2 aberrations. A series of BAC clones encompassing and flanking the EVI1 gene covering ~2 Mb were evaluated in total but narrowed to a set of two probe combinations extending 1.2 Mb; one probe set encompasses the EVI1 gene (RP11-82c9) and extends telomeric (RP11-362k14) while the second probe set covers the EVI1 gene (RP11-82c9) and extends centromeric (RP11-24L16). Each probe was mapped to normal metaphase chromosomes to determine their exact location and probe hybridization characteristics, before evaluation with the inv(3)(q21q26.2) positive Kasumi-4 cell line, 10 known negative samples and 33 patient samples with known 3q26.2 rearrangements by conventional cytogenetics collected at various treatment time points. Using this probe combination, normal interphase cells show two fusion signals corresponding to co-localization of the two probes on the EVI1 locus, whereas positive samples showed clear separation of the dual color probes, including 8 positive samples with variant signal patterns for a 3% cutoff for negativity despite the vast breakpoint heterogeneity observed. Interestingly in AML and MDS, the inversion breakpoints are usually 3 to EVI1 whereas 3q26.2 translocation breakpoints were more frequently 5 to EVI1, and most inv(3) CML samples showed a breakpoint within the EVI1 gene. However, two 3q26.2 translocation samples were found to have breakpoints 3 to EVI1. This study demonstrates that despite the extensive breakpoint heterogeneity observed with 3q26.2 aberrations, a robust FISH assay is achievable and effective for the detection of 3q26.2 abnormalities in myeloid malignancies.

A haplotype in FFAR1 (GPR40) predisposes individuals to Type 2 diabetes. *P. Banerjee[1], L.S. Wood[1], M.L. Millham[2], D.S. Lee[3], A.S. Robertson[2], J. Johnson[4], K.L. Houseknecht[2]* 1) Pharmacogenomics, Molecular Profiling, Pfizer Global Research and Devlopment, Groton, CT; 2) Department of Cardiovascular, Metabolic & Endocrine Diseases, Pfizer Global Research and Devlopment, Groton, CT; 3) Statistics, Pfizer Global Research and Devlopment, Groton, CT; 4) Metabolex, Inc., Hayward, CA.

FFAR1 (GPR40) is a G-protein coupled receptor highly expressed in pancreatic beta cells in rodents and humans and facilitates glucose-induced insulin secretion in response to mid to long-chain fatty acids in vitro. It has been reported that thiazolidinedione drugs can activate FFAR1 in some cells. To further examine the function of this gene in vitro, we stably transfected FFAR1 clones into HEK293 cells. Upon fatty acid exposure, cells expressing FFAR1 exhibited mobilization of intracellular Ca2+ stores quantified by fluorometric imaging plate reader (flipr). We found a significant, differential functional response to thiazolidinedione drugs (but not fatty acids) among cell lines expressing FFAR1 with the Arg and His alleles of the SNP, rs2301151 [Arg211His}. To further investigate the functional consequences of this polymorphism, we examined whether rs2301151 and other SNPs in the FFAR1 gene region are associated with the increased risk of developing Type 2 diabetes. We genotyped 3 SNPs (rs12975589, rs2301151 and rs387083), in 276 Caucasian Type II diabetic subjects and 1989 non-diabetic controls. The results of logistic regression modelling for each marker identified rs387083 as having a moderate association with diabetes ($p=0.0283$, unadjusted for multiple comparisons) after adjusting for BMI. BMI was a highly significant ($p<0.0001$) covariate associated with probability of developing diabetes. Based on the LD results, haplotypes were estimated for rs2301151 and rs387083 and examined for a haplotype-trait association. The results of the haplotype trend regression (HTR) test indicate that the A-G haplotype is associated with an increased risk of diabetes (p-value=0.0115, adjusted for BMI). These results suggest that a haplotype in the FFAR1 region might contribute to susceptibility towards developing diabetes in Caucasian subjects.

The effects of cytogenetic factors on the survival of a child with ALL. *H. Cangul[1], T. Yakut[1], T. Gulten[1], A. Meral[2], B. Baytan[2]* 1) Department of Medical Genetics Uludag University School of Medicine, Bursa, Turkey; 2) Department of Child Hematology, Uludag University School of Medicine, Bursa, Turkey.

Acute lymphoblastic leukemia (ALL) is the most common form of childhood leukemias and constitutes 80% of all leukemia cases under the age of 15. Cases with ALL respond well to therapy. The qualitative and quantitative detection of specific chromosomal abnormalities has an important merit as a prognostic marker besides age, leukocyte count, and immunophenotyping in estimating prognosis, assessing the clinical status of the cases before and after therapy, and in monitoring minimal residual disease. The rearrangements t(9;22) and t(4;11), and hypodiploidies indicate poor prognosis whereas hyperdiploidy favors a good one. The case presented here was diagnosed at 13 months of age and stratified into the high-risk group based on age, leukocyte count, and immunophenotyping. In molecular cytogenetic analysis by FISH, whereas the translocations of t(9;22), t(4;11), t(15;17), and t(8;21) were negative, the copy numbers of chromosomes 8 and 21 were increased. The case was treated according to standard protocols but died within one and a half years. Although hyperdiploidy suggests a good prognosis, the findings of our case show that potential good prognostic effects of trisomies 8 and 21 failed to counter-balance the poor prognosis in a patient clinically stratified into the high-risk group. This provokes further studies with large series to evaluate the relationship between prognosis and cytogenetic characteristics in leukemia patients.

Two Novel SMAD4 Mutations and Nonclassical Pathology in Juvenile Polyposis Syndrome. *C. Cremin[1], T. Moyana[2], E. Tomiak[3], M.T. Geraghty[3]* 1) Hereditary Cancer Program, BC Cancer Agency, Vancouver, BC, Canada; 2) Department of Pathology, Ottawa Hospital, Ottawa, Canada; 3) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, Canada.

We describe two patients with novel SMAD4 mutations, who had quite dissimilar manifestations of Juvenile Polyposis Syndrome (JPS). The first patient presented with anemia and endoscopic examination showed numerous polyps restricted to the colorectum. The second patient also presented with symptoms of anemia but was found to have numerous polyps restricted to the stomach. Pathologic examination of the resected stomach showed profuse polyposis. In both cases, the histology of the polyps was consistent with juvenile polyposis but with nonclassical features, as illustrated in this report. Analysis of genomic DNA revealed that both patients had truncating mutations in the SMAD4 gene. Taking our current findings in conjunction with previous reports that demonstrated an association between gastric polyposis and SMAD4 mutations, as well as reports that documented nonclassical juvenile polyp morphology in individuals with a SMAD4 mutation, we would like to suggest that SMAD4 gene analysis should be considered for cases of severe gastric polyposis, regardless of polyp histology.

Improvement in swallowing in Miglustat-treated Niemann-Pick disease type C children. *Y.H. Chien, W.L. Hwu, N.C. Lee, L.K. Tsai, A. C. Huang* Dept Medical Genetics, Natl Taiwan Univ Hosp, Taipei, Taiwan.

Niemann-Pick disease type C (NP-C) is a neurodegenerative disease characterized by impaired intracellular trafficking and sequestration of macromolecules. Studies in an animal model of NP-C disease showed that miglustat delayed the onset of neurological dysfunction, increased life span, and reduced ganglioside accumulation and neuropathological changes in those mice. Preliminary result for a clinical trial also suggested a positive effect of miglustat. Two children, age 14 and 9 years, with abnormal cholesterol esterification and filipin staining were enrolled in our study. Milgustat dosages, based on their body surface, were 150mg and 100mg three times daily, respectively. The efficacies were evaluated by neurological examination, videofluoroscopic studies (VFS) for swallowing assessments, MMSE, Purdue Peg Board, liver and spleen organ volumes, chitotriosidase, and quality of life. There was no weight loss or unpreventable gastro-intestinal disturbances during treatment. The initial VFS of the older boy showed oropharyngeal dysphagia with significant symptomatic aspiration. After 6-months treatment, aspiration decreased significantly. He was able to walk and write again after the treatment. The younger patient also had improvement in oral dysphagia. He further showed improvements in MMSE, Purdue Peg Board, and quality of life. Their liver and spleen volumes and chitotriosidase levels remained stationary during this period. The older boy suffered from migratory, diffuse pain over face, throat, back, joints and feet, though electrophysiologic studies failed to demonstrate the presence of peripheral neuropathy. The management included dose reduction to 100mg three times a day and analgesics, but the latter might have in turn led to memory loss and hallucination. Therefore, miglustat seems to be able to reverse some of the symptoms in NP-C patients, but more experiences are certainly required.

Partial rescue of truncating mutations in the *ATRX* gene through unusual intra-exonic splicing. *R.J. Gibbons[1], N. Malik[1], C. Fisher[1], A. Fryer[2], D.R. Goudie[3], I.D. Krantz[4], J. Traeger-Synodinos[5], E. Kanavakis[5]* 1) MRC Molecular Hematology Unit, Weatherall Institute of Molecular Medicine, John Radcliffe Hosp, Oxford, UK; 2) Clinical Genetics, Alder Hey Childrens Hospital, Liverpool, UK; 3) Human Genetics Dept of Pathology, Ninewells Hospital and Medical School, Dundee, UK; 4) Division of Human Genetics, The Childrens Hospital of Philadelphia, Philadelphia, PA 19104, USA; 5) Medical Genetics, University of Athens, St. Sophias Childrens Hospital, Athens 11527, Greece.

Nonsense mutations or frameshifting deletions or insertions are often predicted to lead to protein truncation and when they lie upstream of important functional domains they are commonly presumed to be null alleles. We have identified, in 5 unrelated families, 4 such mutations within the *ATRX* gene. They lie within 24bp of each other in the middle of a 3kb coding exon. Surprisingly, protein analysis by western blot showed that in addition to the predicted truncated protein product, some apparently full-length protein was also encoded by the mutant alleles. Analysis of the ATRX transcripts revealed a previously unsuspected pattern of alternate splicing within this large exon which was present in both normal and mutant cell lines. This leads to the in frame loss of 87bp of sequence and the omission of these mutations from the alternate spliceform. To date, all predicted truncating mutations in ATRX have been shown to be rescued to some degree. It seems likely that true null alleles in the human are lethal as has been demonstrated for the ATRX knockout in mouse.

Creating meaning from the mania: Identifying potential candidate genes for bipolar disorder using fine mapping, expression arrays and association analysis in an Irish bipolar disorder sample previously linked to 14q21-32. *S.E. Dobrin[1], F. Cassidy[2], C. Zhao[1], J.C. Badger[1], S. Roche[2], P. McKeon[2,3]* 1) Center for Human Genetics, Marshfield Clinic Research Founation, Marshfield, WI; 2) Smurfit Institute of Genetics, Trinity College Dublin, Dublin 2, Ireland; 3) Department of Psychiatry, St Patrick's Hospital, Dublin 8, Ireland.

We previously carried out a 10cM whole genome scan in a sample of 60 Irish bipolar affective disorder (BPAD) affected sib pairs (ASPs). The most significant result was on chromosome 14 at 76cM (peak marker D14S588 (68.21MB), multipoint NPL=3.28, under the narrow, BPAD type I, disease model). The region of the chromosome with nominal p-values <0.05 was quite substantial, extending from 47cM to 122cM; therefore, we undertook a fine-mapping analysis of this region. 100 SNP markers, at a 0.6cM resolution, were analyzed in an extended sample of 88 ASPs. Linkage analysis was carried out using Genehunter Plus which resolved our original linkage peak to 3 separate peaks. The most significant NPL score was at rs1885590 (66.8MB) which is located within intron 2 of the MPP5 gene (multipoint NPL=3.21, narrow disease model) and is very close to the original peak. An additional 80 SNPs are being genotyped to further resolve this region to 0.2cM. All markers were also tested for association in 125 bipolar type I trios. Four SNPs had p-values <0.05: rs229646 (64.26MB), rs2885128 (75.85MB), rs2148564 (93.14MB), and rs2010649 (94.87MB). rs229646 is located within intron 8 of KIAA0599 (pleckstrin homology domain containing, family G (with RhoGef domain) member 3) and rs2148564 is located in intron 22 of KIAA1409. We also used the data from a separate whole genome expression array study on post-mortem brain samples provided by the Stanley Foundation to identify potential candidate genes from the original linkage peak region of chromosome 14. Here we present the complete results from our linkage, association, and expression analyses detailing the novel candidate genes under investigation.

Mapping of small RNAs in the human ENCODE regions. *C. Borel, M. Gagnebin, C. Gehrig, E. Kriventseva, E. Zdobnov, S.E. Antonarakis* Dept Genetic Medicine, Univ Geneva Medical Sch, Geneva, Switzerland.

Large-scale efforts have significantly contributed to the current understanding of the complexity of the human transcriptome. Yet, most experiments have been focused on transcripts longer than 100 bp, missing shorter RNAs. In this study, we examined the expression of small RNAs in the ENCODE regions, representing approximately 1%; of the human genome from 44 loci. We used the Affymetrix ENCODE tiling arrays that interrogate expression of every 22nt using overlapping 25mer probes to map the size fractioned small RNAs (from 19 and 50nt) in 4 different cell lines (HepG2, HelaS3, GM06990, SK-N-SH). The labelling of those small RNAs was performed with polymerase A and a labelled poly(A)-tail was synthesized. We observed about 7500 small RNA signals. Only 8% of which overlap exons of annotated Gencode genes, whereas the majority map to intergenic (35%) and intronic (51%) regions. The data analysis also showed that i) 35% of the 3or 5 UTR exhibit evidence of transcription of small RNA, ii) 20% of small RNA is cell type specific, iii) 25% of signals show evidence of overlapping transcription on both strands of the genome. We performed the same experiment after stimulation of SK-N-SH cells by Retinoic Acid (6uM, 48 hrs). We found that 17% of the small transcripts are differentially expressed (5 fold) and responded to an induced developmental program. This is consistent with a biological function of these transcribed regions. As we expect some of these small RNAs to be microRNAs, we used comparative sequence analysis to detect evolutionarily conserved and stable RNA stem-loop structures characteristic to microRNAs precursor genes. A high fraction of the predictions overlapped with the detected expression, and we selected some of the candidates for testing by northern-blot.

Investigation of HSA21 microRNAs expression in Down Syndrome. *M. Gagnebin, C. Borel, S. Deutsch, S. E. Antonarakis* Dept genetic medical, Univ Geneva Medical Sch, Geneva, Switzerland.

Down Syndrome is a disorder due to an extra copy of chromosome 21. Our understanding of the molecular pathogenesis is remarkably poor since it is not clear how the extra copy of HSA21 leads to a wide range of phenotypes. We investigated a new class of functional sequences: microRNAs (miRNAs), that act primarily as post-transcriptional repressors of target genes through 3UTR interactions. We have used quantitative real-time PCR to accurately measure the expression of miRNAs. Due to their small size (~22nt) and the absence of poly(A) tail, a specific assay was designed to reverse transcribe each mature miRNA with specific stem loop primers. We analysed the expression of the 4 known HSA21 miRNAs (miR-125b, miR-let7c, miR-155, miR-99) and 5 non-HSA21 miRNA in lymphoblastoid cell lines from 14 normal and 14 trisomy 21 unrelated individuals. Only miR-155 is significantly overexpressed (2 fold) in the trisomic lymphoblastoid cell lines. We analysed also the expression of those miRNAs in different tissues of one set of monozygotic twins discordant for trisomy 21. We observed a significant overexpression of 1) miR-Let7c in trisomic heart, 2) miR-125 in trisomic brain, 3) miR-125, miR-155, miR-99 in trisomic kidney. This tissue specificity supports the conclusionis that miRNA expression is controlled by tissue-specific regulatory mechanisms. We conclude that HSA21 microRNAs are overexpressed in trisomy 21 individuals in a tissue dependant manner. We are currently investigating the identification of the target transcripts that are functionally regulated by these specific miRNAs and may contribute to a cellular phenotype.

Kinship Estimation by Machine Learning Approach. *J. Ge[1,2], M.B. Rao[1,2], R. Chakraborty[1,2]* 1) Dept Biomed Engineering, Univ Cincinnati, Cincinnati, OH; 2) Center for Genome Information, Dept. Environmental Health, Univ Cincinnati, OH.

Kinship estimation, otherwise called determination of biological relationships between individuals, is relevant in genetic epidemiological investigations, forensic case-works, paternity testing, and victim identifications in mass disaster cases. Two genetic factors, genotyping error and population substructure, causes inaccuracies of kinship estimation from genotype data. Genotyping errors reduce the precision of likelihood estimation, and population structure mimics excess homozygosity in comparison to the Hardy-Weinberg expectations in the population. Generally traditional maximum likelihood methods, either based on single locus (i.e., scores derived from Identity-by-State, IBS) or multipoint linkage information (i.e., Markov Chain based models), perform well in distinguishing common relationships, but to reach a satisfactory precision for close relationships, at least 200 markers (i.e., half genome-scan) are required. Loss of information (e.g., use of only mean IBS scores), attendant to the traditional methods can be minimized by using Machine Learning algorithms (MLAs), as MLAs can utilize other features of IBS scores, offering opportunity for precise estimation of kinship with lesser number of genetic markers. In our study, two learning methods, Support Vector Machine (SVM) and Decision Tree (DT), are used. Theoretically SVM provides the best generalization ability on unseen data, compared with other classification methods, and DT explicitly gives the significance of inferred kinship. Extensive simulation experiments with unlinked loci showed increased efficiency of kinship estimation, compared with traditional methods even in the presence of genotyping errors and population substructure. However, for linked loci the gain of efficiency is more modest. Using real datasets encompassing most of the common relationships, empirical gain of efficiency of MLAs in comparison to the traditional methods are also evaluated. (Research supported by a grant form the Department of development, State of Ohio, and NIH grant GM 41399).

CRYBA4, a Novel Human Cataract Gene that is also Involved in Microphthalmia. *G. Billingsley[1], S. Santhiya[2], A.D. Paterson[1, 6], K. Ogata[3], S. Wodak[3], S.M. Hosseini[1], M.S. Manohar[2], P. Vijayalakshmi[7], P.M. Gopinath[8], J. Graw[4], E. Héon[1, 5]* 1) Program of Genetics & Genomic Biology, The Hospital for Sick Children, Research Institute, Toronto, ON, Canada; 2) Dr ALM Postgraduate Institute of Basic Medical Sciences, Department of Genetics, University of Madras, Taramani, Chennai, India; 3) Center for Computational Biology, The Hospital for Sick Children Research Institute; 4) GSF-National Research Center for Environment and Health, Institute of Developmental Genetics, Neuherberg, Germany; 5) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, University of Toronto; 6) Department of Public Health Sciences, University of Toronto; 7) Arvind Eye Hospital and Post Graduate Inst. of Ophthalmology, Madurai, India; 8) Science Centre, Manipal Academy of Higher Education, Manipal, India.

Genetic analysis of a large Indian family affected with AD congenital lamellar cataract allowed us to identify a novel cataract gene, CRYBA4. Following a genome wide screen, linkage analysis identified a maximum LOD score of 3.20 (=0.001) with marker D22S1167 of the -crystallin genes cluster on chromosome 22. A c.317TC sequence change, which segregated with the disease status, was identified in CRYBA4 exon 4. To date, CRYBA4 was the only gene in this cluster not associated with either human or murine cataracts. The change, predicted to substitute the highly conserved hydrophobic Phe 94 by hydrophilic Ser, was not observed in 239 healthy control individuals. Protein modeling suggested a significant reduction in the intrinsic stability of the mutant crystalline monomer, which would impair its ability to form the association modes critical for lens transparency. Considering that CRYBA4 associates with CRYBB2 and that CRYBB2 has been implicated in microphthalmia, mutational analysis of CRYBA4 was performed in microphthalmia patients (n=32). We identified a c.242TC (Leu69Pro) sequence change in CRYBA4 exon 4 in one patient, which is predicted to disrupt the CRYBA4 -sheet, most probably leading to a structure with reduced stability. This is the first report associating mutations in CRYBA4 with cataractogenesis or microphthalmia.

Laryngeal Anomalies in Van Den Ende-Gupta Syndrome. *O.A. Abdul-Rahman[1], J.D. Carron[2]* 1) Department of Preventive Medicine, University of Mississippi Medical Center, Jackson, MS; 2) Deparment of Otolaryngology and Communicative Sciences, University of Mississippi Medical Center, Jackson, MS.

In 1992, Van den Ende et al. first reported a multiple congenital anomaly syndrome characterized by blepharophimosis, arachnodactyly, and congenital contractures in a Brazilian girl born to consanguineous parents. In 1995, Gupta et al. compared this entity with Marden-Walker syndrome and noted the absence of psychomotor retardation. Several additional patients have been reported with Van Den Ende-Gupta syndrome (VDEGS) broadening the phenotype to include cleft palate, dysmorphic facial features with a beaked nose and mildly crumpled ears, elbow deformities, and enlargement of the cerebellum. We present a 12 month-old African-American female born to non-consanguineous parents who was diagnosed with VDEGS based on the presence of blepharophimosis, beaked nose, crumpled ears, arachnodactyly, and congenital contractures of the hands, elbows, and knees. The patient also had chronic rhinorrhea and was referred for an otolaryngologic evaluation. Direct laryngoscopy identified an unusual laryngeal malformation characterized by large, globular cuneiform cartilages, shortened aryepiglottic folds, a tightly coiled epiglottis, and laryngomalacia. Due to stridor and prolapse of the redundant cuneiform cartilages, supraglottoplasty was performed with removal of the cartilages. Release of the aryepiglottic fold was also performed to separate the epiglottis from the arytenoid cartilages. We propose expanding the phenotype of VDEGS to include laryngeal anomalies and recommend direct laryngoscopy with appropriate intervention in VDEGS patients presenting with chronic rhinorrhea or stridor.

Dp71ab/DAPs complex composition changes during the differentiation process in PC12 cells. *J. Romo-Yáñez[1], V. Ceja[1], R. Ilarraza[1], R. Coral[2], F. Velázquez[3], D. Mornet[4], A. Rendón[5], C. Montañez[1]* 1) Depto. Genética y Biología Molecular, CINVESTAV, Mexico; 2) U. de Inv. Méd. en Genética Humana, CMN siglo XXI, México; 3) Depto. Bioquímica, UANL, México; 4) U. de Montpellier1, Lab. Physiol. des Interactions, EA 701, Institut de Biologie, France; 5) INSERM EMI 99-18, Lab. Physio. Mol. et Cell. de la Retine, France.

Dystrophin Dp71 has been identified as the major DMD (Duchenne Muscular Dystrophin) gene product in brain. Dp71 interacts with DAPs (Dystrophin Associated Proteins), as well as cytoskeletal actin. Dp71 mRNA is alternatively spliced generating different isoforms, one of them, Dp71ab lacks exons 71 and 78. PC12 cells express several Dp71 isoforms including Dp71ab. To gain insight into the function of Dp71 dystrophins, we identified DAPs that interact with Dp71ab during neuronal growth factor (NGF) induced differentiation of PC12 cells. DAPs expression was analyzed by RT-PCR, Western blot and indirect immunofluorescence coupled to confocal microscopy. RT-PCR analysis showed mRNA expression of all sarcoglycans. Inmunofluorescence analysis confirmed the expression at the protein level for these proteins, except -sarcoglycan. The colocalization analysis showed , and -sarcoglycans strongly colocalized with Dp71ab in undifferentiated PC12 cells; these colocalizations decreased in the differentiated state and showed a strong colocalization with -sarcoglycan. Western blot analysis revealed that the expression of -dystroglycan, 1-syntrophin, 1- and -dystrobrevins were not affected during NGF differentiation. In order to identify proteins interacting with Dp71ab, coimmunoprecipitation assays were performed; Dp71ab forms a complex with -dystroglycan, 1-syntrophin, -dystrobrevin, -, - and -sarcoglycans in undifferentiated PC12 cells. In differentiated PC12 cells, the complex composition changes since Dp71ab associates only with -dystroglycan, 1-syntrophin, -dystrobrevin and -sarcoglycan. Interestingly, neuronal nitric oxide synthase protein associates with Dp71ab-DAPs complex during NGF treatment, raising the possibility that Dp71ab may be involved in signal transduction events during neuronal differentiation.

Identification of a novel region for AIS on chromosome 12p with an autosomal recessive model of inheritance. *P. Giampietro[1], C. Raggio[2], C. Zhao[1], D. Dorshorst[1], S. Dobrin[1], J. Weber[4], R. Blank[3]* 1) Marshfield Clinic, Marshfield, WI; 2) Hospital For Special Surgery, New York, NY; 3) University of Wisconsin, Madison, WI. GRECC Service, William S. Middleton VAMC, Madison, WI; 4) Prevention Genetics 3700 Downwind Drive Marshfield, WI.

Identification of a novel region for AIS on chromosome 12p with an autosomal recessive model of inheritance P. Giampietro1, C. Raggio2, C. Zhao1, D. Dorshorst1, S. Dobrin1, J. Weber4, R. Blank3. 1) Marshfield Clinic, Marshfield, WI; 2) Hospital For Special Surgery, New York, NY; 3) University of Wisconsin, Madison, WI. GRECC Service, William S. Middleton VAMC, Madison, WI; 4) Prevention Genetics 3700 Downwind Drive Marshfield, WI.
Adolescent idiopathic scoliosis (AIS) is defined as a lateral curvature of the spine of 10 or greater which affects children during their most active growth phase. It is a complex, common,genetically heterogeneous condition, with genetic and environmental influences. The estimated frequency of AIS is 2-3% in the general population. Autosomal dominant with variable penetrance, multifactorial and X-linked dominant modes of inheritance have been suggested. Previous studies have demonstrated genetic heterogeneity for AIS with linkage to 17p11, 19p13.3, 6q, distal 10q and 18q. No causative genes have yet been identified. Molecular hypotheses include connective tissue matrix alterations, neuromuscular imbalance and altered vestibular function. Multiple-point linkage analysis was performed on 54 samples from 7 multi-generation AIS families.Phenotype was determined by clinical evaluation and radiographic analysis. Genotyping was performed with 400 microsatellite markers at a density of 10 cM, on average.Using multipoint analysis option in Genehunter with a disease frequency of 1-3%, HLOD scores of 3.45 and 1.94 were obtained under both autosomal recessive model and dominant model at markers GATA49D12 and GATA4H03, respectively. The markers are 6 cM apart and lie in a gene rich region at approximately 31cM and 13.4Mb on chromosome 12p. Fine mapping studies are in progress to narrow down this region.

Bayesian Networks for Modeling SNP Markers. *H. Dong*[1], *L. Jin*[1], *M. Xiong*[1,2] 1) Genetics, Fudan University, Shanghai, China; 2) Biostatistics, University of Texas Health Science center at Houston.

Mutations of DNA sequence are a major force for the occurrence of SNPs. Sequence evolution causes variations of SNPs in populations. SNPs are nonrandomly assembled along the genome. The dependence and structural complexity of SNPs are essential dynamic properties of SNPs in population. However, most studies of SNPs variation have ignored the structural properties of SNPs. The concepts of pair-wise linkage disequilibrium (LD) and haplotype block only partially characterize the structure complexity of SNPs. Similar to our society in which we live in a world of networks, the term "network" also turns out to be a central notion in investigation of variation of SNPs in population. Bayesian network is a graphic model that efficiently encodes the joint probability distribution for a large set of variables and hence is also suited for modeling SNPs. In this report, we develop a general mathematical framework for studying variation of SNPs. The marker network can be represented by a directed acyclic graph in which nodes represent markers and arcs represent probabilistic dependence between the markers. The algorithms for learning structure of SNPs network and estimating parameters in the network have been developed. The relationship between the LD and network structure, and the haplotype blocks and network structure have been revealed. The overall properties of dependence among SNPs and limitations of pair-wise LD for modeling dependence of SNPs have been investigated. The proposed algorithms for learning Bayesian networks of SNPs are applied to SNPs data sets from African, Caucasian and Chinese populations. It turn out that Bayesian networks of SNPs will open a new field in network approach to studying the pattern of LD among SNPs, population structure and evolutions.

A novel DNAI1 mutation in Kartagener syndrome. *I. Gutierrez-Roelens[1], K. Cefle[2], M. Vikkula[1]* 1) Lab Human Molecular Genetics, Christian De Duve Inst, Brussels, Belgium; 2) Division of Medical Genetics, Istanbul Medical Faculty, Istanbul University, Istanbul, Turkey.

Kartagener syndrome (KS) (MIM 244400) is a genetically heterogeneous disorder, characterized by nasal polyposis, bronchiectasis and situs inversus. The disease is inherited as an autosomal recessive trait. Kartagener syndrome and Primary Ciliary Dyskinesia (PCD) are associated with the same respiratory symptoms, but situs inversus is specific to KS. Situs inversus, clearly indicates embryonic disruption of normal left-right patterning. A link between cilia and left-right determination has been suspected in man based on the pathophysiology of PCD and KS. Both disorders result from anomalies of cilia structure (missing or abnormal dynein arms, abnormal radial spokes and missing central pair of microtubules). To date, four dynein genes (DNAI1, DNAH5, DNAH7, and DNAH11) have been identified to be mutated in PCD and KS. In this study, we report a consanguineous family of Turkish origin, composed of two unaffected parents, and four children, two of whom present Kartagener syndrome. Genome wide SNP screening for homozygosity using the 50K SNP chip allowed us to identify a linked region on chromosome 9p21.2-q21.13 where the DNAI1 gene is located. Direct sequencing of the DNAI1 gene permitted us to identify a c.625C>T nucleotide change, which creates a premature stop codon (p.Arg209X) in the 5-coding region. The four unaffected individuals of the family are heterozygous for the C/T alleles, whereas the two affected children are homozygous for the T allele. The c.625C>T substitution generates truncated polypeptides that probably could not play a role in outer dynein arm assembly leading to a loss-of-function of the cilia. (vikkula@bchm.ucl.ac.be) (http://www.icp.ucl.be/vikkula).

Post-marketing surveillance of oral miglustat treatment in patients with Type 1 Gaucher disease. *B. Bembi[1], D. Hughes[2], I.N. van Schaik[3], B. Schwierin[4], C.E.M. Hollack[3]* 1) Metabolic Diseases Unit, Pediatric Hosp B Garofolo, Trieste, Italy; 2) Royal Free and University College Medical School, London, UK; 3) Academic Medical Center, Amsterdam, The Netherlands; 4) Actelion Pharmaceuticals, Allschwil, Switzerland.

A non-interventional, web-based post-marketing surveillance programme was implemented to collect comprehensive baseline and ongoing clinical information on miglustat (Zavesca) use in Type 1 Gaucher disease (GD1), focusing on neurological manifestations. This study aims to enhance the awareness of safety precautions and to stimulate the appropriate monitoring of miglustat use in individuals with GD1. Descriptive statistics were used for the data analysis. From March 2003 to the end of March 2006, information was available on the first 62 GD1 patients (61% females) prescribed miglustat in 13 European countries (44 centres). Overall exposure to miglustat represented a cumulative period of 79 patient-years, with a mean exposure SD of 1511 months. Mean age SD was 4316 years. At baseline, 44 (71%) patients were previously treated with enzyme replacement therapy (ERT) and mean duration SD of treatment was 64 years. Neurological assessment information was available for 51 (82%) patients. Amongst these, 30% displayed neurological manifestations (11% tremor, 8% neuropathy, 8% memory problems, 6% cognitive abnormalities). Twenty (32%) patients had bone pain. In the follow-up period, no adverse events (AEs) were reported in 28 (45%) patients. AEs led to discontinuation in 11 (18%) patients mainly due to gastrointestinal disturbances, with 8 of the 11 cases occurring during the first 6 months treatment. Tremor was reported in 9 (14%) patients, memory problems in 2 (3%) patients. Bone pain was observed in 2 osteoporotic patients showing skeletal symptoms at baseline. Overall, data from the post-marketing surveillance of miglustat in GD1 raised no new safety concerns, particularly no peripheral neuropathy. Web-based post-marketing surveillance is an effective tool for comprehensive safety monitoring of patients receiving miglustat in an international clinical setting.

Analysis of Polymorphisms in Complement Factor H (*CFH*) and Hypothetical *LOC387715* in Mexican Mestizos with Advanced Age-related Macular Degeneration. *A. Contreras[1], I. Silva-Zolezzi[1], A. Hidalgo[1], A. Inchaustegui[1], R.A. Cano Hidalgo[2], J.C. Zenteno Ruiz[2], R. Ayala Ramirez[2], H. Perez-Cano[2], S. March[1], E. Graue[2,3], G. Jimenez-Sanchez[1]* 1) National Institute of Genomic Medicine, Mexico; 2) Fundacion de Asistencia Conde de Valenciana IAP, Mexico; 3) School of Medicine, UNAM, Mexico.

Age-related macular degeneration (AMD) is the most common cause of central blindness in elderly population, it is characterized by poor vision in the central field due to progressive destruction of the macular area. Molecular mechanisms underlying AMD are poorly understood. Recently, several studies identified 2 genes associated to AMD with major but independent contributions: Hypothetical *LOC387715* in whites and Complement Factor H (*CFH*) in non-hispanic whites. More than 80% of the Mexican population is considered Mestizo, resulting from the admixture of any of 62 ethnic groups with the Spaniards in the last 500 years. To evaluate participation of these 2 *loci* in the Mexican Mestizo population, we genotyped 4 SNPs previously associated with AMD in 53 unrelated Mexican Mestizos with advanced AMD and 1088 unrelated controls. These SNPs were, 1 in *LOC387715* (rs10490924) and 3 in *CFH,* 2 intronic SNPs (rs1410996, rs380390) and the Y402H variant (rs1061170). Our results are consistent with a significant association of the *LOC387715* variant with advanced AMD in Mestizo patients from Mexico City (O.R. 8.555, C.I. [4.157-17.609], p-value=1.146×10^{-11}). No significant association was found for any of the *CFH* SNPs analyzed in our sample. Our results suggest that *LOC387715* could be an important contributor to advanced AMD in the Mestizo population, similar to data reported for white patients (Jakobsdottir J et al., 2005, *Am J Hum Genet* 77: 389-407). Interestingly, we did not find association to *CFH*. This may be due to sample size or most likely, to a different molecular mechanism of this complex disease in the Mexican Mestizo population. To confirm these results and identify additional *loci* associated with susceptibility to AMD in the Mexican Mestizo population, we are conducting a genome-wide association study in a larger sample of these patients.

A prospective study of neurological manifestations and other comorbidities in adult Type 1 Gaucher disease. *M. Beck[1], L. Marodi[2], M. Biegstraaten[3], I.N. van Schaik[3], C. Niederau[4], D. Hughes[5], P. Giraldo[6], C.E.M. Hollack[3]* 1) Pediatric Dept, Univ Mainz, Mainz, Germany; 2) University of Debrecen, Debrecen, Hungary; 3) Academic Medical Centre, Amsterdam, The Netherlands; 4) Klinik fur Innere Medizin, Universitat Essen, Dusseldorf, Germany; 5) Royal Free Hospital, London, UK; 6) Miguel Servet University Hospital, Zaragoza, Spain.

Gaucher disease (GD) is a complex disorder and comprehensive information on its natural history is relatively limited. Central and peripheral nervous symptoms have been reported as secondary manifestations of Type 1 Gaucher disease (GD1). To further investigate these findings, a multinational (5 countries, 6 centres) prospective study has been set up and is currently ongoing with the endorsement of the European Working Group on Gaucher Disease (EWGGD). The objective of this study is to determine whether neurological symptoms are present in GD1. The primary endpoints are the prevalence and incidence of peripheral neuropathy (PN) in GD1 patients who have not received miglustat. Diagnosis of PN will be confirmed based on analysis of symptoms and electrodiagnostic assessments validated by an independent central assessor. Secondary endpoints are incidence of peripheral neuropathies over 2 years, and changes from baseline of various clinical and biological parameters such as neurological and neuropsychological status, skeletal symptoms, plasma electrophoresis and quality of life. Descriptive statistics will be used for data analysis. This study will recruit up to 100 patients with GD1, either untreated or treated by enzyme replacement therapy. As of April 2006, seventy-four patients have been enrolled. Analysis of baseline data is currently ongoing. This first set of analyses will provide information on several aspects of the natural history of GD1, with a special focus on the prevalence of peripheral and central neurological manifestations. The comprehensive information provided by this study will contribute towards a better understanding and management of this disease.

All is heterogeneous: Surveying clinical, genetic, and allelic heterogeneity in autosomal recessive congenital ichthyosis. *K.M. Eckl[1,4], J. Kurtenbach[1], M. Nätebus[1], W. Küster[2], H. Traupe[3], A. Önal Akan[1,4], H.C. Hennies[1]* 1) Dermatogenetics, Cologne Ctr for Genomics, Univ Cologne, Cologne, Germany; 2) TOMESA Clinics, Bad Salzschlirf, Germany; 3) Dermatology, Univ Münster, Münster, Germany; 4) Faculty Mathematics and Natural Sciences, Univ Cologne, Cologne, Germany.

Autosomal recessive congenital ichthyoses (ARCI) form a group of rare, severe disorders of keratinization. Phenotypes and genotypes are extremely heterogeneous. Underlying genes were described at five loci. This project started in 2002 is the first long-term ARCI study that focuses on molecular mechanisms and cellular structures. We describe molecular and clinical findings in 300 families with ARCI originating from Middle Europe, Turkey, and India. We and others showed that one third of patients carry mutations in *TGM1*. In *ALOXE3* and *ALOX12B* coding for epidermal lipoxygenases 12R-LOX and eLOX-3 we identified 20 novel point mutations in 26 families, including 15 missense mutations. Mutated genes were expressed in HEK-293 cells, total protein was isolated and incubated with the genuine substrates, and enzymatic activity was determined. Analysis of reaction products demonstrated lack of enzyme activity. The only active mutant c.434G>A in *ALOXE3* was a splice-site mutation as verified in a cell-based mini-gene assay. This work showed that missense mutations in *ALOX12B* or *ALOXE3* lead to enzyme inactivation and the ARCI phenotype. Until now, we analysed 182 ARCI patient samples and 144 control samples for mutations in *ichthyin*, recently found to be mutated in ARCI patients. Five different mutations on 40 chromosomes of 31 unrelated patients were identified. However, two mutations previously found in patient samples were also identified on 26 control chromosomes. *Ichthyin* was cloned for functional studies, a polyclonal antibody was generated. Mutation analysis of the most recently identified genes *ABCA12* and *FLJ39501* is under way. Genotype/phenotype correlation studies showed that mutations in *ALOX12B* or *ALOXE3* result in a mild form of ARCI. This is in contrast to the findings in patients with mutations in *TGM1* which give rise to severe forms of ARCI in many cases but can also be associated with self-healing collodion baby.

Mendelian Randomisation using ApolipoproteinAV and lipoprotein lipase genotypes provides no evidence that increased plasma triglyceride concentrations are causally associated with insulin resistance. *T.M. Frayling[1], K.J. Ward[1], M.S. Sandhu[2], M.N. Weedon[1], R. Harbord[3], B. Shields[1], B. Knight[1], J. Luan[2], Y. Ben-Shlomo[3], A. Jeffrey[1], T. Wilkin[1], S. Ebrahim[4], N. Timpson[3], D. Lawlor[3], G. Davey-Smith[3], N. Wareham[2], A.T. Hattersley[1]* 1) Peninsula Medical Sch, Exeter, UK; 2) Cambridge, UK; 3) Bristol, UK; 4) London, UK.

Mendelian randomization can be used to dissect the causal direction of two correlated phenotypes. Insulin resistance and triglyceride concentrations are important predictors of type 2 diabetes and cardio-vascular disease. These traits are highly correlated in the normal population but it is not known if high triglyceride concentrations cause increased insulin resistance or vice versa. We analysed three polymorphisms associated with triglyceride concentrations: the S19W and -1131T/C variants in ApolipoproteinAV and the S447X variant in lipoprotein lipase, in 4949 subjects from five UK studies. We hypothesized that if triglyceride concentrations causally altered insulin resistance, participants with increasing numbers of triglyceride raising alleles would have increased insulin resistance. The 19W, -1131C and S447 alleles were associated with, 0.30 (0.22-0.38, $p=2.6x10^{-13}$), 0.27 (95%CI: 0.19-0.36, $p=5.9x10^{-10}$) and 0.2 (0.13-0.26, $p=7.7x10^{-9}$) SD increases in triglyceride concentrations respectively (using logged values). Using all three variants, participants with 1, 2, 3, and 4 triglyceride raising alleles had triglyceride concentrations 0.19, 0.43, 0.71 and 0.93 SD higher than subjects with 0 alleles respectively($p = 1.7x10^{-29}$, trend). There was no association between increasing numbers of triglyceride raising alleles and insulin resistance, as measured by HOMA (p=0.38, trend, using logged values). Measures of insulin resistance by genotype were significantly lower than expected given the association between genotypes and triglyceride concentrations and the association between triglyceride concentrations and insulin resistance ($p<0.0001$). Our study is the first to use two genes in a Mendelian randomization experiment and shows that triglyceride concentrations are unlikely to causally alter insulin resistance in the general UK population.

Detection of a cryptic deletion in a patient with a known duplication of 12q using CGH microarray analysis: Difficulties associated with genotype/phenotype correlations. *N. Champaigne, J. McKenna III, M.J. Gambello* Dept Pediatrics, Univ Texas, Houston, Houston, TX.

We report the results of comparative genomic hybridization array analysis of a patient with a known de novo duplication of 12q. The patient was born with dysmorphic features and multiple congenital anomalies. His clinical findings consisted of small palpebral fissures, flat nasal bridge, bulbous nose, pointed chin, ambiguous genitalia, and duodenal atresia secondary to an annular pancreas. His medical course was further complicated by acute renal failure with a renal biopsy revealing a diffuse mesangial sclerosis variant of congenital nephritic syndrome. Chromosome analysis by G-banding showed additional chromosomal material on the distal end of 12q. FISH studies revealed a duplication of 12q24.32 to 12q24.33. Parental karyotypes were normal. The medical literature was reviewed for similar duplications for potential genotype/phenotype correlations and revealed several cases with variable breakpoints and clinical features ranging from mild to severe. There were no cases associated with congenital nephritic syndrome. To further characterize the breakpoints, analysis with the Agilent human genome 44k oligomicroarray was performed. Microarray data revealed that the duplication actually spanned 12q24.31, 12q24.32 and 12.q24.33 and that there was an unappreciated deletion of proximal 12q24.31. This case highlights the difficulty of using previous case reports to interpret the significance of rare chromosomal rearrangements, as well as to predict the long-term consequences for patients and their families.

Correction of a mitochondrial fatty acid oxidation (FAO) disorder by fibrate: relation to genotype. *S. Gobin-Limballe[1], F. Djouadi[1], F. Aubey[1], S. Olpin[2], S. Yamaguchi[3], R.J. Wanders[4], T. Fukao[5], J. Bastin[1]* 1) CNRS UPR9078, Faculté Necker, Paris, France; 2) Sheffield Children's Hospital, Sheffield, UK; 3) Shimane School of Medicine, Shimane, Japan; 4) Academic Medical Center, Amsterdam, The Netherlands; 5) Gifu University, Gifu, Japan.

We previously showed that fibrates could restore FAO in patient cells harboring defects in Very-Long-Chain-AcylCoA-Dehydrogenase (VLCAD; mitochondrial ?-oxidation), by stimulating residual enzyme activity. Given the large number of VLCAD gene mutations known, we investigated the relation between the nature of the mutations and the response to drug. We used a panel of 41 VLCAD-deficient fibroblast lines with distinct genotypes, representing 50 different mutations. Cells were cultured under standard conditions and 400M bezafibrate was added in the culture medium 2 days before experiments; FAO was then measured using tritiated palmitate. Untreated VLCAD-deficient cells exhibited FAO rates much lower (-30 to -90%) than control. In 60% of the genotypes tested, bezafibrate induced a marked increase in FAO, and complete correction of FAO was reached in 12 cell lines. Altogether, our data identified three groups: - Group 1 -severely deficient cells with nonsense mutations, or missense mutations affecting residues essential for catalysis (G222, G441, R469), these were drug-resistant - Group 2 - missense mutations that showed a response to bezafibrate, although probably leading to enzyme instability or altered catalytic properties as drug-induced FAO rates remained lower than control - Group 3 -, about 30% of cell lines, harbored genotypes that permitted full restoration of FAO by bezafibrate, comprising mild mutations (V283A, G441D, R615Q), that probably do not greatly affect the catalytic site and/or enzyme stability. We will now characterize changes in VLCAD mRNA and residual enzyme levels induced by bezafibrate, as a function of genotype. These data should provide valuable information on structure-function relationships for a future 3-D enzyme model. Furthermore, this study might open to clinical applications by identifying VLCAD mutations and VLCAD deficient patients that are potentially responsive to bezafibrate.

Search for environmental and genetic factors of Congenital Heart Disease in Sao Miguel Island, Azores (Portugal). *R. Cabral[1,2], R. Anjos[3], L. de Fez[1], P.R. Pacheco[1,2], C. Pereira Duarte[4], L. Mota-Vieira[1,2]* 1) Mol Genetics & Pathology Unit, Hospital Divino Espirito Santo, Azores Islands; 2) Instituto Gulbenkian de Ciencia, Oeiras; 3) Pediatric Cardiology Department, Hospital of Santa Cruz, Carnaxide; 4) Pediatric Department, Hospital Divino Espirito Santo, Azores Islands, Portugal.

Congenital heart disease (CHD) is the most frequent of all clinically significant birth defects. Recently, we demonstrated that in Sao Miguel Island the CHD prevalence is relatively high: 9.16 per 1000 live births. Considering that half of the population lives in small rural localities and the internal migration is reduced, aspects that increase endogamy and inbreeding, we performed a structured family questionnaire which includes: 1. queries for CHD risk factors (maternal diabetes mellitus, alcohol and drug abuse by the mother during pregnancy, viral infections of the fetus and genetic conditions), and 2. a detailed family history to construct the ascending genealogy until the 3th generation. To that end, 162 CHD families were contacted by phone and/or letter, 106 (65.4%) of which accepted to participate. We identify 37 (34.9%) multiplex families (with 2 to 5 patients), 6 (5.7%) consanguineous families, and 6 (5.7%) multiplex families with consanguinity. Particular attention will be given to 2 consanguineous families: a sib-sib marriage (F=0.25) and one with 5 CHD siblings (F=0.0039). Moreover, we observe that 61 (57.0%) cases have maternal risk factors, of which 7% has 3 or more risk factors. In order to carry out molecular genetic analysis, a biobank consisting of DNA and RNA from patients and parents was built after informed consent. The first mutation analyzed was the C677T of the MTHFR gene in 469 healthy individuals from Sao Miguel, being 84 (17.2%) homozygous for the mutation (TT) and 221 (45.5%) heterozygous (CT). From these observed genotypes, the C677T allele frequency in Sao Miguel population is 41.5%, the second highest value in Europe. A comparative analysis will be performed for this mutation in the CHD patients, as well as for other candidate genes such as NKX2.5, TBX5 and GATA4. Funded by FCT and DRCT (Azores), Portugal.

Understanding diseases associated with mutations in the GNE gene, coding for UDP-GlcNAc 2-epimerase/ManNAc kinase. *C. Ciccone, D. Krasnewich, R. Klootwijk, I. Manoli, S. Sparks, W.A. Gahl, M. Huizing*
Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

The GNE gene, on 9p12-13, encodes the bifunctional enzyme UDP-GlcNAc 2-epimerase (GNE) /ManNAc kinase (MNK), which catalyzes the first two committed, rate-limiting steps in the biosynthesis of sialic acid. Sialic acid is a negatively charged sugar, typically found as the terminal sugar on glycoconjugates, where it plays a role in a variety of cellular signaling functions. Feedback inhibition of GNE by the final product, CMP-sialic acid, tightly regulates sialic acid biosynthesis. GNE mutations underlie two distinct disorders. Dominantly inherited sialuria is characterized by dramatically *increased* sialic acid levels, developmental delay, coarse facies, and hepatomegaly. Patients have a missense mutation in the allosteric site of GNE, leading to loss of feedback-inhibition by CMP-sialic acid, cytoplasmic accumulation of sialic acid, and urinary excretion of gram quantities of free sialic acid. Recessively inherited Hereditary Inclusion Body Myopathy (HIBM) is characterized by *decreased* sialic acid production. HIBM is a recessive disorder of adult onset with progressive muscle weakness and relative sparing the quadriceps muscles. HIBM patients harbor two GNE mutations within the GNE or NMK domains and outside of the enzymes allosteric site. Our technical ability to quantitate monosaccharides using HPLC/pulsed amperometric detection has allowed us to study the biochemical pathology of GNE mutations in detail. We developed individual GNE and MNK enzymatic assays and determined reduced activities in cultured fibroblasts of patients with HIBM missense mutations in either or both the GNE and MNK enzymatic domains. This loss of enzyme activity impairs sialic acid production and interferes with proper sialylation of glycoconjugates. Understanding the function and regulation of the sialic acid biosynthesis pathway permits the development of diagnostic tests and therapies for HIBM (see abstract of Huizing et al.) and sialuria (see abstract of Klootwijk et al.).

Variants in TGF1 are associated with severe lung disease in homozygous F508 cystic fibrosis patients. *L.A. Bremer, S.M. Blackman, L.L. Vanscoy, J.M. Collaco, K.E. McDougal, G.R. Cutting* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Pulmonary function varies among cystic fibrosis (CF) patients with the same CFTR genotype, indicating that other factors contribute to phenotype variation. A recent case-control study showed that the transforming growth factor beta-1 (TGF1) gene may be a modifier of CF lung disease severity (Drumm, et al). The goal of this work was to evaluate the association of SNPs in TGF1 with CF lung disease severity using transmission tests. Trios selected from the CF Twin and Sibling Study were genotyped for two SNPs in TGF1: C-509T and C+29T (codon 10). Transmission disequilibrium test (TDT) was performed in patients dichotomized for two longitudinal pulmonary phenotypes (BayesFEV1%pred and AvgFEV1CF%). Because body mass index is known to be correlated with FEV1, association of TGF1 with average BMI z-score (AvgBMIZ) was also studied. Twin and sibling analysis indicates that heritability of these three phenotypes ranges from 0.5-0.8. Patients were assigned affected status if they fell below pre-determined threshold levels: BayesFEV1%pred, <68% (severe); AvgFEV1CF%, below 50th percentile (severe); AvgBMIZ, <-0.7 (severe). TDT demonstrated statistically significant association between both the -509T and +29C alleles and severe lung disease (BayesFEV1%pred: 53 trios, p=0.011 and 0.039; AvgFEV1CF%: 96 trios, p=0.025 and 0.017). No transmission distortion was seen in trios classified as having mild lung disease (136 and 160 trios) or in those classified by AvgBMIZ (168 severe trios). Patients stratified according to CFTR genotype (F508/F508 vs. other) demonstrated significant over-transmission of the -509T and +29C alleles in patients with severe CF lung disease (-509T: BayesFEV1%pred, 25 trios, p=0.011; AvgFEV1CF%, 50 trios, p=0.029; and +29C: AvgFEV1CF%, 50 trios, p=0.013). Transmission distortion was not observed in non-F508 homozygotes (28 and 46 trios). This family-based study, along with a case-control study (Drumm, et al), implicate TGF1 as a modifier of CF lung disease severity, in a context dependent on CFTR genotype.

Expression profiling in families with Mitochondrial Myopathy and Sideroblastic Anemia (MLASA) and homozygous mutation in the Pseudouridylate Synthase I (PUS1) gene. *Y. Bykhovskaya, E. Mengesha, N. Fischel-Ghodsian* Medical Genetics Institute, Ahmanson Department of Pediatrics, Steven Spielberg Pediatric Research Center, Cedars-Sinai Medical Center and David Geffen School of Medicine at UCLA, Los Angeles, CA.

MLASA is a progressive oxidative phosphorylation disorder that affects muscle and erythroid cells. Molecular basis of MLASA was recently identified to be the homozygous point mutation C656T (R116T) in the catalytic domain of the PUS1 gene. Biochemical analysis revealed a lack of pseudouridylation at the expected sites in mitochondrial and cytoplasmic tRNAs. In order to further elucidate intracellular pathways through which the homozygous mutation leads to tissue-restricted phenotype, we performed microarray expression analysis of EBV-transformed lymphoblasts from four patients with MLASA, heterozygous parents, an unaffected sibling homozygous for the normal PUS1 allele and three unrelated controls. Expression signals of 47,296 RefSeq annotated and putative transcripts from human expression beadchip microarray were analyzed using BeadStudio and GeneSpring programs. Genes coding for proteins involved in DNA transcription and its regulation, and metal binding proteins, demonstrated major differences in expression between patients and all other individuals with normal phenotype. Genes coding for ribosomal proteins differed significantly between individual with at least one copy of the mutated PUS1 gene and wild-type controls, suggesting a potential compensation mechanism. Specific analyses of pseudouridylation and iron metabolism related genes revealed several differentially expressed genes. Real-time RT-PCR results for selected transcripts were consistent with microarray results. These finding outline several potential genes and pathways involved in the pathogenesis of MLASA in affected tissues, as well as potential compensatory pathways in unaffected tissues, which will be further investigated in a mouse knockout model of MLASA. We gratefully acknowledge support from NIH/NIDDK grant RO1-DK74368.

Recessive Lethal Form of Osteogenesis Imperfecta Caused by Null Mutations in CRTAP. *A.M. Barnes[1], W. Chang[1], R. Morello[2], W.A. Cabral[1], E. Makareeva[3], N. Kouznetsova[3], S. Leikin[3], M.A. Weis[4], D.R. Eyre[4], T.E. Uveges[1], J.J. Mulvihill[5], U.T. Sundaram[6], B. Lee[2], J.C. Marini[1]* 1) BEMB, NICHD/NIH, Bethesda, MD; 2) Baylor Coll. Med., Waco, TX; 3) SPB, NICHD/NIH, Bethesda, MD; 4) U. Wash., Seattle, WA; 5) Children's Hosp. of Oklahoma, Oklahoma City, OK; 6) Dept. Human Genetics, MCV, Richmond, VA.

CASP (cartilage-associated protein), encoded by *CRTAP*, is required for prolyl 3-hydroxylation of fibrillar collagens; loss of its function causes defective osteoid formation and severe osteoporosis in mice. We have identified the first 3 patients with mutations in the coding region of *CRTAP*. All 3 have a severe recessive form of osteogenesis imperfecta (OI), which is lethal in the first year of life. Long bones are extremely osteoporotic and deformed, with prenatal fractures and abnormal modelling. Proband 1 is homozygous for an IVS1+1G>C mutation; his parents were second cousins. The alternatively spliced forms each contain a PTC in intron 1. Proband 2 is homozygous for Gln276Stop in exon 4. Proband 3 is a compound heterozygote of a 16 nt duplication in exon 1, which leads to a PTC in exon 2, and a Met1Ile substitution. Expression of *CRTAP* was quantitated in proband fibroblast total RNA by real-time RT-PCR; probands 1, 2 and 3 had 0, 5-12 and 20-22% CRTAP expression, respectively, compared to normal control. Proband fibroblast collagen is fully overmodified on SDS-Urea-PAGE, as is found in cases of OI with collagen structural defects. Proband secreted collagens have 28-45% more hydroxylysine residues than normal collagen, which is consistent with collagen Tm ~1ºC greater than normal. Mass spectrometry of proband collagen tryptic peptides revealed absence of prolyl-3-OH at the unique Pro986 site in the 1(I) chain of type I collagen in probands 1 and 2, and 20% of normal hydroxylation in proband 3. Absence of CASP in all probands and presence in the parents was demonstrated on Western blot with murine anti-CASP antibody. These recessive null mutations for CRTAP reveal that prolyl 3-hydroxylation of type I collagen is crucial for bone formation; absence of prolyl-3-hydroxylation of types V and IV collagen may also be important.

Project among African Americans to Explore Risks for Schizophrenia (PAARTNERS): Recruitment and Assessment Methods. *M.H. Aliyu[1], M.E. Calkins[2], C.L. Swanson[1], P.D. Lyons[3], R. Savage[1], R. May[1], H.W. Wiener[4], B. Devlin[5], V.L. Nimgaonkar[5], R.C. Go[4]* 1) Psychiatry, University of Alabama at Birmingham, Birmingham, AL; 2) Psychiatry, Neuropsychiatry Section, University of Pennsylvania, Philadelphia, PA; 3) Neurology, University of Virginia, Charlottesville, VA; 4) Epidemiology, University of Alabama at Birmingham, Birmingham, AL; 5) Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA.

The Project among African-Americans to Explore Risks for Schizophrenia (PAARTNERS) is a multi-site, NIMH-funded study that seeks to identify genetic polymorphisms that confer susceptibility to schizophrenia among African Americans by linkage mapping and, possibly, admixture mapping. Because deficits in certain dimensions of cognitive ability are thought to underlie liability to schizophrenia, the project also examines cognitive abilities in individuals affected by schizophrenia and their extended family members. We aim to recruit a sample of 1260 African American families, all of whom have at least one proband with schizophrenia or schizoaffective disorder. The data collection protocol includes a structured Diagnostic Interview for Genetic Studies, Family Interview for Genetic Studies, focused neurocognitive assessment, medical records review, and the collection of blood or buccal cells for genetic analyses. We have currently completed study procedures for 93 affected sib pairs, 403 case-parent trio and 13 multiplex families. A total of 289 probands have completed the best estimate final diagnosis process and 1153 probands and family members have been administered the computerized neuropsychological battery. This project lays the foundation for future analysis of cognitive and behavioral endophenotypes. The novel integration of diagnostic, neurocognitive and genetic data will also generate valuable information for future phenotypic and genetic studies of schizophrenia.

Mutation screening of the PTEN gene in patients with autism and macrocephaly. *C. Betancur[1], G. Cai[2], P. Chaste[1], G. Nygren[3], J. Goldsmith[2], J. Reichert[2], H. Anckarsäter[3], M. Råstam[3], M. Leboyer[1], C. Gillberg[3], A. Verloes[4], J.D. Buxbaum[2]* 1) INSERM U513, Université Paris XII, Creteil, France; 2) Mount Sinai School of Medicine, New York, USA; 3) Department of Child and Adolescent Psychiatry, Goteborg University, Goteborg, Sweden; 4) Clinical Genetics Unit, Hôpital Robert Debré, Paris, France.

The tumor suppressor gene PTEN, located on 10q23, is mutated in a spectrum of disorders (Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome, juvenile polyposis...) collectively referred to as PTEN-hamartoma tumor syndrome. Clinical features include progressive macrocephaly, mucocutaneous changes (hemangiomas, lipomas, tricholemnomas, pigmented spots), fibrocystic breast disease, cerebellar hamartomas (known as Lhermitte-Duclos disease) and colon polyps. Hypotonia, macrocephaly, and in some cases mental retardation and/or seizures may be present. Breast, thyroid and uterine cancers are common in adults. PTEN mutations have been described in a few patients with autism and macrocephaly. In this study, we screened PTEN for mutations and deletions in 88 patients with autism spectrum disorders and macrocephaly (head circumference > 2 SD) recruited by the Paris Autism Research International Sibpair (PARIS) study or by Mount Sinai School of Medicine/Autism Genetics Resource Exchange. Mutation analysis was performed by direct bidectional sequencing of all exons, flanking regions and promoter. Deletions were searched by MLPA. No exonic or whole gene deletions were observed. We identified a previously undescribed de novo missense mutation in exon 8 (p.D326N) in a 5-year-old boy with autism, mild mental retardation and severe, progressive macrocephaly (OFC > 10 SD). Study of 15 polymorphic markers excluded non-paternity. Clinical features included postaxial hexadactyly of the feet (operated) and 3 café-au-lait spots. These findings indicate that molecular screening of PTEN should be considered in patients with autism and marked macrocephaly. Because of tumoral risk, specific medical follow-up need to be proposed to patients with PTEN mutation, as well as genetic counseling and carrier screening in the relatives.

Complement Factor H Polymorphism Tyr402His and Cuticular Drusen. *M.A. Grassi[1,6], J.C. Folk[1], T.E. Scheetz[1,4,5], C.M. Taylor[1], V.C. Sheffield[1,2,3,4,5], E.M. Stone[1,3,4,5]* 1) Ophthalmology, University of Iowa, Iowa City, IA; 2) Pediatrics, University of Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute, Chevy Chase, MD; 4) Center for Bio-informatics and Computational Biology, Iowa City, IA; 5) Carver Family Center for Macular Degeneration, Iowa City, IA; 6) Heed Ophthalmic Foundation, Cleveland, OH.

The c.1204T>C, p.Tyr402His allelic variant in the complement factor H (CFH) gene is associated with a 3-fold increased risk for age-related macular degeneration (AMD). A high frequency of the histidine allele has also been noted in patients with membranoproliferative glomerulonephritis type II. We sought to determine the histidine frequency in patients with the cuticular drusen phenotype of AMD. 50 individuals were identified who met the criteria for the cuticular drusen phenotype using a standard threshold photograph. DNA samples were genotyped using a PCR based NIaIII restriction digest assay. 700 individuals with typical AMD and 252 controls were also genotyped. Fishers exact test was used to analyze the significance of allele frequency differences. The histidine variant was present in 70% (0.70+/-0.05) of the cuticular cohort; 55% (0.55+/-0.01) of the more typical AMD cases; and 34% (0.34+/-0.02) of controls. The association between the cuticular drusen phenotype and the histidine allele was highly significant [p=0.0034, OR 2.0 (1.21-3.07) vs. AMD cases; p=3.02e-11, OR 4.54 (2.79-7.50) vs. controls]. Genotype distribution between the three groups was similarly significant [p=0.0004]. The cuticular drusen phenotype is highly associated with the Tyr402His variant of the CFH gene. The significantly higher histidine allele frequency in this group compared to the typical AMD cohort suggests that the complement cascade may play a greater role in the pathogenesis of the cuticular drusen sub-type than in AMD as a whole.

Genotyping of factor VIII by TTGE (Temporal Temperature Gradient Gel Electrophoresis) and I-PCR (Inverse-Polymerase Chain Reaction) followed by sequencing in a family segregated with severe hemophilia A. *S.P. Chang[1,2], M. Chen[1,3], D.J. Lee[1], M.C. Shen[1,4,5]* 1) Department of Medical Research, and Center for Medical Genetics, Changhua Christian Hospital, Changhua, Taiwan; 2) Department of Bioscience Technology, Chang Jung Christian University, Taiwan; 3) Department of Obstetrics and Gynecology, and Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 4) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 5) 5. Department of Internal Medicine, Changhua Christian Hospital, Changhua, Taiwan.

We devised a novel strategy of combining TTGE (temporal temperature gradient gel electrophoresis) and I-PCR (inverse-PCR) to detect a novel frameshift mutation, c.3331-3333del A, of the human factor VIII gene in a Taiwanese family segregated with severe hemophilia A. TTGE was regarded to be unable to detect mutations smaller than 3-bp size variation (whether deletion or addition). Here we developed a modified strategy of TTGE in this sex-linked recessive disorder by mixing the wild-type allele with the DNA we wished to examine in a 1:1 ratio of quantity and successfully hunted the 1-bp deletion. This report adds a novel mutation of human factor VIII gene and also provides a technically interesting modification to the existing mutation screening strategies for sex-linked recessive disorders.

Localization of a Prostate Cancer Predisposition Gene to a 416,515 bp Region on Chromosome Xq28 in Utah High-Risk Pedigrees. *L.A. Cannon-Albright, J.M. Farnham, N.J. Camp* Biomedical Informatics, University of Utah, Salt Lake City, UT.

Previously we observed significant linkage confirmation for HPCX in Utah high-risk prostate cancer pedigrees (LOD=2.74; p=0.0002). Here we describe our localization efforts using additional genetic markers and statistical recombinant mapping. Linkage analyses were performed using MCLINK, a Markov chain Monte Carlo method, with the Smith parametric model. Classical multipoint LODs were calculated for each pedigree. The most likely haplotype configuration for each pedigree was also determined. It is known that genetic heterogeneity is extremely problematic for localizing linkage regions. Noise from unlinked pedigrees can shift linkage evidence and mislead fine-mapping efforts. Here we have focused on linked pedigrees only. We identified 32 high-risk extended Utah pedigrees with pedigree-specific LOD>0.588 (p=0.05) between DXS1200 at the q-telomere; inspection of the haplotype configurations suggested that twenty of these had at least three prostate cancer cases sharing a segregating haplotype. These 20 pedigrees were used for localization. For each pedigree, the multipoint LOD graph was used to infer recombinants, such that a sharp decrease in the LOD (>0.5 LOD units) was considered evidence for a recombinant, since such a decrease indicates a loss in sharing. With imperfect information content, the LOD may decrease over several cM and across several markers. The innermost (high) position before the change in LOD indicates the innermost position of the recombinant, and the outermost (low) position after the LOD change, the outermost position. To remain conservative, we considered only the outermost recombinant positions. The positions of all recombinants inferred across all 20 localization pedigrees were overlaid to identify the consensus region. We identified a 3-recombinant consensus region (region bound by three recombinants on each side) between DXS1193 and DXS7493, a 4.1 cM region of 2,868,449 bp at Xq28. This region contains approximately 34 genes. Within this, the 2-recombinant consensus region is only 1.1 cM (416,515 bp) and contains only two genes. We are currently pursuing mutation screening in haplotype carriers in these two candidate genes.

Valid Haplotype Association Analyses Accounting for Phase Uncertainty. *N.J. Camp, J. Wong, A. Thomas*
Biomedical Informatics, University of Utah, Salt Lake City, UT.

Consideration of haplotypes of candidate genes is the basis for an effective association study of complex diseases. A problem, however, arises because composite genotypes are the observed data. Haplotypes are not directly observed; they are estimated from genotype data. Generally, haplotypes are maximum likelihood estimates (MLE) established using, for example, an expectation-maximization (EM) algorithm. If such estimated haplotypes are considered and analyzed as if they were directly observed data, without considering the phase uncertainly, inflation of the type I errors may occur and tests become anti-conservative. One solution is to use a likelihood approach to consider all possible haplotypes with their corresponding probabilities. Here we discuss an alternative approach using Monte Carlo testing, and introduce hapMC, a JAVA program, that performs such analyses. The key to the Monte Carlo procedure is to appropriately match the observed statistic and the simulated null statistics that form the null, such that a valid test of the correct size is maintained. This is achieved as follows: MLE haplotypes are established for the observed data (cases and controls separately), and the statistic of interest calculated, ignoring the phase uncertainty. The composite genotype data are permuted across all individuals, MLE haplotypes are established for the permuted data (cases and controls separately), the statistic of interest calculated, again ignoring the phase uncertainly, and stored as a null statistic. The permutation procedure is repeated multiple times and a null distribution estimated, from which the observed statistic is assessed for significance. An alternate procedure for estimation of the null distribution is, instead, to use haplotype frequencies estimated from the observed data to generate the null composite genotype data. This second procedure allows the user to estimate MLE haplotypes across cases and controls together. Our program, hapMC, performs the necessary Monte Carlo procedure and EM estimates of haplotypes to provide valid haplotype tests for various standard association statistics, appropriately accounting for phase uncertainty.

Genetic polymorphism of CTLA-4 gene and cervical squamous cell carcinoma among Taiwanese women. *T.Y. Chang[1], Y.C. Yang[1, 2, 4], Y.J. Lee[1, 3, 5], T.H. Su[2, 4], C.K. Chen[1], H.F. Liu[1], C.C. Chu[1], M. Lin[1]* 1) Department of Medical Research, Mackay Memorial Hospital, Taipei, Taiwan; 2) Department of Gynecology and Obstetrics, Mackay Memorial Hospital, Taipei, Taiwan; 3) Department of Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 4) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 5) College of Medicine, Taipei Medical University, Taipei, Taiwan.

Human papillomavirus (HPV) is considered to be a necessary but not sufficient cause for cervical cancer. It is now recognized that host immunogenetic background play an important role in the outcome of HPV infection and the subsequent development of cervical cancer. Cytotoxic T-lymphocyte antigen-4 (CTLA-4) is a molecule expressed mainly on activated T cells and is important for the down-regulation of T-cell activation. The aim of this study is to investigate if polymorphisms of the CTLA-4 gene are associated with HPV-induced cervical cancer in the Taiwanese population. The -318 C/T, +49 A/G, and CT60 polymorphisms were genotyped in 165 cervical squamous cell carcinoma (CSCC) patients and 366 age/sex matched healthy controls by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) method. The presence and genotypes of HPV in CSCC patients were determined by E6, E7-based nested PCR. We found that the frequencies of -318 C/T genotype (25.9% vs. 17.2%; OR = 1.68; 95% CI = 1.06-2.67; P = 0.027) and T allele (12.8% vs. 5.7%; OR = 2.44; 95% CI = 1.24-4.81; P = 0.009) were significantly increased in CSCC patients as compared to the control population. No significant associations were found for the +49 A/G and CT 60 A/G polymorphisms. Our results suggest that -318 C/T variant in the promoter region of the CTLA-4 gene takes part in the development of CSCC in the Taiwanese population.

Father-to-daughter transmission of Cornelia de Lange syndrome caused by a mutation in the 5 untranslated region of the NIPBL gene. *G. Borck, M. Zarhrate, C. Cluzeau, E. Bal, J.-P. Bonnefont, A. Munnich, V. Cormier-Daire, L. Colleaux* INSERM U781, Hôpital Necker-Enfants Malades, Paris, France.

Cornelia de Lange syndrome (CdLS) is a developmental disorder characterised by typical facial dysmorphism, growth and mental retardation, microcephaly, and various malformations. Mutations in the NIPBL gene have been identified in ~40% of reported cases, suggesting either genetic heterogeneity or that some NIPBL mutations are not detected by current screening strategies. We screened a cohort of 21 patients with no previously identified NIPBL anomaly for mutations in the 5 untranslated region (5UTR) and the proximal promoter of the NIPBL gene. We identified a heterozygous deletion-insertion mutation in exon 1, 321 nucleotides upstream of the translation initiation codon (c.-321_-320delCCinsA) in one affected girl and her mildly affected father. This mutation altered highly conserved nucleotides, was not found in 400 control alleles, arose de novo in the father and co-segregated with the disease in the family. Using real-time quantitative PCR, we showed that NIPBL mRNA expression was lowered in patients lymphocytes compared to control samples. Finally, we showed that, when subcloned into a luciferase reporter vector, the mutation leads to a significant reduction of reporter gene activity. Our results demonstrate that mutations in the 5 non-coding region of the NIPBL gene can be involved in the pathogenesis of CdLS. Mutations affecting this region of the gene might be associated with a milder phenotype.

Geographic Distribution of Polymorphisms in Folate Metabolism Genes in Mexico. *L.A. Alfaro, I. Silva-Zolezzi, A. Contreras, R. Goya, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Hyperhomocystinemia and folate deficiency are risk factors for birth defects, complications during pregnancy, cardiovascular diseases, psychiatric disorders and cancer. Polymorphisms in genes encoding folate-dependent homocysteine pathway enzymes and other proteins related to folate metabolism have been associated to these conditions. Given the interaction between homocysteine and folate metabolism, particular combinations of genetic variants may underlie susceptibility to a diversity of serious clinical conditions. Except for the *MTHFR* 677C>T allele, most of the associations observed in different populations remain unconfirmed or controversial. To improve the design of association studies with common diseases in the Mexican population, we analyzed geographic distribution of allele frequencies of *MTHFR* 677C>T and 1298A>C, *MTRR* 66A>G, *MTHFD1* 1958A>G, *SLC19A1* 80A>G, and *TCN2* 776C>G, in ~1200 Mexican Mestizos from six different states: Guerrero, Guanajuato, Sonora, Veracruz, Yucatan and Zacatecas. Results show the following average allelic and genotypic frequencies associated to the phenotypes in the studied population, as well as the observed range between states: 1) *MTHFR* 677C>T, T=0.484 (0.432-0.575) and TT=0.229 (0.189-0.342); 2) *MTHFR* 1298A>C, C=0.142 (0.085-0.256) and CC=0.027 (0.006-0.073); 3) *MTRR* 66A>G, G=0.765 (0.663-0.858) and GG=0.597 (0.461-0.749); 4) *MTHFD1* 1958G>A, A=0.577 (0.468-0.629) and AA=0.333 (0.207-0.395); 5) *SLC19A1* 80A>G, A=0.530 (0.426-0.520) and AA=0.244 (0.168-0.275); and, 6) *TCN2* 776C>G, G=0.338 (0.289-0.351) and GG=0.115 (0.082-0.157). For the *MTHFR* our results are similar to reported frequencies in the Mexican population: for 677C>T, T (0.43-0.58), TT (0.170-0.357), and for 1298A>C, C (0.147-0.280), CC (0.023-0.155). In addition, our results show significant differences between several states, indicating that geographic distribution analysis of these allele frequencies will be of relevance to better design association studies for these genes in Mexican Mestizo population.

Mismatch repair detection technology as a tool for high throughput somatic mutation screening. *S. Bentivegna, A. Seymour* Pfizer Global Research and Development, Groton, CT.

The process of tumorigenesis occurs through the acquisition of a series of specific genetic alterations. Somatic point mutations and small insertions and deletions represent an important subgroup of these alterations but are often difficult to detect in the tumor genome via traditional screening technologies due to varying levels of infiltrating normal tissue present in the sample. Affymetrix has developed a mismatch repair detection (MRD) technology that utilizes a bacterial mismatch repair system in vivo to detect somatic mutations with a high degree of parallel processing. In this study, we evaluate the sensitivity of the MRD platform to detect somatic mutations in cancer cell line and colorectal and breast tumor DNA samples.

The coding regions of 30 kinase genes were screened in a panel of DNA samples derived from 54 colorectal tumors, 38 breast tumors and 23 cancer cell lines. Additionally, DNA derived from matched normal tissue for each tumor sample was screened in order to determine the germline variation present in each sample. A total of 311 somatic mutations were detected via MRD, all confirmed by dideoxy DNA sequencing. Here, we present the data detailing the frequency of these mutations, their locations within the genes, the effects on the open reading frames and the class of sample in which they occur. Moreover, we discuss the consistency of our data with findings that have been well documented in the scientific literature, including an increased incidence of somatic mutation in the BRAF and KRAS genes in colorectal cancer.

Evaluation of Ancestry and Linkage Disequilibrium Sharing in Admixed Population in Mexico. *J.K. Estrada, A. Hidalgo-Miranda, I. Silva-Zolezzi, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

More than 80% of the Mexican population is considered Mestizo, resulting from the admixture of ethnic groups with Spaniards. To generate an initial estimate of ancestral contribution (AC) of populations from Europe, Africa and Asia to the Mexican Mestizos, we genotyped 104 samples from the states of Sonora (n=20), Yucatan (n=17), Guerrero (n=21), Zacatecas (n=19), Veracruz (n=18) and Guanajuato (n=8) using the 100K Affymetrix SNP array, and used data from the International HapMap Project as the parental population information. From 3,055 ancestry informative SNPs reported by Smith et al. and Choudhry et al., we identified 105 present in the 100K array and used them to calculate AC from each population to our sample. To infer AC we used Structure software under the admixture model. Based on this analysis, the average AC in our samples is 58.96% European, 10.03% African and 31.05% Asian. Sonora shows the highest European contribution (70.63%) and Guerrero the lowest (51.98%) where we also observe the highest Asian contribution (37.17%). African contribution ranges from 7.8% in Sonora to 11.13% in Veracruz. Based on these data, we grouped our population according to European AC (<50%, 50-60%, 60-70% and >70%). We used the Carlson algorithm to derive European tagSNPs from the 100K marker set. To explore Linkage Disequlibrium Sharing (LDS) between Mestizos and Europeans, we calculated the proportion of tagSNP-marker pairs that maintained an $r^2$0.8 in each evaluated population. In general, comparison of LDS between European and Asian population is ~73%, whereas comparison with African population is ~40%. Mestizos from Guerrero show the lowest LDS (74%), whereas those from Sonora show the highest (77%). Similar results are seen in the group of lower (<50%) and higher (>70%) European ancestry. Our results suggest that the Mexican Mestizo population shows ancestry-based stratification that will requiere the appropriate corrections to avoid spurius results in association studies. Our results show that admixed populations have unique patterns of LD depending on levels of ancestral contribution.

Stimulation of respiratory chain (RC) complexes in RC-deficient patient cells: a pharmacological approach. *J. Bastin[1], F. Aubey[1], A. Munnich[2], F. Djouadi[1]* 1) CNRS UPR9078, Faculté Necker, Paris, France; 2) INSERM U781, Hôpital Necker, Paris, France.

We tested the ability of drugs acting as agonist of PPARs (peroxisome proliferator activated receceptors) to stimulate the expression of RC complexes in cell lines from control or from patients with various RC defects. In control fibroblasts, cell treatment by 400M bezafibrate for 2 days resulted in an increase in the levels of complex II (+30%), III (+50%), and IV (+50%), determined by spectrophotometry, or western-blot analysis. Quantitative RT-PCR studies showed that this was accompanied by parallel increases in RC complex mRNA. The effects of bezafibrate were then tested in cells carrying mutations in nuclear genes encoding complex II (SDH-FP), complex III (BCS1) or complex IV (COX 10, SURF 1). This confirmed the stimulatory effects of bezafibrate and, in particular, revealed that this drug could enhance the gene expression and protein levels of deficient RC complexes. Additional data were obtained in muscle cells from patients presenting a myopathic form of COX deficiency with unknown molecular basis. Indeed, myoblast exposure to bezafibrate allowed to fully correct the initial COX enzyme defect (-60% compared to control) that was found in untreated cells of these patients, and this drug effect was confirmed in myotubes differentiated from myoblasts. Western-blot analysis showed that bezafibrate increased 2-fold the expression of nuclear (COX2) and of mitochondrial-encoded (COX4) protein subunits. Induction of COX activity after drug treatment was also demonstrated by histochemical staining of patient myoblasts. In parallel, gene expression levels of COX4 (+31%) and COX 2 (+39%) as well as mRNA of muscle specific subunits (COX7a and COX8a, +40%) were found significantly increased in response to the drug. Altogether, these data indicate that bezafibrate can trigger an increase in the level of deficient RC complex in patient cells, and this likely involves a stimulation of gene expression of the mutated protein. This study also suggests a possibly new approach for the correction of RC deficiency, for which therapeutic approaches remain extremely limited.

Mouse models: using mutant phenotypes to investigate human disease. *S.M. Bello, D.L. Burkart, M.A. Cassell, L.L. Washburn, B. Richards-Smith, A. Anagnostopoulos, R. Babiuk, H. Onda, M. Tomczuk, I. Lu, H. Dene, C. Smith, J.T. Eppig* The Jackson Laboratory, Bar Harbor, ME.

Mammalian models of human disease are critical to increasing our understanding of disease mechanisms and discovering potential new therapies. The use of the mouse to create such models is facilitated by the wealth of genetic tools available, including high-resolution genetic maps, myriad inbred strains, a sequenced genome, and well-developed transgenic techniques, as well as the accessibility of all life stages of the mouse to investigation. The Mouse Genome Informatics Database (MGI, http://www.informatics.jax.org/) provides integrated access to genetic and phenotypic data for mouse models of human disease.

In MGI, models of a disease are annotated to the Online Mendelian Inheritance in Man (OMIM) term for that disease. In addition a detailed phenotypic description of the model is entered using the Mammalian Phenotype ontology, a vocabulary of phenotypic traits. Use of these vocabularies allows researchers to easily access the data using many different approaches. For example, one can ask "What mutation or combination of mutations produce mouse models of Insulin-Dependent Diabetes Mellitus?" or "What mutations modify the severity of Insulin-Dependent Diabetes Mellitus in mouse models of the disease?" Or one can search for specific phenotypes, such as hyperglycemia and polyphagia, to identify models that reproduce select symptoms of the disease.

MGI currently has nearly 1600 genotypes annotated to OMIM terms and over 10% of OMIM terms have one or more associated mouse models.

Supported by NIH grant HG00330.

Mutational Screening of *CDO* using dHPLC in Holoprosencepahly (HPE) Patients. *S. Domene[1], M. Ouspenskaia[1], E. Roessler[1], R. Krauss[2], M. Muenke[1]* 1) NHGRI, NIH, Bethesda, MD; 2) Mt. Sinai School of Medicine, NY.

Holoprosencepaly (HPE) is the most common structural anomaly of human brain development, with a prevalence of 1 in 250 conceptuses and 1 in 16000 at birth. Mutations in at least eight different genes account for only 25 percent of the total cases. Among these HPE genes, several encode components of the Sonic Hedgehog (SHH) pathway: the secreted ligand SHH, its receptor, PTCH, and the transcription factors GLI2 and ZIC2.

CDO is the founding member of a distinct subfamily of the Ig superfamily (IgSF) that has recently been described to bind Shh, and likely modulate its action in the forebrain during early embriogenesis. Patterning of the midline of the ventral floorplate and midface is particularly sensitive to Shh signaling strength; this might explain why Shh depends on Cdo for augmentation of this important midline signal. In addition, the originally described Cdo knock-out mouse exhibits the hallmark facial defects associated with microforms of HPE, a single central incisor, which led to our study of this gene as a potential candidate gene for HPE. Cdo is not essential for Shh signaling in general, as other Shh-dependent body structures, such as the limb, develop normally in $Cdo^{-/-}$ animals. DHPLC analysis for all 19 coding regions and intron-exon boundaries of human CDO (followed by sequencing of abnormal chromatograms) in 285 HPE patients and 96 normal controls was performed. A total of 38 polymorphisms (detected equally in patients and controls) and 6 missense mutations (that appear to be disease-specific) were identified. It will be interesting to study the functional consequences of these missense mutations to see if they might underlie some cases of HPE alone, or in combination with other genes involved in midline development.

Phenotypic heterogeneity of N370S homozygotes with type 1 Gaucher disease: An analysis of 798 patients from the ICGG Gaucher Registry. *C. Fairley[1], A. Zimran[2], M. Cizmarik[3], J. Yee[3], N. Weinreb[4], S. Packman[1]* 1) UCSF, CA; 2) Shaare-Zedek Med Ctr, Israel; 3) Genzyme Corp, MA; 4) Univ Res Found for Lysosomal Storage Disorders, FL.

Purpose: The N370S/N370S genotype is thought to confer a mild phenotype presenting in adulthood in patients with type 1 Gaucher disease. We aimed to describe the heterogeneity and severity of the presenting phenotype of N370S homozygotes. **Methods:** The clinical characteristics at or near the time of diagnosis of all N370S homozygotes with available data enrolled in the International Collaborative Gaucher Group (ICGG) Gaucher Registry were analyzed. The same characteristics for all N370S compound heterozygotes with available data were analyzed for comparison. **Results:** 798 N370S homozygotes were identified; 32% were diagnosed before age 20y. 1,278 N370S compound heterozygotes were identified; 64% were diagnosed before the age 20y. At diagnosis, N370S homozygotes versus N370S compound heterozygotes had the following clinical characteristics: irreversible skeletal lesions (infarctions or AVN) 17% (34/198) vs 26% (76/290); decreased lumbar spine BMD (Z-score -2.5) 11% (8/70) vs 8% (4/49); anemia (age and sex-adjusted) 18% (59/327) vs 29% (145/494); thrombocytopenia (Plt <60k/mm^3) 9% (29/327) vs 16% (73/453); hepatomegaly (>1.25x nl) 44% (83/190) vs 72% (141/195); and severe splenomegaly (>15x nl) 11% (22/193) vs 39% (77/195). **Conclusions:** N370S homozygosity does not appear to invariably confer a mild, adult-onset phenotype. N370S homozygotes may present with severe clinical manifestations or be diagnosed before the age of 20y. The proportions of severely affected N370S homozygotes may be overestimates as asymptomatic patients may not be diagnosed nor be enrolled in the Registry. N370S compound heterozygotes are more likely than N370S homozygotes to present with a severe phenotype and more likely to be diagnosed before the age of 20y. The phenotypic heterogeneity of N370S homozygotes should be considered in genetic counseling and clinical decision-making.

Identification of entire LMX1B gene deletions in nail patella syndrome: final evidence for haploinsufficiency as the main pathogenic mechanism underlying dominant inheritance in man. *E.M.H.F. Bongers[1], I.J. de Wijs[1], E. Levtchenko[2], C. Marcelis[1], L.H. Hoefsloot[1], N.V.A.M. Knoers[1]* 1) Dept of Human Genetics, Radboud University Medical Centre Nijmegen, Nijmegen, The Netherlands; 2) Dept of Paediatric Nephrology, Radboud University Medical Centre Nijmegen, Nijmegen, The Netherlands.

Nail patella syndrome (NPS) is an autosomal dominant disorder characterized by nail and skeletal malformations, nephropathy, and glaucoma caused by mutations in the transcription factor LMX1B. Glomerular podocytes from Lmx1b-/- mice reveal aberrant foot processes and slit diaphragm formation. It is as yet unclear why heterozygous LMX1B mutations cause NPS nephropathy in humans, whereas Lmx1b+/- mice develop no renal symptoms. The hypothesis that haploinsufficiency is the main mechanism underlying dominant inheritance in human NPS is based on the fact that the same phenotypic variability is observed in individuals with LMX1B missense, nonsense, frameshift or splice-site mutations and that the range and severity of symptoms varies both within and between families. This assumption is supported by the lack of any dominant-negative effect observed by in vitro-experiments studying missense and truncation LMX1B mutations. By MLPA analysis with specific probes for the different exons 1-8 of LMX1B, we found a deletion of the entire gene in two unrelated individuals and a deletion of exons 3-8 in another patient from eight classic NPS families (3/8; 38%) in which no mutation could be detected by sequencing LMX1B. This first identification of entire LMX1B deletions strongly confirms the hypothesis that haploinsufficiency is the principal pathogenic mechanism of NPS. The fact that NPS nepropathy is observed in individuals with heterozygous deficiency of LMX1B and resembles a milder variant of kidney disease in Lmx1b-/- mice, whereas Lmx1b+/- mice are phenotypically normal, supports the assumption that a difference in dosage sensivity for this gene emerge in the two species.

Analysis of enzyme replacement therapy dose-response relationships in patients with type 1 Gaucher disease. *G. Grabowski[1], J. Charrow[2], C.E.M. Hollak[3], K. Kacena[4], P. Mistry[5], S. vom Dahl[6], A. Zimran[7]* 1) Cinn Childrens Hosp, OH; 2) Northwest Univ Sch Med. IL; 3) AMC, Netherlands; 4) Genzyme Corp, MA; 5) Yale Univ Sch Med, CT; 6) St Franziskus-Hosp, Germany; 7) Shaare-Zedek Med Ctr, Israel.

Objective: To analyze if enzyme replacement therapy (ERT) with imiglucerase demonstrates dose-response relationships in patients with type 1 Gaucher disease (GD) within the range of doses used in routine clinical practice and across disease parameters.**Methods:**The analysis included all patients with type 1 GD with intact spleens enrolled in the ICGG Gaucher Registry, diagnosed in 1980 or later, and for whom 12 mo of follow-up data were available as either ERT-naïve or ERT-treated. ERT dose was defined as the average dose over the first 3 yr of treatment. Propensity score matching was used to control for differences in baseline disease severity between groups. Hemoglobin, platelet count, liver and spleen volumes were assessed. For each parameter, a stepwise analysis examined ERT response (ERT vs. no ERT), followed by analysis of dose-response relationships. Non-linear mixed effects models were constructed for follow-up (0-60 mo). The rate (t50) and extent (Emax) of ERT treatment effect for each parameter were compared across groups.**Results:**975 patients met the inclusion criteria (795 ERT-treated, 180 ERT-naïve). The most frequent dosing regimens were 15, 30, 60 U/kg/2wk. Propensity scoring matching resulted in four statistically similar groups of 78 patients each (no ERT; ERT at 15, 30, 60 U/kg/2wk). Statistically significant dose-response relationships were found across groups for each parameter analyzed: hemoglobin, platelet count, liver and spleen volumes, in regard to rate and extent of improvement over 60 mo.**Conclusions:**ERT with imiglucerase results in statistically significant dose-dependent improvement in hematological parameters and organomegaly in patients with type 1 GD. Propensity scoring matching and non-linear mixed effects models can be used to assess outcomes based on observational data from an international rare disease registry. Further analysis of clinically significant disease parameters is ongoing.

Screening of deletions and duplications in 1500 genomic loci in a single assay. *J. Fan[1], S.J. White[2], M. Bibikova[1], L. Zhou[1], J. Chen[1], E. Wickham-Garcia[1], M.E. Kalf[2], M. Kriek[2], G.J.B. van Ommen[2], M.H. Breuning[2], L. Guo[3], S.-H. Lu[3], Q. Zhan[3], W. Jiang[3], O. Chan[4], J. Wang-Rodriguez[4], D.L. Barker[1], J.T. den Dunnen[2]* 1) Illumina, Inc, San Diego, CA, USA; 2) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, Nederland; 3) Cancer Institute, Chinese Academy of Medical Sciences, Beijing, China; 4) The VA Medical Center, UCSD, San Diego, CA, USA.

Copy number variations (CNV), i.e. deletions and duplications of genomic DNA, are known to be involved in many genetic diseases. Recent genome-wide analyses revealed extensive CNV in the human genome, the vast majority of which have not been correlated directly with disease. We have developed a highly multiplexed genotyping assay (GoldenGate assay) coupled with a universal BeadArray readout for CNV testing of hundreds to thousands of genomic regions in hundreds to thousands of samples. Specifically, we designed an array for parallel analysis of 1,500 genomic loci, which allows detection of all known trisomies, sub-telomeric rearrangements and micro-deletion syndromes as well as providing a low-resolution whole genome CNV scan. We first assayed genomic DNA isolated from patient blood samples. Analysis of X- and Y-chromosome probes showed excellent quantitative discrimination between males and females. We applied the assay to a variety of known variations, from whole-chromosome trisomies to subtle DMD-gene rearrangements (deletions, duplications, triplications), and were able to detect all known rearrangements reliably. Analysis of samples from 170 patients with mental retardation of unknown etiology revealed, based on the criteria selected, 20-30 new CNV's, which are currently being analyzed in more detail. We also analyzed 43 pairs of gDNA extracted from formalin-fixed cancerous and adjacent normal tissues of esophageal cancer patients. Highly reproducible genomic deletions and amplifications were detected in these archived tissue samples. Our data indicate that screening a selected set of 1500 loci using a bead-based assay is a rapid, sensitive and cost-effective method for detecting copy number changes in up to 96 samples simultaneously.

Assessing Exclusionary Power of a Paternity Test Involving a Pair of Alleged Grandparents. *D. Einum[1], R. Staub[2], M. Scarpetta[3]* 1) Sorenson Genomics, 2495 South West Temple Ave., Salt Lake City, UT 84115; 2) Orchid Cellmark, 13988 Diplomat Drive, Suite 100, Farmers Branch, TX 75234; 3) Orchid Cellmark, 2947 Eyde Parkway, Suite 110, East Lansing, MI 48823.

The power of a genetic test battery to exclude a pair of individuals as grandparents is an important consideration for parentage testing laboratories. However, a reliable methodology to calculate such a statistic using short tandem repeat (STR) genetic markers has not been presented. Two formulae describing the Random Grandparents Not Excluded (RGPNE) statistic at a single genetic locus were derived: RGPNE = $a(4-6a+4a^2-a^3)$ when the paternal obligate allele (POA) is defined and RGPNE = $2[(a+b)(2-a-b)][1-(a+b)(2-a-b)] + [(a+b)(2-a-b)]$ when the POA is ambiguous. A minimum number of genetic markers required to yield cumulative RGPNE values ≤ 0.01 was calculated using weighted average allele frequencies of the CODIS STR loci. RGPNE data for actual grandparentage cases are also presented to empirically examine the exclusionary power of routine casework. A comparison of RGPNE and Random Man Not Excluded (RMNE) values demonstrates the increased difficulty involved in excluding two individuals as grandparents compared to excluding a single alleged parent. A minimum of 12 STR markers is necessary to achieve RGPNE values ≤ 0.01 when the mother is tested; >25 markers are required without the mother. Cumulative RGPNE values for each of 22 non-exclusionary grandparentage cases were ≤ 0.01 but were significantly weaker when calculated without data from the mother. Calculation of the RGPNE provides a simple means to help minimize the potential of false inclusions in grandparentage analyses. This study also underscores the importance of testing the mother when examining the parents of an unavailable alleged father (AF).

Molecular studies and phenotype correlation in Costello syndrome. *K.W. Gripp[1], L. Nicholson[1], K.M.B. Vinette[2], A.E. Lin[3], J.D. Hoffman[4], D.L. Stabley[2], K. Sol-Church[2]* 1) Genetics, A. I. duPont Hosp, Wilmington, DE; 2) Biomed. Research, A.I.duPont Hosp, Wilmington, DE; 3) Genetics& Teratology, MGH, Boston, MA; 4) Genetics, Tufts-NEMC, Boston, MA.

Costello syndrome (CS) is a rare tumor predisposition syndrome having phenotypic overlap with cardio-facio-cutaneous (CFC) syndrome. The discoveries of *HRAS* mutations in CS (Aoki 2005) and *BRAF, KRAS, MEK1* or *MEK2* mutations in CFC (Niihori 2006; Rodriguez-Viciana 2006; Schubbert 2006), all involving the RAS-ERK-MAPK cascade, provide insight into the biological mechanism resulting in phenotypic similarities.
Of 60 pts enrolled in our CS study, we detected an *HRAS* mutation in 44 (73%)(G12S noted in 40). Two pts had a mutation resulting in G12A; and one each showed a G12C or G13C change. We hypothesized that all *HRAS* mutations occurred in the paternal germline. Informative families had paternal origin in 14 and maternal in 2, a result neither consistent with our hypothesis nor with an equal chance for maternal and paternal origin (P=0.0018). One unusual pt in whom standard analysis failed to show a mutation was found to have somatic mosaicism. Allelic quantitation revealed presence of the G12S mutation in 25-33% of buccal cell DNA, but 1% of blood DNA. Further studies in the 16 *HRAS* mutation negative pts showed 5 *BRAF* and 1 *MEK1* mutations, consistent with a CFC diagnosis.

We conclude that an *HRAS* mutation confirms a clinical CS diagnosis; conversely, the lack of an *HRAS* mutation likely excludes CS and further studies may reveal a mutation consistent with CFC. Clinical evaluation and critical interpretation of molecular results remain essential, as demonstrated by the pt with somatic *HRAS* mutation mosaicism. Most, but not all, *HRAS* mutations occur in the paternal germline, and there is no apparent phenotypic difference between maternally and paternally derived cases. While the genotype phenotype delineation is hampered by the fact that 40/44 (91%) share the G12S change, we found no difference in the characteristic anomalies of the few pts with other *HRAS* mutations.

The Role of A-Tail Heterogeneity in Alu Retroposition Efficiency. *M.S. Comeaux, P. Deininger* Tulane Cancer Center, Tulane University HSC, New Orleans, LA.

Over 50% of the human genome is composed of repetitive DNA. The most numerous mobile element in the genome is the approximately 300 bp Alu, which is found roughly 1.1 million times, accounting for about 11% of the genome. Alu elements contribute to human disease directly, by inserting new copies of itself into gene-rich regions that alter gene expression, and indirectly, due to unequal homologous recombination causing duplication or deletion of genetic material. Alu elements are transcribed by RNA polymerase III, and the transcripts are reverse-transcribed and inserted into new genomic locations after hijacking the ORF2 protein of L1 elements. Only the youngest of these Alu elements are currently active in the human genome. It does not appear that transcription is the primary factor controlling Alu activity. It has been shown that the length of the A-tail is one of the key differences between the older and younger Alu elements and that its length plays a role in the ability of an Alu element to retropose in the genome. However, the observed difference is much too small to explain the lack of amplification of the older Alu elements. Another key difference between the older Alus and the younger ones is that the older ones have more disruption in the A-tail than their younger counterparts. In this study, several different Alu elements were generated that have variable levels of disruption in the A-tail region. By utilizing a retroposition assay adapted from Dewannieux et al., we have compared the retroposition ability of Alu elements with variable levels of A-tail disruption. We observe that modest levels of sequence interruption have little impact on the amplification rate of Alu elements. However, larger levels of heterogeneity result in a significant decrease in its ability to retropose. This difference, however, is still insufficient to explain the almost total lack of amplification of the older Alu elements. Thus, we are currently characterizing other typical differences between old and young Alu elements to identify the features that define a highly active Alu element from the vast bulk of inactive elements.

Two stage whole genome linkage analysis of a phonological working memory component phenotype of dyslexia: Identification of a locus on chromosome 4p. *Z. Brkanac, N.H. Chapman, R.P. Igo, J.B. Thomson, M. Matsushita, T. Holzman, V.W. Berninger, E.M. Wijsman, W.H. Raskind* University of Washington, Seattle, WA.

Dyslexia is a common and complex genetic disorder. To elucidate the genetic architecture of dyslexia, we are using an approach that couples careful phenotypic evaluations with univariate component based linkage analyses. Impaired working memory is a common characteristic of dyslexia. We have shown through aggregation and segregation analyses that working memory phenotypes have a genetic basis in our sample. We assessed phonological working memory with the Non Word Repetition (NWR) task of the Comprehensive Test of Phonological Awareness. Families were collected through probands with Verbal IQ (VIQ) 90, and performance on at least one of ten measures of reading or writing below the population mean and 1 SD below VIQ. Two genome scans with 10 cM resolution were performed through the Marshfield Center for Human Genetics. The first sample consisted of 438 people from 51 families selected for power to detect linkage for NWR. The second sample consisted of 693 people from 93 families chosen without regard for NWR performance. Linkage analyses were performed using Variance Component (VC) and Markov-chain Monte Carlo (MCMC) joint segregation and multipoint linkage methods, followed by parametric analyses in regions of interest. In the first genome scan numerous linkage signals met our preset criteria for a region of interest: VC dominance lod score 1.0 and MCMC intensity ratio (IR) 5.0. Follow up parametric lod scores > 2.0 were obtained on chromosomes (chr) 4p, 7q, 12p and 17q. Signals on chr 4p, 7q and 12p were also seen in the second scan. Combined analysis of both data sets significantly increased the VC dominance lod score to 2.1 and MCMC IR to 20 on chromosome 4. Our study has identified a novel locus on chr 4p for NWR in families with dyslexia. This region contains the gene cluster of GABA receptor subunits that are involved in the mediation of fast synaptic inhibition. In depth analysis to further refine the location of interest and to evaluate the candidate genes is ongoing.

A new autosomal dominant distal myopathy: linkage to chromosome 3q and candidate gene analysis. *A. Gad[1], D. Chen[2], M. Matsushita[1], M. Kumar[1], L. Chen[1], J. Wolff[1,3], H. Lipe[3], T. Bird[1,2,3,4], W. Raskind[1,4]* 1) Depts of Medicine and; 2) Neurology, University of Washington, Seattle, WA; 3) GRECC and; 4) MIRECC, VA PSHCS, Seattle, WA.

We studied a four-generation American family with an adult onset myopathy, characterized by progressive muscle weakness and atrophy, distal greater than proximal, and hypoactive reflexes. EMGs suggested a myopathy with occasional myotonia-like activity. Muscle biopsy revealed a chronic, non-inflammatory necrotizing myopathy. Unexpectedly, given the absence of dementia or brain atrophy, diffuse -synuclein positive Lewy bodies were seen in the frontal cortex, cingulate gyrus, amygdala, substantia nigra, pons and midbrain of an affected person who died at age 88. DNA was obtained from 14 individuals. A DNA test for type-1 myotonic dystrophy was negative and targeted analysis excluded linkage to Welander myopathy (2p), Udd (2q31-33), Nonaka myopathy (9p1-q1), MPD3 (8p22-q11, 12q13-q22), Markesbery-Griggs (10q22.2-q23.3), and Laing myopathy (14q11). Assuming a disease frequency of 0.0001 and 90% penetrance, power analysis suggested that a maximum lod score of 3.21 at a recombination fraction () of 0.00 could be obtained with the available samples. Using the same penetrance estimate, a whole genome scan at 10 cM level found strongly suggestive evidence of linkage to chromosome 3 with a two-point lod score of 2.36 at =0.00. Other loci providing positive lod scores were ruled out with additional markers and haplotype analysis. Finer scale mapping provided maximum two-point and multipoint lod scores of 2.94 at =0.00 for D3S1614. By haplotype construction, a 5 cM critical region between D3S1264 and D3S3725 in 3q26.1-3 was defined. All affected individuals and two unaffected people, one of whom is younger than the average age of onset, carried the disease-associated haplotype. The 40 genes mapped to this region have been prioritized as candidates based on expression patterns and their known functions. A new polymorphism was detected in *PI12/SERPINI1* but no coding region sequence alterations were found in *GPR160*, *MYNN* and *CLDN11*. Analyses to detect gross genomic or splicing abnormalities are ongoing.

Mutator genes permissive for genomic rearrangements at *Alu* repeats. *K.M. Chisholm[1], P.L. Welcsh[2], M.-C. King[1,2]* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA.

Tumors display a high degree of genetic heterogeneity suggesting that genomic instability drives carcinogenesis. Genomic instability is under genetic control and the genes responsible are likely critical to tumor development. At the BRCA1 tumor suppressor locus, large genomic deletions frequently occur as inherited mutations in families and as somatic loss of heterozygosity in breast tumors. These genomic deletions appear to be the result of aberrant homologous recombination between *Alu* repetitive elements, which are densely packed at the BRCA1 locus. My hypothesis is that loss of function of mutator genes that suppress homologous recombination would increase the frequency of genomic rearrangements, and thus may contribute to the development of breast cancer. My goal is to identify such mutator gene(s) using BRCA1 as a model. I have created a construct incorporating two identical *AluSp* sequences flanking URA3. These *Alu* repeats have been identified as the site of rearrangement in many inherited BRCA1 mutations. This construct has been inserted into a yeast transformation plasmid, and then screened for deletion of the URA3 marker in 99.2% of the Saccharomyces Genome Project collection of (4672) yeast strains comprised of all viable single gene knockouts. Of these strains, 11.8% revealed an increased rate of rearrangement. Upon further evaluation, 12 strains appeared to be candidate mutators, with mutation rates 1.5 to 10.61 fold over wildtype. These strains include known mutators such as *tsa1* and *elg1*, as well as DNA helicases and proteins involved in meiotic recombination. Human homologs have been identified for seven genes. Currently, these genes are being screened for mutations in high-risk breast cancer families who are wildtype for all known breast cancer predisposing genes and in sporadic breast tumors. These genes are also being evaluated as modifiers of BRCA1 in families with known BRCA1 mutations. Though the primary aim of this research is to identify mutator genes involved in breast carcinogenesis, these same genes may be involved in other cancers as well.

Experience with parental sample submission in abnormal array CGH cases: Is free parental testing helpful? *J. Coppinger, B.A. Bejjani, L.G. Shaffer* Signature Genomic Laboratories, LLC, Spokane, WA.

Parental testing is routinely recommended for the evaluation of cytogenetic abnormalities of uncertain clinical significance, or abnormalities that may have occurred due to a cytogenetic rearrangement in a parent. The percentage of parental samples received is usually suboptimal in these circumstances, and literature evaluating the genetic counseling process and impact on submission of parental samples is limited. In the past few years, comparative genomic hybridization has emerged as a promising cytogenetics application that improves the diagnostic potential for microscopic and submicrocopic chromosome abnormalities. Yet, analysis of parental samples remains an essential step for complete clinical interpretation of unbalanced translocations, subtelomeric alterations, de novo deletions/duplications, suspected polymorphisms, and results of unclear significance detected by array CGH. We report our experience with the receipt of parental samples for testing in abnormal cases in our first 3600 consecutive clinically diagnostic array CGH cases. A total of 303 (8.4%) abnormal cases were identified, and of these, 166 (54.8%) required parental samples for complete clinical interpretation. Parental samples were received in 88 (53%) of cases. To assess whether cost of testing may be a barrier to submission of samples, parental testing was offered at no charge beginning in January, 2006. Analysis of parental samples received 1 month out and 3-4 months out identified an increase from 38% to 62%, thereby confirming that cost is likely one barrier to parental testing. Other potential barriers may include clinicians interpretations of abnormal test results, sub-optimal communication of the need for parental samples to patients or parents, family dynamics or psychosocial barriers, or other possibilities. Identification and elimination of barriers to parental testing will provide more complete interpretations of abnormal test results, improving the potential for accurate diagnosis, genetic counseling, and medical management of patients.

Variations in RANK Gene are Associated with Adult Height in Caucasians. *Y. Chen[1,3*], D.H. Xiong[2,3*], T.L. Yang[4], F. Yang[1,3], H. Jiang[1,3], F. Zhang[3,4], H. Shen[2], P. Xiao[2,3], H.W. Deng[1,2,4], * Equal contribution* 1) Laboratory of Molecular and Statistical Genetics, Hunan Normal University, Changsha, China; 2) Departments of a) Orthopedic Surgery and b) Basic Medical Sciences, University of Missouri-Kansas City, Kansas City, USA; 3) Osteoporosis Research Center and Department of Biomedical Sciences, Creighton University, Omaha, USA; 4) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, Xi'an Jiaotong University, Xi'an, China.

Height is a complex trait significantly influenced by genetic factors, with the heritability ranging from 48% to 98%. Previous genetic studies on height have yielded a number of important genomic regions and candidate genes that may account for the variation of height in human populations. However, more height genes still wait for identification. Recent studies have revealed that RANK (tumor necrosis factor receptor superfamily, member 11a) is a vital factor for chondroclastic/osteoclastic differentiation and activity that influence the morphology of growth plates as well as the linear bone growth. Despite its importance to bone physiology, little effort has ever been done to find out whether the RANK polymorphisms are associated with adult height variation in the normal populations. Herein, we performed a family based association test (FBAT) in 1873 white subjects from 405 nuclear families. Eighteen single nucleotide polymorphisms (SNPs) and 7 blocks in the RANK gene were studied in terms of their association with the variation of final adult height. One SNP, called rs6567274, was detected to be significant (P = 0.0032) even after multiple-testing correction. In corroboration with single-locus analysis, a major haplotype in block 5 bearing the variant T of rs6567274 was significantly associated with higher stature (P = 0.0073). Our findings firstly suggested that the genetic variants of RANK might contribute to the adult height variation. Further researches on RANK need to be launched to replicate the present results and further unravel the molecular mechanism underlying the significant associations discovered.

Dense SNP marker analysis identifies regions of linkage for rheumatoid arthritis. *C.I. Amos[1], W.V. Chen[1], X. Liu[2], D. Mosher[3], W. Maksymowych[4], D. Zhu[1], S. Shete[1], K. Siminovitch[2]* 1) Epidemiology, U.T. M.D. Anderson Cancer Center, Houston, TX; 2) Department of Medicine, University of Toronto and Mount Sinai Hospital, Toronto, Canada; 3) Dalhousie University, Halifax, Nova Scotia, Canada; 4) University of Alberta, Edmonton, Alberta, Canada.

Dense linkage analysis using SNPs increases information for linkage studies, but also can increase the probability of obtaining false positive linkage evidence when SNPs are falsely assumed to be in linkage equilibrium. We analyzed data from Affymetrix 100K analysis of 79 sib pairs affected with Rheumatoid Arthritis who did not have parental samples. Results of linkage analysis that assumed linkage equilibrium showed several regions with LOD scores exceeding 3. To check the validity of these findings, we compared results from two approaches to adjust for linkage disequilbrium (LD). First, we adopted an 'interleaving' method of Baccanu (Genetic Epidemiology 29:195-203, 2005) in which the data were divided into 10 disjoint sets of markers. Then, we performed analysis using SNPLINK (Bioinformatics 21:3060-1, 2005) to remove any remaining markers that showed excessive LD ($R^2 > 0.7$). Results from these 10 runs were then averaged and the empirical p-value was obtained at each point. Alternatively, we used Merlin (Am J Hum Genet. 77:754-67, 2005), which allows for LD by 'clusting' tightly linked markers. Results of these analyses led to diminished Z-scores compared with not allowing for LD, but analysis using Merlin appeared excessively conservative as it led to a far greater reduction in the number of markers that were retained for analysis. For example, on chromosome 6 we found that 22% of markers were dropped by the interleaving approach while 88% of markers were dropped by the clustering approach. Z-scores that were obtained on chromosome 6p in the HLA region were 2.14 by interleaving and 0.72 by clustering. Interleaving identified regions on chromosomes 1 and 8 with maximal Z-scores of 2.32 at 82.5 Mb and 2.48 at 19.42 Mb. These results indicate the promise that is provided by the interleaving approach, though integrating the data from the multiple scans presents challenges in data handling.

Genotype-phenotype correlation in mitochondrial optic neuropathies. *P. Amati-Bonneau, M. Ferré, C. Verny, M. Barth, V. Guillet, A. Chevrollier, Y. Malthièry, D. Bonneau, P. Reynier* Dept Biochem & Molecular Biol, INSERM U694,CHU Angers,France.

Mitochondrial optic atrophies, due to the degenerescence of retinal ganglion cells and optic nerve fibers, include Autosomal dominant optic atrophy (ADOA), Leber's hereditary optic neuropathy (LHON) and autosomal dominant optic atrophy and cataract (ADOAC). ADOA generally starts in childhood and is characterized by a progressive decrease in visual acuity and optic atrophy.Mutations in the optic atrophy 1 (OPA1) gene are implicated in about 40% of the cases of ADOA. OPA1 encodes a dynamin-related GTPase, located in the mitochondrial inter-membrane space. LHON, which is caused by specific mutations in mitochondrial DNA, is characterized by severe optic atrophy responsible for acute or subacute visual loss, usually starting between the ages of 18 and 35. In addition to optic atrophy, some patients present neurological signs of central nervous system involvement. ADOAC, a rare phenotype of optic atrophy and cataract, is due to mutations in a mitochondrial protein nuclear encoded (OPA3). We report here a molecular study of 600 patients with optic atrophy referred to our center for molecular diagnosis purpose during the period 2001-2005. Of these, 60% were familial and 40% sporadic cases or more often with unknown mode of inheritance.The mutation responsible for the disease was identified in 290 patients (49%). Mitochondrial DNA mutations (LHON) were found in 90 patients (15%), OPA1 mutations in 186 patients (31%) and OPA3 mutations in 14 patients (2%). Several ADOA patients were affected by additional neurological signs such as neurosensorial deafness or peripheral axonal neuropathy. A specific genotype-phenotype correlation was observed in patients harboring the R445H OPA1 mutation and optic atrophy associated to deafness. About 10% of sporadic patients carried pathogenic mutation in the OPA1 gene.Mitochondrial DNA and OPA1/3 gene analyses allow diagnosing about 50% of the patients. Our results suggest that patients with hereditary optic neuropathies could greatly benefit from neurological investigations and that sporadic optic atrophy need to be explored at the molecular level.

Another case with Uterine aplasia, ovarian dysgenesis, amenorrhea and impuberism: a variant from Mayer-Rokitansky-Kuster- Hauser syndrome or a coincidental association? *M. Colombani[1], E. Sapin[2], D. Cau[3], N. Lentz[4], C. Thauvin-Robinet[1], F. Huet[5], L. Faivre[1]* 1) Centre de Genetique, Hopital dEnfants, Dijon, France; 2) Service de Chirurgie Pediatrique, Hopital dEnfants, Dijon, France; 3) Service de Pediatrie et Neonatalogie, H Chalon sur Saone, France; 4) Service de Gynécologie, Chalon sur Saone, France; 5) Departement de pédiatrie, Hopital d'Enfants Dijon, France.

Mayer-Rokitansky-Hauser syndrome (MRKH) is characterized by the association of congenital absence of the vagina, rudimentary uterus, normal tubes and ovaries, normal female secondary sexual characteristics, and normal endocrine and cytogenetic evaluations. Four atypical cases have been described in the literature, associating absence of uterus to gonadal dysgenesis and normal female karyotype. Authors discussed that such cases represent a rare variant of MRKH or a coincidental association. Here we describe a 15½-year-old girl presenting with primary amenorrhea and impuberism. She was the third child of consanguineous parents originated from Senegal. Family history was negative. Her twin brother and her 19-year-old sister had a normal puberty with menarche at age of 14. The proband had a history of autoimmune thyroiditis in childhood. At time of examination, her height was 168 cm, her weight was 58 kg with a normal body mass index. The secondary sexual characteristics assessment showed absence of breast development, pubic and axillary hair (Tanner stage 1) are noted. Prepubertal external genitalia and a vagina ending in a blind pouch were found at the gynecological exam. There was no sign of masculinisation and she had a normal psychomotor development. Endocrine evaluation revealed a hypergonadotropic hypogonadism. Standard cytogenetic examination revealed a normal female karyotype, 46 XX. Antimullerian hormon was absent. Cardiac and renal ultrasounds are normal. Delayed bone age was also noted (13½ for a chronological age of 15½ years). Pelvic ultrasound showed a complete absence of uterus and an absence of gonads. Coelioscopic study revealed two ovarian bandelets in favor of gonadal dysgenesis and normal fallopian tubes. This is the fifth case with the association of absence of uterus and gonadal dysgenesis in a female with a 46,XX karyotype, which could be in favor of a genuine entity.

Modulation of genetic susceptibility by behavioral factors and glucose regulation status in the general population exemplified by the impact of the *APOA5* -1131T>C variant on serum lipids. *G. Andersen[1], T. Sparsø[1], S.I. Castella[1], A. Albrechtsen[1], C. Glümer[1,2], K. Borch-Johnsen[1,2,3], T. Jørgensen[2], T. Hansen[1], O. Pedersen[1,3]* 1) Steno Diabetes Center, Gentofte, Denmark; 2) Research Centre for Prevention and Health, Glostrup University Hospital, Glostrup, Denmark; 3) Faculty of Health Science, University of Aarhus, Aarhus.

Previous studies suggest that the C-allele of the *APOA5* -1131T>C polymorphism confers an increase in serum triglyceride concentrations. The aim of the present study was at the population level to estimate the effect of the *APOA5* -1131T>C polymorphism on fasting serum lipids and to elucidate the potential modulating impact of health behavior and glucose regulation status. The *APOA5* -1131T>C polymorphism (rs662799) was genotyped in a population-based sample of 5,873 treatment-naïve Danes (2,929 men, 2,944 women; age 46 8 years; BMI 26.3 4.6 kg/m^2) using chip-based MALDI-TOF mass spectrometry. The *APOA5* -1131T>C polymorphism was associated with dyslipidaemia in a case-control study of 1,439 patients with dyslipidaemia and 4,432 normolipidaemic subjects, $P = 4x10^{-6}$ for minor allele frequency (8.2 % [7.2-9.2 %] vs. 5.7 % [5.2-6.2 %]) and $P = 1x10^{-5}$ for genotype distribution. Correspondingly, in the total population of 5,873 participants the C-allele was associated with increased fasting serum levels of triglyceride ($P = 1x10^{-15}$) and total cholesterol ($P = 0.0003$) and decreased fasting serum HDL-cholesterol ($P = 0.004$). Significant epistasis on fasting serum triglyceride concentrations was observed between the *APOA5* -1131T>C polymorphism and smoking ($P = 0.0003$), daily alcohol intake ($P = 0.005$), and dietary monounsaturated fatty acid intake ($P = 8x10^{-6}$). The effect of the polymorphism on fasting serum triglyceride was more profound in people with impaired glucose regulation than for glucose-tolerant subjects ($P = 5x10^{-9}$). In conclusion, at the level of the general population of middle-aged people the common C-allele of the *APOA5* -1131T>C polymorphism greatly influences the fasting serum lipid levels. Importantly, the impact of this gene variant on fasting serum triglycerides is strongly modulated by behavioral factors and hyperglycaemia.

SCA17 transgenic mice show a severe neurodegenerative phenotype. *P. Bauer, Y. Golub, C. Bauer, T. Ott, T. Hennek, O. Riess* Dept Medical Genetics, Univ Tubingen, Tubingen, Germany.

SCA17 is a progressive neurodegenerative disease leading to cerebellar ataxia and dementia. Several accessorial symptoms such as Parkinsonism, dystonia, and psychiatric disturbances commonly aggravate to disease course. Genetically, a CAG/CAA expansion in the TATA binding protein (TBP) is expanded in SCA17 patients, leading to an expanded polyglutamine chain in this ubiquitously expressed transcription factor. We have generated transgenic mice overexpressing a 64 CAG/CAA repeats containing human TBP (Q64TBP) gene under the control of the truncated human prion protein promoter (PrP). Transgene expression throughout different brain regions (cortex, basal ganglia, cerebellum, and brain stem) was clearly demonstrable for both: Q64TBP transcripts and the respective transgenic protein, as analyzed by in-situ hybridization and Western Blot. Five months old transgenic animals displayed a severe motor deficit, objectified in the Accelerod paradigm and had a mean survival of less than 8 months. We present detailed morphologic and phenotypic data of the first rodent model of SCA17 allowing to study the pathogenesis of progressive human disease.

Higher prevalence of Hirschsprung disease in China explained by a common *RET* mutation. *M. Garcia-Barcelo[1], J. Amiel[2], G. Antinolo[3], S. Borrego[3], G. Burzynski[4], I. Ceccherini[5], E. Emison[6], C. Eng[7], R. Fernandez[3], P. Griseri[5], R. Hofstra[4], C. Kashuk[6], F. Lantieri[5], S. Lyonnet[2], X. Miao[1], P. Tam[1], A. Tullio-Pelet[2], K. West[6], A. Chakravarti[6]* 1) Dept Surgery, Univ Hong Kong, Hong Kong, China; 2) Dept Génétique et Unité INSERM U-393, Paris, France; 3) UC Genética y Reproducción, HH UU Virgen del Rocio, Sevilla, Spain; 4) Dept Medical Genetics, Univ Groningen, The Netherlands; 5) Lab di Genetica Molecolare, Ist Gaslini, Genova, Italy; 6) Inst Genetic Medicine, Johns Hopkins Univ Baltimore, USA; 7) Dept Molecular Genetics, Ohio State Univ, Columbus, USA.

RET is the major gene implicated in Hirschsprung disease (HSCR), congenital megacolon. TDT analysis of 13 *RET* SNPs on 876 HSCR families from three continents showed that all SNPs tested were associated with HSCR. The largest contribution to risk was made by an enhancer mutation in intron 1. This mutation is predominantly associated with male patients with the least severe form of HSCR. The overall frequencies of the HSCR-associated SNPs and haplotypes were significantly higher in Chinese, in both patients and general population. The haplotype composition also differed between populations: two main HSCR-haplotypes (long and short), sharing the 5 *RET* region were identified in Caucasians while only one (long) in Chinese. SNPs and haplotypes were tested in an expanded Chinese case-control sample. By estimating the association of each single SNP conditional on the haplotype background, five markers (including the enhancer mutation) wrere highly correlated with HSCR. These 5 markers were distributed across the shared 5 region coinciding with a single origin for a HSCR susceptibility locus. The most frequent haplotype in the Chinese patients (long) was also the most prevalent in the general population. Over 55% of the patients were homozygous for the long HSCR-associated *RET* haplotype and 72% homozygous for all those haplotypes comprising the most HSCR correlated markers. This detailed profile of the *RET* gene in the Chinese population provides an insight for the higher incidence of the disease in this population.

P-Values For Haplotype Association May Be Very Different Depending On The Analysis Method. *E. Fransen, M. Thys, E. Van Eyken, L. Van Laer, G. Van Camp* Dept Medical Genetics, University of Antwerp, Antwerp, Belgium.

Testing a candidate gene for association with a some disease often involves haplotypes-based association testing in addition to singleSNP association testing. It has been suggested that haplotype analysis could be more powerful than single SNP testing. When working with independent (non-family) samples, these analyses need to include haplotype inference. Many methods for haplotype inference and haplotype association testing are available, and its not always clear what the most appropriate method is. Four SNPs in a candidate gene for otosclerosis (binary trait) were typed and individually tested for association using the Armitage test. Then we compared various methods for haplotype-based association studies. This included the programs WHAP, FAMHAP, HTR (Haplotype Trend Regression) or PHASE2.0. In each of these programs, the haplotype inference and the association test is performed simultaneously. In addition, a two-step procedure was followed, where first the most likely haplotype of each subject was inferred using either SNPHAP, PHASE2.0, FAMHAP or HTR , along with its likelihood. Subsequently, these inferred haplotypes were tested for association using either a weighted c^2 test using the likelihood of the inferred haplotype as a weight factor in the analysis. We observed very different p-values depending on the method. The same dataset can show a highly significant association with one method, whereas a different method shows no or only a marginal association.

Significant Linkage to Airway Responsiveness on Chromosome 12q24 in Families of Children with Asthma in Costa Rica. *J.C. Celedon[1,2,3], M.E. Soto-Quiros[4], L. Avila[4], S.L. Lake[1,3], C. Liang[1], E. Fournier[4], M. Spesny[4], C.P. Hersh[1,3], J.S. Sylvia[1], T.J. Hudson[5], A. Verner[5], B.J. Klanderman[1,3], N.B. Freimer[6], E.K. Silverman[1,3], S.T. Weiss[1,3]* 1) Channing Lab, Brigham & Women's Hosp, Boston, MA; 2) Division of Pulmonary and Critical Care Medicine, Beth Israel Deaconess Medical Center, Boston, Massachusetts; 3) Department of Medicine, Harvard Medical School, Boston, Massachusetts; 4) Division of Pediatric Pulmonology, Hospital Nacional de Niños, San José, Costa Rica; 5) McGill University and Genome Quebec Innovation Centre, Montreal, Canada; 6) Department of Psychiatry, University of California at Los Angeles, Los Angeles, California.

We enrolled 8 pedigrees ascertained through Costa Rican schoolchildren with asthma(physician-diagnosed asthma, >=2 respiratory symptoms or asthma attacks in the previous year, airway hyper-responsiveness or bronchodilator responsiveness) and >=6 great-grandparents born in the Central Valley of Costa Rica. A genome scan with short-tandem repeat (STR) markers spaced every ~8 cM was performed, and genome-wide linkage analyses of asthma (n=638) and airway responsiveness (n=488) were conducted. Nonparametric two-point linkage analysis of asthma was peformed by the NPL-PAIR allele-sharing statistic, and variance component models were used for the multipoint linkage analysis of airway responsiveness (dose-response slope to methacholine). All analyses were repeated after exclusion of the phenotypic data of ever-smokers. Two-point linkage analysis for asthma showed some evidence of linkage to chr. 12q, particularly in nonsmokers ($P < 0.01$). Multipoint linkage analysis for airway responsiveness revealed suggestive evidence of linkage to chromosome 12q24 (LOD=2.33 at 146 cM) in nonsmokers. After genotyping 18 additional STR markers on chr. 12q, there was significant evidence of linkage to airway responsiveness on chromosome 12q24 (LOD=3.79 at 144 cM) in nonsmokers, with a relatively narrow 1.5-LOD unit support interval for the observed linkage peak (142 to 147 cM). Our results suggest that chromosome 12q24 contains a locus (or loci) that influence a critical intermediate phenotype of asthma (airway responsiveness) in Costa Ricans.

Genetic heterogeneity in Stüve-Wiedemann Syndrome. *N. Dagoneau[1], L.I. Al Gazali[2], A. David[3], E. Flori[4], A. Green[5], B.C.J Hamel[6], M. Le Merrer[1], F. Prieur[7], A. Raas-Rothschild[8], J. Vigneron[9], A. Munnich[1], V. Cormier-Daire[1]*

Pinard, Nancy, France.

Stüve-Wiedemann syndrome (SWS) is a severe autosomal recessive condition characterized by bowing of the long bones, with cortical thickening, flared metaphyses with coarsened trabecular pattern, respiratory distress and hyperthermic episodes responsible for early lethality. Studying a series of 19 SWS families, we have mapped the disease gene to chromosome 5p13 and identified null mutations in the LIFR gene, responsible for an impairment of the JAK/STAT signalling pathway in patient cells. Following this initial study, we have collected the samples of 17 additional SWS families. Among them, we identified LIFR mutations in 10 families including six novel mutations responsible for either a premature stop codon (in exon 3, 8, 11, 15) or an aminoacid change in the Ig-like and FNIII domains (L292P, A622V). In the other 7 families, the absence of LIFR mutation prompted us to perform a linkage analysis in the consanguineous families (4/7) and to exclude the 5p13 locus as the disease locus. In addition, we have tested the activation of the JAK/STAT pathway in the fibroblasts from 4 patients with no LIFR mutation and observed a normal activation of this pathway in response to LIF excluding the LIFR as the disease gene. Finally, we reviewed the manifestations of the SWS patients with no LIFR mutation and failed to identify any distinctive feature. Taken together, our data show that SWS is a clinically homogeneous but genetically heterogeneous condition. Ongoing studies will help to further understand the pathogenesis of SWS.

A point mutation in the 3 untranslated region of *CNTN4* is associated with spinocerebellar ataxia type 16. *Y. Fukumaki[1], S. Miura[1,2], H. Shibata[1], H. Furuya[3], Y. Ohyagi[2], M. Osoegawa[2], Y. Miyoshi[2], H. Matsunaga[1], N. Takeuchi[1], A. Shibata[1], N. Matsumoto[1], A. Iwaki[1], T. Taniwaki[2], H. Kikuchi[2], J. Kira[2]* 1) Research Center for Genetic Information, Medical Inst Bioregulation, Kyushu University, Fukuoka, Japan; 2) Department of Neurology, Neurological Institute, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; 3) Department of Neurology, Neuro-Muscular Center, National Omuta Hospital, Omuta, Japan.

Spinocerebellar ataxia type 16 (SCA16) is an autosomal dominant form of pure cerebellar syndromes and has been mapped to chromosome 8q22.1-24.1. We reanalyzed the linkage of the original pedigree using two additional subjects and revealed that SCA16 links not to 8q22.1-24.1 but to 3p26.2-pter (maximum LOD score = 5.177) partly overlapping with the region of spinocerebellar ataxia type 15 (SCA15) which is also an autosomal dominant form of pure cerebellar syndromes. We screened all exons of seven genes located in the critical region and identified only one point mutation (C4256T) in the 3 untranslated region (3-UTR) of the contactin 4 gene (*CNTN4*) on chromosome 3p26.2-p26.3, which cosegregated with the disease. This mutation was not detected in 520 control subjects. Therefore, we concluded that *CNTN4* is the responsible gene of SCA16. As we were unable to prove that the single nucleotide substitution in the 3-UTR of *CNTN4* is an immediate cause of SCA16, there is still a possibility that the T-allele is tightly linked with the true SCA16 causative allele nearby. We also discuss the relation between SCA15 and SCA16 in terms of clinical and genetic aspects.

The rare form of Pseudohypoparathyroidism type Ic (PHP-Ic) is caused by mutations in the C-terminal of the GNAS gene. *L. de Sanctis[1], B. Ceoloni[1], F. Cresi[1], M. Street[2], M. Salerno[3], S. Grosso[4], W. Ahrens[5], O. Hiort[5]* 1) Dept. Pediatric Sciences, Univ Torino, Torino, Italy; 2) Dept. of Pediatrics, University of Parma, Parma, Italy; 3) Dept. of Pediatrics, Federico II University, Naples, Italy; 4) Dept. of Pediatric, University of Siena, Siena, Italy; 5) Klinik für Kinder- und Jugendmedizin, Universitätsklinikum Schleswig-Holstein, Lübeck, Germany.

The Pseudohypoparathyroidism (PHP) is a heterogeneous group of disorders characterized by PTH resistance and divided in Ia, Ib, Ic and II type on the basis of clinical, hormonal, biological features. PHP-Ia and Ic patients shared multihormone resistances (to PTH, TSH and FSH/LH) and the Albright Hereditary Osteodystrophy (AHO) phenotype. An impaired in vitro Gs-alpha protein activity, caused by loss-of-function mutations spread throughout the coding region of the GNAS gene, has been described in the PHP-Ia condition. The in vitro Gs-alpha protein activity is normal in the PHP-Ic type; recently, one GNAS mutation in the C-terminal of the gene, encoding for the receptor-binding domain, has been indicated as responsible for this rare form of PHP. We report 3 subjects with multihormone resistances and AHO phenotype in which the molecular analysis by PCR amplification and direct sequencing of entire coding region of GNAS gene allowed to detect the causal mutation in the last exon of the gene (E392X in 2 patients and E392K in the third). The in vitro Gs-alpha protein activity, performed in each subject, was normal (108.1% for the patient with E392K, 102.1% for the patients with the E392K mutation), thus indicating the PHP-Ic subtype. This study reports 2 new mutations in the GNAS gene causing the rare form of PHP-Ic. It confirms that a defect in the receptor-mediated Gs-alpha activation can be responsible for this disorder, accordingly to the pathogenetic mechanism proposed for the first mutation described. A nucleotide change at the receptor binding domain could thus explain the clinical features related to an impaired Gs-alpha activity, notwithstanding normal in vitro functional assays, that explore the retained adenylate cyclase activity of the protein.

Evaluation and validation of Preimplantation Genetic Diagnosis (PGD) by PCR analysis: comparison of the blastomere and corresponding embryo genotype. *J. Dreesen[1,3], M. Drüsedau[1], H. Smeets[1,3], C. De Die-Smulders[1], J. Dumoulin[2], J. Evers[2], J. Geraedts[1,3], J. Herbergs[1,3]* 1) Depts. Clinical Genetics; 2) Obstetrics & Gynaecology, Academic Hospital Maastricht; 3) GROW, Maastricht University, Maastricht, The Netherlands.

PGD can be an alternative for prenatal diagnosis for couples at high risk of a monogenic disorder. Unaffected embryos, genotyped by analysis of biopsied blastomeres, are selected for embryo transfer (ET). The aim of the present study is to validate the PGD-PCR procedure, and determine the diagnostic value. PCR analysis of embryos not selected for ET and unsuitable for cryopreservation after PGD were used as golden standard. According to embryo morphology quality scores, embryos on day 4 post fertilization (day ET) were divided into class 1-4, with class 4 being the lowest embryo morphology score. The genotype from the biopsied blastomere and the corresponding embryo were compared. To establish the validity of PGD-PCR procedure, sensitivity(Se), specificity(Sp), and Likelihood Ratio (LR) were calculated for the total, class 4 excluded and class 4 embryo group. For the diagnostic value, Positive- (PPV) and Negative Predictive Value (NPV) were calculated. In our centre 80 women underwent PGD-PCR, resulting in 793 embryo genotypes, 241 unaffected embryos were used for ET. From 447 embryos the blastomere genotype has been compared with the reanalysed embryo genotype. PGD-PCR blastomere outcome, scored as affected or aberrant in 234/241 positive embryos (Se; 97,1%), and scored unaffected in 181/206 negative embryos (Sp: 87,9%). Out of the 7 false negative embryos, 6 were graded as class 4. The Se in the class 4 embryo group was 90,2% (55/61) and Sp 93,2% (41/44). Exclusion of class 4 embryos resulted in a Se of 99,4% (179/180), a Sp of 86,4% (140/162) and a LR positive test of 7.3 and LR negative test of 0.006. The PPV of an abnormal PGD-PCR is 89.1%, the NPV of a normal PGD-PCR is 99.3% in this group. PGD-PCR procedure is validated as a diagnostically reliable method for selecting unaffected embryos for ET. Accuracy of PGD-PCR analysis improves by rejecting class 4 embryos for ET.

PCSK9, from gene to protein and plasma. *M. Abifadel, B. Jessica, A. Marques, M. Devillers, D. Erlich, J.P. Rabès, C. Boileau, M. Varret* INSERM U781, INSERM U781 hôpital Necker, France, Paris cedex 15, France.

Autosomal Dominant Hypercholesterolemia (ADH) is one of the most frequent human inherited disorders. Until 2003, mutations in two major genes, LDLR and APOB, had been clearly implicated in the disease. We were the first to identify a third gene involved in ADH by positional cloning in French non LDLR/non APOB families. The PCSK9 gene (Proprotein Convertase Subtilisin Kexin 9) encodes an enzyme Narc-1 (Neural Apoptosis Regulated Convertase). Several hypercholesterolemic mutations of PCSK9 have been reported: S127R, F216L, D374Y, R218S and R357H and three variations have been associated with LDLR mutations in patient with severe hypercholesterolemia. Two non sense variations Y142X and C679X (frequency of 2% in black Americans) were associated with a reduction of LDL-cholesterol levels and of CHD. The R46L variation (frequency of 3.2% in white Americans) is associated with a reduction of LDL-cholesterol of 15% and 47% of CHD. We studied the frequency of 2 variations in 600 Caucasian (400 hypercholesterolemic and 200 normolipemic) subjects. R46L was found only in the control population with a frequency of 2%. A443T was found in a woman aged 50 who presented with mild hypercholesterolemia and no mutation in LDLR and APOB genes. This variation was not found in 340 French Caucasians controls. This variation turns out to be a rare polymorphism in whites, more frequent in blacks, associated with lower plasma levels of LDL-C but which has been found in both low and high LDL-C subjects in the Dallas Heart Study. We have also studied PCSK9 protein in the plasma of two S127R carrier patients by western blot analysis after resolution by SDS-PAGE (4-12%). The profile found for these plasmas was not different from the control. The S127R mutation doesnt seem to modify the molecular weight of the secreted PCSK9 forms. But modifications of its interaction with other proteins or of the amount of PCSK9 secreted cannot be ruled out and are under investigation. PCSK9 is an attractive therapeutic target for LDL-C lowering but further investigations are required to understand its precise role in cholesterol homeostasis and to identify its substrates and inhibitors.

GeneSniffer, A Gene Prioritisation Tool: New Developments and Application to Type 2 Diabetes Genetics. *K. Elliott[1], W. Rayner[1], E. Zeggini[1], S. Wiltshire[1], JT. Bell[1], M. McCarthy[2], Int Type 2. Diabetes 1q Cons[1]* 1) WTCHG, Oxford, UK; 2) OCDEM, Oxford, UK.

Researchers pursuing large-scale genetic studies face enormous challenges in interpreting their association findings in the context of local genomic annotation and the extensive biological information available from numerous online databases. We have previously presented a datamining tool, GeneSniffer, developed to aid the integration of large scale genetic data with diverse sources of biological information. For each of the genes in a region the program interrogates information from NCBIs Gene, OMIM, PubMed, UniGene, HomoloGene, BLAST and Jacksons MGI databases, using a list of weighted disease-specific keywords, and a disease relative score is generated. We used GeneSniffer to generate Type 2 Diabetes(T2D) candidacy scores for each of the 428 genes in the replicated 1q T2D linkage region. The 1q Consortium has undertaken high-density mapping of between 3536 and 3922 SNPs (ave 1SNP/5kb) in 4472 individuals from 8 populations. SNPs in the vicinity of 6 genes showed significant association with T2D. A Wilcoxon rank test was used to test the correlation between high GeneSniffer scores and proximity to associated SNPs for the 428 genes in the 1q region. A significant p-value of 0.0095 indicated that GeneSniffer identified candidate genes with a significant chance of harbouring disease causing polymorphisms. The scope of GeneSniffer has been extended to screen gene products from the NCBIs Gene database, for curated interactions, sourced primarily from BIND and HPRD. We have applied this approach to the Warren 2 Consortium T2D pedigree resource. GeneSniffer revealed a network of genes, known to interact at the protein level, that is consistent with the preliminary evidence for epistasis at the linkage level in these data. We are currently extending the search for more complex network patterns and are formally assessing the statistical significance of our findings. GeneSniffer can be applied to any disease, and will be used to assist the ongoing gene identification efforts of the Type 1 Diabetes, T2D, 1q and Wellcome Trust Case Control International Genetics Consortia.

Genetic Partitioning of Polycystic Ovary Syndorme (PCOS) families provides evidence for two susceptibility loci within the TGFbeta signaling pathway. *C. Ackerman, M. Urbanek* Medicine/Endocrinology, Northwestern University, Chicago, IL.

PCOS is the most common cause of anovulatory infertility among reproductive age women in western societies and is also associated with metabolic abnormalities including obesity, cardiovascular disease, and a 7x increased risk of developing type 2 diabetes mellitus. While there is a strong familial component to PCOS, the mode of inheritance of PCOS is unclear and its etiology remains unknown. To date the strongest evidence for a PCOS susceptibility locus ($p<0.0006$) is D19S884, a dinucleotide repeat polymorphism, mapping to an intron of the fibrillin-3 gene (FBN3) in which allele 8 (A8) has been shown to be associated with PCOS in multiple cohorts. The follistatin gene (FST) is a second PCOS susceptibility locus that showed significant evidence for linkage with PCOS in preliminary studies ($p=0.0003$) although these findings were not replicated in follow-up study. Interestingly both fibrillins and follistatin are thought to affect TGFbeta signaling by sequestering and thereby biologically inactivating TGFbeta ligand(s). Therefore, these genes may act in a complementary manner to alter the signaling pathway. We used genetic partitioning of multiplex PCOS families to investigate this question by dividing 78 multiplex PCOS families into D19S884 A8+ ($n=25$) and D19S884 A8- ($n=53$) subsets and evaluating evidence for linkage with PCOS at FBN3 and FST in each group. In the complete dataset FBN3 had 59% identity by descent (IBD) ($p=0.027$) and FST 58% IBD ($p=0.053$). However, for FBN3 the A8+ families had 77% IBD ($p=0.0007$) while the A8- families had no evidence for association with PCOS (IBD=53%, $p=0.53$). The converse was true for FST; A8+ families have no evidence for sharing (IBD=48%, $p=0.84$) while A8- families have significant evidence for linkage (IBD=62%, $p=0.014$). These analyses support the hypothesis that the TGFbeta signaling pathway contribute to the etiology of PCOS and that at least two genes in this pathway, FBN3 and FST, contribute to PCOS. Additionally, genetic partitioning can improve the power to detect linkage in small sample sizes by reducing genetic heterogeneity.

Mitochondrial coupling defect in fibroblasts from patients with Mnf2-related Charcot-Marie-Tooth type 2A. *D. Bonneau, D. Loiseau, C. Verny, A. Chevrollier, V. Guillet, MA. Pou, Y. Malthièry, P. Amati-Bonneau, P. Reynier*
Department of Genetics and Biochemistry, INSERM U694,CHU Angers,France.

Charcot-Marie-Tooth(CMT) disease is one of the most frequent inherited neurological disorder affecting about 1/2,500 individuals. It refers to an heterogeneous group of progressive peripheral neuropathies leading to length-dependent loss of sensation, weakness, muscle atrophy, loss of deep tendon reflexes and foot deformities. Various additional symptoms such as optic atrophy or spastic paraparesis can be associated to the different forms of the disease. Age of onset, expressivity and severity of the disease are variable. CMT are classically classified in predominantly demyelinating (CMT type 1) or axonal (CMT type 2). CMT2 has been subdivided into eight groups by linkage studies and five genes involved in these forms have been identified so far. CMT2A (MIM 118210) was mapped to chromosome 1p35-36. Two genes have been associated in this locus, KIF1B (kinesin family member 1B) and Mfn2 (Mitofusin 2). The Mfn2 gene encodes a dynamin GTPase, located in the outer mitochondrial membrane, that is an essential component of the mitochondrial fusion machinery. Mutations of Mfn2 were recently found to be responsible of most cases of Charcot-Marie-Tooth (CMT) disease type 2A. We investigated mitochondrial energetic metabolism and structure in skin fibroblasts of 4 patients presenting novel missense mutations in Mfn2 in comparison to controls. We found a significant mitochondrial coupling defect responsible for a 30% reduction of the mitochondrial membrane potential (m). The morphology of mitochondrial network was not altered. This result suggests that Mfn2-related Charcot-Marie-Tooth patients have a dramatic decrease in the efficiency of oxidative phosphorylation that might be contribute to the axonal degeneration.

Natural History of Autosomal Recessive Polycystic Kidney Disease/Congenital Hepatic Fibrosis (ARPKD/CHF).

M. Gunay-Aygun[1], E. Font-Montgomery[1], P. Choyke[2], L. Guay-Woodford[3], T. Heller[4], R. Kleta[1], P. Mohan[5], Z. Quezado[6], W. Gahl[1] 1) NIH, NHGRI, MGB, Bethesda, MD; 2) NCI; 3) University of Alabama, Birmingham AL; 4) NIDDK; 5) CNMC, Washington, DC; 6) NIH Clinical Center.

ARPKD/CHF is a developmental disorder of the kidneys and liver caused by mutations in the *PKHD1* gene. The kidney cysts in ARPKD are non-obstructive dilatations of the collecting ducts. CHF, an invariable part of ARPKD, results from malformation of the developing ductal plate. Approximately 30-50 percent of ARPKD patients present perinatally with enlarged kidneys. Although severely affected neonates die in infancy, survival has dramatically increased because of wide availability of prenatal ultrasound and improved neonatal care. In most patients both kidney and liver disease are progressive, with variable rates of deterioration. More than half of the patients require renal transplantation before 20 years of age. Portal hypertension, the major clinical problem associated with CHF, causes hypersplenism and esophageal varices. A subset of patients also exhibit cystic dilatation of the medium sized and larger intrahepatic bile ducts (Carolis syndrome). Hypertension, renal insufficiency, bleeding from esophageal varices, and recurrent cholangitis are the major sources of morbidity; only symptomatic therapy is available. The natural history of ARPKD has not been elucidated in a detailed, longitudinal fashion. To date, we have evaluated 55 patients through an ongoing natural history study of ARPKD/CHF (www.clinicaltrials.gov, trial NCT00068224). Here we present data on 35 typical ARPKD/CHF patients, based on clinical and/or molecular data. Significant findings include normal urinary protein, glucose and calcium excretion, largely intact proximal tubule function, mildly impaired distal tubule function, normal plasma norepinephrine, mildly elevated serum ammonia, and small cystic dilatations of the peripheral intrahepatic bile ducts in the face of normally sized central ducts. We continue to produce comprehensive longitudinal data on ARPKD/CHF to provide the groundwork for more focused studies and future therapeutic interventions.

The CIDR GWA LIMS -- A Laboratory Process Tracking System for the Illumina HumanHap300 and Human-1(100K) BeadChip Products. *M. Barnhart, J. Goldstein, B. Craig, C. Bark, R. King, K. Hetrick, K.F. Doheny, L. Watkins* IGM/CIDR, Johns Hopkins Univ/CIDR, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) is a centralized facility established to provide genotyping and statistical genetics services for investigators seeking to identify genes that contribute to human disease. In January 2006, CIDRs technology development team began genotyping ~2,600 samples from a Finland-United States Investigation of NIDDM Genetics (FUSION) case-control pilot project in order to evaluate the performance characteristics of the Illumina HumanHap300 beadchip product. Informatic support was unavailable for this Infinium product at that time. Although Illumina was developing a LIMS, CIDR required an immediate solution in order to ensure the highest level of data quality possible. Having created a custom data entry system for the Infinium 100K (Human-1) product, CIDR used the existing codebase, whose development involved approximately 500 hours of programming time over a two-month period, to create a similar LIMS for the HumanHap300 product. Modifying the 100K LIMS to accommodate lab processes unique to the HumanHap300 product involved approximately 30 additional hours of programming time over a one-month period. Both the original and the derived LIMS consist of a Java Swing graphical user interface (GUI) backed by a MySQL relational database management system (RDBMS) that tracks each sample through all stages of processing, from DNA plate through association to a beadchip, while recording reagent lot numbers, reaction temperatures, and other variables essential to quality control. Rigorous data validation ensures that reagents scanned are valid for each phase and that each plate or beadchip scanned is ready for processing in the phase being recorded. When processing for a set of samples is complete, users can generate an import file for the Illumina BeadStudio software as well as a variety of quality-control reports for the production laboratory. Source code is available upon request.

Portal Hypertension Associated with Autosomal Dominant Polycystic Kidney Disease (ADPKD). *E. Font-Montgomery[1], I. Ocak[2], P. Choyke[2], L. Guay-Woodford[3], T. Heller[4], R. Kleta[1], P. Mohan[5], Z. Quezado[6], M. Gunay-Aygun[1], W. Gahl[1]* 1) MGB, NHGRI, NIH, Bethesda, MD; 2) NCI; 3) University of Alabama, Birmingham, AL; 4) NIDDK; 5) CNMC, Washington,DC; 6) NIH Clinical Center.

The characteristics of liver disease differ in autosomal dominant (AD) compared with autosomal recessive (AR) polycystic kidney disease (PKD). All ARPKD patients have congenital hepatic fibrosis (CHF), often with portal hypertension. A subset of patients exhibit cystic dilatations of the medium sized and larger intrahepatic bile ducts (Carolis Syndrome), caused by ductal plate malformations affecting the central biliary system. In contrast, the liver disease of ADPKD is relatively benign. Cysts develop from the peripheral liver tissue (von Meyenburg complexes), and are disconnected from the biliary system. Portal hypertension rarely occurs. Under the NHGRI natural history protocol on ARPKD/CHF (www.clinicaltrials.gov, trial NCT00068224), we evaluated 2 ADPKD families with CHF and portal hypertension. In one family, the 52-year-old father was on dialysis. His 33-year-old daughter presented with hepatosplenomegaly at 6 months and was diagnosed with CHF by liver biopsy. She required esophageal variceal banding and renal cyst decompressions in young adulthood. Her daughter (16) and son (14) had kidney cysts without liver involvement. In the second family, the 9-year-old index case presented at age 4 with esophageal variceal bleeding. Several relatives in 3 previous generations had ADPKD without portal hypertension. Her asymptomatic 14 year old brother had kidney cysts, splenomegaly and esophageal varices and her 12-year-old brother had only renal involvement. Sequencing of the *PKD1*, *PKD2* and related genes and potential modifiers might shed light on the reasons for intrafamilial variability of the liver phenotype in these families.

A genome-wide scan for genes involved in vesicoureteral reflux. *D.E. Barton[1,2], H. Kelly[1,3], A. Yoneda[1,3], J.M. Darlow[1,3], D. Shields[3], C. Molony[4], A.J. Green[1,2], P. Puri[3]* 1) National Centre for Medical Genetics and Department of Medical Genetics, University College Dublin, Ireland; 2) Conway Institute for Biomolecular and Biomedical Research, University College Dublin, Ireland; 3) Children's Research Centre, Our Ladys Children's Hospital, Crumlin, Dublin, Ireland; 4) Rosetta Inpharmatics, Seattle, Washington.

Vesicoureteral reflux (VUR, OMIM 193000), the reverse flow of urine from the bladder towards the kidney, is found in 1-2% of children. It is a common cause of end-stage renal disease and severe hypertension in children. VUR is caused by a shortening of the segment of the ureter that runs through the submucosal layer of the bladder wall. Milder grades may resolve with age but more severe grades require medical or surgical intervention. Genetic studies indicate that VUR is heterogeneous; inheritance appears to be autosomal dominant in many families. Blood was collected from 167 Irish families with more than 1 child affected with VUR. We are using an affected-sib-pair approach to search for VUR genes. We studied the numbers of sib-pairs to see if there was any distortion of the expected 50:50 distribution of same-sex versus opposite-sex pairs. Of 104 independent sib-pairs, same-sex pairs outnumbered opposite-sex pairs by almost 2:1 (^{2}=7.01, p = 0.008). This novel finding suggests either a pseudoautosomal location for a gene involved in VUR or another sex-specific mode of inheritance or expression of the disorder. We carried out a genome scan using 4753 SNP markers on 620 samples from 133 families. Multipoint linkage analysis of the autosomal data indicated 11 regions with p<0.01, on 1q23-25, 2q37, 4p15, 6q24-25, 6q27, 7q36, 10q26, 13q33, 16q24, 20p12 and 21q22. We then removed families of cases with duplex ureters (n=20), reasoning that these may be a different aetiological subset, and reanalyzed. Some peaks diminished and some increased, giving 4 highly significant signals, at 2q27 (p=0, NPL 4.35), 6q25 (p=0.00006, NPL 3.21), 7q36 (p=0.003, NPL 2.50) and 10q26 (p=0.00012, NPL 2.94). Candidate genes for VUR are now being investigated in these regions. Genes at some of the peaks that diminished may be associated with duplex ureteric budding.

Lack of response to high dose ERT in a patient with Type III Gaucher Disease and a mesenteric mass consisting of Gaucher Cells. *D. Freedenberg[1], M. Dudek[1], G. Tiller[3], A.. Bircher[1], W. Rhead[2]* 1) Dept Peds, Div Med Gen, Vanderbilt Univ School of Medicine, Nashville, TX; 2) Dept of Peds Medical College of Wisconsin Miwaukee, WI; 3) Kaiser Medical, California.

We report a 13 year old hispanic female with type III Gaucher disease and a mesenteric mass consisting of Gaucher cells that is unrepsonsive to high dose ERT. The child was diagnosed with Type III Gaucher disease at the age of 2 years after an evaluation for organomegally. Her molecular studies noted her to be homozygous for L44P mutation. ERT with Cerezyme at standard dosage of 60-90 units/kg biweekly was started at age 2. She appeared to have a decrease in splenic volume, although at 8 years was still noted to have a spleen that was 3.5 times normal, and hepatic volume that was 1.2 normal. She did not appear to have symptomatic bone involvement and was noted to have cognitive delays. Hematologic parameters had normalized. At age 11 years she developed symtoms of abdominal obstruction. At laporotomy she was noted to have a large multi cystic mass with a portion of the mass encasing the mesenteric vasculature. She had multiple areas of studding along the omentum and the mesenteric nodules apppeared to be lymph nodes. The cyst was decompressed but the mass was unable to be resected. Bx of the omental nodules, peritoneal fluid lavage, cystic wall, and seeding nodules, all noted histiocytic infiltration. Electron microscopy confirming the presence of Gaucher cells. She has now received 28 months of high dose ERT at 90u/kg of Cerezyme weekly. Monitoring CT of the abdomen noted no change in size of the mass but increased clacification of the mass that is now characterized as a large soft tissue mass encasing the SMA and infiltrating the greater omentum with associated bowel wall thickening. Her biomarkers note the ACE in the normal range, chitotriosidase is undetectable and Trap remains elevated, although decreasing. Our patient illustrates that there appear to be visceral compartments that are inacessable to ERT and there may be unexpected complications of Gaucher disease, even in patients on ERT. She will be started on substrate reduction therapy in addition to standard dosing of ERT.

Investigation of the putative axonal guidance gene *ROBO4* in attention-deficit/hyperactivity disorder. *K.M. Dorval[1], K.G. Wigg[1], J. Crosbie[2], R. Tannock[2], J.L. Kennedy[3], A. Ickowicz[2], T. Pathare[2], M. Malone[2], R. Schachar[2], C.L. Barr[1,2]* 1) Dept Cell & Molecular Biol, Toronto Western Research Inst, Toronto, ON, Canada; 2) The Hospital for Sick Children, Toronto, ON; 3) Centre for Addiction and Mental Health, Toronto, ON.

Purpose: To determine the association of variants in the *ROBO4* magic roundabout gene with attention-deficit/hyperactivity disorder. **Methods:** Recently, an inversion observed at chromosome 13q31.1;31.3 in a proband presenting with ADHD and TS led to the investigation of the *Slit* and *Trk-like* family member 1 gene (*SLITRK1*). Further analysis revealed two rare *SLITRK1* variants in probands with TS and ADHD or obsessive compulsive symptoms. These variants functionally decreased protein expression and dendritic outgrowth. We sought to investigate other genes involved in the *SLIT/ROBO* signaling pathway in ADHD. Four single nucleotide polymorphisms (SNPs) were genotyped in the *ROBO4* gene in 232 nuclear families identified through ADHD probands. Transmission of alleles from heterozygous parents to affected offspring was examined using the transmission/ disequilibrium test (TDT). Quantitative trait analysis was performed using the FBAT program. **Results:** One of the four SNPS located in intron 2 (rs4078483) demonstrated a trend for association with ADHD as a categorical trait (2=2.960, p=0.085). The remaining SNPs (rs4635093, rs6590109, rs12823) did not reveal significantly biased transmission (p 0.320). Quantitative trait analyses did not reveal any significant association of the *ROBO4* variants with the ADHD symptom dimensions of inattention or hyperactivity/impulsivity (p 0.330). **Conclusions:** Variants in the *ROBO4* gene were not significantly associated with ADHD. Based on the implication of the *SLITRK1* gene in ADHD and TS and the *ROBO1* gene in developmental dyslexia, further analysis of the role of putative axonal guidance genes in the pathogenesis of neuropsychiatric disorders is warranted.

Genetic heterogeneity in hereditary capillary malformation. *M. Amyere[1], I. Eerola[1], N. Revencu[1], L. Boon[1, 2], M. Vikkula[1]* 1) Lab Human Molecular Genetics, Christian de Duve Institute & UCL, Brussels, Belgium; 2) Centre for Vascular Anomalies, Division of Plastic Surgery, Cliniques universitaires St-Luc & UCL, Brussels, Belgium.

Capillary malformation or 'port-wine stain' is a common vascular malformation affecting cutaneous capillary vessels in 0.3% of newborns. Sometimes it occurs in combination with other vascular anomalies, such as in Sturge-Weber syndrome, Klippel-Trenaunay syndrome, and Parkes Weber syndrome (Boon et al., 2005). Capillary malformations are usually not inherited. We recently recognized atypical capillary malformations to be the hall-mark of a hereditary condition that we named capillary malformation-arteriovenous malformation (CM-AVM). Its defining features are atypical cutaneous multifocal capillary malformations often in association with high-flow lesions. This phenotype is caused by mutations in the RASA1 gene (Eerola et al., 2003). Herein, we report a Japanese family with inherited classical CM. No mutation was found in RASA1 using DHPLC (denaturing high-performance liquid chromatography) and direct sequencing in affected patients. Linkage analysis with markers in RASA1 locus also excluded the RASA1 gene. These results support the etiological distinction between CM-AVM and classic CM, and suggest a genetic basis in some cases for classic CM. (http://www.icp.ucl.ac.be/vikkula)(vikkula@bchm.ucl.ac.be).

A new locus for keloids with hypertrophic scarring. *L. Boon*[1], *M. Amyere*[2], *M. Vikkula*[2] 1) Centre for Vascular Anomalies, Cliniques universitaires St-Luc & UCL, Brussels, Belgium; 2) Laboratory of Human Molecular Genetics, Christian de Duve Institute & UCL, Brussels, Belgium.

Keloids consist of pathologic fibrosis which occurs in the skin after trauma and which grow beyond the boundaries of the injury. These cutaneous lesions are formed by excessive deposition of extracellular matrix, mainly collagen. Keloids occur in people of all racial backgrounds; however, individuals of African descent are more susceptible. Linkage of two keloid African-American and Japanese families has been reported to loci on 2q23 and 7p11 (Marneros et al., 2004). We have performed linkage analysis in a Belgian family to test if it is also linked to one of these loci. The affected individuals of this family showed formation of small keloids and hypertrophic scars. Linkage analysis was performed using dense microsatellite maps inside the linked regions. The LINKAGE and GENEHUNTER packages were used for parametric (LOD) and non-parametric (NPL) analysis. They excluded both 2q23 and 7p11. Genome scan using the GeneChip Human Mapping 10K SNP Array shows linkage to a locus of 13 Mb with maximum Lod scores 2.5. This finding provides further evidence for locus heterogeneity genes that regulates formation of keloids with hypertrophic scars. (http://www.icp.ucl.ac.be/vikkula)(vikkula@bchm.ucl.ac.be).

Plasma obestatin and ghrelin levels in subjects with Prader-Willi syndrome. *M.G. Butler, D.C. Bittel* Children's Mercy Hospital and University of Missouri-Kansas City, Kansas City, MO.

Prader-Willi syndrome (PWS) is a complex obesity disorder characterized by feeding difficulties and failure to thrive during infancy but excessive food intake, rapid weight gain and obesity during early childhood. Food intake is regulated by the hypothalamus but directly influenced by gastrointestinal peptides responding to the nutritional status and body composition of an individual. Ghrelin is a 28-amino acid peptide derived by post-translational processes from preproghrelin and secreted by the stomach. Ghrelin increases appetite, food intake and body weight while leptin (secreted by adipose tissue) and peptide YY (released by the intestine) inhibit food intake. Ghrelin is reportedly elevated in PWS infants, children and adults and binds to a growth hormone secretagogue receptor in the hypothalamus. Obestatin, a recently identified 23-amino acid peptide also derived post-translationally from preproghrelin, works in opposition to ghrelin by decreasing appetite. Obestatin does not readily cross the blood-brain barrier but is highly conserved across species with sequence homologies of 87% between rodents and humans. Serum obestatin concentrations in rodents are more than 300 pg/ml but no published data exists in humans. Hence, peptide YY, leptin, ghrelin and now obestatin are primary candidates to investigate in PWS which affect eating behavior. We report fasting plasma obestatin and ghrelin levels in 16 subjects with PWS (mean age = 16.0 $\pm$ 13.3 years; age range 1-44 years) along with age and gender matched controls. Significantly higher obestatin levels were seen in the 16 PWS subjects (398 $\pm$ 102 pg/ml) compared with 16 controls (325 $\pm$ 109 pg/ml; matched t-test, $p = 0.04$), as well as 5 young (3 years old) PWS subjects (460 $\pm$ 49 pg/ml) compared with 5 young controls (369 $\pm$ 96 pg/ml; matched t-test, $p = 0.03$). However, no difference in ghrelin levels were seen in the two subject groups. No significant correlation was observed for either peptide when compared with body mass index but a significant negative correlation was seen for ghrelin and age in PWS subjects. Our report represents the first study of obestatin measures in humans.

Experimental identification of regulatory Conserved Non-Coding sequences (CNCs) using the chicken genome.

C. Attanasio[1], F. Chiodini[2], C. Wyss[1], J-M. Matter[2], S.E. Antonarakis[1] 1) Dpt Genetic Medicine & Development, University of Geneva Medical School, Switzerland; 2) Dpt of Biochemistry, Sciences II, University of Geneva, Switzerland.

Comparative genome analysis across mammals has revealed a large number of highly conserved non-coding sequences (CNCs). We had studied CNCs from 21q and found that their evolutionary features strongly suggested functional importance. However, the function of the majority of these sequences is unknown. We hypothesised a possible role of a subset of CNCs in transcriptional regulation. *In vitro* luciferase and DNaseI hypersensitive assays were used to evaluate this putative regulatory function; the results of both assays in more than 110 sequences revealed that only 15% of CNCs have properties of transcriptional regulators. This suggests that there may be insufficient evolutionary distance between humans and others mammals to easily distinguish conserved regulatory sequences. The chicken contains a more divergent genome for comparative analysis; we thus hypothesised that human-chicken genome comparisons could provide improved phylogenetic resolution for identification of regulatory elements. Alignment of 21q CNCs with the chicken genome revealed that ~5-6% of these are conserved down to birds (100bp, 70% homology). The homogenous proliferating neuroepithelium of the early developing chick retina offers the opportunity to evaluate the transcriptional potential of CNCs in precursors (undifferentiated) cells. We thus electroporated chick retinas (embryonic day E3 & E6) with GFP-reporter vectors to determine the regulatory potential of a set of those CNCs. Analysis of 15 CNC sequences and non-conserved single copy control sequences suggests that the majority of human-chicken CNCs (80-85%) strongly activate the GFP expression in explanted retina. Interestingly, we observed that some CNCs behave as enhancers in early retina (E3) but not at later developmental stages (E6). Our results suggest that the chicken genome could be used to identify transcriptional regulators among the mammalian CNCs, and that many human-chicken CNCs act at early stages of development.

UMOD-related familial juvenile hyperuricemic nephropathy : mutation detection rate and mutational spectrum.

K. Dahan[1], L. Labriola[2], M. L. Lizon[1], M. Smaers[1], O. Devuyst[2], Y. Pirson[2] 1) Human Genetics Unit, UCL Saint-Luc Hosp, Brussels, Belgium; 2) Division of Nephrology, UCL Saint-Luc Hosp, Brussels, Belgium.

A mutation in the UMOD gene has emerged as the major cause of familial juvenile hyperuricemic nephropathy (FJHN). However, the mutation rate detection as well as the spectrum of mutations remains to be evaluated in a large cohort of families. We report on these findings in 50 families (31 from France, 11 from Belgium, 2 from Italy, 2 from Morocco, 1 from England, 1 from Australia, 1 from Germany and 1 from Netherlands) with FJHN. In all kindreds, at least one affected individual had a history of either progressive renal insufficiency related to a histological or clinical picture of chronic interstitial nephritis or hyperuricemia (serum uric acid level > 6 mg/dl) preceding renal failure or disproportionate to the rate of glomerular filtration. In addition, a history of either gout in childhood or in young adulthood or chronic renal failure (CRF) or both was present in at least one first-degree relative among 6, 17 and 27 of families respectively. Two propositus had preserved renal function (2/50, 4%) at a mean age of 53 (range : 35-71), 19 had CRF (19/50, 38%) at a mean age of 40 (range : 2-72) and 29 had reached end-stage renal failure (ESRF) (29/50, 58%) at a mean age of 43.1 (range : 28-64). Renal imaging available in 23 propositus, all with CRF or ESR, revealed the presence of cysts in 14 of them (19/23, 82%). Twenty-one patients had mutation in UMOD gene (21/50, 42%). Of the 21 changes (19 missense, one in-frame deletion and one splicing mutation), all are unique with the exception of a cysteine substitution (p.C315Y) also seen in 2 unrelated patients. These mutations are distributed throughout the exon 4 (18/21, 86%) and 5 (3/21, 14%). This mutational study shows a mutation detection rate of 42 % in a large cohort of FJHN families and confirms that missense mutation involving the 5 region corresponding to codons 32 to 315 of Tamm Horsfall protein is the major mechanism for UMOD defect (19/21, 90%).

Locus homogeneity in Glomuvenous Malformation. *P. Brouillard[1], L.M. Boon[1, 2], O. Enjolras[3], J.B. Mulliken[4], M. Vikkula[1]* 1) Lab Human Molecular Genetics, Christian de Duve Institute & UCL, Brussels, Belgium; 2) Centre for Vascular Anomalies, Cliniques universitaires St-Luc, Brussels, Belgium; 3) Pediatric Vascular Clinic, Hôpital d'Enfants A. Trousseau, Paris, France; 4) Vascular Anomalies Center, Children's Hospital, Harvard Medical School, Boston, MA, USA.

Glomuvenous malformation (GVM) is a localized cutaneous vascular lesion histologically characterized by the presence of maldifferentiated smooth muscle-like glomus cells around distended vein-like channels. GVM is caused by mutations in Glomulin (GLMN) (Brouillard et al., 2002). Most mutations lead to premature termination codons, probably resulting in loss-of-function. Glomulin is specifically expressed in vascular smooth muscle cells (vSMCs), but its exact function remains unknown (McIntyre et al., 2004). The TGF and HGF signaling pathways may be involved. Hypothesis of paradominant inheritance was supported by the identification of a double-hit mutation in one lesion, resulting in complete localized loss of glomulin. Moreover, we showed that glomus cells in GVM do not express glomulin nor another late vSMC marker, smoothelin-b, whereas earlier differentiation markers are detected (McIntyre et al., submitted). Thus, GLMN plays a role in the differentiation of vSMCs, which have deviated in their differentiation process due to lack of glomulin expression. To date, we have identified altogether 30 different mutations in 86 families, one of them being present in 40% of them. As a mutation was identified in each family with clear GVM diagnosis, it suggests that no locus heterogeneity exists for GVM. (brouillard@bchm.ucl.ac.be).

Mutation analysis of the three FHM genes in a set of 29 sporadic hemiplegic migraine patients. *B. De Vries[1], K.R.J. Vanmolkot[1], A.H. Stam[2], J.B. Koenderink[3], E. Babini[4], G.M. Terwindt[2], M. Pusch[4], A.M.J.M. Van den Maagdenberg[1,2], R.R. Frants[1], M.D. Ferrari[2]* 1) Department of Human Genetics, Leiden University Medical Centre, Leiden, The Netherlands; 2) Department of Neurology, Leiden University Medical Centre, Leiden, The Netherlands; 3) Department of Pharmacology and Toxicology, Nijmegen, The Netherlands; 4) Insititutio di Biofisica, Genova, Italy.

Patients with sporadic (SHM) and familial forms of hemiplegic migraine (FHM) have similar clinical characteristics, including attacks of migraine with aura associated with hemiparesis. It is unknown whether FHM and SHM share a genetic etiology. Here, we report on sequence analysis of the three FHM genes CACNA1A, ATP1A2, and SCN1A in 29 well-characterized SHM patients. Patients were considered sporadic when none of the first-degree relatives had hemiplegic migraine. We identified a total of seven missense mutations, of which 2 were found in the CACNA1A gene, four in the ATP1A2 gene and one in the SCN1A gene. Different studies were performed to determine the functional consequences of these mutations. In conclusion, we identified mutations in 7 out of 29 SHM patients; four mutations were located in the ATP1A2 gene. Therefore, our findings suggest that the ATP1A2 gene is a good candidate for genetic testing in SHM cases. In the majority of our SHM cases however no mutations were found, indicating that other genetic factors might be involved as well.

Severe palpebral hamartoma and aplasia cutis congenita in a child with Schimmelpenning-Feuerstein-Mims syndrome. *M. Gerard[1], D. Bremond[2,3], V. Desilets[4], M. Elmaleh[5], M.L. Jaquemont[1], C. Baumann[1], A. Verloes[1,3]* 1) Medical genetics, Hôpital Robert Debré, Paris, France; 2) Ophthalmology, Hôpital Robert Debré, Paris, France; 3) INSERM U6764, Hôpital Robert Debré, Paris, France; 4) Pediatrics, Hôpital Ste Justine, Montréal, Canada; 5) Radiology, Hôpital Robert Debré, Paris, France.

Schimmelpenning-Feuerstein-Mims syndrome (OMIM 165630), or epidermal nevus syndrome, associates ocular anomalies, cerebral defects, and systematized linear sebaceous nevus following the lines of Baschko. All cases are sporadic. The mechanism suggested by Happle is a dominant lethal gene arising as a somatic mutation in the early embryo, and surviving by mosaicism (Happle and al., 1986). Ocular anomalies are frequent, such as extension of nevus to lid, coloboma of lid or/and iris and retina, epibulbar lipodermoid, corneal opacities, optic nerve hypoplasia, oculomototor dysfunction, nystagmus, or cortical blindness. We followed a 3 months-old girl born to non-consanguineous parents, with a linear sebaceous nevus, localised on the back, with verruquous development on a pigmented band of the arm, and association with severe ophthalmologic malformations, bilateral superior ablepharon (agenesis of superior lid), peri-ocular calcified hamaortomas with colobomatous microphthalmia. Inferior lids were normal. A cutaneous aplasia of the scalp was associated. Facial scanner identified hamartomas of superior lids with macro-calcifications of the ocular globe fused with the orbit roofs. Abnormal ossification or calcification joined the intern part of the lid with a frontal insertion. Such an ablepharon with calcified hamartoma of lids have been rarely described in SMS, and no aplasia cutis. The epidermal nevus is non specific, and can be seen in SPS, Proteus syndrome, CHILD, nevus comedonicus, and pigmented hairy epidermal nevus (Happle, 1995). Ablepharon is a rare dysmorphological pattern, found in ablepharon-macrosomia syndrome (OMIM 200110), and Barber-Say syndrome (OMIM 209885). It will be of interest to study the genes responsible for osseous formation in the hamartomas of the lids, on tissue samples post reparative surgery.

A copula approach to missing data in genetic association studies. *G.M. D'Angelo*[1], *E. Feingold*[1, 2] 1) Biostatistics, University of Pittsburgh GSPH, Pittsburgh, PA; 2) Human Genetics, University of Pittsburgh GSPH,Pittsburgh, PA.

A limited amount of research has focused on association studies with missing genotype data. Typically, missing data is assumed to be missing completely at random (MCAR) and complete case analysis is the method of choice resulting in biased and inefficient results. When fitting models with genotypes at several markers as simultaneous predictors, the complete case approach can lead to significant reduction in sample size. To address the problem where the SNPs are missing at random (MAR), we suggest using a copula approach to improve the coefficient estimates and their standard errors in a logistic regression model. An advantage of employing the copula is that the joint distribution of the outcome and covariate is specified, and since the covariates are missing their distributions must be specified. An added benefit to the copula approach is that it can handle nonmonotonic data. We compare the copula approach to multiple imputation and complete case analysis.

Association of Polymorphisms in S-nitroso-glutathione Reductase with Asthma. *S. Choudhry[1], L. Liu[2], L.G. Que[3], C. Eng[1], S. Nazario[4], J. Casal[4], A. Torres[4], I. Gomez[4], J.K. Fagan[5], J. Salas[6], R. Chapela[6], J.G. Ford[7], P.C. Avila[8], W. Rodriguez-Cintron[4], E.G. Burchard[1]* 1) Department of Medicine, University of California, San Francisco; 2) Department of Microbiology & Immunology, University of California, San Francisco; 3) Center for Comparative Biology of Vulnerable Populations, Duke University; 4) San Juan VAMC, School of Medicine, University of Puerto Rico; 5) The Harlem Lung Center, Harlem Hospital, New York; 6) Instituto Nacional de Enfermedades Respiratorias, Mexico City; 7) Johns Hopkins Bloomberg School of Public Health, Baltimore; 8) The Feinberg School of Medicine, Northwestern University.

S-nitroso-glutathione (GSNO), a bronchodilator present in airway lining fluid (ALF) of healthy people, is depleted from ALF of asthmatic patients. Depletion of GSNO may contribute to impaired airway relaxation in asthmatics. Genetic deletion of GSNO reductase (GSNOR), the enzyme important for S-nitrosothiols metabolism in vivo, protected mice from experimental asthma. To determine whether polymorphisms in the GSNOR gene are associated with asthma, we carried out family-based transmission disequilibrium tests (TDT) in Puerto Rican and Mexican trios with asthma. Puerto Ricans and Mexicans have the highest and the lowest asthma prevalence, respectively, in the US. We identified 39 SNPs in the GSNOR gene by sequencing 72 Puerto Ricans, Mexicans and African Americans with asthma. Many SNPs identified in the gene were in strong linkage disequilibrium. Five SNPs, one in promoter region and four in 3 UTR were selected for further genotyping in 386 Puerto Rican and 300 Mexican asthmatic trios. TDT analysis showed that several GSNOR SNPs, including the SNP in the promoter region (p=0.05) and 3 SNPs (p=0.03 to 0.008) in the 3UTR, were significantly associated with predisposition to asthma in the Puerto Rican cohort. Significant association of GSNOR and asthma in Puerto Ricans was further supported by haplotype analysis (p=0.02). No association of the GSNOR SNPs with asthma was found in Mexicans. Our data suggest a genetic association of GSNOR and asthma in Puerto Ricans, and further implicate GSNO metabolism in asthma pathogenesis.

A descriptive study of international genetic counselor education: program features and student characteristics.

S.M. Gilinsky[1], R. Medh, PhD[1], F. Field, MS, CGC[1], S. Charnofsky, PhD[1], J.G. Edwards, MS, CGC[2] 1) California State University, Northridge, Northridge, CA; 2) University of South Carolina School of Medicine, Columbia, SC.

There is an increasing international demand for genetic counselors, and as a result new training programs are being developed yearly. Today, training programs exist in at least 15 countries around the world. Most studies of genetic counseling education have focused on programs in the U.S. and less is known about the greater international genetic counseling community. This study describes the current state of international genetic counseling programs and explores the characteristics of students attending these programs. Program directors completed a survey of their programs structure and admissions characteristics. Students participated in a survey assessing their experience and personal characteristics prior to entering their program. Twenty-five programs in 14 countries completed the first survey. Data were also collected from 126 students training in 11 countries. These data show that programs vary in number of yearly applicants and students in attendance, and in the duration of the training curriculum. Students were born in 30 countries on 6 continents, yet they are demographically similar and have similar backgrounds. Most students had prior experience in biological science, research, or healthcare, and more than 75% were motivated to enter the career based on a desire to help others, an interest in genetics, and the desire for intellectual stimulation at work. International students were an average of 6 years older and had more advanced study and work experience than students in the U.S. (Lega, et al. 2005). Overall, 90.7% of students were confident in their career choice, although over 50% considered their opportunities for employment to be limited. This study uncovered variations in program structure and student characteristics of internationally. The common backgrounds and motivations found among students, despite their numerous nationalities and countries of training, may reflect an underlying genetic counseling philosophy that attracts certain individuals to the career.

Combined Linkage and Association Mapping of Quantitative Trait Loci with Missing Genotype Data. *R. Fan[1], L. Liu[1], J. Jung[2], M. Zhong[1]* 1) Dept Statistics, Texas A&M Univ, College Station, TX; 2) Department of Human Genetics, University of Pittsburgh, Graduate School of Public Health, Pittsburgh, PA 15261.

In this study, the impact of missing genotypes is investigated for high resolution combined linkage and association mapping of quantitative trait loci (QTL). Two regression models, ``genotype effect model" and ``additive effect model", are proposed to model the association between the markers and the trait locus. The expected number of genotypes or alleles is used as weight to model the effect of the genotypes or alleles. By analytical formulae, we show that the ``genotype effect model" can be used to model the additive and dominance effects simultaneously; the ``additive effect model" only takes care of additive effect. Based on the two models, F-test statistics are proposed to test association between the QTL and markers. The non-centrality parameter approximations of F-test statistics are derived to make power calculation and comparison, which show that the power of the F-tests is reduced due to the missingness. By simulation study, we show that the two models have reasonable type I error rates for a dataset of moderate sample size. The method are applied to analyze the angiotensin-1 converting enzyme (ACE) data.

CRISPLD2 and Nonsyndromic Cleft Lip with or without Cleft Palate. *B.T. Chiquet[1,2], S.H. Blanton[3], S. Stal[4], J.B. Mulliken[5], J.T. Hecht[1]* 1) University of Texas Medical School at Houston; 2) University of Texas Dental Branch at Houston; 3) Duke University Medical Center, Durham, NC; 4) Texas Children's Hospital, Houston; 5) Children's Hospital, Boston, MA.

Nonsyndromic cleft lip with or without cleft palate (NSCLP) is a common birth defect with a birth prevalence of 1/700 live births. NSCLP is a complex disorder postulated to be caused by multiple genes and environmental factors. Candidate gene testing has identified a number of genes that contribute to NSCLP. Previously, we identified a significant association with an allele in D16S3037 (p=0.000063), a STR marker at chromosome 16q24.1, and NSCLP. The cysteine-rich secretory protein LCCL domain containing 2 (CRISPLD2) gene is immediately 5 of D16S3037. CRISPLD2 was previously reported to be expressed in the placenta, brain and soft tissue, but the biologic function has not been identified. The proximity of CRISPLD2 to D16S3037 made it a prime candidate gene for NSCLP. SNP genotyping and *in situ* hybridization of CRISPLD2 was performed. Sixty-three multiplex NSCLP families and 287 simplex parent-child NSCLP trios were genotyped using TaqMan SNP genotyping assays for 15 SNPs flanking and spanning CRISPLD2. Fourteen of 15 SNPs were in HWE. There were significant allele frequency differences between Hispanic and non-Hispanic white populations for 8 of 15 SNPs. As a consequence, data analysis was performed separately for each population. In the white population, there was significant association between SNP rs1546124 and NSCLP (p=0.00167). rs1546124 is in exon 2, which is located 51 base pairs 5' of the CRISPLD2 protein start codon. Three additional nonsynonymous SNPs in the coding region of the CRISPLD2 protein have been identified and are currently being genotyped to test for association with NSCLP. To test if CRISPLD2 is expressed during craniofacial development, *in situ* hybridization was performed using a probe amplified from a RIKEN mouse cDNA clone of CRISPLD2. Preliminary results suggest that CRISPLD2 is expressed in the naso-/oropharynx area during mouse embryogenesis as well as other tissues (ie, liver). These results suggest that variation in CRISPLD2 may be involved in the etiology of NSCLP.

Trisomies 13 and 18: population rates, characteristics, and prenatal diagnosis, metropolitan Atlanta, 1994-2003.

K.S. Crider, R.S. Olney, J.D. Cragan National Center on Birth Defects and Developmental Disabilities, CDC, Atlanta, Georgia.

BACKGROUND: In recent years, prenatal diagnosis and elective pregnancy termination have affected the reported birth prevalence of trisomies 13 and 18. METHODS: We examined the prevalence and characteristics of these conditions using 1994-2003 data from a population-based surveillance system, the Metropolitan Atlanta Congenital Defects Program (MACDP). In 1968, MACDP began ascertaining structural defects and chromosome abnormalities among infants and fetuses born at 20 weeks gestation to residents of metropolitan Atlanta through hospital record reviews. In 1994, MACDP abstractors began to visit the offices of perinatologists to ascertain pregnancies diagnosed with defects prenatally. RESULTS: Inclusion of prenatal diagnoses increased the population prevalence (number of cases per number of live births) of trisomy 13 by 44.4% from 1:11,470 to 1:6,372 (n = 72) and of trisomy 18 by 44.7% from 1:4,498 to 1:2,493 (n = 184). Among affected pregnancies ascertained only from perinatal offices, 85.6% were electively terminated. Among all affected pregnancies, an amniocentesis was reported for 71.0% of those with trisomy 13 and 72.9% with trisomy 18. The reported rates of amniocentesis remained stable throughout the 10-year period. As expected, maternal age 35 years was a risk factor for both conditions. However, while 67.1% (n = 55) of the trisomy 18 case mothers were 35 years, only 46.9% (n = 15) of the trisomy 13 case mothers were 35 years. Among live births, 60.4% (n = 32) with trisomy 18 and 48.3% (n = 14) with trisomy 13 were female. In contrast, among electively terminated pregnancies (generally between 15 and 21 weeks gestation), only 48.3% (n = 43) of the fetuses with trisomy 18 and 42.4% (n = 14) of those with trisomy 13 were female. CONCLUSIONS: Inclusion of prenatal diagnoses from perinatal offices markedly increased our ascertainment of both trisomy 13 and trisomy 18 and affected characteristics such as sex ratios. Inclusion of pregnancies that are prenatally diagnosed is critical for accurate surveillance and population-based analyses of these conditions.

The design and performance of a genome-wide association study to identify genetic predispositions to rare adverse drug reactions. *M.G. Ehm[1], M.L. Jones[2], J. Almenoff[1], V. Ameen[1], S.-A. Bacanu[1], M.R. Barnes[1], T. Bhinder[1], S.R. Browning[3], K. Davies[1], S. Gordon[1], S. Haneline[1], K.S. King[1], E.H. Lai[1], M.R. Nelson[1], S. Ray[1], A.D. Roses[1], S. Subramanian[1], D.P. Yarnall[1], I. Johnson[1], L.C. McCarthy[1]* 1) GlaxoSmithKline, Res Triangle Park, NC; 2) North Carolina State University, Raleigh, NC; 3) University of Auckland, Auckland, New Zealand.

Adverse drug reactions (ADRs) can pose a serious threat to the health of patients receiving a drug as well as threaten the viability of an otherwise efficacious drug that is in development or even approved for marketing, if the potential benefits do not outweigh the risks. In many cases, genetics is believed to play an important role in determining ones risk of experiencing an ADR. We present the case of one drug which is associated with two relatively rare (~0.1%) and different ADRs. Due to the low frequency of these ADRs, only 9 cases of each ADR were ascertained using post-marketing data with informed consent for genetic research. We ascertained an additional 225 drug-treated patients that did not experience these ADRs as controls. After carrying out a pathway-focused candidate gene study, we completed a genome-wide association study using three available genetic marker panels: the Affymetrix 100K genechip, a custom 266,719 SNP panel from Perlegen, and the Affymetrix 500K Early Access genechip. Power to identify associations as well as the information captured by this comprehensive genome scan will be summarized. A small number of highly significant results were validated using alternative genotyping methods showing that as expected not all highly significant SNPs will be repeatable. A variety of analysis methods and plots were used, which ultimately identified a number of biologically relevant regions that may have future drug development and diagnostic value. We report the challenges and opportunities faced in conducting such a whole-genome screen and implications for future research on the genetics of ADRs.

Asthma and genes encoding components of the vitamin D pathway. *Y. Bosse[1], C. Laprise[2, 3], M. Lemire[1], J.H. White[4], T.J. Hudson[1]* 1) McGill University and Genome Quebec Innovation Centre, Montreal, PQ, Canada; 2) Community Genomic Medicine Centre, University of Montreal, Chicoutimi University Hospital, Chicoutimi, PQ, Canada; 3) Université du Québec à Chicoutimi, PQ, Canada; 4) Department of Physiology, McGill University, Montreal, PQ, Canada.

Genetic variants within the vitamin D receptor (VDR) gene were associated with asthma and atopy. We hypothesize that polymorphisms in other genes of the vitamin D endocrine system are associated with atopic and asthmatic phenotypes. Twelve candidate genes were chosen for this study. Genes encoded components of the vitamin D metabolism pathway (CYP27A1, CYP27B1, CYP2R1, CYP24A1, GC) or were known to be transcriptionally regulated by vitamin D (IL10, IL1RL1, CD28, CD86, IL8, TSLP, SKIIP). For each gene, we selected the maximally informative set of common SNPs (tagSNPs) using the CEPH HapMap dataset. These were genotyped in a French-Canadian family sample ascertained through asthmatic probands (422 nuclear families, 1277 persons) and evaluated using the FBAT program. For asthma, twelve SNPs located within five genes reached a p value threshold below 5%. CYP24A1, responsible for the inactivation of the active form of vitamin D, and IL10 showed the strongest and the most consistent results. Six out of the eight genotyped SNPs in the CYP24A1 gene were associated with asthma, atopy or IgE levels (range of p values = 0.049 to 0.002). For IL10, five SNPs out of the eight were associated with asthma (range of p values = 0.03 to 0.012). SNPs in the CYP2R1, IL1RL1 and CD86 genes also suggested association with asthma related-phenotypes (p 0.05). In conclusion, a number of genes involved in the vitamin D endocrine system demonstrated modest evidence of association with asthma-related phenotypes. Replication of positive findings is currently underway in two independent samples.

Identification of genes required for normal forebrain development using ENU mutagenesis. *D. Beier, A. Tilt, Y. Yun, R. Stottman* Div Genetics, Brigham & Women's Hosp/Harvard Medical School, Boston, MA.

The forebrain is the largest portion of the human brain and is responsible for higher order cognitive functions. Despite its central importance, many of the genes required for cortical development remain unknown. To address this, we have begun an ENU mutagenesis screen in the mouse. We use a 3-generation breeding strategy to obtain autosomal recessive mutations and observe for phenotypes at E18.5. This stage of development, just before birth, allows the embryo to survive with severe defects in organogenesis that would be lethal in a newborn animal. These should resemble birth defects seen in the human newborn population and provide animal models of clinical significance. Indeed, the utility of this approach has been validated by its application for the discovery of a causal gene for congenital diaphragmatic hernia (Ackerman et al., PLoS Genetics, 2005). Our approach is designed to be unbiased, which should serve to uncover novel or poorly annotated genes with a role in nervous system development, as well as implicate genes in brain development which have been previously characterized in other physiological settings. Our neurodevelopmental screen has three components: a) a morphologic examination complemented by histological analysis, b) use of a RARE-lacZ reporter allele to highlight distinct brain structures, and c) use of *Lis1* as a sensitizing mutation. While the screen is still in progress, we have already identified multiple lines of interest. Some of the mutations affect multiple tissues in the embryo, while others appear to be specific to the brain. The most intriguing phenotype shows severe cortical agenesis as well as defects in the appendicular skeleton. Other mutations show significant neuronal heterotopias or changes in brain size. Several phenotypes appear normal upon gross examination and are only detectable upon histological analysis. One line highlights the utility of a reporter allele as the phenotype is only revealed by the perturbation of its expression pattern in the cortex. Several mutants have been mapped using a whole-genome SNP genotyping panel (Moran et al., Genome Research 2006) and positional cloning is in progress.

The Keratodermas: Dilemmas in Diagnosis and Treatment. *R. Blackston[1], N. Brady[1], S. Dills[1], W. McLean[2]* 1) Div Med Gen, Dept Pediatrics, Emory Univ Sch Medicine, Atlanta, GA; 2) Ninewells Hospital and Medical School, Dundee, Scotland, United Kingdom.

The keratodermas are a heterogenous group of disorders of keratin accumulation usually of hands, feet, and pressure areas. Classification and nomeuclature are long, confusing. There are multiple etiologies; they can be chronically recurrent, and often debilitating. Advances in genetic DNA studies in recent years have brought greater clarity to the genetic mutations and variability of these disorders. The course of keratoderma can be chronically recurrent, painful, and debilitating with no specific therapeutics aside from supportive care such as soaking and debridement. The following case presentation manifests the difficulties of diagnosis, therapeutic interventions, and painful disability. R.R. was first seen at age 8 years, with onset peeling and accumulations of paraffin cakes on the soles of her feet at age 4 years. The waxy cakes thickened, were painful, and were treated with periodic debridement. The pain precluded weight bearing and often required narcotic pain medicines. She was described as having hyperkeratosis or possible psoriasis. Biopsies showed hyperkeratotic accumulations but did not clarify a specific diagnosis. At the first visit to our clinic, we noted thick paraffin like layers on the soles of the feet, thickened, sand-paper like feel of skin, and thick hair. She was bright, but in pain and required a wheel chair. Family history was negative for similarly affected relatives. A diagnosis of pachyonychia congenita was entertained. We referred to the pachyonychia project where she was able to get DNA studies for this rare dominant condition. Four keratin genes K 6A, K 6B, K16, K17, and also connexin 30 were performed in Dr. McLeans lab in Scotland, with all studies normal. Specific diagnosis remains unknown, though DNA studies of other keratodermas are being considered. This case indeed evidences the dilemmas faced by patients with these challenging disorders. Hopefully further DNA advances will elucidate the etiology, genetic patterns and new therapies.

Evaluation of Five Parameters Relating to Genetics Education in the International MD Program at Universidad Autónoma de Guadalajara, School of Medicine: Are There Implications for Enhanced USA-Mexico Collaboration in Genetics Education and Research? *J.S. Eperjesi[1,2], N.N. Batta[1,2], R.J. Samouh[1,2], M.A. Gutierrez-Franco[1,2], F.G. Martinez-Sandoval[1,2]* 1) Department of Medical Genetics, Universidad Autónoma de Guadalajara, Guadalajara, Jalisco, Mexico; 2) International MD Program, Universidad Autónoma de Guadalajara, Guadalajara, Jalisco, Mexico.

Substantive efforts are being made at Universidad Autónoma de Guadalajara School of Medicine (UAGSOM), the only medical school in Mexico with an international MD program (IP) and significant numbers of American students, to incorporate core competencies developed in recent years by the AAMC and ASHG into the medical genetics (MG) curricula. In this study, we investigated American student perceptions relating to MG education at UAGSOM in order to gain insights for 1)the advancement of genetics teaching by UAG faculty to American students and 2)the possibilities of exchange of knowledge, skills and attitudes in MG between USA and Mexico. We developed a student-centered survey for first semester US students enrolled in the IP who had taken the formal didactic course in MG from March-May 2006. It consisted of 5 questions to which students were asked to assign quantitative ratings as responses (i.e. 1=lowest; 5=highest); questions pertained to the utility of the MG course vis-a-vis clinical assignments in the Mexican community setting, and the importance of international collaboration between Mexico and USA for research, education and public awareness of genetics. All first semester US students (n=72) responded to the survey. Although other classes might be different, simple analysis by scantron technology warrants consideration as follows: 1) Mexican faculty is doing positive work in teaching MG to US students in a manner relevant for treatment of Mexican and international patients; 2)there is strong support among the students we surveyed for student-presentations as a learning tool for MG; 3)US students strongly support bilateral cooperation between Mexico and USA in the area of MG education, collaborative research and public awareness. This is an area we hope to pursue through fortifying relationships between experts in both countries.

Novel Unbiased Cloning Vectors, Methods, and Applications. *R. Godiska[1], N. Ravin[2], S. Vande Zande[1], V. Gilbert[1], D. Mead[1], C. Wu[1]* 1) Lucigen Corp., Middleton, WI; 2) Centre BioEngineering RAS, Moscow, Russia.

The quality of genomic libraries depends greatly on the cloning vectors and methods used for construction. Conventional cloning vectors create numerous clone gaps, due to inherent bias common to most plasmid, fosmid, and BAC vectors, including: 1) vector-driven expression of deleterious sequences, 2) insert-driven transcription into the vector that interferes with vector stability, 3) instability of secondary structures formed by tandem repeats and palindromic sequences, 4) supercoiling, and 5) unreliable antibiotic selection. The pSMART series of transcription free cloning vectors were developed to alleviate these problems. These vectors lack an indicator gene and associated promoter, have termination signals on either side of the insertion site, and are kanamycin or chloramphenicol resistant. The pSMART vectors show much higher stability of inserts containing AT-rich sequences, direct and inverted repeats, coding regions, or other deleterious DNAs. A novel E. coli cloning vector, pJAZZ, is stably maintained as a linear plasmid and incorporates transcription-free cloning capabilities. This linear plasmid shows unprecedented ability to maintain large AT-rich DNAs and di-, tri-, and tetra-nucleotide repeats. In standard BAC libraries, additional cloning bias and gaps are due to the preparation of DNA fragments. These libraries are based on partial restriction digestion of high molecular weight (HMW) genomic DNA. Because restriction sites are not evenly distributed across a genome, such BAC libraries are substantially biased, with numerous gaps. Generating as much as 20X genomic coverage in a partial-digest BAC library can not eliminate this bias. Whereas this problem may be avoided by randomly shearing HMW genomic DNA for BAC cloning, fragments larger than 100 kb are so fragile that no randomly sheared BAC library with large inserts has been reported. Recently we have successfully developed techniques to construct unbiased, randomly-sheared BAC libraries with large inserts (e.g., over 100 kb). With these novel techniques and tools, we are cloning previously unclonable DNA and working toward filling existing gaps in the human genome.

Texas institute for genomic medicine (TIGM): Knocking out all murine genes in embryonic stem cells. *R. Finnell[1], D. Markesich[2], G. Hansen[2], C. Friddle[2], A. Abuin[2]* 1) Texas Institute for Genomic Medicine, Houston, TX; 2) Lexicon Genetics, INC, The Woodlands, TX.

With support from the state of Texas, TIGMs mission is to create the worlds largest collection of mouse embryonic stem cells that have been engineered for the study of gene function, allowing researchers to identify genes that could lead to advancements in human healthcare. At the present time, TIGMs genetic resources include the Lexicon Genetics OmniBank I gene trap library of 275,000 ES cell clones in the 129 strain containing approximately 14,000 genes or 64% of the mouse genome. In addition, Lexicon Genetics has indicated a willingness to make available to TIGM, over time, mutated ES cell clones of up to an additional 3000 distinct genes, generated using gene targeting in 129 ES cells, pursuant to Lexicons existing contract with the National Institute of Environmental and Health Sciences (NIEHS) or similar arrangements contemplated under the NIHS repatriation initiative. There is an additional OmniBank II gene trap library under exclusive construction for TIGM that, when completed in early 2008, will contain 350,000 ES cell clones in the C57BL/6J strain containing approximately 16,000 genes or 73% of the mouse genome. TIGM has taken delivery of over 90,000 ES cell clones consisting of ISTs that have been mapped to the genome. This combined resource of genetically modified embryonic stem cells in two murine strains represents a unique resource that is intended to be widely distributed at reasonable costs to the academic and biotechnology research communities, to accelerate the pace of medical discoveries, and to foster the development of the biotechnology industry in Texas and worldwide.

Toward the development of an adolescent-focused framework for genetic counseling. *M.L. Galvin[1,2], C. Shuman[1,2], R. Babul-Hirji[1,2], D. Chitayat[1,2,3], M.J. Esplen[4], M. Kaufman[1,2]* 1) Hospital for Sick Children, Toronto, ON, Canada; 2) University of Toronto, Toronto, ON, Canada; 3) Mount Sinai Hospital, Toronto, ON, Canada; 4) Toronto General Hospital, Toronto, ON, Canada.

Adolescents undergo important emotional and cognitive developments, including increased autonomy and individuality. These developmental changes present unique challenges to medical professionals who work with this patient population. As the field of genetic counseling grows, genetic counselors are increasingly called upon to provide counseling to adolescents. Few studies have been published, however, regarding best practice guidelines for genetics health care providers to use when working with adolescent clients and their parents. The objective of the present study was to explore the challenges faced by genetic counselors when counseling adolescents. A focus group, consisting of eight genetic counselors who have experience working with adolescents, was facilitated in order to explore and describe the experiences of working with this population. The focus group was audio taped and transcribed. The transcriptions were coded for emergent themes using manual analysis. Focus group participants identified three domains that were particularly challenging: (i) balancing adolescent counseling and informational needs with parental needs, (ii) encouraging adolescent involvement in their own health care, and (iii) incorporating the developmental level of the adolescent in counseling and discussion of psychosocial issues. Genetic counselors also discussed what further information would assist them in addressing the identified challenges. Participants were interested in learning about developmental approaches to counseling adolescents and techniques for providing information to adolescent clients. The findings from this study were combined with information from the current adolescent medicine and psychology literature to develop a preliminary framework which offers specific techniques, resources, theories, and conceptualizations that genetic counselors can draw upon when working with adolescents. The ultimate goal of this framework is to enhance the genetic counseling encounter with adolescent clients.

A second-generation combined linkage-physical map of the human genome. *F. Chen[1], C. He[1], X. Kong[1], W. Chen[2], M. Hansen[4], F.L. Hyland[3], G.C. Kennedy[2], S. Murray[4], Y. Turpaz[2], F.M. De La Vega[3], J. Ziegle[3], T.C. Matise[1]* 1) Genetics Dept, Rutgers Univ., Piscataway, NJ; 2) Affymetrix, Inc., Santa Clara, CA; 3) Applied Biosystems, Foster City, CA; 4) Illumina, Inc., San Diego, CA.

Accurate and comprehensive linkage maps are critical for the success of positional cloning projects and other genetic studies. We have constructed a second generation high-resolution genetic map that includes a much larger set of polymorphic markers (N=28,219) than the first version and is consistent with the latest genome assembly (NCBI Build 36). To build the new combined linkage-physical map, a set of SNP genotype data including 5,172 SNPs from the Affymetrix Human Mapping 10K Array, 3,506 SNPs from the Applied Biosystems SNPlex Human Linkage Mapping Set 4k, and 4,782 SNPs from the Illumina Linkage IV Panel were collected and integrated into our existing data set (N=14,759). In the initial mapping stage, only markers with known physical positions were used and were added to the map only if the results of linkage analysis were consistent with physical position. Markers with no physical position were added in later steps using only linkage information. The data were also cleaned by removal of genotypes that are likely to be erroneous, identified as those that lead to close double-recombination events. Then markers whose linkage positions did not originally match physical position were re-evaluated against the more complete map. Finally, Those markers which still had discordant positions were assigned to map intervals determined by linkage analysis. This map represents the most comprehensive linkage map ever constructed. The average map resolution is 0.17 cM (127kb) between neighboring markers, with 58 percent of neighboring markers showing no recombination events. This map is a valuable tool for obtaining map distances for linkage studies to identify genetic loci. It is disseminated via our MAP-O-MAT website (http://compgen.rutgers.edu/mapomat).

Analysis of Genetic Polymorphisms Associated to Cardiovascular Disease in Mexican Mestizo Population. *E. Balam-Ortiz, J. K. Estrada, A. Inchaustegui, I. Silva-Zolezzi, K. Carrillo, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Cardiovascular diseases (CD) are the leading cause of death in Mexico.1-Adrenergic receptor (*ADRB1*), 2-adrenergic receptor (*ADRB2*) and angiotensin-II receptor type 1 (*AGTR1*), mediate the effects of catecholamines and angiotensin II, that increase heart rate, contractility, renin release and lipolysis. SNPs in these genes influence the risk for CD and the therapeutic response to -adrenergic antagonists. To evaluate geographical distribution of variants in these genes in Mexico, we genotyped 6 functional SNPs in 180 Mestizo volunteers from 5 states (n=880): Zacatecas (Zac), Sonora (Son), Yucatan (Yuc), Veracruz (Ver), and Guerrero (Gro). MAFs showed: 1) *ADRB1* 145A>G (rs1801252) Zac=0.20, Yuc=0.31, Son=0.28, Ver=0.33 and Gro=0.35; 2) *ADRB1* 1165C>G (rs1801253) Zac=0.18, Yuc=0.12, Son=0.14, Ver=0.1 and Gro=0.1; 3) *ADRB2* (rs1042713) Zac=0.42, Yuc=0.41, Son=0.44, Ver=0.37 and Gro=0.49; 4) *ADRB2* (rs17287411) Zac=0.19; Yuc=0.15, Son=0.23; Ver=0.13 and Gro=0.1; 5) *AGTR1* 43732C>T (rs5182) Zac=0.5, Yuc=0.39, Son=0.56, Ver=0.45 and Gro=0.42; and, 6) *AGTR1* 44325A>C (rs5186) Zac=0.36, Yuc=0.25, Ver=0.32, Son=0.29 and Gro=0.29. All variants were in HWE. Genotypic frequencies of *ADRB1* 145A>G were different ($p<0.005$) to those for Caucasians (CEU), Han Chinese (CHB), Japanese (JPT) and Africans (YRI) in dbSNP. Similar results were obtained for *ADRB1* 1165C>G except when compared to JPT. Unphased haplotypes and LD analysis between *ADRB1* 145A>G and 1165C>G showed complete LD in all states but Gro where LD was minimum. Haplotype blocks were compared with populations from the International HapMap Project, showing that all included states share a similar block structure with CEU, except Gro who was similar to YRI. This is consistent with Gro being a state with a higher African ancestral contribution. Our results show that SNPs in *ADRB1, ADRB2* and *AGTR1* in Mexican Mestizos have significant MAF differences between some states and, in some cases with other populations. This suggests genetic stratification in Mexican Mestizo population that may influence results in genetic association studies.

Allelic Frequencies of Polymorphisms Associated to Type 2 Diabetes in Mexican Population. *L. del Bosque-Plata, A. Inchaustegui, K. Carrillo-Sanchez,, G. Jimenez-Sanchez* Investigation, National Institue of Genomic Medicine, Mexico, D.F., Mexico.

Type 2 Diabetes (T2D) affects approximately 5% of the general population, with a prevalence in Mexico of ~10.8%. Increased genetic risk for T2D has been associated to specific polymorphisms in several genes. However, only a few of them have been replicated in different populations. More than 80% of the Mexican population is Mestizo, resulting from the admixture of any of the 62 ethnic groups living in Meso-America with Spaniards. To explore the hypothesis of different allele frequencies in T2D-associated genes in different geographic areas in Mexico, we analyzed SNPs in nine genes previously associated to the disease ($p<0.01$): sulfonylurea receptor (ABCC8), potassium inwardly-rectifying channel (KCNJ11), glucagon receptor (GCGR), peroxisome proliferator-activated receptor gamma (PPARG), hepatocyte nuclear factor 4A (HNF4A), solute carrier family 2, member 1 (SLC2A1), calpain-10 (CAPN10), glucokinase (GCK) and, transcription factor 7-Like 2 (TCF7L2). We included 1104 individuals from 6 states of Mexico: Guanajuato, Guerrero, Sonora, Veracruz, Zacatecas and Yucatan. Initial results include average of minor allele frequencies (MAF), as well as ranges between the lowest and highest frequencies by states:PPARG (rs1801282) G=0.12 (0.06-0.17);CAPN10 (rs297576) G=0.09(0.07-0.13);KCNJ11 (rs5219) T=0.39(0.36-0.44);HNF4A (rs2144908) A=0.49(0.43-0.58) and TCF7L2 (rs185384) A=0.19(0.15-0.26). We compared average MAFs from Mexican Mestizo population with that of other populations reported by the International HapMap Project. Interestingly, the KCNJ11 functional SNP showed a higher MAF in all states of Mexico (Zacatecas 0.45, Sonora 0.39, Veracruz 0.39, Guanajuato 0.38, Guerrero 0.37 and Yucatan 0.37) than that reported for Caucasians (0.34), Yorubans (0.08), Han Chinese (0.24) and Japanese (0.30). These results support the hypothesis that the Mestizo population has differences with other populations and between geographical regions within Mexico. This information will contribute to stratify populations in association studies and will increase our knowledge of genetic predisposition to T2D.

High resolution analysis of cytogenetic aberrations in hepatocellular carcinoma using oligo array CGH. *A. De Witte[1], L. Guo[2], J. Collins[1], Y. Dragan[2]* 1) Agilent Technologies, Inc., Santa Clara, CA; 2) National Center for Toxicological Research, FDA, 3900 NCTR Road, Jefferson, AR.

Hepatocellular carcinoma (HCC) is one of the most commonly occurring tumors in the world. The major etiologies of HCC are chronic hepatitis B virus (HBV) or hepatitis C (HCV) infection, exposure to aflatoxins, chronic liver disease and alcohol abuse. Chromosomal aberrations play an important role in liver cancer development and progression. In this study, we report the analysis of genomic changes in DNA samples collected from 11 HCC patients (aged 46-72; 10 male) comparing the neoplasms with the surrounding tissue from the same individual. Microarrays consisting of ~185,000 in situ synthesized 60-mer oligonucleotide probes optimized for array CGH (Comparative Genomic Hybridization) applications (Agilent Technologies) were used. We compare our results with published aberrations identified by lower resolution techniques such as conventional CGH based on the use of fluorescence in situ hybridization (FISH), spectral karyotyping (SKY) and BAC (bacterial artificial chromosomes) array-based CGH. We observed recurrent DNA copy number changes, including a characteristic 8p deletion and 8q amplification. We mapped several breakpoint regions associated with aberrations to the gene resolution level and we discovered novel small aberrations in several samples. Our results contribute to a more detailed description of genetic aberrations associated with HCC and demonstrate that oligo array CGH enables the mapping of breakpoints at a much higher resolution than traditional techniques.

Differential expression profiling of oral squamous cell carcinoma identifies the involvement of a major signaling pathway. *S. Chakraborty[1], S.M.A. Mohiyuddin[2], K.S. Gopinath[3], A. Kumar[1]* 1) MRDG, Indian Institute of Science, Bangalore, Karnataka, India; 2) RL Jalappa Hospital and Research Centre, Kolar, India; 3) Bangalore Institute of Oncology, Bangalore, India.

Oral squamous cell carcinoma (oral cancer) accounts for almost 40% of all cancers in India. Despite rapid advancement in therapeutic strategies, its low five-year survival period remains unchanged in the past two decades. Thus, finding a biological tumor marker to increase the early diagnosis and treatment monitoring rates is of paramount importance. To elucidate the molecular alterations underlying oral cancer, we employed the DDRT-PCR technique. Our DDRT-PCR profiling showed 51 fragments (cDNAs) that were differentially regulated. Of these, 27 fragments were confirmed as true differentials by reverse Northern analysis. Eight of the genes have been validated by RT-PCR in a panel of 16 matched normal and tumor patient samples and show potential as future therapeutic targets. One of the genes identified by DDRT-PCR has been shown to interact with another tumor suppressor gene which is an important regulator of a major signaling pathway. Investigation of the mechanism of downregulation of this tumor suppressor gene, which we observed in patient samples, led to the detection of loss of heterozygosity at the gene locus. Analysis of some of the key players of this pathway by RT-PCR revealed aberrant gene expression patterns. Hyperphoshorylation of some of the kinases in this pathway in oral tumors also indicated its constitutive activation. Probing the oral transcriptome by DDRT-PCR has identified some interesting genes not associated with oral cancers earlier. Our initial results seem to implicate the involvement of a major signaling pathway that may play a role in triggering the onset or progression of a subset of cancers of the oral cavity for the first time. The results will be presented and discussed (Financially supported by DBT and CSIR, New Delhi).

Karyotyping analysis in mentally retarded children and babies born with dismorphic features from Pediatric North-West India population. *B.S. Chavan, S. Mishra, A. Sehgal, G. Kaur* Genetic Centre,, Goverment Medical College and Hospital, Chandigarh, UT, India.

We have done karyotyping in 20 mentally retarded children, referred from mental retardation centre, GIMRC, Chandigarh. Five cases were diagnosed with trisomy 21, one child with mosaicism. Rest of the children were found having normal karyotyping, indicating other biochemical metabolic defects. Out of 30 cases with dismorphic feature referred by the Pediatric department we have reported ten cases of Downs syndrome, with mongoloid features muscular hypotonea, brachycephaly, protruding tongue, small low set ears upward sloping paplpebral fissures, single palmar crease, flat nasal bridge. It is noteworthy here that one case of Klinefelters syndrome with 47, XXY karyotype is also observed. The affected individual was 18 days old baby with the features of low set ears malformed right sided pinna, high arched palate, abnormal cry, wide spaced nipple, tuft of hair at sacral region, sandal gap in right foot, short neck and ambiguous genitalia and rest of the babies were observed to be with normal karyotype. In addition, we have done karyotype in 35 couples with recurrent spontaneous abortion and karyotype observed in these cases was normal, no gross translocation was observed.

Modeling the mutational effects on calcium binding to the epidermal growth factor (EGF) domain of fibrillin-1.

S-C. Chao[1,5], C-H. Tsai[2], Y-J. Lin[2], J-S. Chen[3], C-H. Lin[2], L. Chuang[4], J-M. Wu[2], S-J. Lin[2], H.S. Sun[1,3] 1) National Cheng Kung University, Institute of Molecular Medicine, Tainan, Taiwan; 2) Department of Pediatrics, National Cheng Kung University Hospital, Tainan, Taiwan; 3) Institute of Basic Medical Sciences, National Cheng Kung University Medical college, Tainan, Taiwan; 4) Department of Obstetrics and Gynecology, National Cheng Kung University Hospital, Tainan, Taiwan; 5) Department of Obstetrics and Gynecology, PingTung Christian Hospital, PingTung, Taiwan.

Fibrillin-1 gene (FBN1) encodes a key structural component of the elastin-associated microfibills of the extracellular matrix in connective tissues. Mutations in the FBN1 gene have been associated with a broad spectrum of disorders (i.e., the type I fibrillinopathies), including Marfan syndrome (MFS) and neonatal MFS (nMFS). Although previous studies of type I fibrillinopathies have shown remarkable clinical heterogeneity of the diseases, the underlying mechanism that causing the heterogeneity remains largely unknown. We have identified a novel heterozygous mutation in the exon25 of the FBN1 gene in a female newborn nMFS case. The G3208C (D1070H) mutation is located on the highly conserved calcium binding epidermal growth factor like domain 12 (cbEGF12). Because the base substitution is predicted to impair calcium binding onto this region, we further modeled the 3D structure of altered proteins to illustrate the conformational effect of this amino-acid substitution. Results of molecular modeling support the hypothesis that the base substitution affect calcium binding onto the cbEGF12 domain and severely damage the fibrillin-1 function. Our data suggest an important aspect to dissect the complicated correlation of genotype-phenotype link in type I fibrillinopathies as well as other phenotypically diverse disorders.

DFNB21 locus, the second cause of autosomal recessive non- syndromic hearing loss in Iranian population. *N. Bazazzadegan[1], N. Meyer[4], K. Kahrizi[1], M. Mohseni[1], P. Imani[1], S. Arzhangi[1], B. Azadeh[3], A. Daneshi[2], M. Farhadi[2], R.J.H. Smith[4], H. Najmabadi[1]* 1) Genetics Research Centre, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 2) Research Centre of Ear, Nose, Throat, and Head and Neck Surgery, Iran university of Medical sciences, Tehran, Iran; 3) Isfahan province welfare consultation centre, Isfahan, Iran; 4) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology Head and Neck Surgery, University of Iowa, IA, United States.

Background: Genetic factors are thought to account for approximately one half of cases of childhood hearing loss, the majority of which is non-syndromic and not associated with other abnormalities. The autosomal recessive non-syndromic hearing loss is associated with mutations in a majority of DFNB loci. Mutations in the gene encoding Alpha Tectorin (TECTA) are associated with both dominant and recessive modes of inherited hearing loss. Mutations in this gene previously have been reported in one family in Lebanese population therefore the objective of our study was to determine the prevalence of this gene in our population. Materials and methods:Eighty five families with autosomal recessive non-syndromic hearing loss with two or more affected children originating from different ethnic groups of Iranian population that were negative for GJB2 and GJB6 mutations, that are located on the most prevalent locus (DFNB1) of hearing loss, were screened for DFNB21 locus by linkage analysis . We used D11S1998, D11S4464, and D11S1299 STR markers for this study. Results: Four out of eighty four families were linked to this locus. Two novel mutations have been detected so far. In two families a 266 Del T mutation and a large 9611bp deletion that starts from intron 9 which includes exon 10 in TECTA gene were detected. Mutation detection of the other two families is performing. Conclusion: We concluded after DFNB1, Tecta gene mutations are responsible for the most prevalent cause of autosomal recessive non- syndromic hearing loss in Iranian population.

Investigation of four MCPH loci (MCPH1, MCPH2, MCPH3, MCPH5) based on Homozygosity mapping in 30 families. *S. Esmaeeli Nieh[1], S.S. Abedini[1], K. Kahrizi[1], F. Behjati[1], S. Ghasemi Firoozabadi[1], V. Hadavi[2], R. Vazifehmand[1], D. Habibi[1], M. Falah[1], A. W. Kuss[3], S. Banihashemi[1], H.H. Ropers[3], H. Najmabadi[1, 2]* 1) Genetics Research Center, University of Social Welfare & Rehabilitation sciences,Tehran, Iran; 2) Kariminejad and Najmabadi Pathology and Genetics Center, Tehran, Iran; 3) Max Planck Institute for Molecular Genetics, Berlin, Germany.

Microcephaly is defined as a reduction in head circumference and this clinical finding infers that an individual has a significant diminution in brain volume. Microcephaly can be usefully divided into primary microcephaly, in which the brain fails to grow to the correct size during pregnancy, and secondary microcephaly, in which the brain has the expected size at birth but subsequently fails to grow normally. Seven out of ten Non-Syndromic Autosomal Recessive Mental Retardation (NS-ARMR) loci are associated with microcephaly, including MCPH1-MCPH6 which belong to the family of MCPH (autosomal recessive primary microcephaly),and ARFGEF2. Based on MCPH heterogeneity studies in Pakistani and Indian population MCPH5, MCPH2, MCPH3, MCPH1 are more common MCPH loci. The objective of this study was to investigate four more common MCPH loci in 30 Iranian families. Each family was subjected to complete clinical examinations and karyotype abnormalities. We performed Homozygosity mapping by using STRs (Short Tandem Repeats) markers. In MCPH5 linked families, we amplified entire the ASPM gene In order to determine the mutations in this gene by using DNA-sequencing method. Among 30 families analyzed, 3 families were linked to MCPH5 locus,3/30 (10%), two families had genotype data which were consistent with linkage to the MCPH2 locus, 2/30 (6/7%), the remaining 25 families were not linked to these four loci, 25/30 (83/3%). So far, the results of DNA-sequence analysis of 1 families which were linked to MCPH5 locus, revealed a previously unreported mutation, C>T change at nucleotide position 3055 (c.3055C>T) in exon11 in a homozygous state resulting a mutation at codon position 1019 (R1019X). This novel mutation was associated with novel phenotype.

Evolutionary structural dynamics of macaque chromosome 6 neocentromere. *F. Antonacci[1], N. Archidiacono[1], A. Cellamare[1], P. DAddabbo[1], E.E. Eichler[2], M. Rocchi[1], M. Ventura[1]* 1) Department of Genetics and Microbiology, University of Bari, 70126 Bari, Italy; 2) Department of Genome Sciences, University of Washington School of Medicine, Seattle, Washington 98195, USA.

Evolutionary centromere repositioning is the ectopic seeding of a centromere in a new location along the chromosome coupled with the inactivation of the old centromere. The new centromere rapidly evolves the complexity that characterizes a normal centromere, by recruiting satellite DNA and by generating/recruiting pericentromeric segmental duplications. The dynamics of this rapid evolution is obscure. Our previous studies on the evolutionary history of human chromosome 6 disclosed that both macaque (Macaca mulatta, MMU) and human chromosome 6 centromeres were the result of centromere repositioning events that independently occurred in the Old World monkey ancestor and Hominoidea ancestor, respectively. Here we report on the assembly of ready-to-sequence BAC contigs spanning the centromeric transition of macaque chromosome 6. BAC-end sequencing and FISH analysis of these BACs provided a unique opportunity to compare the organization of the MMU6 evolutionary neocentromere with the fully-sequenced orthologous human region, at 6q24, representing the ancestral organization of the region before centromere seeding. The comparison revealed that the region involved in neocentromere reorganization was relatively small (~250 Kb), and that this short DNA segment was duplicated on both sides of the MMU centromere. These sequences were pushed apart to accommodate a large block of alpha satellite DNA, and the pericentromeric sequences were enriched with stretches of alphoid sequences. The region, in humans, appears to be a gene-desert, and no sequences from other pericentromeric regions were involved in the reshuffling.

The HUGO Gene Nomenclature Committee. *E.A. Bruford[1], M.W. Wright[1], K.M.B. Sneddon[1], T.P. Sneddon[1], M.J. Lush[1], V.K. Khodiyar[1], R.C. Lovering[1], C.C. Talbot Jr.[2], S. Povey[1]* 1) HUGO Gene Nomenclature Committee, University College London, London NW1 2HE, United Kingdom; 2) Johns Hopkins School of Medicine, Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD 21205-2196, USA.

The HUGO Gene Nomenclature Committee (HGNC) is an essential component of human genome management, and since 1989 has been the single authority for providing unique and user-friendly nomenclature for all genes in the human genome. Nomenclature is assigned primarily to protein-coding genes, pseudogenes and non-protein-coding (npc) RNAs, and to phenotypes and genomic features based on community requests; a recent area of interest has been the naming of variable copy number genes and npcRNAs. Approved gene symbols are based on names describing structure, function or homology wherever possible, and are stored in a searchable public database (www.gene.ucl.ac.uk/nomenclature) containing manually curated data and links to other databases. Researchers are encouraged to contact the HGNC (nome@galton.ucl.ac.uk) to confirm and request approved nomenclature for specific genes and gene groupings, and a panel of around 100 specialist advisors advise on the nomenclature of over 70 specific gene families. The HGNC have a very strong and active collaboration with the Mouse Genomic Nomenclature Committee (MGNC), which has proven essential in the parallel naming of orthologous human and mouse genes. A recent addition to the HGNC website is the HGNC Comparison of Orthology Predictions (HCOP) search tool which allows users to compare the orthology assertions between human, mouse, rat and chicken genes as predicted by various orthology resources. The HGNC has a strong working relationship with other database curation groups, and also actively add Gene Ontology (GO) annotation terms to the GO database. Many databases prominently display HGNC nomenclature; entering HGNC approved symbols into a search tool will allow the user to retrieve information about the genes, including the structure and function of the encoded proteins, known genetic variation and clinical phenotypes, and related genes both in humans and in other species.

A multiple testing correction method for genetic association studies using correlated single nucleotide polyphisms. *X. Gao* Dept Statistics, North Carolina State Univ, Raleigh, NC.

Multiple testing is a challenging issue in genetic association studies using large numbers of single nucleotide polymorphism (SNP) markers, many of which exhibit linkage disequilibrium (LD). Failure to adjust for multiple testing appropriately may produce excess false positives or overlook true positive signals. The Sidak and Bonferroni methods of adjusting for multiple comparisons are easy to compute, but are well known to be conservative in the presence of LD. On the other hand, permutation-based correction can correctly account for LD among SNPs, but is computationally intensive. Recent attempts to quickly and accurately adjust for multiple testing have lead to advances in both areas. However, given information about the degree of LD, these methods remain unnecessarily conservative or difficult to compute. In this work, we propose a new multiple testing correction method, $CLDM_{eff}$, for association studies using SNP markers. It is shown to be simpler and more accurate than the recently developed methods and is comparable to the permutation-based correction using both simulated and real data. The efficiency and accuracy of the $CLDM_{eff}$ method makes it an attractive choice for multiple testing adjustment when there is high intermarker LD in the SNP dataset.

Quantifying, testing and correcting for population stratification in association studies: a unified approach. *P. Gorroochurn[1], G.A. Heiman[2], S.E. Hodge[1,3], D.A. Greenberg[1,3]* 1) Division of Statistical Genetics, Department of Biostatistics, Columbia University, New York, NY; 2) Dept of Epidemiology, Mailman School of Public Health, Columbia University, New York, NY; 3) Clinical-Genetic Epidemiology Unit, New York State Psychiatric Institute, New York, NY.

The HapMap project has given association studies a tremendous opportunity to uncover the genetic basis of complex diseases. However, persistent issues in such studies remain the proper quantification of, testing of, and correction for population stratification (PS). In this paper, we propose a resolution of all these issues through a single quantity (). Previously, we defined a quantity , which can be estimated in a case-control study by using suitable neutral loci from the controls, and showed how this estimated value can be used to quantify and correct for PS. We now present a novel method to test for PS, based on the estimated value of . A major novel feature of our testing procedure is its ability to test for either (i) strictly any PS (i.e., H_0: =0), or (ii) only PS that is practically important (i.e., H_0: $=_0$, where $_0$ is the minimum value of interest to the investigator). We performed simulations to compare our correction procedure with genomic control (GC). Our simulations show that, when =.05, GC becomes over-conservative when 1.0 (rejecting at an average rate of only 2.5%), and loses considerable power when 2.0. In contrast, our correction procedure maintains good Type I error rates and power for all values of , i.e. across all levels of PS.

Milroy disease: Prenatal diagnosis and phenotypic variability within a family. *T.A. Burrow, M.J. Walker, R.J. Hopkin* Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Milroy disease, congenital hereditary lymphedema, frequently results from mutations in *VEGFR3*, with consequential abnormal embryonic development and function of the lymphatic system. Congenital lower extremity lymphedema is the most common presentation. Severity is usually mild to moderate; however, it is quite variable and more severe manifestations have been reported. We describe a two-generation family including four individuals with Milroy disease who exhibit a very broad spectrum of phenotypic features.

The proposita is a 26-year-old Gavida 4, Para 4 Caucasian whose congenital lower extremity lymphedema resolved spontaneously by one year of age with no further symptoms. Three of her four children were also affected. Her first child was prenatally diagnosed with lower extremity lymphedema and a cystic hygroma; the latter resolved prior to delivery. At birth, he had a webbed neck, mild dysmorphic features, and lower extremity lymphedema. The lymphedema has improved, but still persists. At eight years of age, he was diagnosed with osteosarcoma of the right leg. Her second pregnancy resulted in the neonatal death of a male infant with lymphedema, IUGR, and anhydramnios due to ureteral obstruction, which were diagnosed prenatally and at autopsy. In her third pregnancy, a female was prenatally diagnosed with lymphedema, cystic hygroma, and pericardial and pleural effusions. At birth, a webbed neck and mild pedal edema were observed. The child experienced significant pulmonary disease due to chronic pleural effusions and pulmonary lymphangiectasia, which gradually improved over time. In addition, she exhibited failure to thrive, which improved with intervention.

This family illustrates the broad degree of phenotypic variability and serious complications that can be observed in Milroy disease. Fetal ultrasonography is useful in prenatal diagnosis of Milroy disease in at-risk families, and in this family, reveals the dynamic nature of the disorder between the prenatal and postnatal periods.

Simple Correction for Population Stratification Using a Novel Confounder Score. *M.P. Epstein[1], A.S. Allen[2], G.A. Satten[3]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Dept of Biostatistics & Bioinformatics, Duke Univ, Durham, NC; 3) Centers for Disease Control and Prevention, Atlanta, GA.

Case-control studies of disease-gene association must often correct for potential bias resulting from the effects of population stratification. We propose a novel correction based loosely on the confounder-score approach of Miettinen (1976). Using data from all subjects, our approach first models the probability of disease as a function of genotypes at a number of null loci using either logistic regression or, if the number of null loci is large (which may be the case in whole-genome association analyses), a high-dimensional procedure such as partial-least squares. We next use the predicted probability of disease given the null-loci genotypes to assign subjects to different strata and subsequently use the stratum assignment as a covariate in a logistic-regression model to assess association between a locus of interest and disease. The resulting association between a genotype at a locus of interest and disease is valid even if population stratification exists in the sample. We feel the confounder-score approach is computationally simple and has the ability to use an enormous number of (correlated) null loci to infer substructure. Additionally, the approach makes fewer modeling assumptions than existing approaches and can easily be extended to haplotype or other kinds of multi-locus association analyses. We will illustrate our approach using both real and simulated data.

A MULTICENTER, OPEN-LABEL STUDY TO EVALUATE THE SAFETY AND RESPONSE TO AN 8-DAY COURSE OF SAPROPTERIN DIHYDROCHLORIDE(TETRAHYDROBIOPTERIN or 6R-BH4) IN SUBJECTS WITH PHENYLKETONURIA (PKU) WHO HAVE ELEVATED PHENYLALANINE LELELS.

B.K. Burton[1], D. Grange[2], A. Milanowski[3], J. Vockley[4], V. Abadie[5], C. Harding[6], E. Crombez[7], D. Dobbelaere[8], A. Smith[9], A. Dorenbaum[10] 1) Children's Memorial Hospital, Northwestern University Feinberg School of Medicine, Chicago, IL; 2) St. Louis Children's Hospital, Washington University School of Medicine, St. Louis, MO; 3) Instytut Matki i Dziecka, Warszawa, Poland; 4) Children's Hospital of Pittsburgh, Pittsburgh, PA; 5) Hôpital Necker-Enfantes Malades Pediatrie Generale, Paris, France; 6) Oregon Health & Science University, Portland, OR; 7) UCLA Medical Center, Los Angeles, CA; 8) CHRU de Lille - Hôpital Jeanne de Flandres, Lille, France; 9) Pacific Data Designs, San Francisco, CA; 10) BioMarin Pharmaceutical, Inc., Novato, CA.

Sapropterin can lower phenylalanine (Phe) levels in patients with PKU and may provide a novel approach to treatment. To identify patients for enrollment in a Phase 3 study, we conducted a multicenter, open-label trial and evaluated the safety and response to an 8-day course of sapropterin. A total of 490 subjects were enrolled with minimum blood Phe levels of 450uM. 485 subjects completed the 8-day (1 day) course of sapropterin 10mg/kg/day and had blood Phe level results for baseline and day 8. The percent of subjects who experienced a 30% Phe drop from baseline on day 8 was 54.4% (31/57) in subjects with baseline Phe 600uM, 23.6% (37/157) in subjects with baseline Phe 600 to 900 uM, 9.6% (13/135) in subjects with baseline 900 to 1200uM, and 7.4% (10/136) in subjects with baseline Phe 1200uM. Among responders, mean(SD) blood Phe levels were 784.0 (294.8)uM on day 1 and 390.6 (207.9)uM on day 8. The mean (SD) change in blood Phe levels was -393.4 (188.3)uM. The majority of adverse events were mild and all events resolved without complications. None of the events were assessed as clinically significant. Sapropterin was well tolerated and effective in rapidly reducing Phe levels in PKU patients across the entire spectrum of PKU phenotypes. These results are consistent with prior data on PKU response to 6R-BH4.

Identification of novel genes contributing to the severity of phenotype in chromosome 17 rearrangements. *S. Girirajan[1], S.R. Williams[1], J. Garbern[3], D.J. Bunyan[4], E. Hatchwell[5], S.H. Elsea[1, 2]* 1) Department of Human Genetics; 2) Department of Pediatrics, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA; 3) Departments of Neurology and Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI; 4) Wessex Regional Genetics Laboratory, Salisbury District Hospital, Wiltshire, Salisbury, U.K; 5) Cold Spring Harbor Laboratory, Genome Research Center, Woodbury, NY.

Rearrangements due to homologous and non-homologous mechanisms involving region-specific low copy repeats or segmental duplications cause deletions/duplications in disease-associated genomic regions. While a number of clinical cases of multiple congenital anomalies/mental retardation syndromes can be attributed to deletions and duplications pertaining to a single chromosomal region, sometimes the variability and severity of the phenotype warrants further molecular studies. To delineate the chromosomal extent of the deletion/duplication and also to identify other possible genomic rearrangements that contribute to the severity of phenotype, whole genome array-comparative genomic hybridization (aCGH) was performed on a cohort of previously diagnosed cases of 17p11.2 rearrangements. The results obtained were confirmed by fluorescent *in situ* hybridization (FISH) using locus-specific probes, while some breakpoints were confirmed at a higher resolution by multiplex ligation-dependent probe amplification (MLPA). Two genes, amiloride sensitive cation channel 1 (*ACCN1*) and glutamate receptor, ionotropic, kainate 3 (*GRIK3*) were shown to have de novo copy number changes in two patients with rearrangements on chromosome 17, respectively. *ACCN1* has been implicated in retinal degeneration in mouse models. Further, our patient with deletion breakpoints encompassing *ACCN1* has significant retinal changes suggesting a causative role for this gene in retinal pathology in this patient. The severity and complexity of the phenotype in these individuals prompted these studies and indicate the importance of considering aCGH to identify genes in other genomic regions that may contribute to the phenotypic variability and severity in known chromosomal disorders.

An association study of ninety-three candidate genes in bipolar disorder. *D. Absher[1], J. Li[1], R.C. Thompson[2], M. Burmeister[2], L.J. Scott[2], Y. Li[2], F. Meng[2], W. Guan[2], M.P. Vawter[4], P. Choudary[3], H. Tomita[4], S.J. Evans[2], W.E. Bunney[4], E.G. Jones[3], J.D. Barchas[5], A. Schatzberg[1], H. Akil[2], S.J. Watson[2], M. Boehnke[2], R.M. Myers[1]* 1) Stanford Human Genome Center, Palo Alto, CA; 2) University of Michigan, Ann Arbor, MI; 3) University of California Davis, Davis, CA; 4) University of California Irvine, Irvine, CA; 5) Cornell University, New York, NY.

Bipolar disorder is a psychiatric disease with a prevalence of ~1% in all human populations. It displays strong familial aggregation and is thought to result from a complex genetic etiology involving multiple genes. While linkage studies have identified some loci of interest, few of these have been confirmed in subsequent studies. We have undertaken a candidate gene approach that involves genotyping 476 bipolar cases and 470 controls for 1,536 SNPs located in 93 genes. The bipolar cases are from the NIMH Human Genetics Initiatives collection and the controls are ethnically matched NIMH control samples that have completed a psychiatric screen. We selected genes for this study based on their association with bipolar disease in previous studies, as well as their aberrant expression in our microarray experiments with human brain mRNA, and their implication in animal models with similar phenotypes. For each of the 93 genes, we selected SNPs from HapMap II to cover all LD bins (r2 > 0.8) containing SNPs with a MAF >= 5%. All genotyping is being performed with Illuminas GoldenGate platform. We will present our preliminary findings.

Autosomal dominant Vocal Cord and Pharyngeal Weakness with Distal Myopathy (VCPDM, MPD2, 5q31): Refinement of the candidate interval and identification of a second VCPDM family. *S.M. Garvey[1], J. Senderek[2], I. Tournev[3], C. Stendel[2], A. Urtizberea[4], V. Guergueltcheva[3], V. Mihailova[3], H. Feit[5], J. Weis[2], H. Lochmüller[6], J.S. Beckmann[7], E. Seboun[8], M.A. Hauser[1], C.E. Jackson[9]* 1) Center for Human Genetics, Duke University Medical Center, Durham, North Carolina, USA; 2) Aachen University of Technology, Aachen, Germany; 3) Department of Neurology, Sofia Medical University, Sofia, Bulgaria; 4) AFM et Généthon, Evry, France; 5) Department of Neurology, Henry Ford Hospital, Detroit, Michigan, USA; 6) Department of Neurology, Friedrich-Baur-Institute, Ludwig-Maximilians-University, Munich, Germany; 7) Department of Medical Genetics, University of Lausanne and Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 8) Division de Génétique et de Microbiologie, Université Pierre et Marie Curie, Paris, France; 9) Department of Medicine, Scott & White Memorial Hospital, Temple, Texas, USA.

Vocal cord and pharyngeal weakness with distal myopathy (VCPDM) is a late-onset, progressive, autosomal dominant neuromuscular condition. VCPDM had been mapped to an 11.8 Mb interval on chromosome 5q31 in a large family from the US. We were able to identify two newly affected patients within the original pedigree. Linkage analysis using densely spaced STR markers from the candidate interval disclosed a critical recombination event in both patients. This reduced the critical region to 5.3 Mb between newly established STR markers AC108764 and AC089765. This interval still contained 62 genes. The most promising candidate gene was *myotilin* (*MYOT*) as *MYOT* mutations cause a similarly progressive and adult-onset muscle disease. However, defects in *myotilin* were widely excluded by various experimental approaches. We studied additional families with a distal myopathy and with or without accompanying vocal cord paralysis by linkage analysis, identifying a large Bulgarian family that also showed linkage to the VCPDM region. The families do not share a common disease haplotype indicating that they probably carry different mutations in the so far unknown VCPDM gene. Mutation screening of candidate genes is currently underway.

Polymorphisms in the integrin super gene family associated with obesity and type 2 diabetes in Japanese American and Japanese population. *T. Awaya[1], Y. Yokosaki[1], F. Higashikawa[1], K. Yamane[2], N. Kohno[2], A. Eboshida[1]* 1) Department of Public Health, Graduate School of Biomedical Sciences, Hiroshima University, Hiroshima, Japan; 2) Department of Molecular and Internal Medicine, Graduate School of Biomedical Sciences, Hiroshima University, Hiroshima, Japan.

Integrins are heterodimeric cell surface glycoproteins that mediate cell-cell and cell-matrix adhesion. Although several polyphorphisms in the integrin gene family are reported to be associated with cardiovascular risks, involvement of genetic variation in this family in obesity or type 2 diabetes is undetermined. In the present study we analyzed 9 SNPs in the integrin gene family, L(Thr402Arg), M(Thr400Met), V(Ile405Val), 2(C804T), 4(Gln844Arg), 9(Gln30Glu), 1(A1176C), 2(C1323T) and 3(Leu33Pro), for obesity and type 2 diabetes. Genomic DNA was isolated from 651 peripheral blood samples, 274 Japanese American in Hawaii(68.713.4 y.o.) and 377 Japanese in Hiroshima(55.312.2 y.o.), and subjected to PCR-RFLP or TaqMan analysis for the polymorphisms. In these 2 populations, where genetic back grounds were homogeneous, it has been reported that Japanese Americans were highly exposed to an American lifestyle, a relatively high fat and simple carbohydrate diet with low physical activity compared to native Japanese. Obesity was defined as body mass index 25 kg/m2 and type 2 diabetes according to WHO criteria, and association was analyzed by logistic analysis adjusted for age and sex. There was no difference in allele frequencies among the 9 SNPs between the 2 populations. We found that 1) C1323T in 2 subunit was associated with obesity in Japanese American population (OR 3.00, 95%CI=1.2 to 7.7, p=0.03, TT vs. CT, CC) but not in Japanese population and 2) Gln844Arg in 4 subunit with type 2 diabetes in Japanese population (OR 5.56, 95%CI=1.1 to 23.3, p=0.04, Gln/Gln vs. Arg/Gln, Arg/Arg) but not in American Japanese population. These results suggest that C1323T polymorphism in 2 subunit appears to be associated with obesity that mainly affected by environmental factors, whereas Gln844Arg in 4 subunit might reflects susceptibility of type 2 diabetes that is genetically regulated and environmentally insensitive.

Under- recognized early manifestation of Prader Willi syndrome. *Y.S. Choy[1], L.H. Ngu[1], W.T. Keng[1], S.K. Tan[3], Ruziana[2], L.C. Bok[3], M. Aminah[2], M.Z. Nirzila[4]* 1) Genetics and Metabolism, Kuala Lumpur Hospital, Kuala Lumpur, Malaysia; 2) Cytogenetic Unit, Kuala Lumpur Hospital; 3) Division of Molecular Pathology Institute of Medical Research, Malaysia; 4) Respiraotry Unit, Pediatric Institute, Kuala Lumpur Hospital.

The well recognized presentation of Prader Willi syndrome (PWS)is characterized by infantile hypotonia , inactivity,failure to thrive and developmental delay followed by childhood obesity. Mortality and morbidity in older individuals were associated with cardio-respiratory insufficiency, diabetes mellitus and obstructive sleep apnoea. The availability of molecular test had enabled us to make early diagnosis in these individuals. In our cohort of 75 patients with PWS, 46 of them (61%) were diagnosed in early infancy and 15 of them (20%) were diagnosed in neonatal period as early as 2nd day. In those diagnosed early, 28 (37%) had recurrent admissions for acute life threatening events (ALTE) in infancy. ALTE was found to be significantly associated with aspiration pneumonia($p<0.001$), sleep disordered breathing($p<0.001$), dilated cardiomyopathy ($p<0.001$)and pericardial effusion ($p<0.01$). Sixteen of them required nasogastric feeding but 10 of them still had respiratory insufficiency,pH study proved significant gastroesophageal reflux disease in them. Six had dilated cardiomyopathy and 3 succumbed. Four had recurrent pericardial or pleural effusion associated with hypothyroidism. Seven of them had proven sleep disordered breathing, which was significantly associated with dilated cardiomyopathy and ALTE. If left untreated it has poor prognostic outcome but home oxygen therapy and vigorous airway management resulted in general clinical improvement. In the second group diagnosed after infancy, they had less feeding problems and none had pneumonia. They presented with neurodevelopmental delay associated with short stature and obesity. Stringent dietary control and vigorous rehabilitative program significantly affected their final outcome. In conclusion, PWS can be usefully classified into 2 major clinical types for management purposes, the severe infantile and the milder childhood type, both having all molecular classes of PWS.

Powerful and efficient whole genome haplotypic analysis using Beagle. *B.L. Browning, S.R. Browning* The University of Auckland, New Zealand.

We show that our variable-length Markov chain (VLMC) haplotypic analysis method [1] can be implemented efficiently to perform haplotypic analysis of whole genome association studies (hundreds of thousands of markers and thousands of samples), and we show that the VLMC method gives increased power to detect low frequency risk-conferring variants relative to single marker tests.

The VLMC model has several advantages over standard haplotypic analysis: there is no need to identify haplotype blocks or choose a haplotype window size, and the model automatically adapts to correlated markers, yielding good power regardless of whether tagging markers are used. The VLMC model automatically clusters similar haplotypes to balance the number of haplotypic tests and information extraction.

Using simulated data that closely approximate empirical data, we show that the VLMC haplotype clusters are more highly correlated than single markers with low frequency disease alleles. Combining single marker and haplotypic tests gave markedly increased power to detect low frequency risk-conferring variants while maintaining power to detect high frequency risk-conferring variants.

We have implemented the VLMC algorithm in a new software package called Beagle. Running time for Beagle is linear in the number of markers and between linear and quadratic in the number of samples. Haplotypic analysis of a phased, real data set of 6600 markers covering 40 Mb genotyped on 1750 samples completed in 3.5 minutes using a single processor. Thus, after phasing data, single marker and haplotypic analysis on 500K markers and 4000 samples can be performed on a single processor in less than 24 hours. Beagle is easy-to-use and can perform allelic and genotypic tests for both single-markers and haplotypes. Beagle can also perform permutation testing to identify markers or haplotype clusters that reach region-wide or genome-wide significance.

POLAR BODY VS. BLASTOMERE BIOPSY FOR PGD. PB OR NOT PB? *G. Altarescu[1], T. Eldar-Geva[1], B. Brooks[1], Y. Kaplan[1], M. Patt[1], E.J. Margalioth[1], A. Lahad[2], E. Levy-Lahad[1], P. Renbaum[1]* 1) Zohar PGD Lab, and IVF unit, Shaare Zedek Medica Center, Jerusalem, Israel; 2) Department of Family Medicine, Hebrew University, Jerusalem, Israel.

PGD may be performed by biopsy of polar bodies(PB) 1 and 2,or blastomeres from 6-8 cell embryos. PB biopsy allows PGD analysis without removing embryonal cells, and for inconclusive cases, a repeat analysis using a blastomere can be performed. Blastomere-PGD allows direct analysis of both maternal and paternal alleles, but is purportedly associated with higher rates of allele drop-out (ADO). We compared the efficiency of biopsy, molecular diagnosis, ADO, and pregnancy rate (PR) for PB vs. blastomere based PGD. Cases of maternal autosomal dominant (AD), X-linked, and autosomal recessive diseases underwent PB-PGD. Blastomere PGD was done for paternal AD diseases, and when an insufficient number of wild-type oocytes were diagnosed by PB analysis. Samples without results for at least one polymorphic marker on either side of the mutation in addition to the mutation itself (or another internal marker) were considered inconclusive. We analyzed 78 cycles of PGD (901 total biopsies) in 48 couples both by intention to treat and actual treatment.35% of cycles were PB only,50% were blastomere only, and 15% had combined PB and blastomere testing. Biopsy success rates were similar for both PB and blastomeres (95%). Successful molecular diagnosis was significantly higher for PB-PGD(88%), vs blastomere-PGD(76%,p=0.02). ADO rate in 947 reactions was significantly lower in PB (5%) vs. blastomeres (16%,p=0.001). Both by interntion to treat and by actual treatment, there was a trend towards higher PR per embryo transfer in PB-PGD (40%) vs blastomere-PGD (23%). The number of embryos transferred was significantly associated with PR (OR 2.4 per additional embryo, p=0.04),and significantly more embryos were available for transfer in PB-PGD vs. blastomere-PGD(p=0.02). PB-PGD leads to a lower ADO rate and a significantly higher diagnosis rate, compared to blastomere-PGD. Pregnancy rate was higher with PB-PGD, possibly because PB-PGD yielded a significantly higher number of embryos available for transfer.

A 2p12 locus with two co-regulated genes is associated to dyslexia in Finnish and German populations. *H. Anthoni[1], M. Zucchelli[1], H. Matsson[1], J. Schumacher[2], J. Nopola-Hemmi[3], H. Lyytinen[4], G. Schulte-Körne[5], J. Kere[1,6], M.M. Nöthen[7], M. Peyrard-Janvid[1]* 1) Dept of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 2) Institute of Human Genetics, University of Bonn, Germany; 3) Dept of Pediatrics, Jorvi Hospital, Finland; 4) Dept of Psychology and Child Research Center, University of Jyväskylä, Finland; 5) Dept of Child and Adolescent Psychiatry and Psychotherapy, University of Marburg, Germany; 6) Dept of Medical Genetics, University of Helsinki, Biomedicum, Finland; 7) Dept of Genomics, Life & Brain Center, University of Bonn, Germany.

Developmental dyslexia is a common, complex disorder characterized by an unexpected difficulty in learning to read despite normal intelligence, senses and education. Genetic loci have been mapped to at least eight different chromosomes, and four candidate genes have been proposed: *DYX1C1*, *DCDC2*, *KIAA0319* and *ROBO1*. We refined our reported 12 Mb dyslexia locus on 2p12 in 19 Finnish kindreds. TDT analysis gave significant p-values for individual markers (p=0.003) and for a four-marker haplotype (p=0.004). The results were replicated on 251 families from Germany, and an overlapping haplotype was identified (p=0.02). To further focus on the 157 kb susceptibility region, marker density was increased to one SNP every 8 kb. Two significant (p=0.005 and p=0.001) overlapping risk haplotypes covering 16 kb were identified in both populations separately and in a joint analysis. Stratification for dyslexia severity on the German sample set increased the OR for the most significant haplotype from 2.2 (p=0.006) to 5.2 (p=0.00005). We characterized thoroughly the three genes in the region, including quantification of gene expression in different parts of brain. Two neighboring genes flanking the associated haplotype were highly co-expressed in fetal and adult brains and in nine separate brain regions. Mutation screening of these two genes in the Finnish families revealed 11 coding changes, with five previously unknown and eight nonsynonymous. We conclude that the two co-regulated transcripts flanking a highly dyslexia-associated haplotype block are excellent candidates for novel dyslexia genes near the *DYX3* locus.

Glutathione-S-Transferase M1, T1, and P1 polymorphisms in childhood asthma from the INMA study: assessing the effects of passive smoking on allergy and wheeze. *F. Castro-Giner[1], M. Àlvarez[1], M. Torrent[2], J. Sunyer[1], X. Estivill[3], R. de Cid[3] on behalf of the INMA Study Group* 1) Centre for Research in Environmental Epidemiology, Municipal Institute of Medical Research, Barcelona, Spain; 2) Area de Salud de Menorca, INSALUD, Menorca, Spain; 3) Gene and Disease Program. Barcelona Node -Spanish Genotyping Center (CeGen), Center for Genomic Regulation (CRG) and University Pompeu Fabra (UPF), Barcelona, Catalonia, Spain.

Asthma is a complex multifactorial disease with a well-defined genetic predisposition and involvement of environmental factors. The glutathione S-transferases (GSTs) are a family of enzymes that protect against oxidative stress by detoxifying various toxic substrates. Several authors suggest a role in asthma pathogenesis for the *GSTT1*, *GSTM1* and *GSTP1* polymorphisms related to modulation of reactive oxygen species (ROS). *GSTM1*, *GSTT1*, and *GSTP1*, have several well-defined genetic polymorphisms named GSTM1-0 and GSTT1-0 in the *GSTM1* and *GSTT1*, respectively, that are null alleles and result in nonfunctional protein, and a common coding polymorphism (105Ile/Val substitution) in the *GSTP1* which has been shown to result in altered catalytic activity. In the present study, GSTT1, GSTM1 and GSTP1 polymorphism are examined related to wheeze, allergy and EST in a children cohort from the Spanish INMA study (Childhood and Environment; http://www.infanciaymedioambiente.org/)(n=373;49%male). We have implemented two semiautomated assays to facilitate the detection of null alleles from *GSTM1*, and *GSTT1*, and the coding variant Ile150Val from the *GSTP1*. Detection of (1) the GSTM1 and GSTT1 null alleles was performed with a modified method from that initially described elsewhere, using a multiplex reaction with a fluorescent-labeled primers assay using the Automated DNA Analyzer ABI XL3100, and (2) analysis of Ile150Val variant in the *GSTP1* with an implemented assay using the Pyrosequencing technology. Frequency of the null alleles were similar to those described in other European populations; 64% for GSTT1-0, 20% for GSTM1-0. Double null genotypes were present in 12% of the individuals analyzed. This work is supported by the FIS:PI04/1705 and Genome Spain.

Induce Mitochondrial mediated apoptosis pathway in Breast cancer tumoral cells lines. *A. Ebrahimi[1,2], M. Houshmand[1], S. Zeinali[2], M. Karimpoor[2], H. Galehdari[3], M. Rostami[1], F. Talebzadeh[1]* 1) Medical genetics, NRCGEB,Tehran, Iran; 2) Biotechnology,Pasture Institue,Tehran, Iran; 3) Genetics Dep. ,Science Faculty, Chamran University, Ahwaz,Iran.

Modulation of apoptosis can be used to treat cancer.The power of apoptosis could be used to alleviate many human diseases. This project focuses on the potential of using apoptosis to treat cancer. Cancer is very common in the developed world such that 1 in 3 people will develop cancer at some point during their lives.apoptosis is a conserved process and so once an effective treatment has been discovered for a particular cancer type, it should be much easier to modify that treatment for other cancer types. Examination of the pathways leading to apoptosis shows many possible points where intervention may be possible.To maintain homeostasis in the human body, an estimated 10 billion cells are made each day just to balance those dying by apoptosis!Death triggering stimuli can take the form of 1)Lack of survival signals e.g. cytokines, growth factors, hormones or 2)Positive inducers of apoptosis (death signals) e.g. receptor ligation, DNA damage (via p53), toxic agents.Different cells exhibit different thresholds to various pro-apoptotic stimuli. For example splenic lymphocytes readily undergo apoptosis when exposed to ionising radiation whereas myocytes are resistant to apoptosis on similar exposure.Two main integration pathways exist and converge to a common execution phase:Death receptor pathway and Mitochondrial pathway.We have designed a double stranded (ds)RNA and The aim of our investigations is to dissect the molecular machinery which mediates gene silencing by antisense RNA and RNAi to trigger mitochondrial mediated apoptosis pathway in tumoral cell lines.

Characterization of expressed anti-parallel transcription units in male germ cells. *W.Y. Chan, S.M. Wu, L. Hovrath, L. Ruszczyk, E. Mikhaylova, O.M. Rennert* Laboratory of Clinical Genomic, National Institute of Child Health and Human Development, NIH, Bethesda, MD.

Transcriptome mapping of developing murine male germ cells using Serial Analysis of Gene Expression (SAGE) revealed the prominent presence of antisense transcripts. Nucleotide sequence analysis of orientation specific RT-PCR products and cloned antisense transcripts showed that the antisense transcripts of four genes, namely,*Uba52*, *Ch10*, *Calm2*, and *Ubb*, were derived from their pseudogenes on different chromosomes. Blasting against the mouse genome showed that these pseudogenes are present in the intron of actively transcribed genes. *Uba52* pseudogene resides in the intron of *Cbx1*; *Calm2* pseudogene is present in the intron of *Prkar2b*; *Ch10* pseudogene is contained in the intron of *Sp3*; and *Ubb* pseudogene resides in the intron of *Catsper2*. Apparently, these pseudogenes were retrotransposed and inserted into the intron of the host genes. The direction of transcription of the functional parent gene is opposite to that of the host gene. Because of the high homology between the functional transcript and its pseudogene, pairing of the pseudogene antisense transcript and the functional transcript would occur. This speculation was supported by the demonstration of the presence of duplex RNA of *Uba52* in cultured cells. For *Uba52*, *Ch10* and *Calm2*, there is no evidence that the antisense strand of the pseudogene is transcribed, and the identified antisense amplicons are likely to be derived from the spliced intron of the host genes. Whether pairing of functional transcript and the pesudogene-containing intron will affect the translation of the functional transcript or the processing of the host gene is unknown. The interaction between the anti-parallel gene pairs, namely, *Uba52*/*Cbx1*, *Calm2*/*Prkar2b*, *Ch10*/*Sp3*, and *Ubb*/*Catsper2* are currently under investigation. These studies demonstrate the complex interrelationship between transcription units and the potential role of pseudogenes, introns, and antisense transcripts as regulators of gene expression.

Survival following treatment with intravenous sodium phenylacetate and sodium benzoate (AMMONUL) for hyperammonemia caused by urea cycle defects. *G.M. Enns[1], S.A. Berry[2], G.T. Berry[3], W.J. Rhead[4], A. Hamosh[5]* 1) Stanford University, Stanford, CA; 2) University of Minnesota, Minneapolis, MN; 3) Jefferson Medical College, Philadelphia, PA; 4) Medical College of Wisconsin, Milwaukee, WI; 5) Johns Hopkins University, Baltimore, MD.

Urea cycle defects (UCDs) are inborn errors of metabolism characterized by hyperammonemic encephalopathy and high morbidity and mortality. The combination of sodium phenylacetate and sodium benzoate in a 10%/10% solution (AMMONUL) is an intravenously administered adjunctive therapy for the treatment of acute hyperammonemic encephalopathy in patients with UCDs. Initial clinical trials demonstrated the potential efficacy of AMMONUL in a small number of UCD patients; ammonia levels typically fell and survival was much improved compared to historical outcomes. We report the results of a 20-year, open-label, uncontrolled study of AMMONUL therapy for acute hyperammonemia caused by UCDs. A total of 1,191 episodes of hyperammonemia in 304 patients with UCDs occurred at 118 hospitals in North America. The mean number of episodes per patient was 3.3 6.16 (range 1 to 79). A total of 1,142 out of 1,191 hyperammonemic episodes in which patients were treated with AMMONUL resulted in survival (96%). Overall, 255 of 304 patients (84%) survived all episodes. Neonates (mortality 27%) and males with ornithine transcarbamylase deficiency (mortality 9%) were more likely to die during an episode ($p<0.001$), compared with older patients and patients with other UCD diagnoses, respectively. Highest mortality was associated with peak ammonia levels of >600 mol/L in neonates (mortality 44%) and >300 mol/L in patients older than 30 days (mortality 6%). Baseline and post-therapy ammonia levels were known for 592 episodes. The median baseline ammonia level was 186 mol/L. The median post-therapy ammonia level was 36 mol/L. The median percent change from baseline was -79%. We conclude that AMMONUL therapy, in conjunction with other treatments, such as intravenous arginine HCl and provision of adequate calories, is effective in normalizing blood ammonia levels. Survival is remarkably improved compared with historical outcomes.

Clinical heterogeneity of familial CHARGE syndrome due to *CHD7* mutation. *A. Delahaye[1], S. Lyonnet[2], S. Wiener-Vacher[3], D. Bremond-Gignac[4], J. Amiel[2], C. Baumann[1], M. Elmaleh-Bergès[5], T. Attié-Bitach[2], A. Verloes[1], D. Sanlaville[2]* 1) Medical genetics department, Robert Debré University hospital, AP-HP, INSERM U676, Paris, France; 2) Medical genetics department, Necker-Enfants Malades University hospital, AP-HP, INSERM U781, Paris, France; 3) ENT department, Robert Debré University hospital, AP-HP, Paris, France; 4) Ophthalmology department, Robert Debré University hospital, AP-HP, Paris, France; 5) Medical imaging department, Robert Debré University hospital, AP-HP, Paris, France.

Background: CHARGE syndrome (OMIM #214800) is a multiple-malformation syndrome with distinctive diagnostic criteria, usually due to *CHD7* (Chromodomain Helicase DNA binding 7) haploinsufficiency. Familial occurrence of CHARGE syndrome is exceptional.

Objective: To describe clinical and genetic analyses in a French family affected by a CHARGE syndrome.

Methods: Clinical study, ophtalmological examinations, vestibular function evaluation and inner ear imaging were carried out. Molecular analysis of the *CHD7* gene was undertaken by direct sequencing.

Results: The two affected brothers had a vestibular dysfunction with hypoplastic semicircular canals, a mental retardation and a facial dysmorphism. None had choanal atresia and only patient 2 presented with coloboma. Patient 1 had multiple congenital abnormalities: bilateral cleft lip and palate, type III oesophageal atresia, complex heart defect and vertebral abnormalities. The mother was only investigated after the discovery of anomalies in her children. A left papillar coloboma and a partial vestibular dysfunction were then detected. Mutation analysis of the *CHD7* gene resulted in the identification of a missense mutation (c.2501CT, Ser834Phe) in the three affected patients.

Conclusion: We report a new missense mutation responsible for a familial mild CHARGE syndrome. Moreover, this observation would shed light on the variable intrafamilial expression suggesting a careful genetic counselling.

Mining the genome diversity of microsatellite markers: genetic signature of population expansion in modern humans. *S. Guha, R. Chakraborty* Center for Genome Information, College of Medicine, University of Cincinnati, Cincinnati, OH.

Microsatellite markers have been the principal types of genomic markers used in studying genetic basis underlying susceptibility to complex diseases, and to understand evolutionary relationships of human populations. As complex disease gene mapping efforts are moving into the paradigm of disease-gene association studies, questions arise as to which populations are most suited for such studies. Prior work implies that small isolated populations and particularly the ones which expanded recently may be more suited to detect disease-gene association due to underlying genetic risk of complex diseases. Using data on 784 microsatellite markers (encompassing 22 autosomal chromosomes) consisting of di-, tri-, tetra-, and pentanucleotide repeat loci from 976 individuals belonging to 36 worldwide populations, we addressed: (a) which population groups show genetic signatures of isolation and/or recent expansion; (b) what is the extent of reduction of genomic diversity of detected isolated populations, and (c) which measures of genetic variation best captures these signatures of population expansion. We found that the heterozygosity and number of segregating alleles show conspicuous signatures of reduced genetic variation in the Native Americans, and in the Oceanians. African populations have the highest diversity. Using the imbalance index estimation we found signatures of recent population size expansion in the populations that show reduced genomic diversity. The Africans also show signatures of population size expansion of most distant past, compared with the other populations. These results are consistent with the Out-of-Africa model of human evolution. Interestingly, variation of genomic diversity by repeat motif size of microsatellite markers in this study is less conspicuous than that has been seen before, perhaps due to the fact in this panel of markers the tetranulceotide loci are most abundant compare to other type of markers. These results have implications with regard to population-specific patterns of genome-wide linkage disequilibria between loci, which have to be investigated in greater details. (Supported by NIH grant GM41399).

Promising susceptibility loci for lipid levels in blood serum detected in extended pedigrees from Samoa. *K. Åberg[1], F. Dai[2], E.D. Keighley[3], G. Sun[4], D. Smelser[4], S. Viali[5], J. Tuitele[6], S.R. Indugula[4], Q. Zhang[4], R. Deka[4], D.E. Weeks[1, 2], S.T. McGarvey[3]* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) International Health Institute, Brown University, Providence, RI; 4) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 5) Tupua Tamasese Meaole Hospital, Apia, Samoa; 6) Tafuna Family Health Center, Pago Pago, American Samoa.

Using variance component linkage analysis, developed to take full advantage of extended pedigree structures, we performed genome-wide scans for lipid-related phenotypes in 35 families (3-2,094 individuals/family) from Samoa. For 576 adults (>18 years of age), lipid profiles, including total cholesterol (CHOL), low density lipoprotein (LDL), high density lipoprotein (HDL) and triglyceride (TG), were determined and 376 autosomal microsatellite markers were genotyped. SOLAR/Loki software was used to calculate multipoint LOD scores. Age and gender were used as covariates. On chromosome 12q24.33 we obtained maximum LODs of 3.05 and 1.84 for LDL and CHOL, respectively. For these phenotypes, we detected a second locus on chromosome 6p21.2-p12.1 with LOD=2.15 and 1.72, respectively. A third locus, with LOD=2.08, was detected for CHOL on chromosome 4p14-q12. For TG we detected LOD=1.85 on chromosome 5q35.3 and LOD=1.69 on chromosome 15q12. Telomeric, on chromosome 15q14, we found a promising QTL for HDL with LOD=2.61. Interestingly, cholesterol related traits have previously been reported to 4q12 as well as to 6p12 while TG has been reported to 15q12. Currently, we are extending our investigation to include additional adults (n=677) from American Samoa. The two populations from the Samoa islands have a common population history but, in contrast to Samoa, the environment in American Samoa has been extensively modernized during the last decades. By performing combined linkage investigations with these sample sets, we will increase the power to detect linkage, as well as to explore gene x environment interactions.

An interactive web-based genetics case for medical students. *J. Cowan[1], S. Albright[2], D. Walker[2], L. Demmer[1]* 1) Department of Pediatrics, Tufts School of Medicine, Boston, MA; 2) Tufts University Sciences Knowledgebase, Boston, MA.

As part of a comprehensive effort to expand and integrate genetic education throughout the four year curriculum at Tufts, an interactive web-based case was developed and introduced into the Year 2 medical student genetics course. The exercise reinforced concepts taught in class in addition to emphasizing self-directed learning and applied ethical concepts. The case centered around a couple with a family history of MR and a balanced translocation. Students were asked to complete pedigree analysis, devise testing strategies, perform a literature search, identify unbalanced karyotypes and evaluate FISH results for PGD. Students received immediate feedback upon submission of each answer. Completion of the exercise was required, and concepts emphasized in the case were reflected on the final exam. Time spent on the case, and answers to questions were tracked anonymously.

Results:174 of 175 students worked through the case. 25% of students completed the case during the 2nd week and 72% in the final week of the class. Completion during the 2nd week was associated with a higher number of correct answers, with 78% getting 10 or more of 13 answers correct. 69% of students completed the work in 60 minutes or less. No one question was answered correctly by all students and the majority of questions (10/13) was answered correctly by 79-97% of the class. We learned that our explanations of pedigree construction, unbalanced translocations, and the ethics of informed consent could be improved (correct response rates only 64%, 63% and 66%). Evaluation of write-in answers revealed that 86% of students successfully initiated self-directed learning. 165 students evaluated the exercise and on a scale of 1-5 gave the case an average rating of 4.3 for quality, 4.2 for effectiveness as a learning tool, and 4.4 for ease of navigation.Written student comments were highly favorable.

Conclusion: Development of a web-based, interactive case emphasizing self-directed learning and applied ethics appears to be a welcome and effective educational tool for second year students.

Effect of methylparaoxon on chromosomes from human lymphocytes, in vitro. *I. Aranha, L. Almeida* Inst Biol, PHLC S-525-6, Univ Estado Rio de Janeiro, Rio de Janeiro, Brazil.

The use of pesticides is still the main strategy to fight plagues in agriculture. Organophosphate esters represent a significant proportion of the world production of pesticides. Methylparation is an organophosphate pesticide largely used. In order to exert its biological effect it must be biotransformed into its corresponding oxon-analogous methylparaoxon, in the liver. Previous work in our laboratory, using the chromosome aberrations assay, in human lymphocytes exposed to different concentrations of the drug (0.1, 0.25 and 0.5 ppm) in vitro, has shown that methylparaoxon was responsible for the alterations in structure observed. The objective of the present work was to study the effect of methylparaoxon on chromosomes of human lymphocytes in vitro, using the micronuclei assay. Blood was collected from healthy donors 18 to 30 years old. Peripheral whole blood cells were incubated at 37^{o}C and 5% CO_2 for 72h, in enriched 1640 medium in the presence of methylparaoxon (0.1, 0.25 and 0.5 ppm). Cells from the same donors not exposed to the drug served as control for the experiment. Cytochalasin B (4g/ml) was added to the cultures 44h postinitiation. After fixation, cells were stained with Giemsa Gurr (2%) and analyzed under the optical microscope. In the samples exposed to the pesticide, 12246 binucleated cells were observed at the 0.1 ppm concentration and 53 of them showed micronuclei. We observed 12144 binucleated cells at the 0.25 ppm concentration and 43 of them had micronuclei. We analyzed 12208 binucleated cells at the 0.5 ppm concentration and observed the presence of a micronucleus in 85 of them. In the control group we observed 12682 binucleated cells and 8 of them had micronuclei. The chi-square test showed that the results were significant ($p<0.0001$) and that methylparaoxon was responsible for the micronuclei observed.

Heterogeneity of genetic structure of Hispanic Populations of Continental United States and its impact on understanding their complex disease risks. *B.M. Chakraborty*[1], *R. Chakraborty*[1, 2] 1) Dept. Environmental Health, Univ. Cincinnati College of Medicine, Cincinnati, OH 45267; 2) Center for Genome Information, Univ. Cincinnati College of Medicine, Cincinnati, OH 45267.

The term Hispanics used for some immigrant populations of US is known to have operational as well as methodological problems in relation to complex disease studies. This research reviews this issue in relation to demographic as well as regional heterogeneities of the Hispanic populations of continental USA. The origin of the Hispanics in different regions varies, and so does their genetic structure. For example, of over 40 million US Hispanics, about 66% are of Mexican origin, and they reside mostly in southern, western, and mid-western regions of the country, but the north-eastern Hispanics of US are predominantly of Puerto-Rican, Cuban, Central, or South American origin. Genetic structure of these regional Hispanics populations also reflects this heterogeneity, in terms of proportions of genes of Native American and African ancestry. The age pyramids of these different groups are also different, contributing towards their late-onset disease morbidity and mortality differences. One striking feature, however, is the gene flow in all regional Hispanic populations has a gender bias, with lesser proportions of genes descending from European maternal ancestry. Comparison of admixture estimates based on autosomal, mitochondrial, and Y-chromosomal markers shows heterogeneity of gender bias of admixtures of the different regional populations more conspicuously. The length of residence in US is also varied between these groups. Consequently, differences of acculturation and adaptation to life styles in the host country, combined with their genetic differences can account for their differences of morbidity and mortality attributable to complex chronic diseases. The conflicting observations regarding the Hispanic Paradox may also be explained by such heterogeneities. Hence, complex disease studies in these populations should consider the context of their cultural and demographic origin, particularly when the gene-environment factor is to be accounted for. (Research supported by NIH grant GM 41399).

Longevity Collection at Coriell Institute for Medical Research: a Resource for the Study of Aging. *D.L. Coppock, C.M. Beiswanger, B. Newman, B.A. Frederick, J. Leonard* Coriell Institute for Medical Research, Camden, NJ.

For studies on successful aging, new resources of lymphoblastoid cell lines/DNA from octogenarians, nonagenarians and centenarians are available from the Longevity Collection from the NIA Aging Cell Repository. The cell lines/DNA were prepared from blood samples that were donated by men and women who have reached great age and whose current health is good. Collection from additional donors over the age of 90 is continuing. Most donors have been interviewed to collect critical information about their age, medical history, family medical history, and demographics. The data are self-reported, although every effort has been made to verify the age. Data collected include history of major diseases and disorders including heart, lung, cancer, diabetes gastrointestinal, immune problems, smoking and drinking habits, demographic characteristics, and the number of family members who have lived over 90 years. Ages of those currently available are from 80 to 103 years old with 6 centenarians, 38 nonagenarians and 79 octogenarians including 66 women and 57 men. For each participant, a lymphoblastoid cell line has been prepared from a blood sample. Each line has been karyotyped. Constitutional abnormalities were detected in three cases [46,XX,inv(4)(p16q21), 45,XY,der(14;21)(q10;q10), 46,XX,t(11;22)(q23.3;q11.2)]. One third of the cultures presented with clonal abnormalities, which may have occurred in vitro. The majority of these were gains or losses of X or Y or trisomy 12. Of those donors reporting, 33% reported one or more cancers; 60% reported hypertension or heart disease; <9% reported lung disease and 6% reported diabetes. These samples provide a resource for the study of aging at the cellular and genomic level. Additional information about the Longevity Collection can be found at: http://ccr.coriell.org/nia/special/longevity.html.

Long-term benefits of early oral cysteamine therapy in cystinosis. *I. Bernardini, J. Balog, G. Golas, K. O'Brien, R. Kleta, W.A. Gahl* MGB, NHGRI, NIH, Bethesda, MD, USA.

The lysosomal storage disease, nephropathic cystinosis, presents with renal tubular Fanconi syndrome and growth delay in the first year of life. If untreated, glomerular failure occurs by 10 years of age; mortality and multisystemic morbidity occur after renal transplantation. The free thiol cysteamine can lower cellular cystine content by >90%. Early, diligent therapy with oral cysteamine (60-90 mg/kg/d dosed every 6h) has been shown to prevent or attenuate the growth retardation and glomerular deterioration of pre-transplant patients. It also helps prevent the disorders hypothyroidism and pulmonary dysfunction. We recently reported that the frequencies of swallowing difficulty, coronary artery calcification, and posterior segment ophthalmic complications varied directly with years off of cysteamine and inversely with years on cysteamine therapy. We now present data on 100 nephropathic cystinosis patients seen as adults at the NIH between 1986 and 2006 under our natural history protocol. Thirty-three are now deceased; their mean age at last visit was 26 +/- 1 (SEM) years and at death was 29 +/- 1 years. The most common causes of death were: 1) Unknown, sudden; 2) Sepsis; 3) Uremia. At least 30/33 required thyroid supplementation, 20/33 had significant myopathy; 9/33 exhibited diabetes mellitus, and 9/33 had retinal blindness; 12 of 20 males had primary hypogonadism. The mean serum total cholesterol was 201 +/- 12 mg/dL. In considering all 100 adult patients, the frequencies of death in relation to duration of cysteamine therapy were: On cysteamine for <10 y, 45% mortality; on for >20 y, 0% mortality; off cysteamine for <10 y, 4% mortality; off for >20y, 47% mortality. Similar results were found for the frequencies of myopathy and diabetes. We conclude that the late complications of cystinosis are devastating and that early oral cysteamine therapy exerts a dramatic salutary effect on the mortality and morbidity of cystinosis in adults.

Megacystis-Microcolon-Intestinal Hypoperistalsis Syndrome: Diagnosis and Intervention in Four Patients. *Q. Abu Ali[1], C. Kozma[2], S.S. Kaufman[3], T.M. Fishbein[3], C.S. Matsumoto[3], Y. Rekhtman[3]* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Department of Pediatrics, Georgetown University Hospital, Washington, DC; 3) Georgetown University Transplant Institute, Georgetown University Hospital, Washington, DC.

Megacystis-Microcolon-Intestinal Hypoperistalsis syndrome (MMIHS), or Berdon syndrome, was first described in 1976. Inheritance is autosomal recessive. A genetic locus for MMIHS maps to 15q24. It is characterized by marked dilatation of the urinary bladder, external appearance of "prune belly", microcolon, dilated small intestine, and intestinal hypoperistalsis. Generally, it is lethal during the first year of life. We report four patients who were diagnosed with MMIHS. Patients A, B, and C were siblings to the same non-consanguineous Caucasian parents. Patient D was an offspring to non-consanguineous African American parents. Coincidentally, all four patients were born in the same geographical area. Patient A/male, diagnosed prenatally, was a still born at approximately 5 months gestation. Patient B/female was diagnosed prenatally and died at 5 months of age. Patients C/female and D/male were diagnosed prenatally, listed for multiple visceral organ transplants, and had normal karyotype, echocardiogram, and ganglion cells of the mesenteric plexus. Patient C had a classical "prune belly" appearance. MMIHS is a rare autosomal recessive disorder that manifests as gastrointestinal and genitourinary systems malformations. It should be differentiated from "prune belly" syndrome and chronic idiopathic intestinal pseudo-obstruction (CIPO) syndrome. Generally, there is a 3-4:1 female to male ratio, suggesting either underdiagnosis and/or a higher lethality prenatally in males. Prenatal diagnosis is possible, which enables parents to make informed decisions regarding the pregnancy. To date, no commercial diagnostic testing is available. Clinical differentiation between MMIHS, prune belly syndrome, and CIPO might not be simple, but carries a significant role in the extent of medical, surgical, and genetic counseling interventions offered. More clinical reports are needed to outline the natural history of this condition.

Angiotensin II Type 1 Receptor Blockade Improves TGF-induced Failure of Muscle Regeneration in the mdx Mouse Model of Duchenne Muscular Dystrophy. *R.D. Cohn[1], J.P. Habashi[2], B.L. Loeys[1], E.C. Klein[1], M. Gamradt[1], T.M. Holm[1], D.P. Judge[3], H.C. Dietz[1]* 1) Institute of Genetic Medicine and HHMI, Johns Hopkins Univ Sch of Med, Baltimore, MD, USA; 2) Division of Pediatric Cardiology, Dept of Pediatrics, Johns Hopkins University Sch of Med; 3) Division of Cardiology, Dept of Medicine, Johns Hopkins University Sch of Med, Baltimore, MD, USA.

We have previously shown that increased TGF activity causes abnormal muscle regeneration and myopathy in fibrillin-1 deficient mice, a model of Marfan syndrome. Systemic antagonism of TGF via administration of TGF-neutralizing antibody or the angiotensin II type 1 receptor (AT1) blocker losartan restores abnormal muscle regeneration and prevents subsequent development of myopathic features. Impaired satellite cell performance and muscle repair has also been shown to play a significant role in the disease progression of various forms of muscular dystrophy. Here we demonstrate that myopathic changes in the dystrophin-deficient mdx mouse model of Duchenne muscular dystrophy associates with excessive TGF signaling, as evidenced by increased phosphorylation of pSmad2/3. Systemic TGF antagonism via losartan improves the satellite cell response to toxin induced-injury in the mdx mouse. Losartan-treated mdx mice have improved steady-state muscle architecture and a near-normal amount of actively regenerating, neonatal myosin positive fibers four days after induced injury. After 18 days, losartan-treated mdx mice show only minimal amount of fibrosis, as demonstrated by vimentin expression, when compared to placebo-treated mice. Moreover, long-term administration of losartan leads to improved functional performance as demonstrated by increased muscle grip strength and decreased muscle fatigue in mdx mice. Together, our data demonstrate that treatment with the FDA approved medication losartan attenuates TGF-induced failure of muscle regeneration and represents a promising therapeutic strategy for the treatment of Duchenne muscular dystrophy. Given that losartan is widely used to treat hypertension and has an exceptional tolerance profile in all age groups, we propose that a clinical trial using losartan is warranted.

A Common Ancestral Haplotype Located at 4q13.2 Confers Susceptibility to ADHD. *M. Arcos-Burgos[1], M. Jain[1], S. Domene[1], S. Shively[1,2], D. Wallis[1], H. Stanescu[1], J.D. Karkera[1], M.T. Acosta[1], K. Berg[1], R. Kleta[1], E. Roessler[1], A. Vortmeyer[2], D. Pineda[3], J.D. Palacio[3], F. Lopera[3], J. Meyer[4], K.P. Lesch[5], J.E. Bailey-Wilson[1], F.X. Castellanos[6], M. Muenke[1]* 1) NHGRI, NIH, Bethesda, MD, USA; 2) NINDS, NIH; 3) Neurosciences Group, University of Antioquia, Medellín, Colombia; 4) Verhaltensgenetik, University Trier, Germany; 5) Department of Psychiatry and Psychotherapy, University of Wurzburg, Germany; 6) New York University Child Study Center, New York, NY, USA.

Attention-Deficit/Hyperactivity Disorder (ADHD) (OMIM 143465), the most common behavioral disorder of childhood, affects 8-12% of children worldwide. We described linkage of ADHD to a locus at 4q13.2 in families from a genetic isolate in Colombia, South America. Fine mapping and a second set of families (n=120) from this same isolate validated our linkage results and defined a minimal critical region (MCR). A common haplotype (frequency, 22.2%) within this MCR was found in LD to ADHD ($P < 2.7*10-5$). ADHD susceptibility haplotype variants reconstructed from 23 additional markers, iteratively validated the presence of the core haplotype in additional ADHD familial samples from the US (n=185, $P<3.1*10-3$) and from Germany (n=244, $P<3.8*10-5$) ($Ppooled< 3.01*10-8$) (RR 2.6). Variants complementary to the susceptibility haplotype conferred protection against ADHD. The haplotype defines a single gene. A phylogenetic reconstruction using the chimpanzee sequence for our gene as an out-group revealed the ADHD susceptibility haplotype ancestral to the protective variants. We also demonstrated that the gene we identified is expressed specifically in brain regions associated with ADHD. This is the first gene with variants conferring susceptibility to ADHD with an effect size (genotype relative risk) greater than 2.0. In addition, the evolutionary history and the high frequency of the susceptibility haplotype suggests that a selective advantage may be involved. The susceptibility gene will be fully characterized at the presentation of this work.

Pregnancy complications, risk perceptions, and reproductive planning in families affected with Neurofibromatosis Type 1. *J.L. Geurts[1], P.M. Veach[2], J. Kao[2], B.S. LeRoy[1]* 1) Genetics, Cell Biology and Dev, University Of Minnesota, Minneapolis, MN; 2) Educational Psychology, University of Minnesota, Minneapolis, MN.

Neurofibromatosis Type 1 (NF1) is a complex inherited condition, with variable expression. Published reports suggest that women with NF1 have an increased risk for pregnancy complications and neurofibroma growth during pregnancy. However, data regarding severity and frequency of problems are incomplete, contradictory and often outdated. In the present study 119 individuals with NF1 or their partners, recruited from two NF websites, responded to an on-line survey regarding pregnancy experience and reproductive planning. Major research questions were: 1) What is the incidence of pregnancy complications among women with NF1? 2) What percentage report NF1 symptom exacerbation during pregnancy? 3) How concerned are women about their health during pregnancy? 4) Are they knowledgeable about pregnancy risks? 5) How has NF1 affected reproductive planning decisions? and 6) To what extent has NF1 affected respondents relationships and daily life? Present findings indicate possible increased risk for pregnancy complications and symptom exacerbation for women with NF1, including: cesarean section (36.7%), low birth weight baby (31.9%), growth of existing neurofibromas (50%), and growth of new neurofibromas (68.8%). Across all women with NF1, mean ratings of concern about neurofibroma growth and effects of NF1 on their health during pregnancy were mild to moderate; t-tests indicated that those who had not been pregnant reported significantly greater concern than those who had been pregnant ($p < .001$). Sixty percent of women with NF1 reportedly had heard or read about NF1 possibly causing pregnancy complications, and 44.5% reported that this knowledge negatively affected their reproductive decision-making. Both females and males with more severe NF1 reported greater negative effects on relationships and on daily functioning. Samples of respondents written comments, and practice and research recommendations will be presented.

An algorithm for simulating genetics data based on linkage and linkage disequilibrium maps. *C. Chen[1,2], L.-Y. Wei[1], S.S. Shete[3]* 1) Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Institute of Chinese Medical Science, China Medical University, Taichung, Taiwan; 3) Department of Epidemiology, University of Texas MD Anderson Cancer Center, Houston, TX, USA.

Recently, marker location databases that integrated linkage, linkage disequilibrium (LD) and physical maps provided more accurate estimations of locus-locations and inter-marker distances. In particular, the resolution of linkage maps, specifying distance in crossover counts, can be enhanced by interpolating dense locations from linkage disequilibrium (LD) maps, which specifies distance in LD unit (LDU). In this study, based on the linkage and LD maps, we proposed an algorithm to generate genetic data that retains the characters of target regions in every aspect for empirical calculation. The algorithm can be divided into five steps. (1) SNPs in the region of interests are assigned to blocks such that all SNPs within a block have the same location in the LD map. The SNP locations in LDU can be obtained from location databases or estimated from real data using the LDMAP program. (2) Haplotypes and haplotype frequency distribution in each block are estimated based on real data, which may be provided by user or obtained from publicly available databases, such as the HapMap project. (3) Each block is transformed as a pseudo multi-allelic marker and each haplotype acts as an allele. The inter-marker recombination is estimated by interpolating the locations of the last SNP of the first block and the first SNP of the second block from linkage and LD maps. (4) The information of the pseudo markers and recombination are then applied to generate genetic data using existing linkage simulation programs. (5) The simulated pseudo markers are finally translated back to the corresponding SNPs. The use of the existing linkage simulation programs that generated genotypes for specified pedigrees and genotypes conditional on phenotypes may sufficiently fulfill various sampling schemes used in family- and population-based genetic studies. In summary, data generated by this algorithm preserved not only the historic linkage disequilibrium structure among SNPs but also crossover events in the targeted data.

Phenylketonuria (PKU) disease knowledge and health locus of control. *M. Applegarth[1], V. Vandergon[1], M. Fox[2], N. Dorrani[2], S. Charnofsky[1], C. Palmer[2]* 1) California State University, Northridge, CA; 2) University of California, Los Angeles, CA.

Phenylketonuria (PKU) is a treatable inborn error of metabolism that occurs in approximately 1 in 10,000 to 20,000 live births. Untreated, PKU causes a build up of phenylalanine in the blood and brain resulting in neurologic damage and mental retardation. The current medical recommendation is to continue PKU treatment for life. Several studies have explored different psychosocial factors that may have an effect on diet compliance and metabolic control. The purpose of this study was to determine if a relationship existed between two such factors, PKU disease knowledge and health locus of control (HLOC). These two factors have been shown in earlier studies to independently affect metabolic control and medical adherence. The hypothesis stated that individuals with higher levels of internal HLOC would have higher levels of disease knowledge. Self-administered questionnaires were completed by 16 individuals with PKU and 38 parents of individuals with PKU from the National PKU News listserv and the California Coalition for PKU and Allied Disorders. The questionnaire was designed to measure PKU disease knowledge, Health Locus of Control, and individual health measures including overall health rating and blood phenylalanine level. Results of this study showed a positive relationship between disease knowledge and internal HLOC, and a negative relationship between disease knowledge and blood phenylalanine levels in individuals with PKU. These correlations were not statistically significant, possibly due to the small sample size. The results also showed that almost half of variance in health rating was explained by internal HLOC and disease knowledge in individuals with PKU. In conclusion, the results of this study suggest that disease knowledge and health locus of control are important variables in this population and warrant further investigation. Future research should expand on the current study with larger and more diverse samples and explore other independent variables that may account for the remaining variance in overall health ratings.

PRENATAL DIAGNOSIS OF TRISOMY 18. EXPERIENCE IN THE NATIONAL INSTITUTE OF PERINATOLOGY. *R. Baez-Reyes, G. Noceda-Rivera, G. Razo-Aguilera* Deparment of Genetics, National Institute of Perinatology, MEXICO.

OBJETIVE: To realize an analysis of the factors that guide to the diagnosis of trisomy 18 in prenatal form and to establish a work line for their detection. MATERIALS AND METHODS: We revised the records of 47 cases detected of trisomy 18 that were seen by the consultation of Prenatal Diagnosis, in one period that embraces since January 1st from 1989 to May 31th from 2006: 34 of the patients were prenatal death, 3 had early neonatal death and 10 were considerate by the commitee of perinatal damage. In all cases were confirmed the diagnosis for cytogenetic study: 43 for amniocentesis, 3 for chorionic villus sampling and 1 for fetal urine. RESULTS: Of those 47 cases studied, 46 were regular trisomy and 1 presented a mosaic form, being 30 male fetuses and 17 female fetuses; with a maternal age average of 36.1 years old and gestational age average for last menstruation of 23.9 weeks. We offered cytogenetic study in 31 cases (65.95%) for abnormal ultrasound, in 8 cases (17.02%) for maternal age bigger to 35 years old, mixed factor in 7 cases (14.89%) and previous child with somo defect in 1 case (2.12%). DISCUSSION: The trisomy 18 is associated with multiple severe structural abnormalities that involve to several organs. The ultrasound in this cases play an important paper, as well as the possibility to offer biochemical tests to the patients for a bigger sensibility. Howewer, the definitive diagnosis will always be for cytogenetic study, same that will give us the rule for an appropiate genetic advice.

Linkage disequilibrium in an isolated population from Norfolk Island. *C. Bellis[1], K.N. Begley[2], R.M. Hughes[1], S. Quinlan[1], R.A. Lea[1], S.C. Heath[3], J. Blangero[4], L.R. Griffiths[1]* 1) Genomics Research Centre, Griffith University, Gold Coast, Qld, Australia; 2) Division of Information Services, Griffith University, Australia; 3) Centre National de Génotypage, 2 Rue Gaston Cremieux, Evry, France; 4) Southwest Foundation for Biomedical Research, San Antonio, Texas, USA.

Genetic isolates provide a potentially powerful sample population for disease loci mapping of complex multifactorial traits, due to the combined effects of geographical isolation (and resulting inbreeding) and limited variation in environmental influences. Additionally, such populations generally arise from a small number of founding members, possibly from quite diverse cultural backgrounds, therefore introducing admixture affects. The Norfolk Island community is a population of approximately 1800 current permanent residents, of whom the majority are direct descendents of 18th century English sailors (Bounty mutineers) and Polynesian women. Such a population presents interesting and unique characteristics to a genomic investigation into complex disease analysis, due to the strong family groupings and well-documented family histories. Furthermore, the Norfolk population grew in isolation from other communities and as a result produced a relatively homogeneous genetic pool. We have collected samples from the Norfolk Island adult population, to investigate cardiovascular genes. Initial analysis identified a slightly higher prevalence of cardiovascular disease (CVD) and associated risk factors in the study sample of 602 Norfolk Island individuals when compared to the prevalence of CVD within Australia. Additionally, seven CVD risk associated phenotypes have been demonstrated as showing significant ($p<0.05$) heritability in the Norfolk population and the pedigree should have outstanding power (>90 percent) to localise QTL associated to these traits. The present study is primarily concerned with estimating the extent of linkage disequilibrium within the Norfolk population by analysing microsatellite markers from the Xq13.3 genomic region. The Xq13.3 genomic region has been extensively studied in other genetic isolates and presents a useful criterion for understanding levels of linkage disequilibrium within study populations.

Atypical 22q11.2 distal deletions detected by Chromosomal Microarray Analysis: Clinical significance and cytogenetic evaluation. *S. Ben-Shachar[1], M. Hummel,[2], J. Belmont[1], P. Eng[1], S. Bland[1], T. Appleberry[1], A.L. Beaudet[1], S. W. Cheung[1], A. Patel[1]* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dep. of Pediatrics, W. Virginia University School of Medicine. Morgantown, WV.

Microdeletions within chromosome 22q11.2 cause a variable phenotype, including DiGeorge syndrome (DGS) and velocardiofacial syndrome (VCFS). About 90% of patients show a common recurrent ~3 Mb deletion and about 7% of patients have a smaller ~1.5 Mb recurrent deletion. Both deletions were found to occur as a result of non-allelic homologous recombination between low copy repeats (LCR) sequence substrates located in 22q11.2 region. Interestingly, although 9 different LCRs are located within this region only a few cases of atypical deletions have been described suggesting that such deletions are either less common than expected, do not have a clinical significance, cause a phenotype different than DGS/VCFS or may be lethal. Using Chromosomal microarray analysis (CMA)we have detected 3 unrelated cases of small deletions within 22q11.2, located distal to the 3 Mb common deletion. The BAC clones in the DGS/VCFS region have been selected to flank the majority of the LCR22s. All of the 3 patients had a small deletion of a single clone on the microarray. A deletion between LCR22-5 and LCR22-6 detected by clone RP11-36N5 was seen in 2 cases and a deletion between LCR22-4 and LCR22-5 detected by clone RP11-165F18 was seen in the 3rd case. The deletions were confirmed by FISH. Both patients with the deleted clone RP11-36N5 presented with FTT and facial dysmorphia. One of them had a common truncus arteriosus and developmental delay. They both had a *de novo* deletion suggesting potential pathogenecity. The 3rd patient was presented with FTT, atrioseptal heart defect and hypotonia. Parents were not available for study this patient. The fact that although *TBX1* was not included in these deletions, two of the patients did have a congenital heart defect may suggest a positional effect mechanism. We conclude that distal atypical deletions of chromosome 22q11.2 may be relatively common, clinically significant genetic aberration.

Comprehensive mutation analysis in Costello syndrome, CFC syndrome and Noonan syndrome : clinical and genetic overlap among three disorders. *Y. Aoki[1], T. Niihori[1], Y. Narumi[1], H. Kawame[2], K. Kurosawa[3], H. Ohashi[4], M. Filocamo[5], G. Neri[6], H. Cavé[7], A. Verloes[7], N. Okamoto[8], R.C.M Hennekam[9], G. Gillessen-Kaesbach[10], D. Wieczorek[10], M.I. Kavamura[6], L. Wilson[9], Y. Suzuki[1], S. Kure[1], Y. Matsubara[1]* 1) Dept Medical Genetics, Tohoku Univ Sch Medicine, Sendai; 2) Nagano Childrens Hosp, Nagano; 3) Kanagawa Childrens Med Ctr, Yokohama; 4) Saitama Childrens Med Ctr, Saitama, Japan; 5) IRCCS. G.Gaslini, Genova; 6) Istituto di Genetica Medica, Rome, Italy; 7) Hôpital Robert Debré (APHP), Paris, France; 8) Osaka Med Ctr & Res Inst for Maternal & Child Health, Osaka, Japan; 9) Inst of Child Health, London, UK; 10) Univ Essen, Essen, Germany.

Costello syndrome and cardio-facio-cutaneous (CFC) syndrome are Noonan-related syndromes characterized by heart defects, facial dysmorphism, ectodermal abnormalities and mental retardation. Recently we discovered proto-oncogene *HRAS* mutations in Costello syndrome and *KRAS* and *BRAF* mutations in CFC syndrome, establishing a new role of RAS/RAF/MEK/ERK pathway in human development. To elucidate the clinical and molecular characteristics of Noonan, Costello and CFC syndromes, we have analyzed *PTPN11*, *HRAS*, *KRAS*, *BRAF* and *MAP2K1/2* (MEK1/2) in 50 patients with Noonan syndrome, 35 patients with Costello syndrome and 59 patients with CFC syndrome. Mutations in *PTPN11* were identified in 42% of patients with Noonan syndrome, two patients with Costello phenotype and three patients firstly diagnosed as having CFC syndrome. *HRAS* mutations were detected in 57% of Costello patients. Mutations in *KRAS*, *BRAF* and *MAP2K1/2* were found in 61% of patients with CFC syndrome. Mutations in *BRAF* or *MAP2K1* were detected in two patients with Costello phenotype. No mutations were found in *MAPK3/1* (ERK1/2), downstream of MEK1/2, in mutation-negative CFC patients. The analysis of 81 clinical manifestations in 25 mutation-positive CFC patients showed that wrinkled palms and soles, hyperkeratosis and joint hyperextension, which are important diagnostic features in Costello syndrome, were present in 30-40% of CFC patients. These results suggest that there is significant clinical and molecular overlap among these three syndromes.

Severe Liver Disease and Urea Cycle Disorders. *K. Cusmano-Ozog[1], S.L. Rutledge[2], A. Boneh[3], G. Gottesman[4], M. Tuchman[5], L. Pickler[6], J. Van Hove[6], G.M. Enns[1]* 1) Stanford University School of Medicine, Stanford, CA; 2) University of Alabama, Birmingham, AB; 3) The Murdoch Childrens Research Institute, Melbourne, Australia; 4) St Louis University School of Medicine, St Louis, MO; 5) Childrens National Medical Center, Washington, DC; 6) The Children's Hospital, Denver, CO.

Urea cycle disorders (UCD) typically present in the neonatal period with lethargy and hyperammonemia. Although mild transaminase elevations are common, severe liver disease is relatively rarely reported. We present 8 probands with UCD and significant liver disease. Three were diagnosed with citrullinemia, one male and two females, ranging in age from 3 days to 15 months. Five females were diagnosed with ornithine transcarbamylase (OTC) deficiency and ranged in age from 1 to 7 years. All were noted to have elevated transaminases; AST levels ranged from 101 to 3642 u/L, and ALT from 778 to 2991 u/L. Six of the individuals had a coagulopathy with PT 7-37.1 sec, aPTT 33-74 sec, INR > 1.9-9.4. Hyperammonemia was common (levels 115-400 uM). Four individuals had liver biopsies. One patient was referred for transplantation secondary to acute liver failure. Biopsy did not demonstrate significant pathology. A second patient was initially diagnosed with cholecystitis and underwent cholecystectomy. Liver pathology showed focal bridging fibrosis. Two patients continued to have elevated transaminases despite standard treatment. Liver biopsy from the third patient demonstrated focal hepatocellular necrosis and she underwent transplantation. Biopsy from the fourth patient revealed glycogen distended hepatocytes and diffuse microvesicular steatosis; she is being evaluated for transplantation. The pathogenesis of severe liver disease in UCD is unknown. A diagnosis of UCD, especially OTC deficiency in a female manifesting heterozygote, may be missed if not included in the differential for unexplained liver failure. We recommend obtaining a complete metabolic screen, including quantitative urine orotic acid in any individual that presents with liver disease of unknown etiology. Also, any individual with a UCD should be monitored for possible hepatic disease.

Urinary 1-hydroxypyrene: a biomarker for the effects of genetic polymorphisms on the metabolism of PAHs following different degrees of exposure. *B. Chen[1], M. Shao[2], Y. Hu[1], L. Zheng[1], Q. Wang[1], H. Liu[2], Y. Liu[2], T. Jin[1], D. Lu[2]* 1) Department of Occupational Health, Fudan University, Shanghai, China; 2) State Key Laboratory of Genetic Engineering, Institute of Genetics, School of Life Sciences, Fudan University, Shanghai, China.

In this study 1-hydroxypyrene (1-OHP) was used as a biomarker to explore the metabolism of polycyclic aromatic hydrocarbons (PAHs) following different degrees of exposure. Genetic effects on urinary 1-OHP levels were determined in 19 polymorphisms of 11 metabolizing enzymes including AhR, CYP1A1, CYP1A2, CYP1B1, CYP2E1, EPHX1, GSTM1, GSTT1, GSTP1, UGT1A1 and UGT1A6. According to individual occupational pyrene exposure, 437 coke oven workers (COWs) were divided into two exposure groups as low exposed COWs and highly exposed COWs, both of whom presented higher urinary 1-OHP levels compared with 257 non-occupational exposed controls. Using multiple linear regression models to analyze effects of single polymorphisms or gene-gene interactions on urinary 1-OHP levels, a totally different pattern of modifications was found in three groups: CYP1A1 3801T>C and CYP2E1 RsaI- were marginally significant in the controls, CYP1A1 3801T>C and UGT1A1 12493C>T were marginally significant in the low exposed COWs, whereas eight polymorphisms had marginal or significant effects in the highly exposed COWs including AhR 554K, CYP1A2 5347C>T, CYP2E1 RsaI-, EPHX -362G>A, UGT1A1 -3263T>G, UGT1A6 R184S, GSTP1 I105V and GSTT1 deletion type. The tissue speciality of gene expression and the pathways of pyrene metabolism taken into account, our results suggested that certain polymorphisms appeared to affect the levels of urinary 1-OHP. Unlike CYP1A1 and CYP2E1 which seem to be two major PAHs-metabolizing enzymes in low exposure individuals, the metabolism of pyrene was rather complex in highly exposed workers, in whom urinary 1-hydroxypyrene level might be modified not only by the polymorphisms of phase I enzyme including CYP1A2, CYP2E1 and EPHX1, phase II enzyme including GSTT1, GSTP1, UGT1A1 and UGT1A6, but also by the AhR encoding gene.

Association and Haplotype analysis of GLI1 gene with simple congenital Heart Disease in 12q13. *G.R. Qiu, L. G. Gong, X.Y. Xu, N. Xin, K.L. Sun* Medical Genetics, Basic Medicine, China Medical University, Shenyang, Liaoning, China.

In the candidate region 12q13 of simple Congenital Heart Disease (CHD),we chose four single nucleotide polymorphisms (SNPs) in GLI1 gene and investigated individual SNP distribution and haplotypes analysis in simple CHD patients and normal controls, in order to identidy whether GLI1 gene was the candidate for CHD or not. All subjects were from Northeast Chinese Han. We analyzed genotypes of 4 SNPs, that were C9455A, A10691G, G11388A, and G11888C, in 180 simple CHD patients and 200 normal controls by RFLP and DHPLC. Statistic analysis included Hardy-Weinberg equilibrium Assay, Association study at individual SNP, Linkage Disequilibrium Test, and Haplotype analysis. Our results showed that there was no polymorphism at A10691G in the Northeast Chinese Han. The distribution of allele frequency and genotype frequency at G11888C which was located in the coding-region of GLI1 gene, had significant difference between two groups ($P<0.005$). Linkage disequlibrium Test showed that there existed linkage disequilibrium among C9455A, G11388A and G11888C. Haplotype analysis showed that the distribution of haplotype had significant difference between two groups ($P<0.0001$). C9455/G11388/G11888 and C9455/A11388/G11888 were the common haplotypes in the population, but C9455/G11388/G11888 were much higher in CHD groups than that in normal controls ($P<0.05$). Conclusion Together with our results in family-based association and Haplotype analysis, G11888C located in the coding-region of GLI1 gene was associated with simple CHD, person with G allele at G11888C has much more risk with simple CHD. C9455/G11388/G11888 might be linked with the susceptibility gene of simple CHD.

Congenital hyperinsulinism in Kabuki syndrome. *D. Genevieve[1], D. Sanlaville[1], C. Bellane[2], C. Bernardini[1], A. Munnich[1], M. Vekeman[1], B. Isidore[1], M. Rio[1], V. Cormier-Daire[1], S. Lyonnet[1], P. de Lonlay[3], J. Amiel[1]* 1) Dept de Genetique, Hosp Necker-Enfants Malades, Paris, France; 2) Service de génétique moléculaire, Hôpital Saint Antoine, Paris, France; 3) Service de Maladies Métaboliques, Hôpital Necker-Enfants Malades, Paris, France.

Congenital hyperinsulinism (CHI - MIM 256450), is characterized by profound hypoglycemia related to inappropriate insulin secretion due to focal adenomatous hyperplasia or diffuse pancreatic insulin hypersecretion. Recently, several gene involved in CHI have been identified namely the KIR6.2, SUR, Glucokinase, GLDh and S-CHAD genes. Syndromic forms of hyperinsulinism are rare and include Perlman, CDG-Ib, Simpson-Golabi-Behmel, and Wiedemann-Beckwith syndromes. Here we report on 4 patients with clinical and biological evidences of CHI, each of which presented with Kabuki syndrome (KS), a MCA/MR syndrome characterized by distinctive facial features, post-natal growth retardation, feeding difficulties, dermatoglyphic anomalies, skeletal dysplasia and mental retardation. Treatment with Proglicem allowed to normalize glycemia in all 4 patients. Hyperinsulinism was transitory in 2 patients and persistent in 2 others with an exhaust to Proglycem requiring other treatments such as somatostatin. CHI was associated with clinical features consistent with diagnosis of KS namely distinctive facial features, post-natal growth retardation, dermatoglyphic anomalies and mental retardation. The molecular bases of KS are hitherto unknown, and several unrelated chromosomal anomalies have been reported. KIR6.2 and SUR gene mutations were excluded by direct DNA sequencing in our patients. We believe that KS is a newly recognized cause of syndromic CHI and that this diagnostic should be envision in CHI patients presenting with feeding difficulties, mental retardation, malformations and/or facial dysmorphism.

A genome-wide association study in breast cancer. *D. Easton[1], P.D.P. Pharoah[2], A.M. Dunning[2], K. Pooley[2], D.R. Cox[3], D. Ballinger[3], D. Thompson[1], D.G.R. Evans[4], D. Eccles[5], N. Rahman[6], M.R. Stratton[6], J. Peto[7], O. Fletcher[7], B.A.J. Ponder[2]* 1) CR UK Genetic Epidemiology, University of Cambridge, Cambridge, United Kingdom; 2) Deparment of Oncology, University of Cambridge, Cambridge, United Kingdom; 3) Perlegen Sciences, Mountain View,CA; 4) St Mary's Hospital, Manchester, United Kingdom; 5) Wessex Clinical Genetics Service, Princess Anne Hospital, Southampton, United Kingdom; 6) Institute of Cancer Research, Sutton, Surrey, United Kingdom; 7) London School of Hygiene and Tropical Medicine, London, United Kingdom.

Breast cancer exhibits familial aggregation, consistent with variation in genetic susceptibility to the disease. Less than 20% of the familial risk of breast cancer is accounted for by known susceptibility genes such as BRCA1&2, and the residual genetic variance is likely to be due to variants conferring more moderate risks. To identify further breast cancer susceptibility alleles, we conducted a two stage genome-wide association study. In the first stage, 227,876 SNPs were genotyped in 408 breast cancer cases with a positive family history and 400 controls. These SNPs report on ~64% of known common SNPs in HapMap, with a minimum r2 of 0.8. 12,026 SNPs showing the strongest associations in stage I were genotyped in a further 4,037 cases and 4,012 controls. After adjusting for the potential confounding effects of population stratification using genomic control, 69 SNPs showed significant associations with breast cancer at Ptrend<.0001, and 24 at Ptrend<.00001, compared with ~36 and ~5 respectively that would be expected by chance alone. For the most significant SNP, the estimated ORs in stage II were 1.26 (95%CI 1.12-1.34) in heterozygotes and 1.56 (1.38-1.77) in homozygotes (combined Ptrend=1.6×10^{-18}). The 30 most significant SNPs are being further evaluated in >20,000 cases and matched controls in an international consortium (BCAC). None of these 30 SNPs were in previously suggested candidate genes, and 16 were not within any known gene. These results indicate that susceptibility to breast cancer may be largely mediated through a large number of variants each conferring a small risk of disease.

Elastogenesis in MPS IVA patients fibroblasts and identification of mutations in GALNS gene. *L. Carraresi*[1], *M.A. Donati*[1], *A. Caciotti*[1], *E. Procopio*[1], *C. Valleriani*[1], *R. Parini*[2], *G. Sersale*[2], *D. Antuzzi*[3], *R. Ricci*[3], *O. Gabrielli*[4], *G. Parenti*[5], *M. Sibilio*[5], *M. Filocamo*[6], *S. Tomatsu*[7], *A. D'Azzo*[8], *A. Morrone*[1], *E. Zammarchi*[1] 1) Pediatrics,Florence Italy; 2) S.Gerardo Hosp,Monza; 3) Catholic Univ,Rome; 4) Ped Clinic,Ancona; 5) Pediatrics,Naples; 6) Gaslini Inst,Genoa; 7) Pediatrics,St. Louis,USA; 8) Genetics,St.Jude,Memphis.

Mucopolysaccharidosis IVA (MPS IVA, Morquio A) is an autosomal recessive storage disorder caused by deficiency of lysosomal N-acetylgalactosamine-6-sulfate sulfatase (GALNS), that hydrolyses the sulphate ester groups of keratan sulphate (KS) and condroitin-6-sulfate (C6S). MPS IVA patients show a broad spectrum of clinical severity. Classical forms are characterised by severe bone dysplasia and normal intelligence. We describe 9 unrelated MPS IVA patients with different clinical phenotypes. Molecular analysis of the patients GALNS gene identified 9 known and the following 5 new mutations: H142N, C507L, K129X, c899-1GC, c1365-1GA. At RNA level, the mutation c899-1GC causes exon 9 skipping, resulting in a frameshift and early stop codon; instead, no transcript was detected in patients with the known c120+1GA mutation. The H142 is highly conserved among eukaryotic sulfatases, suggesting that H142N is responsible for a severe phenotype. It has been shown earlier that in patients with GM1-gangliosidosis and Morquio B disease a primary defect in the Elastin Binding Protein (EBP) important for elastic fiber assembly results in impaired elastogenesis. The latter phenotypic aberration was also demonstrated in patients with secondary EBP defect due to accumulation of C6S (Costello syndrome), dermatan sulphate (Hurler disease) and KS (GM1 gangliosidosis). Based on these results, we have now tested whether accumulation of KS and C6S in MPS IVA also leads to impaired elastogenesis. Quantitative Real-Time PCR analysis carried out on total RNA from patients fibroblasts showed no variations on EBP mRNA levels in comparison with controls. Otherwise, on Western blots probed with an anti-EBP antibody the expression levels of EBP appeared reduced in some patients fibroblasts, suggesting a secondary deficiency of this protein also in MPS IVA.

Long Distance Transcription Networks Characterize ENCODE Regions. *S.E. Antonarakis[1], F. Denoeud[2], A. Reymond[1,3], P. Kapranov[4], A. Frankish[5], J. Harrow[5], R. Guigó[2], T.R. Gingeras[4], ENCODE Project Consortium* 1) Genetic Medicine Dpt, University of Geneva Medical School, Switzerland; 2) Center for Genomic Regulation; Barcelona, Catalonia, Spain; 3) Center for Integrative Genomics; University of Lausanne, Switzerland; 4) Affymetrix, Inc.; Santa Clara, CA, USA; 5) European Bioinformatics Institute; Wellcome Trust Genome Campus, Hinxton, Cambridge, UK.

As part of the Encyclopedia of DNA Elements (ENCODE) project, the location of transcription sites across 1% of the human genome has been determined in multiple cell lines and tissues using tiling microarrays. There is a complex organization of lattice-like networks of transcription indicating that intergenic regions comprise only 10% of the genome. 15% of the ENCODE sequences are detected as processed transcripts, of which >30% correspond to previously unannotated transcription. These novel transcription sites are not under detectable selective evolutionary constraints. 5 RACE/microarray tiling array experiments of 359 annotated genes in 12 tissues, revealed the presence of many novel exons. Almost half (2,324 of 4,573) of all RACEfrags correspond to unannotated sites of transcription. Most of novel RACEfrags are cell lines/tissue specific. RACEfrags provide evidence of novel exons for 90% of the loci successfully assayed (316 out of 359). For 261 protein coding genes (66% of loci), RACEfrags detect distal novel exons, extending the loci beyond the annotated 5 boundaries. The average distance of these new distal RACEfrags is between 50-100 kb (in 20% >200 kb) from the "known" transription start site. In 224 (62% of loci), the extended RACEfrags reach to another upstream protein-coding gene, often transversing many intervening genes. In 180 of these (50% of loci) the elongated transcripts appear to incorporate exons of another upstream protein-coding transcript (chimeric transcripts). A total of 538 RACEfrags, were analyzed using RT-PCR, and tiling array resolution, cloning and sequencing. 314 (58%) of the 538 exons provided RT-PCR/microarray results confirming connectivity of the distal exon with a site within the downstream coding transcript.

FXR1P modulates FMRP affinity for G-quartets structure, increasing the dynamics of FMRP/FXR1P/RNA complex. *B. Bardoni[1], E. Bechara[1], L. Davidovic[1,2], M. Melko[1], M. Bensaid[1], E.W. Khandjian[2], E. Lalli[3]* 1) Dep.Human Genetics, CNRS UMR6543, Nice, France; 2) Dep. of Medical biology, Universite' Laval,Quebec, Canada; 3) IPMC, CNRS UMR 6097, Valbonne sophia Antipolis, Nice, France.

Fragile X syndrome is the most frequent form of inherited mental retardation and is due to silencing of the Fragile X Mental Retardation gene 1 (FMR1). FMR1 encodes FMRP, an RNA binding protein involved in several steps of mRNA metabolism: nucleocytoplasmic trafficking, translational control and also transport to specific locations for localized translation (e.g. synapses in neurons). Even if several hundreds of mRNAs have been identified as putative targets for FMRP, up to date only 3 sequences/structures have been shown to be bound with high specificity by FMRP: G-quartets forming structure, kissing complex and poly(U) stretches. FMR1 is a component of a family including two other genes: fragile X Related gene 1 (FXR1) and Fragile X Related gene 2 (FXR2), coding for the two proteins FXR1P and FXR2P, respectively, which have high homology with FMRP particularly at the level of functional domains: KH, RGG box, Nuclear Localization Signal (NLS) and Nuclear Export Signal (NES). In addition, the 3 proteins are able to interact forming heterodimers and larger complexes. FXR1P/2P are supposed to have a function very similar and probably overlapping with FMRP. As a consequence, they have been hypothesized to be able to partially compensate FMRP absence in Fragile X patients. In this study we test the ability of FXR1P to bind the G-quartet forming RNA structure and its ability to influence FMRP affinity for this structure. Indeed, FXR1P and FMRP mutually increase their affinity for G-quartet RNA, increasing the dynamics of the FXR1P/FMRP/RNA complex formation. These findings suggest that FXR1P has a non-redundant action with FMRP in modulating its RNA binding capacities. This result may be important to decipher the molecular basis of fragile X syndrome, through the understanding of the action of FMRP in the context of its containing multimolecular complex.

Mutational analysis of EFHC1 gene in Italian families with Juvenile Myoclonic Epilepsy. *F. Annesi*[1], *G. Annesi*[1], *A. Gambardella*[1,2], *Gruppo di studio Lega Italiana Contro lEpilessia*[3] 1) Inst of Neurol Sciences, National Research Council, Mangone, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 3) LICE.

In this study, we screened for mutations in the EFHC1 gene 25 families from Italy in which at least two members had a typical form of Juvenile myoclonic epilepsy (JME). JME is a common form of generalized epilepsy starting in adolescence. Recently, a major JME locus was mapped to chromosomal region 6p12.p11 and it was associated with mutations in the EFHC1 gene. This gene contains 11 exons and encodes a protein of 640-amino acids that contains 3 DM10 domains and an EF hand calcium-binding motif. Twenty-five families were selected and families with fewer than two affected members were excluded from the study. In each patient the diagnosis of JME was done according to the ILAE criteria. After informed consent, DNA was isolated from peripheral blood lymphocytes by standard methods and each exon of EFHC1 gene was amplified and sequenced using intronic primers. We have identified three heterozygous mutations: the F229L mutation, previously described, and the novel mutations P429P and R353W among affected members of 5 unrelated families. EFHC1 gene has been associated with JME in six out 44 families from Belize, Los Angeles, and Mexico. The authors detected 3 heterozygous mutations (F229L, D210L, D253Y) and one double heterozygous mutation (P77T, R221H). The results of our study are important as they extend for the first time the distribution of EFHC1 mutations to Caucasian populations. Moreover, our data provide further evidence for the high level of genetic heterogeneity associated with JME, as most of our JME families did not carry any mutations. This study was partially supported by Italian League Against Epilepsy.

Sense and antisense RNAs are transcribed from a loosened heterochromatic structure at D4Z4 in Facio-Scapulo-Humeral Muscular Dystrophy. *M. Rossi[1], A. Cellini[1], E. Ricci[1], P. Tonali[1], L. Felicetti[2], P. Venditti[1]* 1) Neurology, Catholic University, Rome, Italy; 2) UILDM, Rome section.

The 3.3 kb KpnI tandemly repeated sequences are implicated in Facio-Scapulo-Humeral Muscular Dystrophy (FSHD). In healthy individuals the 4q subtelomeric repeat array (D4Z4) varies between 11 and more than 100 copies; a decrease in the number of units below the threshold number of 10 leads to disease. The underlying molecular mechanism still remains largely unsolved, even though several lines of evidence suggest a chromatin involvement in the pathogenesis of the disease. We probed healthy and FSHD affected individuals for specific hallmarks of condensed chromatin structure, namely DNA methylation and histone-H3 lysine-9 methylation. We could confirm DNA hypomethylation of D4Z4 in FSHD patients, even though bisulfite allele-specific genomic sequencing revealed a complex methylation pattern within the tandem repeat unit, with highly methylated regions alternating with undermethylated ones. Accordingly we found a relief in the histone-H3 lysine-9 methylation status in affected individuals versus unaffected at D4Z4. Finally we report that the loss of proper heterochromatinization in FSHD patients is associated with aberrant transcription of ncRNA species within the repeats that could deregulate the gene expression program of the cell.

The association of two SNPs in the brain-derived neurotrophic factor (BDNF) gene with depression: findings from the British Women's Heart and Health study. *L. Chen[1], D. Lawlor[1], I. Day[2], S. Lewis[1], S. Ebrahim[3], G. Davey-Smith[1], Y. Yao[1,4]* 1) Department of Social Medicine, University of Bristol, Bristol, UK; 2) Human Genetics Division, University of Southampton, School of Medicine, Southampton, UK; 3) Department of Epidemiology and Population Health,London School of Hygiene & Tropical Medicine, London, UK; 4) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, USA.

Depression remains to be a significant health concern with a lifetime risk of up to 17%. Both clinical and pharmacologic studies have implicated the brain-derived neurotrophic factor (BDNF) gene as a susceptibility locus for the development of depression. However, previous genetic association studies have not consistently exhibited the relationship between the mutation allele of BDNF (Val66Met) and an increased risk of depression. This study aimed to test for an association between BDNF and depression status by examining the distribution of two functional single nucleotide polymorphisms within BDNF locus, -270 CT in the promoter region and Val66Met in the BDNF coding region in three case groups; 1) currently taking anti-depressant (n=406), 2) positive response to EuroQol mood question (n=811), and 3) ever diagnosed as depression (n=553) and 2,367 ethnically matched controls. All of the participants in the study were recruited into the British Women's Heart and Health Study (total participants =3548, aged between 60 and 79). The minor allele frequencies for -270 CT and Val66Met were 0.05 and 0.20, respectively. The D prime between the two SNPs is 1.0 with the R-square of 0.014. We did not detect evidence for positive associations between the above genetic polymorphisms and depression status when the two SNPs were analyzed separately. However, when we analyzed two polymorphisms together as a haplotype, the prevalence of case group reporting ever diagnosed as depression; was marginally higher in the women with the TG haplotype than among those carrying CG haplotype with an odds ratio of 1.25 (95% confidence interval = 0.94 -1.66) (after adjust for BMI). We would like to note that this potential finding needs further confirmation in samples of greater size.

Dynamics of GLB1 gene expression levels by RT PCR and molecular analysis of GM1 gangliosidosis and Morquio B patients. *A. Caciotti[1], M.A. Donati[1], E. Procopio[1], M. Filocamo[2], W. Kleijer[3], W. Wuyts[4], B. Blaumeiser[4], A. DAzzo[5], L. Simi[6], C. Orlando[6], F. McKenzie[7], A. Fiumara[8], E. Zammarchi[1], A. Morrone[1]* 1) Dept Pediatrics,Florence,Italy; 2) Gaslini Inst,Genoa,Italy; 3) Dept Clin Genet,Rotterdam,Holland; 4) Dept Med Gen,Wilrijk,Belgium; 5) Dept Genet,St Jude Childrens Hosp,Memphis,USA; 6) Dept Clin Physiopath,Florence,Italy; 7) Hunter Genet,Waratah,AU; 8) Dept of Ped,Catania,Italy.

The human GLB1 gene gives rise to two alternatively spliced transcripts that encode the -galactosidase (GLB1) and the elastin binding protein (EBP). Mutations at the GLB1 locus, responsible for the lysosomal disorder GM1 gangliosidosis and Morquio B, may affect both proteins or GLB1 only. EBP acts as a molecular chaperone, protecting tropoelastin from degradation and facilitating its assembly into a microfibrillar scaffold and, when affected, contributes to specific clinical features of GM1 gangliosidosis patients. We report the development of a quantitative assay based on Real-Time PCR for assessing levels of GLB1 and EBP transcripts in patients samples. We also characterized the GLB1 gene mutations in 1 Morquio B and 9 GM1 gangliosidosis patients in order to correlate the genetic lesions with mRNA expression levels and clinical phenotypes. Mutation analysis led to identification of 5 new mutations (c.18351836delCC; p.R148C; c.1068+1GT; c.245+1GA; p.P549L) 6 known (p.R59H; p.R201H; p.G123R, p.W273L, c.1480-2AG; c.75+2dupT) and 1 new polymorphism (c.1233+8TC). Quantitative RT-PCR on total RNA from all patients fibroblasts showed differential levels of GLB1 and EBP mRNA that correlated with the mutation type. The three GM1 gangliosidosis patients carrying splicing defects had reduced levels of both mRNA. One of these patients, homozygous for the c.245+1GA mutation, showed a complete absence of the EBP mRNA. Comparative analysis of the patients' phenotypes will enable a more thorough correlation between GLB1 genetic lesions and specific clinical manifestations. This fast method for detection of GLB1 gene alternatively spliced transcripts could be applied to other lysosomal disease-causing genes that give rise to multiple mRNAs.

Further evidence that D90A mutation is recessively inherited in ALS patients in Southern Italy. *F.L. Conforti, T. Sprovieri, R. Mazzei, C. Ungaro, A. Patitucci, A. Magariello, AL. Gabriele, M. Muglia, A. Quattrone* Institute of Neurological Sciences, Mangone, Cosenza, Italy.

Amyotrophic Lateral Sclerosis (ALS), an adult-onset motor neuron degeneration is caused by mutations in the Cu/Zn superoxide dismutase (SOD1) gene. All the SOD1 mutations are autosomal dominantly inherited with the exception of D90A, very frequent in Scandinavian population, and D96N which can act as recessive. Only few cases of D90A heterozygous ALS in Belgian and Russian patients have been reported, all of them inherited as dominant trait. Up to now, in Italy, only two sporadic ALS cases carrying the D90A mutation have been reported in homozygous state. The aim of this study is to investigate the presence of D90A mutation in ALS patients in Southern Italy. One hundred and fifty-four ALS patients (8 familial ALS and 146 sporadic cases, 76 men and 78 woman; mean age 60.32 years, SD 10.22, range 36 to 88 years) from Southern Italy were screened for SOD1 mutations in exon 4. DNA was extracted by standard procedure and PCR products were subjected to enzymatic digestion with Fnu4H I and analyzed by direct sequencing. In our study, of 154 cases investigated three ALS patients (2%)with mild phenotype showed the homozygous D90A mutation. Two out of three patients were familial cases(FALS)and the remaining patient was an apparently sporadic case (SALS). We also screened the available members of one of the FALS cases. In this family we identified an affected and an unaffected individual carrying the D90A mutation in homozygous and heterozygous state respectively. Our study provides further evidence that D90A is an autosomal recessively inherited mutation in ALS patients in Southern Italy. Previous data reported that all ALS patients homozygous for the D90A show a phenotype characterized by slow progression of the disease, with little variation between patients. According to the literature, our patients show a mild phenotype with a prolonged survival. An explanation for the recessive and the dominant inheritance of the D90A, and the different expressed phenotype was suggested by Parton and coll. who indicated the presence of a cis-acting disease modifier in the recessive haplotype.

Neurofibromatosis type 2 (NF2) in children under 1 year of age: a clinical and molecular study. *A.L. Gabriele[1], M. Ruggieri[2,3], C. Nucifora[3], A. Patitucci[1], T. Sprovieri[1], A. Magariello[1], R. Mazzei[1], F.L. Conforti[1], C. Ungaro[1], M. Muglia[1], A. Quattrone[1,4]* 1) Institute of Neurological Sciences (ISN)- CNR, Mangone, Cosenza, Italy; 2) ISN, CNR, Section of Catania, Italy; 3) Department of Paediatrics, University of Catania, Italy; 4) Institute of Neurology, University of Magna Graecia, Catanzaro, Italy.

To identify the earliest (i.e., disease onset < 1 year of age) clinical presentations of neurofibromatosis type 2 (NF2) 1,2, to characterise its natural history and to investigate the NF2 mutations at this young age 3.Two NF2 children (1 boy, 1 girl), out of the 28 (aged 4-18 years) diagnosed as having the disease according to current NF2 criteria 1, had their first disease manifestations under 1 year of age: both were prospectively followed up and investigated according to our protocol for paediatric NF2 2. Molecular analysis of the NF2 gene was carried out by means of Denaturing High Performance Liquid Chromatography (DHPLC) and sequence analysis.The boy (aged 7 years) presented at age 4 months with right lens opacities and imaging evidence of bilateral colpocephaly and high signal (calcified) lesions in the posterior periventricular regions. MRI scans at age 8 months confirmed these findings and revealed bilateral vestibular schwannoma. He developed multiple (> 40) skin NF2-plaques in the limbs with no neurological or hearing dysfunction. At his last head and spinal MRI the schwannoma and the periventricular lesions did not progress with any additional lesions. The girl (aged 10 years) presented at age 4 months with pigment retinal hyperplasia misdiagnosed as retinal folds. She was first referred to us at age 7 years for a pelvic bilateral plexiform schwannoma (operated). At that age the child had multiple (> 20) NF2-plaques in the four limbs; head and spinal MRI scan revealed bilateral vestibular schwannoma, high signal lesions in the temporal periventricular regions and a cervical meningioma (operated). At his last MRI control the vestibular schwannoma and the high signal lesions were stable. No neurological or hearing deficits ensued. Molecular genetic analysis carried out in both children revealed so far a novel mutation in the exon 3 of the NF2 gene in the boy: this mutation was a small insertion of 4 bases pair (c.281_282 ins CCTT). This mutation was not detected in 100 control chromosomes from matched healthy individuals. In 5 previous NF2 cases disease onset was < 1 year of age : to the best of our knowledge however this is the first time 2 that: (1) bilateral eight nerve tumours in NF2 children do not show progression after a long follow-up period; and (2) NF2 children develop large numbers of skin NF2-plaques in atypical localisations.

Natural history of 1p36 deletion syndrome: experience with 60 cases. *A. Battaglia[1,2], J.C. Carey[2], H.E. Hoyme[3], ICSG* 1) Stella Maris Inst. Pisa, Italy; 2) Medical Genetics, Dept. Pediatrics, University Utah, SLC, USA; 3) Medical Genetics, Dept. Pediatrics, Stanford University, USA.

From the recent literature it appears that 1p36 deletions account for 0.15-1.2% of idiopathic DD/MR. 1p36 deletion syndrome is a newly recognized segmental aneusomy condition with an estimated incidence of 1/5,000 newborns. Although about 90 cases have been reported so far, there is still little data on its natural history. Information given to parents at the time of diagnosis tends to be skewed to the extreme negative. To help delineate more thoroughly the natural history of monosomy 1p36, and to obtain better information to answer parents questions in a clinical setting, we evaluated 60 patients (female/male ratio: 2/1), in different centers, with the syndrome. One third of them were detected by standard cytogenetics, whereas the other two thirds by subtelomeric FISH analysis. OFC was at/below the 2 centile, and height/weight ranged between <3rd-50th centile. All patients had a distinct craniofacial appearance with tower skull, prominent forehead, deep-set eyes, straight eyebrows, epicanthus, midface hypoplasia, broad nasal root/bridge, long philtrum, pointed chin; associated with brachy/camptodactyly, and short feet. 70% of the patients had CNS anomalies (ventricular dilatation; cortical atrophy; multifocal white matter T2 hyperintensity); 70% had heart defects (ventricular myocardium non-compaction [n=15]; ASD; VSD; PDA; tetralogy of Fallot); 50% had seizures (infantile spasms; partial and generalized seizures); 40% had hearing impairment; 40% had skeletal anomalies; 100% had mild/profound DD/MR, and 95% had hypotonia. 80% had no speech, whereas the remaining 20% pronounced either isolated words or simple words associations. Just over 25% was able to walk alone, and 70% had a behavior disorder. A slow, but constant progress in development was observed in all cases overtime. The non-compaction of the ventricular myocardium, and all seizure types were well controlled by the usual pharmacotherapy. In conclusion, the combined cases of our sample represent considerable experience, providing new information on several aspects of this important and frequent deletion syndrome.

UNUSUAL CO-EXISTENCE OF MILD PKU AND FABRY DISEASE: CASE REPORT. *D. Concolino[1], M. Rapsomaniki[1], M.T. Moricca[1], E. Disabella[2], E. Arbustini[2], P. Strisciuglio[1]* 1) Department of Pediatrics, University of Catanzaro, Catanzaro, Italy; 2) Department of Cardiology, I.R.C.C.S. Policlinico San Matteo, Pavia, Italy.

Phenylketonuria is inborn error of the metabolism resulting from a deficiency of phenylalanine hydroxylase. Fabry disease (FD) is an X-linked lysosomal storage disorder due to a deficiency of the enzyme alpha-galactosidase A (GALA) with subsequent accumulation of globotriaosylceramide in the lysosomes of various tissues leading to clinical symptoms. The GALA gene is localized on Xq22.1 and over 300 mutations have been reported.The disease affects kidney, myocardium, central nervous system, skin and, in many patients, the gastrointestinal tract. FD usually becomes clinically manifest in childhood with generalized pain, acroparaestesia, non-specific GI symptoms and hearing problems. We report here the discover of Fabry disease in a 3 year- old boy with mild PKU detected at birth by neonatal screening.The patient was first seen in our department at the age of 20 days because affected by mild PKU and was subjected to a dietetic treatment with a good compliance. Growth, neurological and psychological development, were normal. At the age of 21 months he showed a reduction of the weight, lack of appetite, abdominal pain and periodically appearance of not specific attacks of gastroenteritis resolved spontaneously and not correlated with the dietetic treatment. These symptoms associated to a familiar history of renal failure and cerebral stroke on young familiars, suggested a possible Fabry disease. The reduced plasma a-galactosidase A, decreased GALA activity in leucocytes and the molecular analysis (Arg 112 His in exon 2) supported our hypothesis.This co-existence of mild PKU and Fabry disease is very rare and made very difficult to attribute the clinical symptoms of lack of appetite, abdominal pain and non-specific gastroenteritis attacks to an other disease different from PKU.This case helps to define the clinical phenotype of Fabry disease in children for early diagnosis. The ERT treatment should be initiated at an early stage, prior to the onset of irreversible complications.

Autosomal dominant seborrhea-like dermatitis caused by a mutation in *ZNF750*, a novel putative C2H2 zinc finger protein. *R. Birnbaum, A. Zvulunov, D. Hallel-Halevy, R. Ofir, E. Cagnano, O.S. Birk* The Morris Kahn Laboratory of Human Genetics, National Institute for Biotechnology and Soroka Medical Center, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer-Sheva, Israel.

Seborrheic dermatitis (SD) and Psoriasis are common chronic papulosquamous dermatoses. Occasionally, distinction between these entities can be obscured by overlapping clinical features, particularly when the manifestations are limited to the scalp and face. An Israeli Jewish Moroccan family (44 affected individuals in 5 generations) presented with autosomal dominant seborrhea-like dermatosis with psoriasiform elements: enhanced keratinocyte proliferation, parakeratosis, follicular plugging, *Pityrosporum ovale* overgrowth, and CD4 lymphocyte infiltrate. Through genome wide linkage analysis we mapped the disease gene to a 0.5cM region on 17q25 (maximum lod score 8.8 at theta=0), within a locus previously associated with psoriasis (*PSORS2*). Sequencing of candidate genes within that locus identified a mutation in *ZNF750* ,a novel putative transcription factor. The mutation fully abrogates the putative active domain of the encoded protein. The gene is normally expressed in keratinocytes but not in fibroblasts or CD4 lymphocytes (activated or not), suggesting that the primary event leading to the disease is in keratinocytes. *ZNF750* is the first gene shown to be associated with SD, and the first gene associated with Mendelian heredity of a non-arthritic variant of psoriasis.

Germline and somatic mosaicism at the PHOX2B locus in Late-Onset Central Hypoventilation syndrome. *J. Amiel, D. Trochet, L. de Pontual, A. Munnich, S. Lyonnet* Genetics, Hôpital Necker, University Paris5, Paris, France.

Idiopathic late-onset central hypoventilation syndrome (LOCHS) is a rare disorder occurring from early childhood to adulthood. The physiopathological relationships between LOCHS and congenital central hypoventilation syndrome (CCHS) have been debated and the question of whether both disorders can result from heterozygous PHOX2B gene mutations. Here we report a series of 25 patients with LOCHS referred from 6 months of age to adulthood. We identified a heterozygous PHOX2B gene mutation in 13/25 patients, the most frequent mutant allele resulting in a +5 alanines expansion of the series of 20 alanines C terminal to the homeodomain of the protein (10 cases). In vitro studies showed a significantly reduced PHOX2B transactivation for all mutations except the +5 alanines expansion. However, spontaneous formation of oligomers occurred starting at +5 alanines expansion suggestive of misfolding mutant proteins. Most mutations were germline while some were somatic mosaics. This has major consequences in terms of genetic counselling. In this series, one adult with LOCHS had a child with CCHS. This raises the question of the follow-up of apparently healthy parents of a CCHS child and found to harbour a somatic mosaic fro a PHOX2B gene mutation (5% of the parents in our series). Among patients with no PHOX2B mutation identified, 3 presented also hypothalamic-related endocrinopathies and behavioral problems, suggesting genetic heterogeneity of idiopathic LOCHS. Altogether, these data demonstrate a genetic link between CCHS and, at least, a subgroup of LOCHS. Genetic heterogeneity of LOCHS is however likely. Furthermore, combined genetic and environmental factors may explain the variability of disease onset ranging for neonatal period to adulthood for an identical PHOX2B gene mutation (+5 alanines expansion).

Methylation Specific PCR (MSP) analysis of APC tumor suppressor gene promoter in adenocacinoma of stomach. *M.R. Alivand[1,2], F. rastgar[1], M. zare[1,2]* 1) biochemistry, National Institute of Genetic Engineering and Biot, Tehran, Tehran, Iran; 2) khatam Institute of Higher Education;depattment of biology,Tehran.

Adenocarcinoma of stomach is among cancers with high mortality rate in the world, for which a high incidence rate has also been reported from Iran. The cancer could only be diagnosed when it is well developed and diffused out to the adjacent tissues which make treatment almost impossible. In order to diagnose and study the molecular basis of the disease, recently attentions were focused on the methylation status of promoters of tumor suppressor genes including Adenomatous Polyposis Coli (APC) both in tissues and preferentially serum. By applying Methylation Specific PCR (MSP), here we studied methylation status of the APC promoter. Our results indicate methylation of APC promoter in %66.6 of tissue samples. We further extended our study to the serum of such patients and the results indicate almost the same percentage of promoter methylation. This report is among the first reports that indicate MSP is also applicable for analyzing APC promoter methylation status in serum samples which clinically is important for diagnosis and evaluation of treatment.

Single nucleotide polymorphisms of DNA repair gene *XPC* and risk of lung cancer in a Chinese population. *Y. Bai[1], J. Yuan[1], Z. Hu[2], X. Yang[1], F. Wang[1], L. Xu[3], M. Shao[4], Y. Wang[4], W. Yuan[3], J. Qian[4], H. Ma[2], Y. Wang[3], H. Liu[4], F. Chen[2], Y. Liu[4], L. Jin[4], Q. Wei[5], H. Shen[2], D. Lu[4], T. Wu[1]* 1) Institute of Occupational Medicine and Ministry of Education Key Lab for Environment and Health, School of Public Health, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China; 2) Department of Epidemiology and Biostatistics, Cancer Research Center of Nanjing Medical University, Nanjing, China; 3) Department of Genetics, Chinese National Human Genome Center at Shanghai, Shanghai, China; 4) State Key Laboratory of Genetic Engineering, School of Life Sciences, Fudan University, Shanghai, China; 5) Department of Epidemiology, The University of Texas M. D. Anderson Cancer Center, Houston, TX, USA.

DNA repair is a major defense against environmental damage to the genome and protect the cell from carcinogenesis. In the nucleotide excision repair (NER) pathway, xeroderma pigmentosum C (XPC) repair protein participates in recognition of DNA damage and initiation of DNA repair. Polymorphisms of the *XPC* gene are thought to have an effect on DNA repair capacity and susceptibility to cancer. In this study, we investigated five *XPC*-related tagSNPs in a case-control study of 1010 patients with newly diagnosed lung cancer and 1011 controls matched on age and sex. In individual tagSNP analysis, we found that the rs3731055AG+AA genotype was associated with a significantly decreased risk of lung adenocarcinoma, but an increased risk of small cell carcinomas. Accordingly, we also found that the haplotype ACCCA was associated with decreased risk of lung adenocarcinoma, but increased the risk of small cell carcinomas, which reflected the presence of rs3731055A allele in this haplotype. Further combined analysis of all five polymorphisms, we found that compared with subjects with 0-3 risk alleles, those having 4-6 risk alleles had a significantly 1.26-fold increased risk of lung cancer, and this association was more evident in the subgroups of young peoples (age < 60), males, light smoker and patients with lung adenocarcinoma. These results suggest that the inherited variation in *XPC* may modulate the risk of lung cancer, especially lung adenocarcinoma.

Estimating the age of four common CFTR mutations in Brittany (western France). *Y. Fichou*[1], *E. Génin*[2], *C. Le Maréchal*[1,3], *V. Scotet*[1], *C. Férec*[1,3] 1) INSERM U613, Brest, F-29220 France; UBO, Faculté de Médecine de Brest et des Sciences de la Santé, F-29238 France; 2) INSERM U535, Villejuif, F-94817 France; 3) EFS-Bretagne, Brest and Centre Hospitalier Régional Universitaire (CHRU) Brest, Hôpital Morvan, Brest, F-29220 France.

Cystic fibrosis (CF) is the most common autosomal recessive disorder in Caucasian populations, characterized by inflammation and chronic infections progressively leading to alteration of pulmonary functions, abnormal exocrine gland secretions, digestive troubles and pancreatic insufficiency. To date, more than 1,400 mutations and sequence variations have been reported (www.genet.sickkids.on.ca/cftr) within the CF transmembrane conductance regulator (CFTR) gene, the CF-causing gene which encodes a cAMP-dependent chloride channel. The F508 mutation, which consists of the deletion of a phenylalanine aminoacid at position 508 of the protein, accounts for 70% of the total mutated alleles and only four additional mutations have a frequency 1% in the general population. However, disparities exist between specific populations depending on their ethnical and/or geographical origins. We have used a simple likelihood-based method to date the most recent common ancestors carrying four CFTR mutations that are preferentially observed in Brittany (western France): $W846X_2$, 1078delT, G551D and F508 mutations. This approach, which assumes that all haplotypes have diverged from a common ancestor, has proven useful for estimating rare mutations (Génin *et al.*, 2004). Ten microsatellite markers flanking the CFTR gene were systematically genotyped in CF patients and relatives (200 individuals) carrying at least one of the mutations of interest. Following phase reconstruction and calculations of haplotype frequencies, it was estimated that the most recent common ancestors lived 625 [375-1,025], 1,000 [750-1325], 1,200 [900-1,550] and 2,875 [2275-3700] years ago, respectively, with a 95% confidence interval. These estimations suggest, as expected, that the F508 mutation is an old event. Furthermore, they also give evidence for important migrations of populations in western Europe in the second part of the first millenium.

An improved genomic control method for association studies: LGC. *W. Fu*[1], *Y. Wang*[1], *L. Jin*[1, 2] 1) State Key Laboratory of Genetic Engineering, School of Life Sciences, Fudan University, Shanghai, China; 2) CAS-MPG Partner Institute for Computational Biology, Shanghai, China.

The presence of undetected population structure with differential disease prevalence among subpopulations can lead to either false positive results or failures to detect genuine associations. One method for correcting such problem is genomic control (GC). The GC method is based on the assumption that the variance inflation factor () is a constant across the genome for all null loci. This assumption leads to under- or over-estimation of which varies greatly across the genome. We therefore propose a locus-specific genomic control method (LGC) to circumvent the problem. We first estimated the , a constant that reflects the difference of the prevalence among subpopulations. The along with the locus-specific Fst can be used to estimate the locus-specific variance inflation factor $_L$ for correcting for the population structure for each locus in association studies. Using simulation, we will show that the improved genomic control method (LGC) performs better than its original version in association studies.

Molecular characterization of the reciprocal translocation t(4,7)(q26;p15) in a patient with mental retardation and congenital defects. *C. Fusco[1], L. Micale[1], S. Calvano[1], B. Augello[1], A. Reymond[2], M. Rocchi[3], L. Zelante[1], G. Merla[1]* 1) Medical Genetics Unit , IRCCS Casa Sollievo della Sofferenza Hospital, S.G. Rotondo, Foggia, Italy; 2) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 3) Department of Genetics and Microbiology, University of Bari, Bari, ItalySwitzerland.

De novo translocations are a powerful tool for the identification of genes associated with complex phenotype and specific disease. We report the case of a 2 years-old subject affected by mental retardation, speech delay and congenital defects. The patient was hypotonic and showed facial phenotype characterized by unilateral strabismus, horizontal palpebral fissures, open mouth with cupids bow, folded down helix. Other congenital defects were bilateral cryptorchidism, pulmonic stenosis and syndactyly of 2nd and 3rd toes. High resolution chromosome analysis showed an apparently balanced reciprocal translocation t(4,7)(q26;p15). Karyotype analysis revealed that parental chromosomes were normal, indicating that the patient's translocation was de novo. FISH analysis demonstrated that the clones RP11-954B12 and RP11-281H13 mapped to both the derivative chromosomes indicating that these BACs spanned the chromosomes 7 and 4 breakpoints, respectively. The HSA7 region covered by BAC RP11-954B12 is rich in Alu repeats and devoid of annotated genes and mapped ESTs, while clone RP11-281H13 encompasses two genes. Using Long PCR, we created overlapping fragment to perform additional FISH analysis to narrow the breakpoint. This approach identified a 10 kb fragment hybridizing to both derivatives. It spans exons 9 to 12 of a novel gene, LOC91431 that encodes a putative helicase. Preliminary characterization showed that this gene is expressed in several tissues such as spleen, colon, muscle, lung, fetal liver, kidney and heart and that its product has a diffuse cytoplasmic and nuclear distribution in transfected HeLa cells. We propose that the complex phenotype observed could be caused by lack of LOC 91431 gene integrity with consequent deregulated gene expression and protein level.

Combining case-control association and allele frequency differentiation to detect malaria resistance genes. *G. Ayodo[1,2,3], A. Ajwang[3], A. Keinan[1,2], A. Price[1,2], M.F. Otieno[3], N. Patterson[2], A.S.S. Orago[3], D. Reich[1,2]* 1) Dept. of Genetics, Harvard Medical School, USA; 2) Broad Institute of MIT & Harvard, USA; 3) Dept. of Pre-Clinical Sciences, Kenyatta University, Kenya.

Nineteen genetic variants have been identified as conferring resistance to severe malaria, but only a few have been replicated, and most studies have been limited to West Africans. We report a replication study in 460 cases from the Luo ethnic group and 470 Luo controls. We confirm that heterozygosity for the sickle-cell trait HbAS ($P<0.02$), heterozygosity for the GT genotype at CD36-1264 ($P<0.03$), and homozygosity for the T allele at NOSA-1659 ($P<0.01$), are all associated to malaria resistance. We do not replicate 16 previously reported associations, suggesting that some may have been spurious, and emphasizing the importance of systematic replication. Failure to replicate associations at these 16 genotypes may also be due to limited sample size, differences between the Luo and the populations in whom the associations were originally found, or differences between the phenotypes we and other groups studied. We also compared the frequency of malaria resistance variants in the Luo to the ethnically closely related Masai. We hypothesized that there would be a higher frequency of malaria resistance alleles in the Luo, due to selection for malaria resistance since the two populations split (the Masai have lived in a high-altitude, low malaria environment since they split from the Luo). Indeed, the sickle cell variant, the CD36 variant, and the Duffy null variant were all strikingly differentiated in frequency. We assessed the statistical significance of the allele frequency differentiation by genotyping 1,536 random SNPs in the Luo and Masai, demonstrating empirically that the level of differentiation at the malaria resistance alleles stands out. We propose that in future, variants conferring resistance to malaria and other infectious diseases may be found not only by case-control analysis, but by combining this information with evidence that the alleles are highly differentiated in frequency comparing exposed and unexposed populations.

X-APL: A family-based association test for the X chromosome. *R.-H. Chung[1,2], R.W. Morris[3], L. Zhang[1,2], Y.-J. Li[2], E.R. Martin[2]* 1) Bioinformatics Research Center, North Carolina State University; 2) Center for Human Genetics, Duke University Medical Center; 3) Department of Anesthesiology, Duke University Medical Center.

Linkage analyses have identified regions on the X chromosome for several diseases, such as Parkinson disease and autism. Association methods can further localize disease susceptibility genes in the linkage regions, however, few family-based association methods are available for testing markers on the X chromosome. Two such tests, XS-TDT and XRC-TDT [Horvath et al. 2000, AJHG], are valid tests of association in family triads or discordant sib pairs, but are not theoretically valid in multiplex families when linkage is present. We have developed a family-based method for testing association in nuclear families, X-APL, which extends the APL method [Martin et al. 2003, AJHG] to X-linked markers. X-APL is based on the difference between the observed number of a specific allele in affected siblings and the expected number conditional on parental genotypes and sibling sex under the null hypothesis of no association or no linkage. Sharing properties of APL, X-APL can use singleton and multiplex families and properly infers missing parental marker genotypes in linkage regions. X-APL was extended to haplotype association analyses. To allow for different penetrances in males and females, separate tests for males and females are provided in X-APL. We used Monte Carlo simulations to verify that X-APL has correct type I error rate. Power analyses showed that X-APL can have substantially more power than XS-TDT. The X-APL test using all data from males and females can have more power than separate tests for males and females when the disease penetrance is similar in both sexes. Tests in males and females alone can have more power than a test using both sexes if the X-linked locus only has effects on one sex. X-APL identified a SNP marker and 2-SNP haplotypes in the MAOB gene significantly associated with Parkinson disease in females but not in males. In summary, X-APL provides a powerful tool for association analysis on the X chromosome using single loci or haplotypes in nuclear family data.

Synergistic effects of nucleotide content on SNP formation. *E. Arehart, N. Barney, W. Holden, J. Hwa, J.H. Moore*
Computational Genetics Laboratory, Dartmouth Medical School, Lebanon, NH.

The fidelity of DNA replication serves as the nidus for both genetic evolution and genomic instability fostering human disease. Single nucleotide polymorphisms (SNPs) constitute greater than 80% of the genetic variation between individuals. A new theory regarding the mechanism for DNA replication fidelity has emerged were selectivity is governed by base-pair geometry and interactions between the selected nucleotide, complementary strand and the polymerase active site. The goal of this study was to identify nucleotide patterns that may predispose specific sites to mutation. We investigated the role of flanking regions within known SNP sequences using the novel multifactor dimensional reduction (MDR) method that was designed specifically to detect synergistic interactions among multiple discrete attributes. The MDR method was used to analyze 2194 human DNA sequences sampled from the Human SNP Database. Each mutation position was evaluated for its flanking nucleotide content (A, G, T, and C) as well as its purine/pyrimidine content. MDR was utilized to identify the best combination of two, three, or four nucleotide content measures that are predictive of each of the twelve possible transition/transversion SNPs. Cross-validation and permutation testing were utilized to minimize overfitting and false-positives due to multiple testing. Information theory was used to decompose each multifactor model into redundant, independent, and/or synergistic effects for statistical interpretation and visualization. We found statistically significant evidence for the presence of independent and synergistic nucleotide position effects on SNP formation. The results of this study highlight the importance of local nucleotide content in biasing certain sites towards mutation. Further, this study demonstrates that multiple nucleotides may work in concert to increase this position bias. Embracing the complexity of nucleotide effects on mutation may prove to be a useful research strategy for understanding the role of flanking regions in DNA polymerase fidelity.

Genetic modifiers of cystic fibrosis-related diabetes. *S.M. Blackman[1], S. Hsu[1], K. Naughton[2], B. Coleman[2], T. Lai[2], A. Bowers[2], D.J. Cutler[2], G.R. Cutting[2]* 1) Division of Pediatric Endocrinology, Johns Hopkins Hospital, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Hospital, Baltimore, MD.

Diabetes is the most common extrapulmonary complication of cystic fibrosis (CF), a multi-system genetic disease caused by defects in an epithelial chloride channel, the cystic fibrosis transmembrane conductance regulator (CFTR). While some loss of exocrine and endocrine function is typical in CF, a subset (20-25%) of CF adults develop defects in insulin secretion, insulin resistance, and an accumulation of islet amyloid polypeptide, features typical of type 2 diabetes in the general population. Using a twin study design, we tested whether modifier genes might contribute to CF-related diabetes (CFRD). CF patients were classified as diabetic based on physician diagnosis and appropriate daily insulin dosage. CFRD was present in 14 of 128 monozygous (MZ) twins, 1 of 45 dizygous (DZ) twins, and 44 of 697 siblings. The relative absence of CFRD in DZ twins is likely due to a lower mean age (8.3 yr) than that of the MZ twins (15.5) and siblings (12.5). Concordance for CFRD was 56% in MZ twins (5 of 9 pairs), and was 27% in siblings (8 of 30 pairs; p=0.1). To account for variation in defects in CFTR, concordance was calculated using patients homozygous for the F508 mutation. Then, 4 of 6 MZ twin pairs (67%) and 3 of 16 sibling pairs (19%) were concordant (p=0.05; Fisher exact). If siblings are used as a proxy for DZ twins in a heritability estimate defined as $h^2=2(MZ\ concordance\ rate - DZ\ concordance\ rate)$, these twins and siblings estimate heritability of CFRD to be 0.6-0.9, which is comparable to heritability estimates for type 1 and type 2 diabetes. An initial genome-wide linkage study has been performed using 402 short tandem repeat markers in 24 individuals from 7 families concordant for CFRD. In addition to CFTR on chromosome 7 (peak LOD score 2.5), regions with similarly high degrees of allele sharing (LOD 2.4-3.0) were identified on chromosomes 3p25 and 10p13-14. Thus, it appears that genes other than CFTR affect the risk of diabetes in CF, and two possible genetic loci have been identified.

G72/G30 transgenic mice and gene expression profiling. *L. Cheng, E. Hattori, A. Nakajima, Y. Tang, E. Gershon, C. Liu* Dept Psychiatry, Univ Chicago, Chicago, IL.

The G72/G30 gene region has multiple reports of association with both bipolar disorder and schizophrenia. We have introduced a human BAC clone containing G72/G30 gene into B6/CBA mice. In the F4 generation of the transgenic mice, real-time PCR revealed stable transmission of BAC DNA between generations. We performed G72/G30 expression study in cDNAs from 16 different human tissues, fetal brain, five brain subregions (amygdala, substantia nigra, thalamus, celebral cortex, hippocampus), and RNA from human fetal and adult whole brains. Eight new alternative splicing forms of G72 were identified, including two isoforms from testis; two from brain (substantia nigra and amygdala); four from transgenic mice brain cortex tissues. G72 expresses at very low level in human testis and brain. In fourteen other human tissues no G72 expression was detected using multiple methods. G72 expresses at a high level in transgenic mouse brain cortex. The transgenic mice may form a living model to study G72 function and its role in disease etiology.

Regulation of RUNX2 at the nuclear lamina. *P. Fonseca[1], G. Zhou[1], P. Hermanns[1], E. Munivez[1, 2], Q.P. Zheng[1], B. Lee[1, 2]* 1) Dept Human Molecular Genetics, Baylor Col Medicine, Houston, TX; 2) Howard Hughes Medical Institute.

RUNX2 is a member of the RUNT family of transcription factors. It is essential for osteoblast formation and chondrocyte maturation. Loss of function mutations in RUNX2 result in the human skeletal disorder cleidocranial dysplasia (CCD). RIP (CBFA1/RUNX2-Interacting Protein) was isolated in a screening of a human osteosarcoma cDNA library using a yeast two-hybrid approach. Two families with rearrangements involving chromosome 8q - where RIP maps - have been reported to have a CCD-like phenotype. In transient transfection experiments, RIP down-regulated the transactivation by RUNX2 in a dose-dependent manner in both 10T1/2 cells and ROS17/2 cells. RIP is mainly localized in the nucleus and it was identified as a component of the nuclear envelope in proteomic screens. Interestingly, mutations in LaminA/C result in several laminopathies, including mandibuloacral dysplasia (MAD). MAD clinical features include hypoplastic clavicles and in some cases delayed closure of cranial sutures, partially phenocopying CCD. Hence, the skeletal defects observed in these patients may be due to disruption of interactions of the nuclear lamina with transcriptional regulators relevant in bone formation such as RIP and RUNX2. GST pull-down experiments showed an interaction between LaminA/C and RIP, as well as the RUNT domain of RUNX2. The tail domain, which is mutated in MAD patients, is responsible for both the interaction between RIP and RUNT. Moreover, LaminA/C could repress RUNX2 transactivation of reporter genes in COS7 cells in a dosage-sensitive way. Mutant versions of lamin carrying MAD mutations seem to lose their repressive action. A GST-pulldown assay revealed that these mutants had altered RUNT domain and RIP binding properties. These data suggest a novel mechanism for transcription regulation of skeletogenesis involving sequestration of a RUNX2 complex at the nuclear lamina.

Alpha-synuclein promoter haplotypes and dementia in Parkinsons disease. *E.V. De Marco[1], P. Tarantino[1], G. Provenzano[1], D. Civitelli[1], F.E. Rocca[1], F. Annesi[1], I.C. Cirò Candiano[1], S. Carrideo[1], V. De Luca[2,3], F. Condino[1], N. Romeo[1], G. Nicoletti[1], R. Marconi[4], M. Zappia[5], G. Annesi[1]* 1) Inst of Neurological Sciences, National Research Council, Cosenza, Italy; 2) Dept of Neurosciences, University of Naples "Federico II", Italy; 3) Dept of Psychiatry, University of Toronto, Canada; 4) Dept of Neurology,Misericordia Hospital, Grosseto,Italy; 5) Dept of Neurosciences, University of Catania, Italy.

Mutations of the alpha-synuclein gene (SNCA) were linked to rare familial forms of Parkinsons disease (PD), while association studies on the promoter polymorphisms gave conflicting results in sporadic patients. No works were produced to test the association of SNCA and dementia in sporadic cases. We performed a case control study to investigate whether genetic variability in the promoter of SNCA could predispose to dementia in PD. A total of 114 demented patients with sporadic PD and 114 non demented patients, matched for age, duration of the disease and origin, were included in the study. The haplotype analysis was based on six polymorphic loci (five single nucleotide polymorphisms and the Rep1 microsatellite) in the promoter of the SNCA gene. Genotyping was performed using different methods: enzymatic digestion, allelic discrimination (ABI PRISM 7900HT), fragment sizing (ABI 3130xl). Statistical analysis were performed using Haploview 3.2 and UNPHASED, treating the multiallelic marker Rep1 as a two-allele system after pooling the rare alleles. Each marker, taken individually, did not show association to dementia. No significant differences were observed in the inferred haplotype frequencies of demented and non demented patients ($p=0.73$). In a previous study we did not find association between the Rep 1 polymorphism of the SNCA promoter and PD in our population, confirming the results obtained by some researchers. Since haplotype analysis has proven to be a more reliable method in association studies, in this work we analyzed a more extended region of the promoter of the SNCA gene . Our data suggest the lack of involvement of the SNCA promoter in the pathogenesis of dementia in PD. Further studies are needed to confirm these results in other populations.

Novel candidate genes for late-onset Alzheimers disease from a focused genome-wide association study of 20K functional variants: A follow up study. *R. Abraham[1], A. Grupe[2], Y. Li[2], P. Hollingworth[1], A. Morgan[1], L. Jehu[1], N. Cope[1], K. Dowzell[1], P. Nowotny[3], D. Rubensztein[4], C. Brayne[4], M. Gill[5], B. Lawlor[5], L. Thal[7], S. Lovestone[6], M. O'Donovan[1], A. Goate[3], M. Owen[1], J. Williams[1]* 1) Dept Psychological Medicine, Cardiff Univ, Cardiff, United Kingdom; 2) Celera Diagnostics, Alameda, CA; 3) Departments of Psychiatry, Neurology & Genetics Washington University School of Medicine, St. Louis, MO; 4) University of Cambridge, Cambridge, UK; 5) Department of Psychiatry, Trinity College, Dublin, Ireland; 6) 6Department of Neuroscience, Institute of Psychiatry, Kings College London, London, UK; 7) 7Department of Neurosciences, University of California, San Diego, La Jolla, CA.

Background We performed a focussed genome-wide association study using independent AD case-control samples collected from the UK and USA (1738 cases,2000 controls). 20,421 putatively functional SNPs, in 12,500 known and predicted genes from the Celera human genome database were tested for allelic association with LOAD. This identified 4 SNPs that showed significant association ($p<0.0003$) in a combined meta analysis across all 4 independent case-control samples. The SNPs were located on chromosomes 14,17,19 and 20. Aim To test the hypothesis that the 4 significant SNPs may be in linkage disequilibrium with causal variants for LOAD, we genotyped additional SNPs around these loci. Methods 63 TagSNPs across 7 genes ($R2 > 0.8$)were genotyped in 1124 cases and 1329 controls from the UK. Results We found increased evidence for association with LOAD with one intronic SNP in a gene encoding a neuropeptide on chromosome 19 (tag SNP p-value 0.0006, original SNP p-value 0.021. In a second gene coding for a key enzyme involved in insulin signalling, 5 out of 13 tag SNPs showed some evidence of association with LOAD (p-value range 0.01 - 0.04). The strength of these associations was comparable to the original significant SNP (p-value 0.009). Conclusions We observed further evidence for a novel susceptibility gene for LOAD on chromosome 19 and suggestive evidence supporting at least one additional loci.

A common founder for the Lrrk2 Gly2019Ser mutation in Italian PD patients. *D. Civitelli, P. Tarantino, G. Nicoletti, I.C. Cirò Candiano, F. Annesi, E.V. De Marco, S. Carrideo, G. Provenzano, P. Spadafora, F.E. Rocca, G. Annesi* Inst Neurological Sciences, National Research Council, Mangone Cosenza, Cosenza, Italy.

The LRRK2 Gly2019Ser mutation was founded in both autosomal dominant parkinsonism linked to PARK8 locus and in sporadic forms of Parkinsons disease (PD). A peculiar chromosome 12q12 haplotype is shared by the European and North African carriers, indicative of a common ancestor. We tested the Gly2019Ser mutation in unrelated Italian PD patients: 450 sporadic and 38 patients with autosomal dominant parkinsonism. Age-at-onset was 30-78 years. Subsequently, we genotyped 14 intragenic and flanking markers (the microsatellite D12S2514, D12S2515, D12S2516, D12S2518, D12S2519, D12S2520, D12S2521, D12S2522, D12S2523, D12S2517 and the SNPs rs1896252, rs1427263, rs11176013, rs11564148) We found the heterozygous Gly2019Ser mutation in 12 sporadic PD patients (2.7%). Moreover, two familial patients (5.2%) carried the Gly2019Ser substitution. One of them was heterozygous and the second one was homozygous. Both mutation carriers and non-carriers exhibited similar clinical features. The age-at-onset ranged from 40 to 77 years. The age-at-onset of homozygous subject was 47. Since the DNA of the family members was not available, the haplotype was unambiguously determined for the single PD patient homozygous for all the examined markers, including the G6055A mutation. In the remaining PD cases, parental phases could not be unequivocally reconstructed, but their genotypes were compatible with a common founder. The minimum shared haplotype (256-G-T-G-A-A-153), including a ~127 Kb region, spans from marker D12S2516 (intron 30) to D12S2519 (3 flanking). Concerning the D12S2515 microsatellite, we found two subclasses of PD patients: the first group carrying al least one 226 bp allele, end the second one with at least the 230 bp allele. This observation could support the recent hypothesis, that a mutation occurring within this polymorphic marker could produce a subhaplotype in the contest of the ancestral haplotype extending beyond the D12S2515 marker, but is also compatible with a recombination event.

Deficiency of Prolyl 3-Hydroxylase (Leprecan) Causes a Novel Recessive Metabolic Disorder of Bone Resembling Lethal/Severe Osteogenesis Imperfecta. *W.A. Cabral[1,2], W. Chang[1], A.M. Barnes[1], D.R. Eyre[3], M.A. Weis[3], S. Leikin[4], E. Makareeva[4], N.V. Kuznetsova[4], K.N. Rosenbaum[5], C. Kozma[6], C.J. Tifft[5], P. Smith[7], J.C. Marini[1,2]* 1) Bone & Extracellular Matrix Branch / NICHD / NIH, Bethesda, MD; 2) MOCB Program, Univ of Maryland, College Park, MD; 3) Orthopedic Research Laboratories, Univ Washington, Seattle, WA; 4) SPB / NICHD / NIH, Bethesda, MD; 5) CNMC, Dept Genetics, Washington, DC; 6) Georgetown Univ Hosp, Dept Pediatrics, Washington, DC; 7) Shriners Hospital, Dept Orthopedics, Chicago, IL.

The majority of cases of Osteogenesis imperfecta (OI) are caused by dominant mutations in COL1A1 and COL1A2, the two genes that code for type I collagen. A recessive form of lethal OI, not caused by collagen mutations, has long been suspected. Recently, a KO mouse for CRTAP (CASP, cartilage associated protein) with severe bone disease and several cases of severe OI with recessive CRTAP mutations have been reported. CASP co-purifies with leprecan, a matrix glycoprotein which is also known as prolyl 3-hydroxylase and believed to modify the Pro986 residue in the 1(I) chain of type I collagen and probably sites in other collagen types. This suggests that leprecan and CASP form a complex which modifies collagen in the ER. Since the enzymatic activity of the complex resides in leprecan, we postulated that leprecan deficiency might result in a severe bone dysplasia. We have identified the first five cases of lethal and severe OI-like dysplasia caused by recessive defects in leprecan (LEPRE1). All probands have null mutations in both alleles with heterozygous parents. Proband leprecan mRNA is absent on real-time RT-PCR, as is leprecan protein on Western blots and 3-hydroxylation of type I collagen on mass spectrometry. Proband leprecan deficiency results in excessive lysyl hydroxylation and subsequent excess glycosylation of type I collagen, showing 3-hydroxylation is essential for helix formation. A mutant allele from West Africa, also found in African-Americans, is present in four of five cases in this report. These insights define a novel metabolic bone disorder and open new avenues of investigation into the role of leprecan in development of bone, lung and other organs.

Differential gene expression of cardiac muscle to ischemia in Atkins Diet dogs using Microarray data. *C.A. Gregory, T.N. Masters, A.A. Fokin, F. Robicsek* Heineman Medical Research Labs, Carolinas Medical Center, Charlotte, NC.

Background: According to the American Obesity Association, obesity is the second leading cause of preventable death in the U.S. Low carbohydrate, high protein and fat diet such as the Atkins diet has been the diet of choice for many dieters. Physicians concerned with overweight cardiac patients have prescribed the Atkins diet. However, little is known how basic heart metabolic reactions may be altered. The purpose of the study was to delineate myocardial response to ischemia in cardiac muscle of dogs on the Atkins vs. normal diet. Methods: Eight dogs were maintained on Atkins Diet for 7 weeks while 9 on a normal diet served as a control. Temporary occlusion of the circumflex coronary artery was used for ischemic challenge of the left ventricular myocardium. Samples of endocardium/epicardium were processed for gene expression profiling using the Affymetrix Canine GeneChip. Results: Using ArrayAssist, 162 genes were significantly (p=0.01) up or down regulated in experimental animals. To delineate genes of interest involved in cardiac energetics, a subset of metabolism genes were created. Significant analysis at p0.05 of a subset of 240 metabolic genes, revealed 12 upregulated genes and 1 down regulated gene. The 12 upregulated genes were analyzed by PathwayAssist and functions were assigned to 8 of the 12 upregulated genes namely FABP1, APOC-1, APOC-2, PRPS1, CROT, IDI1, PTPN6, and PGS1. Conclusions: Energy requirements of the cardiac muscle response appear to be handled by upregulation of FABP1 which roles include fatty acid uptake, transport, and metabolism. Additional energy may have been provided by activation of LPL by both APOC-1 and 2. LPL is known to hydrolyze triglycerides thus providing free fatty acid to the cell. APOC-1 and 2 also play a role as a ligand/bridging factor for receptor-mediated lipoprotein uptake. CROT catalyzes the transfer of fatty acyl groups between CoA and carnitine, critical for mitochondrial transport. The predominance of upregulated genes in lipid metabolic pathways accompanying the Atkins Diet would seemingly reduce the ability of the heart to adequately metabolize carbohydrates during ischemic episodes.

Metabolically Biotinylated Helper Dependent Adenovirus: a new and rapid approach for targeting of High-Capacity Adenoviral Vector. *V.C. Cerullo[1], M.C. Seiler[1], C.C. Clarke[1], A.E. Erez[1], M.B. Barry[2], B.L. Lee[1]* 1) HUMAN MOLECULAR GENETICS, BAYLOR, HOUSTON, TX; 2) Department of Immunology,Baylor, Houston, Texas.

Developing cell-targeting vectors is an important goal in gene therapy. There are several advantages in using helper-dependent adenoviral vectors (HD-Ad) instead of first-generation vectors; HD-Ad contain only the noncoding termini of the viral genome, can deliver large DNA fragments of up to 36 Kb into target cells, elicit reduced toxicity and generate prolonged transgene expression in vivo. To enhance the potential of HD-Ad to transduce different cell types, we constructed a novel metablically biotinylated Helper Virus (Fib2102) to package HD-Ad vectors. Thus, co-infection of a helper-dependent packaging cell line with the fiber-modified helper virus and various HD-Ad constructs would allow the production of fiber-modified HD-Ad expressing different transgenes, obviating the requirement to fiber-modify each individual transgene-expressing HD-Ad. To this end, we modified the c-terminus of the Ad5 fiber by addition of a 70 amino acid biotin acceptor peptide (BAP) in our helper virus backbone by homologous recombination. Adenovirus particles bearing the BAP were metabolically biotinylated during vector production by the endogenous biotin ligase to produce covalently biotinylated virions. The resulting biotinylated vectors can subsequently be used to transduce different cell type receptors by conjugation to specific biotinylated antibodies. In particular, we tested whether a biotinylated HD-Ad generated with this system expressing the LacZ transgene could transduce chondrocytes in vitro. We found that a fiber-modified HD-Ad coupled to the chondrocyte specific -10 integrin antibody was more efficient at transducing a chondrocyte cell line than vectors bearing wild type fiber. In summary, we show the novel construction of a fiber-modified helper adenovirus which can be used to propagate high titers of fiber-modified HD-Ad, which, when coupled to cell-specific antibodies, results in improved transgene expression in vitro. This study demonstrates progress in retargeting strategies for helper-dependent vectors.

Two uncommon dystrophin deletions associated with Becker muscular dystrophy (BMD). *G. Galluzzi[1, 2], J. Mela[1, 2], L. Colantoni[1, 2], R. Verardo[3], S. Servidei[3]* 1) Neuromuscular Disorders, UILDM - Lazio Section, Rome, Italy; 2) IRCCS S.Lucia Foundation, Rome, Italy; 3) Department of Neurosciences, Catholic University, Rome, Italy.

Deletions in the dystrophin gene are the most common disease causing mutations in Xp21-Linked muscular dystrophies: out of frame deletions cause Duchenne phenotype while deletions maintaining the reading frame, are associated with BMD. Out of more than 600 cases of dystrophinopathy we found BMD patients with unusual dystrophin deletions reported only once in literature. An in frame deletion of the region encompassing exon 35 to 44 was found in two oligosymptomatic brothers with high CK (now 18 and 14 year-old) that both had an isolated episode of myoglobinuria at age 12. Western blot demonstrated a smaller and slightly reduced muscle protein. RT-PCR performed on muscle RNA with primers F/R located in exons 33 and 46 showed a cDNA fragment of 634 bp instead of 2,227 bp , consistent with the deletion. The second unusual deletion was detected in a severe BMD patient (current age 17) that showed reduction of dystrophin immunostaining in muscle specimen with N-terminus and rod domain antibodies and a total absence with C-terminus, suggesting a deletion in the distal region of the gene. By DNA analysis we found the deletion of the penultimate exon (78): RT-PCR on muscle RNA with primers F/R located in exon 77 and in the 3UTR showed a cDNA fragment lacking 32 bp corresponding to exon 78 sequence. The mutation results in a frame shift which creates a novel open reading frame in exon 79 and substitutes the normal C-terminus 14 amino acids with 32 new ones. This deletion, although out of frame, due to the particular position at the 3 end of the gene allows the production of an abnormal protein still able to assembly on the membrane and interact with the other dystrophin-associated-proteins. Our findings suggest that in cases of dystrophinopathies the whole gene must be investigated: many genomic regions are not included in most screening protocols and rare deletions such as that reported here, might remain undetected.

Variable size and occurrence timing of CREBBP microdeletions in Rubinstein-Taybi syndrome. *C. Gervasini[1], P. Castronovo[1], A. Bentivegna[1], A. Selicorni[2], F. Mottadelli[1], ML. Uzielli[3], F. Faravelli[4], A. Pessagno[5], E. Lucci-Cordisco[6], AM. Pinto[6], G. Neri[6], L. Larizza[1]* 1) Medical Genetics University of Milan; 2) I Clinica Pediatrica Fondazione Policlinico Milan; 3) Genetics Unit University of Florence; 4) Human Genetics Galliera Hospital Genoa; 5) Molecular Genetics Gaslini Institute Genoa; 6) Medical Genetics Catholic University Rome.

Rubinstein-Taybi syndrome (RSTS) is a rare congenital disorder with a wide severity phenotype spectrum characterized by mental and growth retardation, broad and duplicated distal phalanges of thumbs and halluces, typical facial dysmorphisms and increased risk of tumors. RSTS is associated with microdeletions and point mutations in the gene encoding the CREB-binding protein (CBP) located in 16p13.3. CBP is an histone acetyl transferase which functions as transcriptional coactivator. Here we report on 5 deletions affecting the CBP genomic region identified in a cohort of 31Italian patients (pts), 14 of them carrying a CBP point mutation. By genotyping 3 STR and 1 SNP we identified 2 deletions likely encompassing the whole gene. By FISH analysis using region-specific BAC clones and small-sized CBP-probes we estimated the extent and approximate boundaries of both deletions:one appears to extend fom exon 2 to exon 31 with its proximal breakpoint in the highly unstable region where 16p bkps underlying rearrangements in RSTS and leukaemia are clustered. The second deletion appears to extend both 5 and 3 beyond the gene with a deletion interval more than 500Kb. By FISH analysis we detected 3 additional deletions, all in a mosaic condition: 2 affect the 5end of the gene and one a significant portion of the gene and its 3 flanking region. In all three cases the percentage of deleted cells in the lymphocytes is 50percent, a finding correlated with a moderate phenotype. The clinical presentation of the 2 patients carrying whole gene deletion is severe, with extra signs manifested in the patient with the larger one. In conclusion complementary analyses allowed us to detect 5 deletions, 3 in a mosaic condition, accounting for a 16percent deletion rate, a finding emphasizing underscore of both CBP microdeletions and mosaicism in RSTS pts.

In Vivo Evaluation of Coagulation Factor VIII Variants for the treatment of Hemophilia A by Helper-dependent Adenoviral Vectors. *A.E. Erez[1], V. C. Cerullo[1], M. M. McCormack[1], R.G. Garcia[1], C.C. Clarke[1], S.P. Pipe[2], B.L. Lee[1,3]* 1) Human molecular genetics, Baylor, Houston, TX; 2) Pediatrics and Communicable Diseases, University; 3) Howard Hughes Medical Institute.

Hemophilia A is an X-linked bleeding disorder resulting from a deficiency of coagulation factor VIII (FVIII). FVIII expression after gene transfer is limited by unstable mRNA, interaction with endoplasmic reticulum (ER) chaperones, a requirement for facilitated ER to Golgi transport through interaction with the mannose-binding lectin LMAN1, and the instability of the activated form of FVIII (FVIIIa). Bioengineering of different variants of recombinant FVIII molecules by rational design can overcome these limitations. In this study we evaluated the in vivo efficacy of six different variants of recombinant FVIII. To this end, we generated six different helper dependent adenoviral vectors carrying human cDNAs regulated by the liver tissue restricted PEPCK promoter. To compare the short term efficacy and duration of hFVIII expression and infectivity of the different HDV hFVIII variants, FVIII deficient mice were treated with each vector at a dose of 5X1012 vp/kg via tail vein injection. Plasma was collected at baseline, two and four weeks post-injection and the FVIII biological activity was quantified by Coatest chromogenic bioassay. In this experiment, all vectors expressed functional FVIII at two weeks post-injection. FVIII activity varied from 2-8% in WT FVIII to up to 70% in other constructs. Functional FVIII activity dropped significantly in all vectors by 4 weeks except in the mice treated with an inactivation resistant rFVIII (HDV IR8 hFVIII) suggesting that this variant may exhibit an improved immunological profile. Interestingly, another construct containing the F309S substitution, which decreases binding to the ER protein BiP to increase the rate of secretion of the FVIII variant, appears to significantly improve activity over WT hFVIII in vivo. By using these engineered FVIII variants, longer-lived protein with improved immunological profiles can be generated for gene transfer and protein therapy.

Very early somatic genetic origins of cancer: Can somatic mosaicism of androgen receptor CAG repeat length in early stages of prostate growth and development be a predictor of future cancer? *B. Gottlieb[1,4,6], K. Sircar[2], C. Alvarado[1], A. Aprikian[5], L.K. Beitel[1,3], M. Alam-Fahmy[2], L. Begin[5], M. Trifiro[1,3,4]* 1) Dept Cell Genetics, Lady Davis Institute for Medical Research,; 2) Department of Pathology, McGill University Health Center; 3) Department of Medicine; 4) Human Genetics; 5) Urology, McGill University; 6) Department of Biology, John Abbott College, Montreal, Quebec, Canada.

In recent years the genetic origins of many cancers have been found to be somatic rather than germline. In particular this is true of prostate cancer (PCa). This has been partly due to the use of techniques such as laser capture microdissection (LCM), which has allowed for genetic analysis of specific cancer tissues. Shorter CAG repeat lengths in the androgen receptor gene (*AR*) have been correlated with increased *AR* transactivation activity and are associated with increased risk for PCa. We analyzed and sequenced *AR* CAG repeat lengths in human prostatic tissues from 13 PCa patients, as well as from disease-free individuals as young as I year old. Microdissected PCa lesions, high grade prostatic intraepithelial neoplasia (HGPIN), benign peripheral, transitional and central prostate zones, as well as leukocytes from peripheral blood were examined. Many prostate sections showed AR CAG repeat length heterogeneity in the form of multiple repeat lengths, i.e. somatic mosaicism. These consisted of normal and shortened CAG repeat lengths and even complete CAG repeat deletions. Blood leukocytes, representing germline DNA, predominately showed a single *AR* CAG repeat length per patient. CAG repeat length heterogeneity in both histologically benign tissues from diseased prostates and non-diseased prostates suggests that genetic heterogeneity of the *AR* CAG repeat precedes microscopically recognizable malignant changes and may occur very early in the growth and development of prostate tissue. Whether such genetic heterogeneity is a feature of all prostates must await a much more detailed survey of normal prostate tissues, but it raises some intriguing questions about the very early origins of prostate cancer susceptibility which will be further discussed.

Mutation of a putative potassium channel tetramerization domain gene in familial progressive myoclonic epilepsy. *M. Abramowicz[1], R. Azizieh[1], A. Aeby[2], L. De Meirleir[3], F. Christiaens[4], J. Desir[1], P. Van Bogaert[2]* 1) Dept Genetics, Hosp Erasme - ULB, Brussels, Belgium; 2) Pedi Neurology, Hosp Erasme - ULB, Brussels, Belgium; 3) Pedi Neurology, AZ-VUB, Brussels, Belgium; 4) Pedi Neurology, UCL-St Luc, Brussels, Belgium.

Progressive myoclonic epilepsy (PME) consists of myoclonus, seizures, and a progressive clinical course. PMEs are usually mendelian and transmitted as autosomal recessive traits, e.g., Unverricht-Lundborg and Lafora disease. We investigated three female patients from two consanguinity loops in a large inbred Morroccan family. Epilepsy started at 18-24 months after normal psychomotor development. Seizure types were multifocal myoclonus affecting limbs and face and aggravated by movements, and febrile generalized tonic-clonic in one patient. EEG showed slow dysrythmia, multifocal epileptiform discharges without reproducible temporal relationship with myoclonus and occasional generalized epileptiform discharges. Photosensibility was present in one patient. Giant somatosensory evoked potentials were not found. Cerebral MR imaging and fundoscopy were normal. Known PME-associated diseases were thoroughly excluded. GeneChip analysis of 11K SNPs showed a 15 Mb homozygous haplotype common to the three patients. Further analysis using microsatellite markers confirmed linkage of the disease to a 5 cM pericentromeric region of chromosome 7, with a maximum multipoint LOD of 4.2 at D7S663. In silico inspection showed the gene for a Potassium Channel Tetramerization Domain homolog, *KCTD7*, close to D7S663 within the segment. *KCTD7* contains a BTB/POZ-type domain and has strong homology with the T1 domain of the voltage-gated potassium channels. Direct sequencing of *KCTD7* revealed a C to T transition creating a stop codon in exon 2, homozygous in patients and heterozygous in parents. We conclude that loss of *KCTD7* function in PME is consistent with a defect of membrane repolarization.

Improving the safety of Helper-Dependent Adenoviral Vector gene transfer for Crigler-Najjar Syndrome. *D. Dimmock, N. Brunetti-Pierri, V. Mane, D. Palmer, A. Beaudet, P. Ng* Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Crigler-Najjar syndrome is an inborn error of metabolism characterized by severe unconjugated hyperbilirubinemia caused by a deficiency of uridine diphospho-glucuronosyl transferase 1A1 (UGT1A1). Current treatment relies on phototherapy to prevent kernicterus, and liver transplantation to prevent long term complications.

Life-long correction of hyperbilirubinemia by liver directed gene therapy using a helper-dependent adenoviral vector (HDAd) has been recently reported in the Gunn rat model. However, in that study complete phenotypic correction was only achieved using a dose of $3x10^{12}$ vp/kg and only partial correction was observed at $6x10^{11}$ vp/kg. These doses are above the range used safely in human trials.

To increase the therapeutic index, we injected Gunn rats with an HDAd bearing an improved expression cassette containing the PEPCK promoter, the hUGT1A1 cDNA, the WPRE and a liver specific enhancer (LCR). We observed complete phenotypic correction with $5x10^{11}$ vp/kg and partial correction with $1x10^{11}$ vp/kg. These are the lowest therapeutic doses reported to date.

We have previously shown that hydrodynamic injection of HDAd results in increased expression of secreted proteins compared to conventional injection. Combining this method of delivery with our improved construct, complete correction was achieved with $5x10^{10}$ vp/kg for the duration of the observation period (at least 12 months).

Although hydrodynamic injection is not feasible in large animals, we have developed methods to mimic hydrodynamic injection of HDAd into larger animals which have yielded encouraging results (see Brunetti-Pierri abstract).

Taken together these strategies may offer clinical gene therapy for Crigler-Najjar syndrome.

CGH-array study of 40 holoprosencephaly patients: the observed large scale quantitative alterations continuum is not correlated with phenotypic severity. *C. Bendavid[1,2], C. Dubourg[1,2], S. Le Gallou[1], I. Gicquel[1], L. Pasquier[3], M.R. Durou[2], C. Henry[4], S. Odent[3], V. David[1,2]* 1) UMR 6061 CNRS; 2) Laboratoire de Génétique Moléculaire; 3) Service de Génétique Médicale; 4) Laboratoire de Cytogénétique, CHU de Rennes, France.

Holoprosencephaly (HPE) is the most common developmental brain anomaly in humans, usually associated with facial features. Our group focuses on patients with HPE and normal karyotype. We previously reported our results for point mutations screening and gene dosage in known HPE genes (*SHH*, *SIX3*, *ZIC2* and *TGIF*), describing genomic defects in up to 27% fetuses and 30% newborns. Recently, we screened subtelomeres by MLPA and found alterations in known HPE candidate loci but also in new regions, including many unbalanced translocations. Therefore, we decided to screen HPE patients using CGH-array to assess the frequency, location and size of large scale quantitative alterations through the entire genome.

We used Agilent CGH-array 44K technology. Out of 40 patients, we screened 10 DNA samples with known quantitative anomalies and 30 samples with no alterations identified to date. First we localized the breakpoints of the 10 DNA with known alterations (loss and/or gain in specific loci) and showed no correlation between the size and severity of the defect. Such variable penetrance and genomic plasticity imply a transcriptomic or post-transcriptomic regulation that still needs to be investigated. Out of the 30 DNA with no genetic etiology, we found 5 new rearrangements involving new potential HPE loci located on chromosomes 21q, 20p, 15q, 6q, 5q, 17q and 18q. We observed both isolated or associated genomic loss and gain, the latter suggesting an unbalanced translocation from parental origin. Detected alterations ranged from less than 1Mb to 16 Mb and were not further considered if they involved less than 3 consecutive spots on the array.

Our data strongly reinforce the multigenic and multihit origin in HPE and participate in the explanation for the wide phenotypic spectrum described in this developmental disorder.

Reference DNA in CGH-array studies of inherited anomalies: pool of normal DNA can generate background due to copy number polymorphisms. *V. David[1,2], S. Le Gallou[1], I. Gicquel[1], C. Dubourg[1,2], L. Pasquier[3], M.R. Durou[2], C. Henry[4], S. Odent[3], C. Bendavid[1,2]* 1) UMR 6061 CNRS; 2) Laboratoire de Génétique Moléculaire; 3) Service de Génétique Médicale; 4) Laboratoire de Cytogénétique, CHU de Rennes, France.

CGH-array technique checks on chromosomal imbalances using comparative hybridization on arrays where tailed sequences of the chromosomes have been spotted. Consequently, a quantitative anomaly is detected when patient DNA presents a cluster of chromosomal sequences with a gain or a loss. The aim of this work was to study if gains or losses for non clustered sequences (detected by CGH-array on Agilent 44K technology) could be confirmed, so that to know if these isolated anomalies could be considered as background and /or real copy number variations.

We studied three non- related families (father, mother and one child) to detect gains and losses in the child and their possible parental origin. We tested each DNA against a sex matched DNA pool (made of 10 unrelated "healthy" controls) and compared the status of the children alleles with copy number variations to the copy number of these alleles in their respective parents. We selected "familial" sequences that were quantitatively abnormal for at least the child and one of his parents and tried to confirm these results with duplex quantitative PCR (qPCR). Parents and child qPCR profiles were compared to 5 different control DNA, each extracted from a single "healthy" donor. Out of the "familial" sequences tested, many revealed a normal status with the qPCR method. Therefore, we studied the status of the "healthy" controls used in the pools. We found that some of the controls sequences presented enough copy number polymorphisms to impair the CGH-array familial analysis results.

Consequently, we strongly recommend to test patients DNA against one single "healthy" control at a time and to do the dye swap against another control. Interpretation will be easier if the two controls have been previously compared together and discrepancies validated by qPCR.

The aetiology of ectopic maxillary canine teeth. *S. Camilleri*[1], *C. Lewis*[2], *F. Mcdonald*[1] 1) Department of Orthodontics, Dental Institute of King's College London, London, United Kingdom; 2) Reader in Genetic Epidemiology and Statistics, Division of Genetics and Molecular Medicine, King's College London School of Medicine at Guy's, King's College and St Thomas' Hospitals.

Objectives: To elucidate the mode of inheritance of ectopic canines.

Introduction: The aetiology of ectopic maxillary canines has been proposed to be genetic and is associated with incisor-premolar hypodontia as well as with various other dental anomalies. The Maltese population has a high prevalence of ectopic teeth, especially ectopic canines, as compared to other populations. This has been ascribed to the Founder Effect, the population having grown from under 20,000 to over 400,000 in the past 500 years.

Methods: Thirty consecutive probands with a family history of ectopic canines were identified. 152 first, 51 second and 113 third degree relatives were contacted and their dental status ascertained by direct examination, anamnestic records, or written or telephone questionnaire. Pedigrees were constructed; the risk to the relatives was determined and plotted against the degree of relation.

Results: Analysis of the pedigrees suggests autosomal dominant transmission. 12 percent of first degree relatives had ectopic canines, 3.9 percent had transposed canines and a further 9 percent exhibited hypodontia, in particular upper lateral and lower central incisors. There is an appreciable relative risk in second and third degree relatives. The female to male ratio of the sample is 2.06, with no difference in the incidence of relatives of male or female probands. Penetrance is highly variable as is expressivity, with wide variation in the number and severity of ectopicity of teeth.

Conclusion: The genetic aetiology of ectopic canines is supported by this study. The data points to the action of a single major gene with incomplete penetrance and variable expressivity.

Selecting SNPs for Association Studies with SNPbrowser Software. *F.M. De La Vega, C.R. Scafe, H. Isaac* Applied Biosystems, Foster City, CA.

The design of genetic association studies using single-nucleotide polymorphisms (SNPs) requires the selection of subsets of the variants providing high statistical power at a reasonable cost. SNPs must be selected to maximize the probability that a causative mutation is in linkage disequilibrium (LD) with at least one marker genotyped in the study. The HapMap project performed a genome-wide survey of genetic variation with about a million SNPs typed in four populations, providing a rich resource to inform the design of association studies. A number of strategies have been proposed for the selection of SNPs based on observed LD, including construction of metric LD maps and the selection of haplotype tagging SNPs. Here, we demonstrate the typical workflows for the selection of markers for association studies utilizing the SNPbrowser Software, a freely available, stand-alone application. In our current release we integrated the complete the HapMap project dataset, together with a number of selection algorithms into a single, stand-alone application that provides a fast query capability and swift visualization of SNP and gene annotations, statistical power, haplotype blocks, and LD map coordinates. The wizards provided in the tool enable workflows for the selection of SNPs by spacing on the physical or LD map coordinates, or by selecting tag SNPs that capture the haplotype diversity of a region by a number of methods. These SNP sets have already been filtered by their assay conversion potential to either TaqMan SNP Genotyping Assays or the SNPlex Genotyping System, thus expediting the set-up of genetic studies with an increased probability of success. In addition of the HapMap validated SNPs, SNPbrowser provides access to up to 5 million candidate SNPs, including over 60,000 non-synonymous coding SNPs. The latter represent putative functional variants that can be used on its own for direct association studies, or to supplement mapping studies, allowing researchers to rapidly generate and test functional hypothesis when significant association are found.

Burden of genetic diseases in Colombia: 1996 - 2025. *J. Bernal, F. Suárez* Inst Genetica Humana, Univ Javeriana, Bogota, Colombia.

The public and private health care system in Colombia suffered a reform in 1992, since this reorganization, a better register system of mortality and morbidity was established. Knowing the expected population growing, life expectancy, and the reported incidence and prevalence of the principal genetics diseases (chromosomal and Mendelian) according to previous studies in the country, we calculated the genetic burden of genetic disease after the reform and projected to 2025. We calculated, incidence, prevalence, and disability adjusted life years (DALYs) for fourteen dominant Mendelian diseases, 5 recessives diseases, five X recessive linked diseases and seven main chromosomal disorders. Despite uncertainties about mortality and burden of disease estimates, we found that, with the decrease of childhood infectious mortality and the increase quality of medical attention in the elderly, with a life expectancy of 71.8 years, the burden of genetic disease is increasing in the country, expecting a frequency of 37.3 to 52.8 per every 1.000 habitants. The data also show that in the year 2000 the number of accumulated patients affected with genetic disease was about 2.000.000 and the number is going to increase to 2.866.000 people, with a heavy burden of DALYs of 1.1000.000 every 5 years and of 6.345.000 years during 1994 to 2025. The projected burden of the genetic disease can not be faced with the actual health care system, which lacks of genetics services, follow up of special patients, genetic counseling specialist and modern diagnostic and laboratory methods.

Pairwise relatedness estimation in structured populations. *A.D. Anderson, B.S. Weir* Department of Biostatistics, University of Washington, Seattle, WA.

A maximum likelihood estimator for pairwise relatedness is presented for the situation in which the individuals under consideration come from a large outbred subpopulation of the population for which allele frequencies are known. We demonstrate via simulations that a variety of commonly-used estimators that do not take this kind of misspecification of allele frequencies into account will systematically overestimate the degree of relatedness between two individuals from a subpopulation. A maximum-likelihood estimator that includes Fst as a parameter is shown to work fairly well in this type of situation, even when the value of Fst is misspecified.

Novel, complex interruptions of the GAA repeat in the small expanded alleles of two affected siblings with a mild, late onset form of Friedreich's ataxia. *E.C. Frackelton[1], D.R. Lynch[2], J.M. Farmer[2], J. McCallum[1], C.A. Stolle[1]* 1) Pathology & Laboratory Medicine, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Dept of Neurology, UPenn School of Medicine, Philadelphia, PA.

Friedreich's ataxia (FA) is an autosomal recessive disorder characterized by progressive ataxia and onset usually before the age of 25 years. Most patients have expanded GAA repeats in intron 1 of the FRDA gene. Normal alleles contain 5-33 repeats; premutation alleles contain 34-65 uninterrupted GAA repeats. Disease causing alleles contain between 66-1700 repeats, with the majority of alleles having 600-1200 repeats. Long stretches of GAA repeats assume a novel DNA structure that interferes with transcription, resulting in decreased expression of the gene. The severity of the phenotype in most patients correlates with the size of the smaller expansion. Late onset (26-39 years) and very late onset (>40 years) cases represent atypical presentations of FA. Almost all patients, even with the shortest (<100) GAA repeats, have some symptoms by age 40. Two siblings with an atypical presentation of FA had onset at >60 years of age and a relatively mild form of the disease. Both had a large expansion (~600-1000 repeats) and a small expansion (~120-130 repeats) as determined by long-range PCR. DNA sequence analysis of the small allele revealed mulitple, complex interruptions in the GAA repeats of the composition (GAA)>72+[GAGAAGAAAA]+(GAA)x20+[GAAAAGAA]+[GAGGAA]x4+(GAA)x10. One of these interruptions (GAGGAA) has been reported previously, but two others (GAGAAGAAAA and GAAAAGAA) are novel. Interruptions of trinucleotide repeats are thought to stabilize the repeat sequence and decrease the probability of expansion. In these patients, the longest stretch of pure GAA repeats is ~72, an allele size more consistent with their age of onset and mild disease course. The presence of interruptions in the GAA repeats may not only stabilize the repeat sequence, but also prevent formation of the DNA structure that results in silencing of the expanded allele. These data suggest that DNA sequence analysis of small expanded alleles may provide better phenotype correlation than sizing of the alleles by long-range PCR alone.

Oromandibular limb hypoplasia: report of two patients in Colombia. *R. Garcia, P. Paez, F. Suarez* Inst de Genetica Humana, Pontificia Univ Javeria, Bogota, DC, Colombia.

Oromandibular limb hypoplasia (Hanhart syndrome), is a rare disorder described for the first time in 1950 by Hanhart. The classical features of this disorder affect oral cavity (oromandibular hypoplasia) and limbs (adactylia, hypodactyly ectrodactyly). We present two unrelated female patients with classical phenotype of this syndrome. Case 1: 24 days-old girl born in Bogotá (Colombia) of non consanguineous parents, with micrognathia, hypoglossia, left hand adactylia, right hand ectrodactyly, bilateral clubfoot with oligodactylia. The patient was the product of mother's first 31-week pregnancy. No know teratogenic exposure. Case 2: A 39 years old woman born in Simijaca (Boyaca Colombia) of non consanguineous parents with moderate short stature, severe micrognathia, inexpressive fascies, hypoglossia, anodontia, limbs abnormalities including left hand agenesia, right hand olygodactylia, right food syndactylia and left food syndactylia with olygodactylia. Perinatal history is unknown. No apparent teratogenic exposure. Mental developmental was normal. Both of the patients had a complete radiological assessment which confirmed bone development defects. Two cases were diagnosed with Oromandibular Limb Hypoplasia Syndrome. As far as we know these are the first reported patients in whom clinical and radiological comparisons can be achieved, between a new born and an adult affected with Hanhart syndrome in Colombia.

First 285 Human Subjects of Genetics of Left Ventricular Outflow Tract Malformation Study. *S.M. Fitzgerald, G.A. Zender, K.L. McBride* Center for Molecular & Human Genetics, Children's Research Institute, Columbus, OH.

Congenital heart defects are among the most common of all medically significant birth defects and are a leading cause of infant mortality. Left ventricular outflow tract (LVOT) obstruction malformations, include aortic valve stenosis (AS), coarctation of the aorta (CoA), mitral valve stenosis (MS), hypoplastic left heart syndrome (HLHS) and bicuspid aortic valve (BAV). They are thought to arise embryologically from reduced flow through the LVOT and therefore likely have related genetic and environmental etiologies. To be able to determine the specific causes of LVOT malformations, consent, demographic information and blood samples are collected on affected probands and both parents (trios). Additional data such as family history, pregnancy exposures, maternal health and LVOT diagnoses must be obtained on each proband and other affecteds. We have designed a Microsoft Access database to facilitate gathering, storing and analyzing this data on 500 probands (1500 subjects), using the National Birth Defects Prevention Study questionnaire as a template. We have enrolled 285 subjects in 104 families over the first 13 months; 36% of subjects are probands, 33% mothers, 25% fathers and 6% other relatives. Of probands, 23% have HLHS, 7% Shone complex, 42% CoABAV, 19% ASBAV, 9% BAV, 1% IAA-A. We have blood samples on 67% of the all subjects and 64% of probands. Currently, 66 trios have consented and 35 trios also have blood samples on all members. The pregnancy exposure questionnaire has been completed by 43 families or 41%. Reported prenatal exposures include: medication (56%), cigarette smoking (36%), chemical exposure (19%), hot bath/Jacuzzi (14%), radiation exposure (12%), alcohol (10%), fever (5%), and heavy metal exposure (5%). As these mothers have reported higher than expected rates of exposure during pregnancy, when we reach our recruitment goal of 500 probands we should be able to link genetic with exposure data to establish one or more specific gene-environment interactions contributing to LVOT malformation.

More than you bargained for: Unsolicited Information in Direct to Consumer (DTC) Genetic Tests. *K.A.B. Goddard[1], R.P. Igo, Jr.[1], J. Fishman[2]* 1) Department of Epidemiology & Biostatistics; 2) Department of Bioethics, Case Western Reserve Univ., Cleveland, OH.

DTC genetic tests have recently exploded onto the market, with immediate access available to consumers over the internet. However, regulation is lagging behind, and DTC genetic testing raises novel concerns beyond those of traditional clinical testing. One consideration is the issue of unsolicited information, defined as information revealed by a genetic test that is not in response to its intended purpose. Unsolicited information is a concern because of the potential for others to misuse the information, and the potential for personal distress or interpersonal strife. We illustrate our approach to evaluate unsolicited information using CATGee, produced by DNA Products, Inc. The intended purpose of CATGee is to show an individuals uniqueness, and the product materials explicitly state that no scary health or paternity information is revealed. Consumers are encouraged to compare their CATGee profile with other individuals and with aggregated data for populations. Through a literature review, we found no evidence of pleiotropy for the six microsatellite markers in the CATGee profile. Using published allele frequencies for US Hispanics, US Caucasians, and African-Americans (AA), we computed the posterior probability of each ethnic group for simulated genotypes. Although the median posterior probability was higher than the prior probability for each ethnicity, the ability to predict ethnicity with certainty (e.g., posterior probability > 99%) was limited except for the AA group. We devised two tests to detect common relationship errors for putative full-siblings using the CATGee profile. Using simple allele counting methods comparing the profiles of two putative full siblings, the power was surprisingly high to detect adoption (~60%) and half-sibling (~30%) relationship errors. Using more sophisticated likelihood ratio tests, the power increased to ~80% for adopted siblings and ~40% for half-siblings. The potential for unsolicited information should be evaluated for any DTC genetic test, and policies detailing when and how to reveal such information need to be developed.

Balloon Occlusion Catheter-Based Delivery of HDAd into the Baboon Liver: Stable, High Level Transgene Expression with Minimal Toxicity. *N. Brunetti-Pierri[1], G. Stapleton[2], C. Mullins[2], D. Palmer[1], Y. Zuo[1], M. Finegold[3], A. Beaudet[1], P. Ng[1]* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Pediatric Cardiology, Baylor Col Medicine, Houston, TX; 3) Dept Pathology, Baylor Col Medicine, Houston, TX.

Helper-dependent adenoviral vectors (HDAds) hold tremendous potential for liver-directed gene therapy as they can mediate long-term transgene expression without chronic toxicity. However, due to a nonlinear dose-response, high doses are required to achieve hepatic transduction resulting in dose-dependent acute toxicity. To overcome this important obstacle, we developed a minimally invasive method to preferentially deliver low dose HDAd into the liver of baboons to achieve efficient hepatic transduction. Briefly, a single balloon occlusion catheter was percutaneously positioned in the inferior vena cava of baboon 1 to occlude hepatic venous outflow. $1x10^{11}$ vp/kg of a HDAd expressing the baboon -fetoprotein (bAFP) marker was injected directly into the occluded liver via a percutaneously placed hepatic artery (HA) catheter and left to dwell in the liver for 15 min before balloon deflation. As controls, $1x10^{11}$ vp/kg was administered to baboon 2 by peripheral intravenous injection and baboon 3 by HA injection without balloon occlusion. All procedures were well tolerated, and all three animals returned to their normal pre-injection states with no clinical manifestations of toxicity. Only mild transaminitis was seen in all animals, peaking at 24 to 48 h post-vector but returning towards baseline the next day. Importantly, serum bAFP levels increased 425-fold over baseline for baboon 1, while only a modest increase of 12-fold and 5.6-fold were observed for baboon 2 and 3, respectively. To date, bAFP levels have been sustained (84 days). These results suggest the therapeutic index of HDAd can be significantly improved by delivering the vector preferentially into the liver using a minimally invasive balloon occlusion catheter technique and may be a first step towards clinical application of HDAd for liver-directed gene therapy.

Waardenburg syndrome type 3 or Klein-Waardenburg syndrome. A Mexican family. *G. Garcia-Sanchez[1], C.F. Martínez-Cruz[2,3], D.M. Mendoza-Ugalde[1], M. Díaz-García[1], M.R. Baez-Reyes[4], A. Garcia-Huerta[1]* 1) Instituto Nacional de Rehabilitación. Genética. Mexico; 2) Instituto Nacional de Perinatología.Departamento de Seguimiento Pediatrico.Comunicacion Humana; 3) Instituto Mexicano del Seguro Social. Hospital General de Zona 53; 4) Instituto Nacional de Perinatología.Genética. Email guillegs@yahoo.com.mx.

Waardenburg syndrome type 3 (WS-III; MIM 148820) or Klein-Waardenburg syndrome is characterized by the presence of musculoskeletal abnormalities in association with clinical features of Waardenburg syndrome type 1 (WS-I). Since the description of the first patient in 1947 (D. Klein, Arch Klaus Stift Vererb Forsch 1947: 22: 336-342), a few cases have been reported. Only occasional families have demonstrated autosomal-dominant inheritance of WS-III. In a previous report, a missense mutation in the paired domain of the PAX3 gene has been described in WS-III. In this report, we present a Mexican family (mother and son) with clinical findings of WS-III. Son: 12 years old with, poliosis and premature graying, dystopia canthorum, blue eyes, hyperpigmented spots on thorax and left arm and camptodactily (moderate-severe) and short fingers. Hearing loss, was suspected at 2- 8/12, ABR at 3 years old demonstrated bilateral non-response at 100dB, audiogram al 12 years old shows: bilateral sensorineural profound hearing loss, Father. 42 years old, poliosis and premature graying, dystopia canthorum, blue eyes and mild bilateral flexion contractures of the fingers. Right sensorineural profound hearing loss, onset at 11 years old, aparently non progressive.

X chromosome DNA methylation: a new quantitative assay and preliminary results in women with premature ovarian failure. *K.L. Bretherick[1], M.R. Fluker[2,3], C.J. Brown[1], W.P. Robinson[1]* 1) Dept of Medical Genetics, UBC; 2) Genesis Fertility Center; 3) Dept of Obstetrics & Gynecology, BC Childrens and Womens Hospital; Vancouver, BC, CANADA.

One of the hallmarks of X chromosome inactivation is DNA methylation of the promoter regions of inactivated genes. Since women have one X chromosome inactive in each cell, the proportion of DNA methylation expected at any given locus is 50%. However, the degree of skewed X chromosome inactivation assayed by methylation-sensitive restriction digestion does not always correlate when measured at different loci, suggesting that there may be deviation from the expected 50% on some regions of the X chromosome. We have developed a new assay to assess the percent methylation at a single locus using methylation-sensitive restriction enzyme digestion and quantitative PCR (q-PCR). Digested DNA is amplified by q-PCR with primers that flank a restriction site at the locus of interest, and with primers for an internal control locus that does not have a restriction site. Quantity determined at the locus of interest is normalized to the quantity at the internal control locus, to control for the amount of input DNA. The normalized quantity of digested DNA is then expressed as a percentage of the normalized quantity of an undigested sample, to determine the % DNA that is methylated at the locus of interest. Preliminary results assaying the degree of DNA methylation at the Androgen Receptor gene (AR) promoter show that deviation from the expected 50% methylation is common; with reproductively healthy (RH) controls having an average of 37.010.4% methylation (N=20, range 20-57%). In female controls of ages 5-81 years, there is a trend toward increased methylation at the AR locus with age, with an increase of 0.1% per year (N=31, p=0.26). In addition, women with premature ovarian failure (POF) show increased methylation at AR compared to RH controls; 44.8% in POF patients (N=18) vs. 36.9% in controls (N=20) (p=0.05, 2-tailed t test). These results indicate that there may be a change in AR promoter methylation with age and suggest that there are methylation abnormalities on the X chromosome of women experiencing POF.

Discovery of low abundance sequence variants in mitochondrial heteroplasmy with a Quantitative Sequencing method. *S. Chen, A. Lakdawalla, K. Hunkapiller, C. Brown, E. Gerber, K. Livak* Applied Biosystems, Foster City, CA.

Mitochondrial heteroplasmy has been associated with variability in mtDNA associated disease phenotypes.

The discovery and quantification of mitochondrial heteroplasmy is performed by cloning PCR amplicons of the mtDNA sample and sequencing multiple clones to discover low frequency mutations in a normal background. By improving the detection limit of standard DNA sequencing to low amounts of mixed bases in the sequence the need for cloning can be circumvented.

We will present the quantitative analysis of mixed human mtDNA hypervariable regions and identify low abundance SNPs from the higher abundance background DNA pool.

The quantitative sequencing method would also simplify the discovery of variants in mixed DNA samples (somatic mutations), for the quantitative discovery of DNA methylation sites in heterogeneous samples, and for increasing sequencing efficiency by pooling samples.

The Optimal Minor Allele Frequency (OMAF) for a SNP-Disease Association Studies. *I.P. Gorlov[1], O.Y. Gorlova[1], S. Sunyaev[2], M.R. Spitz[1], C.I. Amos[1]* 1) Epidemiology, UT M. D. Anderson Cancer Center, Houston, TX; 2) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

The ultimate goal of any case control association study is identifying causal polymorphisms modulating risk of common human diseases. Missense mutations are most plausible candidates for causal polymorphisms. In this study we sought to find out whether there is a Minor Allele Frequency (MAF) that maximizes the chances to identify the causal missense mutation in a case-control association study. The MAF can affect the chances to identify a causal SNP because (i) statistical power depends on MAF, an also because (ii) there is an inverse relationship between MAF and the probability for a SNP to be functional. In this study we used PolyPhen and SIFT bioinformatics tools for predicting SNP functionality to identify functional (protein-damaging) SNPs. We found a significant negative correlation between MAF and the probability that a SNP is functional. Joint probability that a SNP is a functional and that it will be detected as significant in a case-control association study is a useful measure to characterize chances of detecting a causal SNP. We named this joint probability the Probability to Detect a True Association (PDTA). We sought to identify MAF for which the PDTA is maximal. This MAF was called Optimal MAF (OMAF). We found an inverse relationship between OMAF and sample size. Deviation of MAF from OMAF decreases chances that a causal mutation will be detected. The effect of the deviation of MAF from the OMAF is much stronger for dominant model compared to the recessive one. Our study suggests that for a given sample size and Odds Ratio (OR) there is a single OMAF. Our study predicts OMAFs for different sample sizes.

Oxidative stress in treated Maple Syrup Urine Disease patients. *A.G. Barschak[1,3], A. Sitta[1,3], M. Deon[1,3], M.C. Pigatto[1], T. Terroso[1], A. Barden[1], C.S. Dutra-Filho[3], M. Wajner[1,3], R. Giugliani[1,3], C.R. Vargas[1,2,3]* 1) Serviço de Genética Médica, Hospital de Clínicas de Porto Alegre, Porto Alegre, RS, Brazil; 2) Departamento de Análises, Faculdade de Farmácia-PPGCF, UFRGS, Porto Alegre, RS, Brazil; 3) Departamento de Bioquímica, ICBS, UFRGS, Porto Alegre, RS, Brazil.

Maple syrup urine disease (MSUD) or branched-chain -keto aciduria (BCKA) is an inherited disorder caused by deficiency in the branched-chain -keto acid dehydrogenase complex (BCKAD) activity. The blockage of this pathway leads to tissue accumulation of the branched-chain amino acids (BCAA) leucine, isoleucine and valine and their respective keto-acids. The symptomatology includes ketoacidosis, hypoglycemia, poor feeding, convulsions, coma, psychomotor delay and mental retardation. The mechanisms of the neurological dysfunction are still poorly understood. In the present work we evaluated some parameters of oxidative stress named thiobarbituric acid-reactive substances (TBARS), total antioxidant reactivity (TAR) and total antioxidant status (TAS) in plasma from MSUD patients under dietary therapy presenting different leucine plasma levels (groups I, II and II). We verified a significant increase of TBARS as well as a decrease of TAR in plasma of the three groups of treated MSUD when compared to control group. However, no difference of TBARS was found between the patients during treatment and at diagnosis. These results suggest that the dietetic therapy do not change the oxidative stress presented by MSUD patients, suggesting that leucine blood levels could not be directly related to oxidative stress in this disease. Financial support: CNPq/PROPESQ-UFRGS/FAPERGS/PROREXT.

A novel gene derived from a segmental duplication shows perturbed expression in Alzheimers disease. *D. Avramopoulos[1], R. Wang[1], M.D. Fallin[2], S.S. Bassett[2]* 1) Psychiatry, Johns Hopkins Univ, Baltimore, MD; 2) Public Health, Johns Hopkins Univ, Baltimore, MD.

Alzheimers disease (AD) is a disabling neurodegenerative disorder with an onset most commonly in late life. Three genes have been identified to date causing earlier onset AD and one other has been shown to be a risk factor for late onset AD (LOAD). The existence of many more is suspected for LOAD yet they remain undetected. A number of studies have reported linkage to a LOAD locus on human chromosome 10, and we have identified a parent of origin effect for that region. We present here a gene on chromosome 10 showing an expression profile that suggests its involvement in LOAD. Its expression is significantly reduced in females and with increasing age, both of which are risk factors for LOAD, and it is further decreased in patients. Interestingly the latter effect is more pronounced in patients with an affected mother, in concordance with our linkage results. Although we originally studied this transcript attempting to measure the product of the alkaline ceramidase gene (ASAH2), a good candidate gene for AD, we found that the transcript is the product of a new gene that we call ASAH2L. This gene is the result of a partial duplication of ASAH2 ~500 Kb away and next to promoter sequences. It carries a polymorphic start codon derived from a single nucleotide change of the original ASAH2 sequence but also other putative translation start sites that would produce novel proteins. ASAH2L is an interesting example of the generation of a new gene, and data from genome databases suggest that the duplication that generated the gene is human specific. Although its function remains unknown our expression data suggest that the ASAH2L transcript might play a role in preventing neurodegeneration.

Imatinib-induced CML remission as evidenced by automated FISH analysis predicts good outcome but is not achieved in patients with der(9) deletion within 30-month follow up. *G. Calabrese[1,2,3], D. Fantasia[2], P. Guanciali Franchi[1,2], R. DiGianfilippo[2], E. Morizio[2], M. Alfonsi[1,2], A. Di Tecco[2], A. Marzoli[2], L. Stuppia[1,3], R. DiLorenzo[4], G. Palka[1,2,3]* 1) Scienze Biomed/Genetica Medica, Univ G D'Annunzio, Chieti, Italy; 2) U.O. Genetica Umana, Pescara Hospital, Pescara, Italy; 3) CESI, Center for Aging, D'Annunzio Foundation, Chieti, Italy; 4) Dept. Hematology, Pescara Hospital, Pescara, Italy.

Seventy patients with CML, 63 in chronic phase (CP), 1 in accelerate phase (AP), and 6 in blastic crisis (BC), were treated with imatinib mesylate (IM). The patients were studied for a 18-61 months follow up period using clinical and haematological features, cytogenetics and FISH analysis with a dual-fusion BCR-ABL probe, and an automated FISH imaging system for rare cell events (BioView-Duet). Before IM treatment 51 patients showed Ph chromosome in all examined cells while in the remaining 19 patients a normal clone was also found. FISH analysis showed BCR-ABL fusion gene in >95% of cells in 49 patients including 9 with a partial deletion on der(9) at band q34. In 18 patients BCR-ABL rearrangement was observed in 5-95% of cells while in 3 it was present in <5% of nuclei. Complete or partial cytogenetic remission rate [CCR or PCR: t(9;22) absent or <35% of cells, respectively] overlapped complete or partial FISH remission rate (CFR or PFR: BCR-ABL absent or <35% of cells, respectively) along all the follow up period being observed in 72% of patients. However, CFR achievement within 12 months of treatment resulted in a disease-free second year of treatment in 94% of patients, while 33% of samples with a CCR actually showed >1% leukaemic cells at FISH analysis. Moreover, FISH unravelled leukaemic cells in 21% of samples unsuitable for cytogenetic investigation from 9 patients who subsequently developed haematological relapse. In patients with partial deletion on der(9), no CCR/CFR was achieved. Clinical and haematological relapse was observed in 4 cases, while in the remaining 5 a PCR/PFR was observed only after 30 months of treatment supporting a negative role of der(9) deletion on IM effect in CML patients as previously reported with other therapy protocols.

Association study of the GABA(A) receptor cluster at 15Q12 with autism in the French Canadian population.

R.F. Gillis[1], J.B. Riviere[1], J. Gauthier[1], N. Girard[1], S. Laurent[1], E. Fombonne[2], R. Joober[3], L. Mottron[4], GA. Rouleau[1,5] 1) Centre Hopitalier de la Universite de Montreal (CHUM), Center for the Study of Brain Diseases, Montreal, QC, H2L 4M1, Canada; 2) McGill University, Department of Psychiatry, the Montreal Childrens Hospital, Montreal, QC, H3Z 1P2, Canada; 3) Department of Psychiatry, McGill University and Douglas Hospital Research Centre, Montreal, QC, H4H 1R3, Canada; 4) Service de recherche, Hôpital Rivière des prairies, Montréal, QC, H1E1A4, Canada; 5) Department of Medicine, Universite de Montreal, Montreal, QC,.

Chromosomal region 15q11-13 has been consistently implicated in autism through numerous avenues such as maternal duplications(3), multiple types of chromosomal abnormalites in the region(2), and presence of autism in patients with Prader-Willi and Angelman syndrome(5). Furthermore, linkage and assocation to this region has been previously described and replicated in different populations of autistic individuals(1,4). 140 trios, of which 70-75% are of French Canadian origin were used in a TDT based association study. 26 SNPs, with an average spacing of 30 Kb, spanning 820Kb of the GABA(A) cluster at 15q12 were selected from the dbSNP and Celera databases based on minor allele frequency > 0.05, spacing and haplotype structure. Three markers were shown to be in transmission disequilibrium including the cytosine of SNP rs2873027 contained within intron 3 of GABRB3 which replicates a previous study4.

Repeated Analysis of Limited Amount of DNA/RNA Samples Using an Irreversible Binding Matrix. *C. Brown, V. Boyd, E. Gerber, K. Hunkapiller, S. Chen, A. Lakdawalla* Applied Biosystems, Foster City, CA.

Substantial libraries (> 100K samples) of characterized formalin-fixed paraffin-embedded tissue sections and the associated information provide an exceptional resource for clinical research. Molecular analyses of these samples are limited to the small amounts of extractable RNA and DNA. Methods like pre-amplification, whole genome amplification, and cloning have been used to augment the quantity of nucleic acids. An alternative approach is to recycle the extracted RNA and DNA for an increased number of analyses.

A binding matrix, based on aluminum and zirconium oxides, can bind to RNA/DNA in an irreversible manner under defined conditions. The bound nucleic acid can be used for multiple enzymatic reactions (reverse transcription and/or PCR) without depleting the bound nucleic acid. The amplified product does not bind to the matrix under the reaction conditions and can be removed for downstream analysis (real-time PCR, sequencing, fragment analysis).

We will present performance data on the sequential PCR amplification and sequencing of limited amounts of genomic DNA in the hypervariable region of mitochondrial DNA.

Linkage studies in an Ecuadorian population with Keratoconus. *B.A. Bejjani[1,4], D. Winters[1], A. Molinari[2], J.A. Pitarque[2], M.H. Chahrour[3], S.M. Leal[3], M. Gajecka[1], R.A. Lewis[3]* 1) Health Research & Education Center, Washington State University, Spokane, WA; 2) Hospital Metropolitano, Quito, Ecuador; 3) Baylor College of Medicine, Houston, TX; 4) Sacred Heart Medical Center, Spokane, WA.

Keratoconus (KC) is a non-inflammatory thinning and anterior protrusion of the cornea that results in steepening and distortion of the cornea, altered refractive powers, and altered visual acuity. Although both genetic and non-genetic factors have been associated with KC, its molecular basis is still elusive. We identified an Ecuadorian cohort in which KC without other ocular or systemic features is transmitted as an autosomal dominant trait with incomplete penetrance. Here we present the results of sequencing and linkage analyses which were performed to verify the association between KC in these Ecuadorian families and the previously reported KC loci. To date, we have examined, collected blood, and purified DNA from 181 individuals from 25 multiplex families with KC. Subjects were diagnosed clinically with KC by slit lamp examination and corneal topography. We excluded previously assigned KC loci on chromosomes 3, 15, 16, and 20 by linkage analysis. Additionally, the coding exons of *VSX1* in 18 individuals from the Ecuadorian families (1 individual from each family with multiple affected individuals) and 2 ethnically matched control individuals (Ecuadorian individuals with no ocular abnormalities) were sequenced. Three single nucleotide polymorphisms (SNPs) in the *VSX1* coding region (18GT, 174GT and 542AG) were identified, but no mutation was found in the gene. Next, we performed a genome-wide screen with fluorescent markers with an average spacing of 10 cM spanning all chromosomes. No evidence for linkage between KC and the analyzed markers was observed. We initiated a second genome-wide screen for a KC locus with fluorescent markers with an average spacing of 5 cM spanning all chromosomes. Genotyping is in progress. Keratoconus in our families is not linked to any of the previously defined KC loci. We have excluded *VSX1* as a candidate for KC in this population.

A high-throughput method for direct sequencing from bacterial cultures. *T. Ganguly, P. Chen, R. Teetsel, L. Zhang*
Dept Genetics, Univ Pennsylvania Sch Medicine, Philadelphia, PA.

Large scale screening of bacterial colonies from shotgun plasmid libraries, cDNA or other libraries by DNA sequencing requires a rapid and cost effective method. DNA sequencing technologies have significantly improved over the years giving rise to enhanced sequence quality, higher throughput, and a substantial reduction in cost. However, in large-scale sequencing projects, the preparation of templates involving cellular growth from bacterial colonies and the subsequent plasmid purification continues to be one of the most costly steps in terms of reagents and labor. Previous attempts to sequence directly from bacterial colony or culture have yielded poor quality data and short sequence reads. The latest advancements in sequencing instrumentation, chemistry, and data analysis tools, available from Applied Biosystems (ABI), have significantly increased the quality and efficiency of direct sequencing as demonstrated by a recent report from ABI that used a proprietary buffer for cell lysis. This prompted us to initiate an effort to reduce or eliminate the reagent cost involved in plasmid DNA preparation for direct sequencing. We would describe a simple, high throughput, and inexpensive method for direct sequencing of high copy number plasmids by heat lysis of bacterial cells in water. The sequence quality and efficiency is comparable to that obtained by using commercial reagents. Furthermore we would present data on the suitability of the cellular lysates for other applications including PCR, restriction digestion and transformation.

A novel dicentric chromosome 13 - a familial variant? *K. Chun, S. Trevisiol, E. Capua, L. Hunniset, D. Allingham-Hawkins, L. Velsher* Genetics Program, North York General Hospital, Toronto, ON, Canada.

A 37.5-year-old woman of Turkish descent and her husband were seen for genetic counseling for advanced maternal age. The couple has four healthy children and is 15 weeks into their fifth pregnancy. Due to neonatal deaths of siblings of both the patient and her husband, chromosome studies were ordered for the couple. The husbands chromosomes were normal. However, both homologues of chromosome 13 for the patient appeared identical and dicentric. C-banding showed two centromeres and NOR staining showed two stalk regions on both chromosomes. FISH analysis using the alpha-satellite probe set for chromosomes 13/21 showed two signals on each chromosome 13. Meanwhile, an MSS result came back positive for Down syndrome and an amniocentesis was performed. The fetus karyotype was normal except for having inherited one copy of the dicentric chromosome 13. Family history revealed that the patients parents are consanguineous. Although UPD studies for chromosome 13 were considered, due to the family history of consanguinity and no abnormal clinical features in the patient and her four children, this novel dicentric chromosome 13 is most likely a very interesting familial variant.

SOX9cre1: a distal *SOX9* regulator that interacts with Hh signaling factors. *G.A. Bien-Willner[1], P. Stankiewicz[1,2], J.R. Lupski[1, 3, 4]* 1) Department of Molecular and Human Genetics, BCM, Houston, Texas; 2) Department Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 3) Texas Childrens Hospital, Houston, Texas; 4) Department of Pediatrics, BCM, Houston, Texas.

Chromosomal rearrangements, such as translocations, can sometimes alter a nearby genes expression resulting in disease, despite the rearrangement breakpoints mapping at great distances from the disease-causing gene. Such phenomena can be defined as position effects, and have led to speculation of the importance of chromatin interactions occurring upwards of a megabase upstream or downstream to certain genes. Position effects have been reported with *SOX9*, which encodes for a transcription factor essential in male sexual development and bone formation. Although haploinsufficiency of *SOX9* results in campomelic dysplasia (CD), several clinical cases of this phenotype have been described with translocation breakpoints mapping as far as 932 kb upstream from the gene. Studying one such case (900 kb upstream to *SOX9*) in the context of an apparent clustering of breakpoints has led to the prediction of a possible cis-acting regulatory element 1.1 Mb upstream of *SOX9*, named SOX9cre1, which may be responsible for a subtle CD phenotype when displaced. We investigated the role of this putative regulator in *SOX9* expression using reporter assays in a *SOX9*-expressing chondrosarcoma cell line, and evaluated the tissue-specific activation of the gene. SOX9cre1 increases the activity of a minimal *SOX9* promoter in reporter constructs nearly three-fold, in a tissue-specific manner, consistent with an enhancer role. In silico studies identified a Gli1 binding site in the 2.1 kb SOX9cre1, suggesting that *SOX9* may be activated directly through the Sonic hedgehog (Shh) or related Hh cell signaling pathways known to be involved in *SOX9* expression. EMSA and functional assays in which reporter constructs are co-transfected with Gli1 and Smad1 of the bone morphogenic protein (Bmp) signaling pathway suggest these transcription factors may directly interact with SOX9cre1. These data support a link between the Hh signaling pathways and *SOX9* regulation, suggesting a mechanism of regulation through distal chromatin interactions.

Fine mapping and confirmation of linkage to chromosome 9q22 in colorectal neoplasia kindreds. *C. Gray-McGuire[1,4], R.C. Elston[1,4], S.D. Markowitz[4,5,6], J. Potter[7], N. Lindor[8], G.L. Wiesner[2,3,4,5]* 1) Dept Epi and Biostat, Case Western Reserve Univ, Cleveland, OH; 2) Dept Genetics, Case Western Reserve Univ, Cleveland, OH; 3) Center for Human Genetics, Case Western Reserve University and Univ Hospitals of Cleveland, Cleveland, OH; 4) Ireland Comprehensive Cancer Center, Western Reserve University and Univ Hospitals of Cleveland, Cleveland, OH; 5) Dept of Medicine, Case Western Reserve University and University Hospitals of Cleveland, Cleveland, OH; 6) Howard Hughes Medical Institute, Cleveland, OH; 7) Fred Hutchinson Cancer Institute and Colon Cancer Family Registry, Seattle, WA; 8) Mayo Clinic and Colon Cancer Family Registry, Rochester MN.

Colorectal Cancer is the second leading cause of cancer in American adults and presents a substantial public health concern. While ~5% of cases are accounted for by familial adenomatus polyposis and hereditary nonpolyposis colon cancer, 20% of cases have a family history of colon cancer. This study is a follow-up of a genome scan for colorectal neoplasia predisposing genes in a European American sample comprising 185 sibling pairs ascertained through two or more sibs with a history of colorectal cancer (Wiesner et al. PNAS, 2003). The primary area of interest from the genome scan was chromosome 9q22.2-31.2. For this study, genotypes for 10 additional markers were generated for 1) a revised version of the sample mentioned above (182 sibling pairs), referred to as ROC and 2) a confirmation collection (CC) of 90 sibling pairs. These fine mapping regions were analyzed using the weighted Haseman-Elston regression (dependent variable is a weighted average of the squared sib-pair trait difference and the squared mean-corrected sum) and the sibling pair mean test. The marker with the strongest signal in the ROC and ROC+CC was D9s1786 (-log p-values =3.25, and 3.38, respectively) the same marker indicated in the genome scan. The mean test yielded -log p-values of 3.30, and 3.79 for the ROC and ROC+CC collections, respectively. These results both confirm the presence of a susceptibility gene on chromosome 9 as well as narrow the region most likely to contain this susceptibility gene to 9q22.31-9q22.33.

Four Genes in the Hypertension Pathway are confirmed to be Genetic Markers for Insulin Resistance. *X. Guo[1], K.D. Taylor[1], S. Cheng[2], B. Fang[1], J. Cui[1], A.H. Xiang[3], M.J. Quiñones[4], J.C. Ramirez[4], W.A. Hsueh[4], T.A. Buchanan[3], L.J. Raffel[1], J.I. Rotter[1]* 1) Medical Genetics Inst, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Roche Molecular Systems, Inc; 3) USC; 4) UCLA.

Insulin resistance (IR), though most often considered in terms of the pathophysiology of type 2 diabetes, also influences blood pressure and is a risk factor for hypertension. Previously, in Mexican-American families ascertained via a coronary artery disease proband (MACAD), we found evidence for association between IR and variations in 6 previously reported hypertension genes: angiotensinogen (AGT), adducin 1 (ADD1), natriuretic peptide precursor A (NPPA), beta-2-adrenergic receptor (ADRB2), sodium channel, nonvoltage-gated 1 alpha (SCNN1A), and nitric oxide synthase 3 (NOS3). We have now genotyped the same SNPs in these 6 genes in an independent cohort of 566 non-diabetic offspring from 150 Mexican-American families ascertained through a hypertensive proband in our Hypertension-Insulin Resistamce project (HTN-IR). As in MACAD, IR was assessed by the euglycemic clamp, in which the glucose infusion rate (GINF) and insulin sensitivity index (SI) were determined. The program QTDT was utilized to evaluate the associations between genetic variations and IR, adjusting for age, sex and BMI. ADRB2, NPPA, NOS3, and SCNN1A were each associated with indices of IR (p= 0.017, 0.008, 0.034, 0.016 resp.). Haplotype analysis with 2 SNPs in NOS3 demonstrated that one haplotype was associated with insulin sensitivity (IS) in both MACAD and HTN-IR samples, providing a strong confirmation for the association. Similarly, specific haplotypes in NPPA and SCNN1A were associated with IR in both samples, while another haplotype in NPPA was associated with IS. In conclusion, we were able to replicate association with insulin resistance in 4 out of the 6 genes, ADRB2, NOS3, NPPA, and SCNN1A. This supports a genetic basis for the known associations among diabetes, hypertension, and insulin resistance, and emphasizes the importance of consistency in phenotype assessment and ethnicity when attempting to confirm genotype-phenotype associations.

Histone deacetylation enhances qkI transcription, an essential factor for promoting oligodendroglia differentiation. *Y. Chen[1], C. Kitchen[1], M. Xia[1], D. Osterhout[2], Y. Feng[1]* 1) Pharmacology, Emory University, atlanta, GA; 2) Cell and Developmental Biology,SUNY Upstate Medical University.

The dynamic regulation of histone acetylation modulates transcription through remodeling the chromatin structure. Although increased histone acetylation is often associated with enhanced transcription, emerging evidence suggests opposite scenarios in which histone deacetylation can also up-regulates transcription. In particular, a global reduction of histone acetylation is accompanied with up-regulated differentiation markers of oligodendroglia, a special type of glia for myelination of the CNS. Moreover, inhibition of histone deacetylase (HDAC) abrogates oligodendroglia differentiation, suggesting that histone deacetylation may enhance transcription of genes that promote oligodendroglia differentiation. However, which genes are directly regulated by such mechanism still remains elusive. Here we report that histone deacetylation up-regulates transcription of the quakingI (qkI) gene, which encodes a selective RNA-binding protein essential for oligodendroglia differentiation. We show that qkI transcription is vigorously elevated upon induced differentiation. In addition, we identified several genetic fragments that mediate differentiation-induced qkI transcription. Interestingly, histone acetylation at the qkI promoter/regulatory elements is reduced during oligodendroglia differentiation. Deletion of these regulatory fragments in the quakingviable (qkv) mutant results in abnormally increased histone acetylation of the qkI promoter and diminished qkI transcription. We further show that HDAC inhibition increases histone acetylation at the qkI promoter, markedly reduces qkI transcription, and abrogates oligodendroglia differentiation, all can be reversed after the inhibitor is removed. In contrast, histone acetylation of the promoter of an adjacent gene, pacrg, is not affected under these conditions. Together, our data suggest that the qkI promoter is sensitive to the dynamic changes of histone acetylation, and qkI transcription is up-regulated upon histone deacetylation, which is a conceivable factor that promotes oligodendroglia differentiation.

Assessing Genetic Literacy in Undergraduate Students. *E.E. Acra[1], C.A. Huether[1], B.V. Bowling[1], H. Bender[2]* 1) Univ Cincinnati, OH; 2) Univ Notre Dame, IN.

Genetics issues play a large role in health and public policy, and new knowledge in the field will continue to have significant implications for individuals and society. It is therefore important to continue improving genetics education at all levels to promote greater genetic literacy. This study assessed both the level of genetic literacy in undergraduate students, and their attitudes toward genetics issues. It also evaluated the effectiveness of different courses in increasing genetics knowledge and the impact of the courses on students attitudes. 416 undergraduate students in seven courses at the University of Cincinnati participated in this study representing both biology and non-biology majors. Data were collected utilizing a modified 35-item inventory of multiple choice and true/false questions from the University of Notre Dame. The inventory was completed by students in general biology and genetics courses: students in a general psychology course were used as a control. Pre-course and post-course scores were compared among courses as well as within each course. Overall students in courses for biology majors scored higher on the pre-course instrument (69.83%) than students in the general psychology course (65.21%) and those in courses for non-biology majors (60.53%). The effect each course had on genetic literacy was also assessed by comparing post-course scores to pre-course scores. Significant increases in knowledge scores were seen in only two of the four courses emphasizing genetics, one course for non-majors and one honors course for majors. The psychology course showed a significant decrease in knowledge scores. Very little change in attitude scores was observed in any of the courses. The results indicate that some genetics courses are not effective in increasing levels of genetic literacy. Course content and pedagogy need to be considered in these courses. However, some of the results, particularly the significant change in the control group, raise concerns that the instrument may not be as reliable as desired. A valid and reliable instrument designed specifically for testing genetic literacy in undergraduates would allow a more accurate measure of students knowledge and course impact.

Phenotypic Spectrum of Adducted Thumbs: Case Report. *M. Descartes, D. McIlvried* Dept Genetics, UAB, Univ Alabama at Birmingham, Birmingham, AL.

Adducted thumbs is a mandatory feature of several syndromes, including whistling face syndrome, congenital contractural arachnodactyly, multiple pterygium syndrome, distal arthrogryposis type I, X-linked recessive hydrocephalus, MASA syndrome, Christian-Adducted thumb syndrome, and adducted thumb-club foot syndrome. All of these conditions can be differentiated on a clinical basis and all have a neuropathic and/or myopathic origin. We report a male patient with isolated adducted thumbs and learning disabilities. The patient is the second child born to a 38 year old G2P1 mother. He was noted at birth to have bilateral adducted thumbs without additional associated complications. At age 8 years, he had normal growth parameters. On physical examination he was noted to have frontal bossing, wide set eyes, downslanted palpebral fissures, overfolded helices and mild joint laxity. Other features included bilaterally adducted thumbs, decreased hypothenar eminence, fifth finger clinodactyly, and plantar gap. He has been diagnosed with ADHD and dyslexia, and his IQ score was reported to be in the 90s. His evaluation has included chromosome analysis in peripheral blood, spine MRI, head CT scan and skeletal survey. The skeletal survey showed adducted thumbs and bilateral hind foot valgus. The other tests were reported as normal. The family history was noncontributory. LICAM mutation analysis and chromosome microarray analysis are pending. X-linked hydrocephalus and MASA syndrome are associated with mutations of the L1CAM gene on Xq28. L1CAM mutations affect mainly the central nervous system and are characterized by a variable phenotype that includes mental retardation, abnormal brain development, spastic paraplegia and adducted thumbs. Recently, Frints et al. (2003) reported a 76 year old male with non-specific mental retardation, bilateral adducted thumbs and a Xp22.1;3p26.3 translocation. The 3p breakpoint disrupted the neural Cell Adhesion L1-Like (CALL) gene, which has been previously linked to non-specific MR and is closely related to LICAM both structurally and functionally. Adducted thumbs may represent a mild manifestation of a phenotypic spectrum associated with mutations in the neural cell-adhesion gene. .

MLS syndrome evaluated by prenatal karyotyping, FISH and array CGH. *C.C. Cain[1], D.O. Saul[1], L. Attanasio[1], A. Hamosh[2], E. Oehler[1], K. Blakemore[1], G. Stetten[1,2]* 1) Department of Gynecology and Obstetrics, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD.

Microphthalmia with linear skin defects (MLS) syndrome is a rare developmental disorder inherited as an X-linked dominant and associated with monosomy of the Xp22.3 region. We describe a severe case of MLS syndrome that presented prenatally with multiple anomalies including cystic hygroma, micropthalmia, intrauterine growth restriction and a complex congenital heart defect. Chromosome analysis of amniocytes revealed a de novo translocation between chromosomes X and Y [karyotype 46,X,der(X)t(X;Y)(p22.3;q11.2).ish der(X)(DXZ1+,DMD+,KAL-,STS-,SRY-),22q11.2(Tuple1x2)]. MLS diagnosis was made at birth and the prenatal karyotype was confirmed. Replication studies showed the translocated X chromosome was inactive in all 20 fibroblasts examined. Comparative genomic hybridization to BAC arrays (array CGH) was used to explore the genomic imbalance and refine the breakpoints of the rearrangement. Array CGH confirmed the X and Y imbalances seen in the karyotype and also showed eleven probes in the MLS region were deleted as a result of the translocation. FISH with BAC clones verified the array findings and placed the X breakpoint in Xp22.2, just proximal to the MLS critical region. In conclusion, the sensitivity of array CGH was valuable in detecting monosomy of the MLS critical region. Array CGH should now be considered for the prenatal diagnosis of MLS syndrome.

Genome-wide strategies to identify DNaseI hypersensitive sites. *G.E. Crawford[1], S. Davis[2], P.C. Scacheri[3], G. Ranaud[2], P.S. Meltzer[2], T.G. Wolfsberg[2], F.S. Collins[2]* 1) Institute for Genome Sciences & Policy, Duke University, Durham, NC; 2) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) Department of Genetics, Case Western Reserve University, Cleveland, OH.

Mapping DNaseI hypersensitive (HS) sites is a highly accurate method of identifying the location of active gene regulatory elements, including promoters, enhancers, silencers, and locus control regions. While Southern blots have been the traditional method of identifying DNase HS sites for the last 25 years, this standard manual method is not readily scalable to studying large chromosomal regions, much less the entire genome. We have developed two high-throughput strategies to identify DNase HS sites across the genome. One method uses next-generation sequencing strategies developed by Solexa and 454 Life Sciences to sequence DNase-treated nuclear DNA, recovering a very large number of short sequence tags at the sites of cleavage. A second method, called DNase-chip, identifies DNase HS sites using NimbleGen tiled microarrays. Both methods have been shown to be highly accurate at identifying valid DNase HS within the representative 1% of the genome identified by the ENCODE consortium. We have recently scaled up the number of tag sequences (1.1 million per cell type) as well as increased the number of tiled microarrays to analyze the entire non-repetitive portion of the human genome. While many DNase HS sites appear immediately upstream or in the first intron of known genes, others appear in intergenic regions or even in gene deserts. Genes that have a DNase HS site nearby are more likely to display elevated gene expression than genes that do not. While many DNase HS sites are found to be present in more than one cell type studied, a number are cell type specific, indicating we have identified tissue-specific gene regulatory elements. As genome-wide sequencing and tiling microarrays become increasingly affordable, it will be possible to apply these methods globally to any tissue from any species with a sequenced genome.

104,268 SNP whole genome association results for alcohol dependence converge with genome scanning data from other addictions. *T. Drgon, C. Johnson, Q.R. Liu, D. Walther, G.R. Uhl* Dept Molecular Neurobiology, NIDA-IRP/NIH, Baltimore, MD.

Association genome scanning can identify markers for the allelic variants that contribute to vulnerability to complex disorders, including alcohol dependence. To improve the power and feasibility of this approach, we have validated 100k microarray-based allelic frequency assessments in pooled DNA samples. We then used this approach to analyze 100k genome scanning data from unrelated alcohol dependent vs control individuals sampled from pedigrees collected by the Collaborative Study on the Genetics of Alcoholism (COGA). Allele frequency differences between alcohol-dependent and control individuals were assessed in quadruplicate at 104,268 autosomal SNPs in pooled samples. Positive SNP clusters nominate interesting genes whose products are implicated in cellular signaling, gene regulation, development, cell adhesion and Mendelian disorders. These data converge with association results from association genome scans for amphetamine dependence, polysubstance abuse and nicotine dependence to extents that are not seen by chance in Monte Carlo simulation studies. These convergent data support polygenic contributions to vulnerability to dependence on a number of different studies, as suggested by classical genetic twin data. Studies using higher marker densities and studies in other samples of alcohol dependent individuals will help assess whether the findings that do not replicate in samples from other addictions represent loci in which allelic variants selectively impact vulnerability to alcohol dependence. The reproducibly-positive SNPs identified here provide new tools to aid the understanding, prevention and treatment of substance abuse and dependence. (Support: NIH IRP, NIDA).

Characterizing karyotypic evolution in adenocarcinoma of the pancreas. *C. Griffin[1,2], J. Kowalski[2], L. Morsberger[1], A. Hawkins[1], A. Blackford[2], C. Yeo[3], R. Hruban[1,2]* 1) Pathology; 2) Oncology; 3) Surgery, Johns Hopkins University, Baltimore, MD.

The high level of karyotypic complexity found in epithelial tumors makes it difficult to characterize cytogenetic evolution. Derivation of such pathways in adenocarcinoma of the pancreas also has been limited because virtually no tumors are resected at an early stage of disease. In addition, the number of primary tumors for which analysis of abnormal karyotypes has been reported is small. We report clonal karyotypic abnormalites from G-band analysis of 36 primary pancreas carcinomas. 91% of the tumors were diploid or triploid. Numerical alterations were common. All chromosomes were involved in gain and/or loss in at least 8 and up to 28 tumors. Chr 18, 17, 6, 21, 22, Y & 4 were most commonly lost in 28, 20, 16, 15, 15, 13 & 12 tumors respectively. Gain of chr 20 was found in 10 carcinomas. Structural abnormalities were common, with a median number of 7 imbalances (excluding whole chromosome loss) per tumor (range 1-15). 16 tumors had dms and/or hsrs, indicating gene amplification. Adding these tumors to those published in the Mitleman database (http://cgap.nci.nih.gov/Chromosomes/CytList) we used statistical methods to begin to determine pathways of karyotypic evolution. Based on analyses of 105 tumor samples (44 with 2N ploidy; 61 with not 2N ploidy) from 9 studies, the number of imbalances (sum of the number of losses and/or gains) per chromosome & tumor was calculated & categorized as either none or at least one imbalance. A test of the null hypothesis of no difference in the percent imbalances between 2N ploidy vs. not 2N ploidy tumors, among all chromosomes was rejected ($p=0.005$), indicating a higher percent of imbalances among not 2N ploidy tumors (60%) vs. 2N ploidy (25%). Chromosomes 10, 16, 22, 8 & 15 were identified as contributing to such a difference. In this analysis, information from ploidy was used as a marker of evolution to address the question of whether there is any particular evolutionary advantage to being diploid. Results from analyses of the temporal evolution of these samples, irrespective of ploidy will be compared.

Mandibulo-facial dysostosis, acral anomalies, and frontonal dysplasia: a new form of Acrofacial dysostosis.
M.C.P. Cernach, N.L.M. Sobreira, D. Brunoni, A.B.A. Perez Centro de Genética Médica, UNIFESP-EPM, São Paulo, São Paulo, Brazil.

Acrofacial dysostosis (AFD) is a condition that involves mandibulo-facial dysostosis (MFD) associated with limb defects in varying degrees [Rodríguez et al., 1990].The more severe forms, considered lethal AFD can be subdivided, more or less confidently, into Nager, POADS, and Rodríguez [Opitz et al., 1993].Nager AFD is characterized by malar, mandibular, and maxillary hipoplasia, macrostomia, abnormal ears, and radial defects. The lower limbs are usually normal. Is an autossomal dominant syndrome with variable expression [Merrer et al., 1989; Goldstein and Mirkin.,1988]. Opitz [1987] has suggested that Nager AFD should be considered an anomaly rather than a syndrome due to the apparent causal heterogeneity of this AFD. POADS differs from the preceding by preferential involvement of ulna and fibula with inconstant involvement of radius. Is an autossomal recessive trait. Lethal cases in the fetal or neonatal period are unusual and show more severe anomalies [Rodríguez et al., 1990; Merrer et al., 1989]In 1990, Rodriguez et al., described three affected sibs with severe, apparently lethal AFD. This syndrome type Rodríguez envolves MFD, predominantly preaxial limb deficiencies, rare postaxial limb anomalies, absent fibulae and ribs, shoulder and pelvic hipoplasia, cardiac malformations, CNS malformations (arrhinencephaly, triventricular hydrocephaly due to aqueductal stenosis, corpus callosum agenesis), absence of lung lobulation and urogenital anomalies [Petit et al., 1992]. Its an autossomal recessive trait.We described a female stillborn with acrofacial dysostosis and frontonasal dysplasia. The patient had protrusion of the forehead with accentuated hypertelorism and nose absence with rhinencephalo. The autopsy showed wide cranial sutures, severe hydrocephaly with distinction of the hemispheres right and left of the brain and preservation of the olfactory bulb, first and second cranial nerves, small kidneys bilaterally, and anal atresia with recto-vaginal fistula. Therefore, for our patient, we suggested to treat in a new form of AFD.

Expanding spectrum of CDG-Ig: Siblings with prenatal-onset skeletal dysplasia, B-cell lymphopenic hypogammaglobulinemia, cardiac and genital malformations, and fatal outcome. *A.A. Basinger[1], C. Kranz[2], M. Gucsavas-Calikoglu[1], C.M. Powell[1], F.W. Henderson[1], H.H. Freeze[2], A.S. Ayslworth[1]* 1) Pediatrics, UNC Chapel Hill, Chapel Hill, NC; 2) Burnham Institute for Metabolic Research, La Jolla, CA.

The congenital disorders of glycosylation (CDGs) are a diverse group of disorders caused by disruption in production of lipid-linked oligosaccharides (LLOs). We present siblings with prenatal-onset skeletal dysplasia, polyhydramnios, and prematurity. Dysmorphic features included broad nose, thick ears, thin lips, micrognathia, inverted nipples, ulnar deviation, long fingers with spatulate tips, fifth finger camptodactyly, nail hypoplasia, and talipes equinovarus. Other features included psychomotor retardation, hypogammaglobulinemia, normal fat distribution, deafness, intestinal malrotation and poor gastrointestinal motility, edema, persistent hyponatremia, and intermittent hypoglycemia and thrombocytopenia. Cardiac malformations include PDA, VSD, biventricular hypertrophy, and arrhythmias. Small penis with hypospadias, hypoplastic scrotum, and non-palpable testes were noted. Radiographic studies showed short limbs, absent ossification of cervical vertebral bodies, short, thin ribs with flared metaphyses, and short humeri, radii, femurs, and tibiae. Both died in infancy, one of overwhelming sepsis and the other of cardiorespiratory failure. Metabolic and molecular studies reveal a type I pattern of abnormal transferrin glycosylation. Activities of phosphomannomutase and phosphomannose isomerase in fibroblasts were normal. HPLC analysis showed that fibroblasts synthesized truncated LLOs, primarily $Man_7GlcNAc_2$, suggestive of CDG-Ig. Mutation analysis of *ALG12* showed that both sibs were compound heterozygotes for a novel mutation 301 A>C (G101Arg) and previously described 437 G>A (R146Q). Congenital disorders of glycosylation should be considered in the etiology of prenatal-onset skeletal dysplasias with cardiac and genital malformations. Precise diagnosis will require collaboration with a laboratory experienced in testing for these novel and complex conditions. (Supported by R01 DK55615 to HHF).

Genome-wide analysis of gene expression in transformed lymphocytes from sib pairs discordant for type 2 diabetes (T2DM). *S.C. Elbein[1,2], W.S. Chu[1,2], S.K. Das[1,2]* 1) Internal Medicine, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Central Arkansas Veterans Healthcare System, Little Rock, AR 72205.

T2DM shows replicated linkage to chromosome 1q21-23, and work from our laboratory has mapped that linkage to the D1S484-D1S2705 region. To further map genes for this region or under control of this region, we examined the differential expression in total RNA isolated from E-B virus transformed lymphocytes (TLs) from 4 sib pairs discordant for both T2DM and marker D1S2705, and selected from families linked to chromosome 1q. All TLs were grown in 10% FBS supplemented RPMI-1640 medium at 5.6 mmol/l glucose (physiologic). GE Healthcare CodeLink Bioarrays (Human ~55K) were hybridized with the biotinylated cRNA target, stained with Cy5-streptavidin and scanned on an Axon GenePix 4000B scanner (performed by GenUS BioSystems, Inc., Northbrook, IL). Data was analyzed with CodeLink and GeneSpring software packages. Intensity was normalized to the median intensity of each array. Comparison of T2DM subjects with controls showed the expression of 28,212 genes in at least 3 members of each group and with <1 standard deviation, whereas pairwise analysis of the discordant siblings showed the expression of 28,864 genes in at least 3 discordant pairs. Groupwise analysis showed 132 differentially expressed genes (>1.5-fold difference and ANOVA p-value <0.05), whereas only 38 genes differed (>1.5-fold difference) between all 4 sib pairs. In total, 20 genes were common to pairwise and groupwise comparisons (11 up regulated and 9 down regulated). Differentially expressed genes mapped to previously reported regions of linkage on chromosomes 1q(2 genes), 11q (2 genes), and 12q (4 genes). Several genes, including DNAJC12 (HSP40; 10q22.1), which showed 4.2-6.8 fold over-expression, are potential candidates for T2DM. A putative gene (Hs.127310) with serine/threonine kinase activity in the linked region at 1q23.3 also showed significant up-regulation (2.4 fold) in the T2DM group. Studies are in progress to confirm these findings with real time PCR and to further examine the role of these genes in T2DM pathophysiology.

Effects of urban migratory patterns on a contemporary regional gene pool of Quebec. *C. Bherer[1, 2], B. Brais[2], H. Vézina[1]* 1) Interdisciplinary Research Group on Demography and Genetic Epidemiology (GRIG), University of Quebec at Chicoutimi, Canada; 2) CHUM Research Centre, University of Montreal, Canada.

Interregional mobility towards urban areas and their periphery has become increasingly important throughout the 20th century. Because of its geographic location (north-east of the Montreal area) and a recent demographic expansion, the Lanaudiere region offers a favorable context to explain and illustrate the effects of these migratory patterns on the structure of its gene pool. This study aims at characterizing intraregional variability and temporal transformation of the Lanaudieres gene pool. A second objective is to gain a better understanding of the role of settlement history in the spread of two founder mutations causing recessive hereditary sensory and autonomic neuropathy type 2 (HSAN2, OMIM 201300). We sampled 400 individuals from 2 subregional populations (north and south) and married in 2 periods (1945-55 and 1985-95). Ascending genealogies of selected individuals were reconstructed using the BALSAC database (average depth: 10 generations). For the 1945-55 period, analyses of kinship and consanguinity in the northern part of Lanaudiere point toward a stronger endogamy than in the southern part, while the distribution and genetic contribution of ancestors are quite similar in the two subregions. For the 1985-95 period, the genealogical indices display much more heterogeneity in the southern part of the region which is consistent with the recent demographic boom in this territory. Overall, a marked reduction of kinship and consanguinity levels in Lanaudiere is observed in this fifty-year period and it can clearly be linked to interregional migratory trajectories toward urban areas. Lastly, we integrated a particular genetic story to this diversity pattern by analyzing the introduction, diffusion and current distribution of the 2 French Canadian mutations causing HSAN2. Analyses of ascending genealogies of carriers and controls allowed us to identify ancestral clusters with the highest probability of having introduced the mutations in the Quebec population.

Molecular analyses of duplications on human chromosome 17p. *W. Bi[1], X. Shi[1], C.M.B.C. Fonseca[1], C. Shaw[1], G. Weissenberger[1], L. Potocki[1,3], J.R. Lupski[1,2,3]* 1) Dept Molecular & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Dup(17)(p11.2p11.2) syndrome is a genomic disorder caused by an interstitial duplication in chromosome 17 sub-band p11.2. We previously reported 7 patients with a common duplication of ~4 Mb that is reciprocal to the common deletion present in >70% of Smith-Magenis syndrome (SMS) patients. Both common deletions and common duplications are mediated by meiotic homologous recombination between non-allelic low-copy repeats, the distal and proximal SMS-REPs. We analyzed the breakpoints in 26 new duplication patients by pulsed-field gel electrophoresis, fluorescence in situ hybridization, and array comparative genomic hybridization. We found that 60% have a common duplication, the reciprocal to the common SMS deletions, and the remaining have uncommon duplications ranging from 1.1 Mb to 15.1 Mb. The patient with 1.1 Mb duplication has the typical features of dup(17)(p11.2p11.2) syndrome, narrowing the critical region of this syndrome from ~4 Mb to 1.1 Mb. The dosage sensitive retinoic acid inducible 1 gene (*RAI1*) that is responsible for the majority of SMS features is located within this region, implicating *RAI1* as the gene responsible for clinical features in the dup(17)(p11.2p11.2) syndrome. Most of the proximal breakpoints in the uncommon duplications mapped within two adjacent BACs very close to the centromere. This contrasts with half of the proximal breakpoints in the uncommon deletions mapping within or adjacent to the proximal SMS-REPs and none close to the centromere. The distal breakpoints in duplications did not cluster and distributed from p11.2 to p13. Therefore, the uncommon duplications in chromosome 17p may be stimulated by centromeric structure and mediated by non-homologous end joining. Note worthily, although uncommon recurrent deletions have been identified in 6 SMS patients, no recurrent reciprocal duplications were identified. Our results suggest that the mechanism applied in the uncommon duplications of 17p may differ from that in the uncommon deletions of 17p.

Molecular and cytogenetic elucidation of a familial case of Prader-Willi syndrome: evidence of a rare imprinting centre mutation. *D. Allingham-Hawkins, C. Gibbons, D. Kennedy, J. Tokunaga, M. Bedford, A. Hunter, K. Chun*
Genetics Program, North York General Hosp, Toronto, ON, Canada.

A 14-year-old boy was referred for genetic assessment due to developmental delay and behavioural problems. Clinical history revealed failure to thrive in the newborn period followed by global developmental delay. A female paternal half-sibling of the patient was reported to have a similar clinical phenotype and had been diagnosed with Prader-Willi syndrome (PWS). In addition, there were other male relatives on the paternal side of the family who reported to have a PWS-like phenotype although these diagnoses have not been confirmed. Methylation studies of the SNRPN gene confirmed a diagnosis of PWS in the patient. Fluorescence *in situ* hydridization studies showed no deletion on either chromosome 15. Because the father was unavailable, uniparental disomy (UPD)studies were performed using a specimen from the patient, his mother and a full male sibling who is also developmentally delayed but does not clinically have symptoms of PWS. UPD studies revealed that the patient does *not* have UPD of chromosome 15 thereby suggesting that an imprinting centre (IC) mutation is present. To further support this, the patient and his unaffected brother appear to share a common paternal chromosome 15 until within the Prader-Willi critical region (PWCR) at which point a crossover event occurs. Mutation studies for an IC mutation are being pursued as are specimens from the affected paternal half-sibling and her mother to further elucidate the haplotype on which the mutation resides. Imprinting mutations occur in <1% of PWS patients and approximately 15% result from small deletions in the PWCR while the majority is epimutations or alterations of the *imprint* rather than the DNA. However, the presence of multiple affected individuals in a family, as in the present case, favours the presence of a deletion (Buiting *et al.*, 2003. *Am J Hum Genet* 72:571). Therefore, although more work is needed for confirmation, this case most likely represents a rare familial case of PWS caused by an imprinting centre mutation.

Genetic associations with response variability on the continuous performance task in AD/HD families. *A.E. Ashley-Koch[1], J.N. Epstein[2], S. Tonev[3], D. FitzGerald[3], E.M. Kane[4], A.D. Anastopoulos[4], A.M. Lachiewicz[5], M.E. Kail[1], L. Exelbierd[1], M.L. Cuccaro[1], J.R. Gilbert[1], S.H. Kollins[3]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Division of Behavioral Medicine and Clinical Psychology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 3) Department of Psychiatry, Duke University Medical Center, Durham, NC; 4) Department of Psychology, University of North Carolina, Greensboro, NC; 5) Department of Pediatrics, Duke University Medical Center, Durham, NC.

Reaction time and reaction time variability on neuropsychological tests have been proposed as endophenotypes for unraveling the genetics of AD/HD. AD/HD children are usually slower and more variable in their reaction times than control children. We have examined genetic associations with four measures of response variability from the continuous performance task (CPT) including commission errors, mean response time (mu), standard deviation of response time (sigma), and tau, an alternative measure proposed by Hervey et al. (in press) which extracts the ex-Gaussian part of the response distribution. CPT data were collected from 53 nuclear families with at least one child aged 5 to 11 years meeting AD/HD DSM-IV criteria. Using a haplotype tagging approach, families were genotyped for 123 SNPs in neurotransmitter candidate genes. CPT measures of tau and sigma were log-transformed for analysis. Preliminary results with QTDT suggest that mu may be associated with genetic variation in the BDNF gene ($p<0.05$ for rs1048221, rs7124442 and rs7934165) while tau may be associated with genetic variation in the DBH gene($p<0.05$ rs2073833, hcv3274654, rs1108580, hcv2253949 and rs1541333). The association of tau with DBH is particularly exciting as hcv2253949 is a coding SNP. Both genes belong to the dopaminergic pathway. These data suggest that both traditional and alternative measures of response variability in CPT performance are associated with genetic variation and that such endophenotypes may be useful for better understanding the biological mechanisms that contribute to the clinical diagnosis of AD/HD.

Identification of a novel major BBS gene (BBS10) coding for a vertebrate specific chaperonine-like protein and mapping of BBS12. *H. Dollfus[1], C. Stoetzel[1], J. Muller[2], V. Laurier[2], E. Davies[3], N. Salem[4], E. Chouery[4], S. Corbani[4], N. Jalkh[4], S. Rix[5], JL. Badano[3], C. Leitch[5], A. Verloes[6], O. Poch[2], D. Bonneau[7], A. Mégarbané[4], P. Beales[5], N. Katsanis[3], JL. Mandel[2]* 1) Laboratory EA 3949, Faculté de Médecine, Université Louis Pasteur, Strasbourg, France; 2) IGBMC, Strasbourg, France; 3) Institute of Genetic Medecine, John Hopkins University, MD, USA; 4) Genetics laboratory, Université Saint Joseph, Beyrouth, Lebanon; 5) Molecular Medecine Unit, Institute of Child Health, University College, London, UK; 6) Service de Génétique, CHU Robert Debré, Paris, France; 7) Départment de génétique, CHU Angers, France.

The phenotype of Bardet-Biedl syndrome (BBS) is defined by the association of retinitis pigmentosa, obesity, polydactyly, hypogenitalism, renal and cognitive impairment. The extensive genetic heterogeneity of this condition was supported by the identification, initially by classical linkage analysis and more recently by comparative genomics, of 9 genes up to the beginning of 2006 (BBS1 to 9) that appear implicated in cilia assembly or function. SNP homozygosity mapping performed on an extended consanguineous Lebanese family permitted us to identify the new BBS10 gene on chromosome 12: unexpectedly patients in different sibships were either homozygous or compound heterozygotes for BBS10 mutations while one sibship carried homozygous missense mutations in BBS2. 311 additional BBS families where tested (from French, US and British cohorts). 16 truncating mutations and 18 missense mutations were found. The C91fsX95 mutation accounts for 46% of the mutational load. Bioinformatic studies revealed that BBS10 codes for a chaperonine-like protein. Unlike other BBS genes, the new gene is vertebrate specific and would have been missed by comparative genomics approaches that were successful for other BBS genes. This gene is mutated in 20 % of families, similar to the BBS1 gene and much higher than for the other BBS genes. Using the same strategy we also mapped a new BBS locus in two consanguineous unrelated families, that share a extended common haplotype over 6 Mb. Testing of candidate genes in this region will be reported.

Clinical and cytogenetic findings in a child with mosaic 45,X/47,X, pseu idic(Y)(q11.2)x2 karyotype. *S. Gupta[1], P. Koduru[1], D. Carey[2], L. Palmer[3], L. Mehta[4]* 1) Laboratory Medicine, North Shore Univ Hosp, Manhasset, NY; 2) Div. of Endocrinology; 3) Pediatric Urology; 4) Medical Genetics, Schneider Children's Hospital, Albert Einstein College of Medicine and NYU School of Medicine, NY.

A newborn infant was evaluated because of genital abnormalities. There were minor dysmorphisms with low set ears, single transverse palmar creases and a sacral dimple. Genitalia were ambiguous, with a short phallus, chordee, penoscrotal hypospadias, a left scrotal sac with a palpable gonad and a flat right hemiscrotum with no palpable right testis. Pelvic ultrasound did not show a uterus or intrabdominal gonads. Serum testosterone was 159 ng/dl, DHT 12 ng/dl, and 17- OHP 38 ng/dl. Blood chromosome analysis showed: 45,X/47,X,inv dup(Y)x2. FISH studies revealed that the abnormal Y was a dicentric Yp isochromosome, with two copies of SRY, one at each end and loss of distal Yq. Hence karyotype was 45,X,/47,X,pseu idic(Y)(pter->q11.2:q11.2->pter). At 5.5 months exploratory laparoscopy showed a right dysgenetic gonad in the inguinal region, attached to a cystic structure and a left scrotal testicle. Pathology showed immature testicular tissue in both gonads, with fibrotic stroma in the right gonad. Chromosome analysis of gonadal biopsies showed similar findings to that in peripheral blood. Interphase FISH on skin fibroblasts with SRY and DXZ1 probes showed 45,X[91.9%]/47,X,abn(Y)x2[8%]/46,X,abn(Y)[1.9%]. The conception was therefore likely to have originated as 46,X,pseu idic(Y)with subsequent mitotic nondisjunction resulting in 45,X and 47,XYY cell lines, with pseu idic Ys. Father had normal 46,XY chromosomes. The phenotype of patients with 45,X/47,XYY ranges from almost normal male to mixed gonadal dysgenesis or Turner syndrome. The presence of a Y isochromosome, Yp/Yq breakpoints and the degree of mosaicism are the variables responsible for phenotype. Information on SRY status is not available in most previous reports; in our case the pseu idic(Y) was detected by the position and number of SRY signals. Accurate characterization of a structurally abnormal Y chromosome, with or without a 45,X cell line, requires molecular cytogenetic testing.

The effects of di(2-ethylhexyl)phthalate (DEHP) on reproduction and reproductive fitness. *S. Gupta, B. Bongiovanni, L.R. Adkison* Genetics, Mercer University School of Medicine, Macon, GA.

This study analyzes the effects of di(2-ethylhexyl) phthalate (DEHP), a plasticizer commonly used to make PVC more flexible and durable, on reproductive fitness and reproduction fitness as measured by viability and fertility, respectively. Using Drosophila melanogaster, the number of offspring and the number of eggs laid were determined when adults and larvae were raised on medium containing the phthalate. Drosophila larvae were raised on medium with different dilutions of DEHP (1:50,000 to 1:1 billion) and compared to Drosophila raised on control medium. F1 and F2 progeny were analyzed and represented over 20,000 offspring. Data were collected for each dilution by gender. Egg-laying experiments were conducted to determine differed in larvae raised on DEHP when compared to controls. Each experiment used either a males or females raised on DEHP crossed with normal males or females, respectively. Over 5,000 eggs laid on a smooth medium were counted.
Multiple, corrected t-test analysis were performed to determine the effects of phthalate in each experiment, comparing each dilution group to each other and the control. DEHP had little effect on progeny counts, whereas it caused a significant reduction in the number of eggs produced. These results demonstrate DEHP-treated F1 larvae and the F2 offspring of these matured larvae are equally viable as controls at eclosion. However, the fertility of DEHP-treated parentals is reduced suggesting the viability of eggs from DEHP-treats parentals may be greater for unknown reasons. These data support a complex interaction of genes and the need for more analyses of how specific genes cause the affects observed.
.

A common epigenetic signature distinguishes human embryonic stem cells from differentiated cell populations.

M. Bibikova[1], E. Chudin[1], B. Wu[1], L. Zhou[1], E. Wickham Garcia[1], Y. Liu[2], S. Shin[2], T.W. Plaia[3], J.M. Auerbach[3], D.E. Arking[4], R. Gonzalez[5], A. Chakravarti[4], A. Maitra[4], M. Rao[2], D.L. Barker[1], J.F. Loring[5], J.-B. Fan[1] 1) Illumina Inc., San Diego, CA; 2) NIA, NIH, Baltimore, MD; 3) ATCC, Manassas, VA; 4) Johns Hopkins University, Baltimore, MD; 5) Burnham Institute for Medical Research, La Jolla, CA.

Human embryonic stem (hES) cells are unique among all human cells in their ability to self-renew and to differentiate into multiple cell types. The pluripotence of hES cells is rooted in their origin from an early stage of embryogenesis, during an active period of epigenetic remodeling of the genome. To begin to understand the epigenetic state of hES cells, we used a new microarray method to measure DNA methylation at 1536 specific CpG sites in the promoters of 371 genes in fourteen independently isolated hES cell lines collected from laboratories around the world at various times in culture. For comparison we also determined the DNA methylation status of a pluripotent human embryonal carcinoma cell line (NTERA2), two human neuronal and two bone marrow stem cell lines, four lymphoblastoid cell lines, five human tissues and 24 cancer cell lines. We found that the undifferentiated hES cells had a methylation profile distinct from those of other cell types, and that this profile was relatively stable during prolonged cell culture. This epigenetic signature is likely to be linked to ES cell-specific properties such as self renewal and pluripotence. From the global methylation profiles, we selected 49 CpG sites from 40 genes that contribute most strongly to the distinct signatures of hES cells, somatic stem cells, fully differentiated cells and cancer cells. We also identified 25 CpG sites from 23 genes that clearly distinguish hES cells from other normal cell types; these should be useful biomarkers for monitoring hES cells for undifferentiated self-renewal and during induced differentiation.

Altered expression of trophoblast-specific genes in preeclampsia. *L. Avila[1], M. Pearson[4], P. vonDadelszen[2], S. Langlois[1], W.P. Robinson[1, 3]* 1) Dept. of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Dept. of Obstetrics and Gynecology, UBC, Vancouver, BC, Canada; 3) Reproductive Health Research Program, Child & Family Research Institute, Vancouver, BC, Canada; 4) Dept. of Medical Genetics, Alberta Children's Hospital, Calgary, AB, Canada.

Successful placentation is crucial for optimal fetal growth and development. Disruption of this process could result in pregnancy complication and poor perinatal outcome. Investigation of altered gene expression in the placenta of such pregnancies can provide insight into the relationship between placentation and disease. Because of the inherent cellular heterogeneity of placentae we initially evaluated normal site-to-site variability in gene expression and devised a sampling strategy useful for clinical studies. To do this we evaluated the expression patterns of two genes involved in trophoblast differentiation and invasion control: E-cadherin and Kiss1, both expressed specifically in the cytotrophoblast. Healthy placentae (N=4) were sampled at 3 sites at 4 depths, and after reverse transcribed to cDNA, mRNA levels were quantified by real time PCR on an ABI 7000. Although intra-placental variability was observed, inter-placental differences were significantly greater than intra-placental variation for both E-cad and Kiss1 ($p<0.0001$; $p=0.019$, respectively). The least intra-placental variability was observed at sites located halfway between cord and placental periphery and at an intermediate depth. This sampling location was used in our subsequent studies. Plac1, a gene expressed in the syncitiotrophoblast and involved in trophoblast differentiation, and Kiss1 expression were then assayed in control (N=4), preeclamptic (N=4) and abnormal maternal serum screen (MSS) (N=4) placentae. Expression of both genes was significantly decreased in the preeclamptic placentae (t-test, Kiss1 $p=0.006$; Plac1 $p=0.003$), but no difference was observed between the abnormal MSS group and control. We are currently evaluating E-cad and Cad11, and will extend these studies to additional trophoblast-specific genes and additional samples. Our goal is to identify molecular markers useful in diagnostic and maintenance of complicated pregnancies.

Development and Use of a Genetic Literacy Concept Inventory for Undergraduates. *B.V. Bowling, C.A. Huether, E.E. Acra* University of Cincinnati, Cincinnati, OH.

There is continued emphasis on increasing and improving genetics education at all levels from grades kindergarten-12 to medical professionals to the general public. Perhaps the most accessible audience with the greatest potential for future impact is that of undergraduate students in introductory biology and genetics courses. However, there has been little effort to assess these students understanding of genetics concepts and more specifically the students level of genetic literacy (i.e. genetics knowledge as it relates to their lives) after completing an introductory course. This project consists of the development and use of a new survey instrument to assess the genetic literacy of undergraduate students taking introductory biology or genetics courses. The Genetic Literacy Concept Inventory is a 35-item multiple choice test that addresses 17 concepts identified as important for genetic literacy. The items were selected and modified based upon reviews by over 25 professional geneticists, genetic counselors, and genetics instructors. The inventory is undergoing additional review for validity and reliability, including student focus group interviews and administration of the test to a control group of students. It is currently being employed as a pre-course and post-course inventory in several introductory biology and genetics courses at 4 colleges/universities in the Cincinnati area. The factors of pedagogy and course content are also being considered for their potential effect on inventory scores. Most significantly, this study directly enhances genetics education research by providing a valid and reliable instrument for assessing genetic literacy in undergraduate students.

Identification of candidate genes specific to asthma and atopy using microarray data. *A. Chamberland*[1,2], *J. Chakir*[2,3], *M-C. Bernier*[3], *M. Laviolette*[2,3], *C. Laprise*[1,4] 1) University of Montreal Community Genomic Medicine Centre, Saguenay, Canada; 2) Laval University, Quebec, Canada; 3) Institut universitaire de cardiologie et de pneumologie de l'Université Laval, Quebec, Canada; 4) Université du Québec à Chicoutimi, Saguenay, Canada.

Background: Allergic asthma and rhinitis share a common inflammatory etiology mediated by different molecular and cellular components. Although a genetic predisposition for atopy, an important determinant factor for these two phenotype expressions, is documented we need to identify specific genetic markers for these complex traits. **Aims:** 1) To compare thousands of gene expression patterns of healthy control, allergic rhinitis, allergic asthmatic and nonallergic asthmatic subjects; 2) To target genes that are specific to asthma and atopy. **Methods:** Bronchial biopsies were performed on 4 healthy control (HC), 4 allergic rhinitis (AR), 4 allergic asthmatic (AA) and 4 nonallergic asthmatic (NA) subjects paired for age. RNA was extracted using the Qiagen kit and microarray expression studies used Affymetrix HG-U133A GeneChips. Candidate genes were selected when they were at least differently expressed in two pairwise comparisons of microarray results and on the basis of their biological functions. **Results:** So far, 3 pairwise comparisons have been completed (HC/AR, HC/AA and AR/AA). Respectively, 140, 69 and 241 transcripts were differently expressed. Among those, 6 are immune signalling molecules and 12 are inflammatory molecules. Definitive candidate genes will be selected when all pairwise comparisons will be completed. **Perspectives:** The expression of 5 candidate genes of asthma and 5 of atopy will be validated by real-time RT-PCR and characterize by immunohistochemistry. Association studies between asthma, atopy and variants that are present in candidate genes will be performed too. Thus, this study should allow targeting biological elements that are specific to asthma and atopy.

Genetic Similarity Matching for Genome-wide Association Studies. *W. Guan, L. Liang, M. Boehnke, G.R. Abecasis*
Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Recently, genome-wide association studies have drawn great interest as a promising tool to dissect complex diseases such as hypertension, diabetes, and bipolar disorder. Although case-control association tests are generally more powerful than family-based association tests, population stratification that can lead to spurious disease-marker association or mask a true association remains a major concern. Several methods have been proposed to match cases and controls prior to genotyping or using genotype data for a modest number of genetic markers. Here, we describe a method for efficient matching of cases and controls after genotyping a large number of genetic markers in a genome-wide association study or large-scale candidate gene association study. Our method is comprised of three steps: 1) calculating similarity scores using the genotype data; 2) conducting optimal matching based on the scores so that matched cases and controls have similar genetic background; 3) using conditional logistic regression to perform association tests. Through simulations we show that out strategy can correctly control false positive rates and improve power to detect true disease predisposing variants. For example, in a simulation in which 300 cases and 300 controls are randomly sampled from two equally sized populations (Han Chinese and Japanese) and assuming a single-locus disease model (prevalence K=6.5% and 13%, $_s$=1.03 and 1.03, in the two subpopulations, respectively), the type I error rate using our method drops from .091 to .052, and the power increases from .23 to .98, compared to a standard chi-square test for contingency tables. We also show that the optimal many-to-one matching has substantial advantages over one-to-one matching. We will illustrate our method with data from the Finland-United States Investigation of NIDDM Genetics (FUSION) genome-wide association study.

SURPRISES AT PRENATAL DIAGNOSIS. *D. Burkhardt, A. Hajianpour, F. Rashidian, C. Lee, L. Drugan, L. Dong, R. Habibian* Cytogenetics, Genzyme Genetics, Monrovia, CA.

The detection of monosomy X in a chorionic villi specimen is not always an accurate indicator of the fetal karyotype, especially in the absence of features common to Turner syndrome observed on ultrasound examination. Only when both the direct preparation and long-term tissue cultures show aneuploidy in almost 100% of the cells can the fetal genotype be determined with any degree of certainty. We present a case of mosaic chromosome aneuploidy detected by FISH performed on a direct CVS preparation (of the nuclei examined, 70% showed one signal for the X chromosome and 30% showed two signals for the X chromosome). Cytogenetic analysis of the long-term tissue culture revealed a 45,X chromosome complement in 29 out of 30 cells examined, with only one cell having a 46,XX chromosome complement. An interphase FISH study from a long-term culture showed 65% of the nuclei with a single signal for the X chromosome and 35% of the nuclei with two signals for the X chromosome. In view of the absence of ultrasound findings and mosaic chromosome and FISH results, a follow-up amniocentesis was performed. Interphase FISH studies showed 97% of the cells to have two X chromosome signals (within our reportable range for a normal result). Cytogenetic analysis revealed a 46,XX chromosome complement in the first 15 colonies examined. Only when additional colonies from three independent cultures were examined 5 out of 30 colonies showed a 45,X chromosome complement. At this stage of the pregnancy the fetus had developed a cystic hygroma. This case illustrates that even after half a century of prenatal diagnosis, there are still surprises. Considering that examination of 15 colonies from amniotic fluid in situ cultures is the universal practice, without CVS examination this case would have been reported as normal. In order to ensure accurate diagnoses in cases where mosaicism may be present, i.e., abnormal fetal ultrasound findings, it is suggested to examine additional cells from all available cultures in addition to the standard analysis.

Alternative dosing regimens of agalsidase alfa (Replagal) in Fabry Disease. *J. Clarke[1], M. West[2], R. Schiffmann[3], J. Bultas[4], M. Askari[3], R.O. Brady[3]* 1) Hospital for Sick Children, Toronto, ON, Canada; 2) Queen Elizabeth II Hospital, Halifax, NS, Canada; 3) National Institutes of Health, Bethesda, MD, US; 4) Charles University Hospital, Prague, Czech Republic.

Agalsidase alfa is used for enzyme replacement therapy (ERT) in Fabry disease at a dose of 0.2 mg/kg infused over 40 minutes every other week (EOW). Agalsidase alfa is produced in a human cell line, and using the approved dosing regimen, reduces plasma globotriaosylceramide (Gb_3) levels in patients with Fabry disease. This study was performed to determine the effect of alternative doses and/or dosing frequencies on plasma Gb_3 levels, a marker of a metabolic effect of agalsidase alfa. In this open-label pharmacodynamic study, 18 ERT-naïve adult males with Fabry disease were randomized to 1 of 5 dosing regimens for 10 weeks: 0.1 mg/kg weekly (n=4), 0.2 mg/kg EOW (n=4), 0.2 mg/kg weekly (n=4), 0.4 mg/kg EOW (n=3), and 0.4 mg/kg weekly (n=3). Plasma Gb_3 concentrations were the primary pharmacodynamic endpoint. Pharmacokinetics of each dose were evaluated by measuring enzyme activity in serum at intervals for 24 hours. Following the initial infusion, the area under the enzyme activity-time curves (AUC) was proportional to dose. Plasma half-life of infused agalsidase alfa was approximately 1 hr (range, 56-76 min) and was independent of dose. Baseline plasma Gb_3 levels averaged 9.12 0.62 nmol/mL (mean SEM). After 10 weeks of treatment, mean plasma Gb_3 had declined by about 50% with all 5 dosing regimens (48-51%, *P*=NS between regimens). This magnitude of reduction is comparable to recently published values in patients treated with agalsidase beta infused at a dose of 1 mg/kg EOW (Wilcox WR, et al. Am J Hum Genet. 2004;75:65-74). In conclusion, mean reduction in plasma Gb_3 levels was similar for all of the agalsidase alfa dosing regimens tested. Based on these observations, the currently recommended dose of agalsidase alfa, 0.2 mg/kg infused EOW, is sufficient to produce maximal reduction of plasma Gb_3 in adult male patients with Fabry disease.

Low bone mineral density (BMD) scores are associated with osteoporotic type fractures in adults with Neurofibromatosis type 1 (NF1). *L. Armstrong[1], P. Birch[1], H. Cheng[2], J.M. Friedman[1], D.A. Hanley[2], T.Y. Kydland[1], D.L. Kendler[3]* 1) Dept Medical Genetics, UBC, Vancouver, BC, Canada; 2) Dept of Medicine, University of Calgary, Alb; 3) Dept of Medicine, University of BC, Vancouver, BC.

Purpose-- Low BMD is known to predict increased bone fracture risk in the general population. Recent studies have shown that people with NF1 often have low BMD measurements. The basis of the low BMD scores in NF1 is a topic of ongoing research. It is unclear whether a low BMD measurement in the context of NF1 is a risk factor for fracture. We studied whether there is an association between site specific BMD and fracture in adults with NF1. **Methods**-- Fifteen individuals with NF1, and over 50 years old, were surveyed for history of fracture since their 40th birthday, occult fracture on spine radiograph, and BMD at the spine, hip, and forearm. Also measured were other determinants of bone health including medical history, medication use, and vitamin D status. **Results**-- Based on BMD scores 5/15 individuals were osteoporotic, and a 6/15 were osteopenic. BMD T score was -2.5 (the WHO definition of osteoporosis) in 5/15 at the forearm, in 1/15 at the hip, and in 0/14 at the spine (scoliosis precluded spine BMD measurement in 1). 2/15 had history of 2 forearm fractures each, 1/15 had had a hip fracture, and no spine fractures were reported or found on the films of the 14 who consented to radiographs. All 5 described fractures occurred in individuals where BMD T score was -2.5 at the fracture site. **Conclusions**-- All fractures were seen in the context of BMD T score -2.5. A larger prospective study is required to confirm this correlation. The fractures and low BMD scores were disproportionately seen in the forearm. This is consistent with a previous report which found that BMD is particularly decreased in non-weightbearing regions in NF1.

Mucolipidosis II and III: Clinical and Molecular Characterization. *M. Friez, S. Cathey, K. Draper, J. Leroy*
Greenwood Genetic Center, Greenwood, SC.

Background Mucolipidosis II (I-Cell disease) and mucolipidosis III (pseudo-Hurler polydystrophy) are disorders of lysosomal enzyme targeting. Both are due to deficiency of UDP N-acetylglucosamine-phosphotransferase (GlcNAc-phosphotransferase), the initial enzyme involved in the formation of the mannose 6-phosphate recognition marker which is essential for the uptake of lysosomal enzymes into lysosomes. GlcNAc-phosphotransferase is an $_{222}$ hexamer encoded by two separate genes. The and subunits are encoded by the *GNPTA* gene and the subunit is encoded by the *GNPTG* gene. Prior to molecular testing, ML II was distinguished from ML III by the severity of the clinical course. The goals of this project are to genotype individuals with clinical ML II or ML III and make genotype-phenotype correlations. **Methods** Molecular analyses, which include sequencing the 21 exons of *GNPTA* in ML II and ML III probands and targeted sequencing in parents, have been completed in 29 of 34 participating families. Pathogenic changes have been found in *GNPTA* in every family. The mutations are found in 15 of the 21 exons. No mutations have been found in *GNPTG*. Clinical data on all patients are being obtained from medical records and questionnaire completed by the parents of affected children. When feasible, patients are examined by Greenwood Genetic Center clinicians. **Results** The patients with the most severe phenotype and clinical ML II have homozygous frameshifts, two different frameshifts, or one frameshift and one nonsense mutation. These patients have evidence of growth retardation at birth and dysmorphic features detected at birth or shortly thereafter. Intellectual development and lifespan are compromised. Individuals with clinical ML III have one missense or splice mutation with one frameshift. These individuals may have no abnormalities noted for the first several years of life. Joint manifestations, particularly limited mobility, are often the first problems appreciated. These individuals also have short stature, but not to the extreme seen in children with ML II. Individuals with the clinical diagnosis of ML II/III have one severe mutation and one milder mutation. They have mixed phenotypes.

Evidence for association of the IL-10 receptor 1 gene with childhood-onset mood disorders. *L. Gomez[1], V.L. Misener[1], K.G. Wigg[1], P. Luca[1], N. King[2], A. Vetro[3], E. Kiss[3], Z. Tamas[4], J.L. Kennedy[2], M. Kovacs[5], C.L. Barr[1,6], The International Consortium for Childhood-Onset Mood Disorders* 1) Toronto Western Research Institute, Toronto, ON, Canada; 2) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, ON, Canada; 3) Department for Child and Adolescent Psychiatry, Szeged University, Szeged, Hungary; 4) Vadaskert Hospital, Budapest, Hungary; 5) School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 6) Hospital for Sick Children, Toronto, ON, Canada.

Inflammatory cytokines induce a syndrome of "sickness behaviour", resembling symptoms typically seen in depression. This has led to the hypothesis that cytokine activity contributes to depressive disorders. A logical extension of this hypothesis is that some variations in cytokine system genes confer risk for depression. To test this, we are investigating cytokine network genes in childhood-onset mood disorders (COMD). Childhood-onset depression is highly heritable, making this a useful approach for identifying genes underlying depression. To test for associations with COMD, we have used the transmission/disequilibrium test (TDT), analysing 386 families with children diagnosed with depression before age 14. Twenty-five polymorphisms in 7 genes have been investigated. These include the genes for 4 inflammatory cytokines, IL-1, IL-1, IL-6 and TNF-, and for 3 anti-inflammatory mediators, IL-10, IL-10 receptor 1 (IL-10R1), and IL-1Ra. TDT analyses showed no significant evidence for association with the polymorphisms, individually (*p*-values>0.05). However, TDT analyses of haplotypes showed significant evidence for association with a 2-marker haplotype (rs4252272[A]/rs2229113[A]) of IL-10R1 (^{2}=5.03; *p*=0.02). Each of the variants comprising this haplotype changes the amino acid (aa) sequence of the IL-10R1 protein (aa138:Ser/Gly and aa330:Gly/Arg, respectively). Moreover, functional evidence for a proinflammatory effect of the 330Arg variant, and the possibility of altered ligand binding due to the Ser138Gly change, have been reported. Evidence for association of these IL-10R1 variants with COMD suggests their involvement in risk for depression, and warrants further investigation.

Utilizing array comparative genomic hybridization (aCGH) to characterize chromosomal stability in microsatellite stable (MSS) young onset rectal cancer. *L. Boardman[1,2], R. Johnson[1,3], K. Hafner[1,3], A. Oberg[1,4], B. Morlan[1,4], R. Jenkins[1,3], S. Thibodeau[1,3]* 1) Mayo Clinic College of Medicine, Rochester, MN; 2) Division of Gastroenterology and Hepatology; 3) Division of Laboratory Medicine and Pathology; 4) Cancer Center Statistics.

Approximately 80% of CRC is MSS. MSS CRC has been considered to have chromosomal instability (CIN), as opposed to microsatellite instability (MSI). Tumor phenotyping studies have depicted a portion of MSS CRC as having little or no genetic changes, being chromosomally stable (CIN-), while others exhibited large gains/ losses of genetic material, being CIN+. We selected a group of MSS rectal cancers from people 50 years old with stage II or Stage III disease to assess DNA copy number changes using the Spectral Genomics aCGH which contains nearly 3000 BACs. In all cases, DNA was extracted from chemoradiotherapy naïve rectal cancer. Eight tumors were diploid, 3 were tetraploid and 9 were aneuploid by flow cytometry. Seven tumors (35%) had low levels of chromosomal disruption with < 1% to 17% of the clones having DNA copy number changes and were classified as CIN-. Five tumors (25%) had > 20 % and 30% < of the clones showing DNA alterations, being intermediate CIN. Eight tumors (40%) had a high frequency of alterations in 30-49% of clones and were classified as CIN+. Copy number gains in >40% of tumors were found in chromosome arms 7p/ q, 13q and 20 p/ q and shared smaller consensus regions of gain. 18 p/ q losses were noted in all CIN + tumors but no CIN- tumors, and 17p was lost in all but 1 CIN+ tumor but only 1 CIN-CRC Consensus regions of loss were shared for 17p/ 18 p/q for all CRC showing loss on these arms. Arms more uniformly affected in CIN+ tumors than CIN- CRC included 4p and/or 4q loss in 75%; 7p and/or q gain in 75%; gain of 13q and 20q in 88% of CIN + CRC. Conclusions: These results substantiate that a subset of MSS CRC will have no or little evidence of CIN and represent the molecular subtype of MSS CIN- CRC. Certain chromosomal arms alterations important in CIN+ do not appear to be affected in CIN - CRC, suggesting that the genes involved in CIN- CRC may differ from those in CIN+ CRC.

Analysis of the interactome of RPS19, mutated in Diamond Blackfan Anemia. *I. Dianzani[1], A. Aspesi[1], S. Orrù[2], M. Armiraglio[1], M. Caterino[2], F. Loreni[3], M. Ruoppolo[2], C. Santoro[1]* 1) Dept Medical Sciences, Univ Piemonte Orientale, Novara; 2) CEINGE Advanced Biotechnologies, scarl, Napoli; 3) Dept of Biology,Univ.Tor Vergata, Roma.

RPS19 is a component of the ribosomal 40S subunit. Its mutations are responsible for Diamond Blackfan Anemia (DBA, MIM 205900), a disease characterized by defective erythroid progenitor maturation and malformations. Dysregulation of RPS19 has been implicated in this defective erythropoiesis, though the link is unclear. Two not mutually exclusive hypotheses have been proposed: altered protein synthesis, and loss of unknown functions not directly connected with RPS19s structural role in the ribosome. A role in rRNA processing has been surmised for the yeast ortholog. Four proteins are known to interact with RPS19: FGF2, C5R1, RPS19BP, PIM1. We have used a proteomic strategy to look RPS19 proteins interactors in order to determine its functions. Proteins were isolated by affinity purification with a GST-RPS19 recombinant protein and identified using LCMS/MS analysis coupled to bioinformatics tools. We identified 159 proteins from the following GO categories: NTPases (ATP- and GTPases; 5 proteins), hydrolase/helicases (19 proteins), isomerases (2 proteins), kinases (3 proteins), splicing factors (5 proteins), structural costituents of ribosome (29 proteins), transcription factors (11 proteins), transferases (5 proteins), transporters (9 proteins), DNA/RNA-binding protein species (53 proteins), other (1 dehydrogenase protein, 1 ligase protein, 1 peptidase protein, 1 receptor protein, 1 translation elongation factor) and 13 proteins of unknown function. Results were validated by affinity purification and western blotting. Interactions were further confirmed by co-immunoprecipitation using a monoclonal RPS19 antibody. Many interactors are nucleolar proteins, thus expected to take part in the RPS19 interactome; however, some proteins suggest additional functional roles for RPS19. It is intriguing that among the direct or indirect RPS19 interactors we found proteins involved in pathologies with phenotypes similar to DBA (i.e.DKC1, RPL24, TCOF1, SBDBS). This suggests a common pathogenetic mechanism.

Analysis of ancestral origins of three populations using *structure*. *C.A. Brandon[1], T. Goldstein McHenry[1], M.E. Cooper[1], B.S. Maher[1], K.M. Bardi[1], J.R. Avila[2], J.C. Murray[2], A.R. Vieira[1], M.L. Marazita[1]* 1) Dept Craniofacial & Dental Gen, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Pediatrics, Univ Iowa, IA.

Assessing ancestral origin is important for human genetic studies due to varying phenotypic prevalences and allelic frequencies. Ancestral origins and ethnicity are often elicited from study subject self-reports which can be problematic in cases where individuals identify with their national affiliation rather than ethnicity, for example in Guatemala which is part of our ongoing studies of Oral-Facial Cleft (OFC) families. In such cases, DNA based methods may be more informative. Therefore, we explored a method using the program *structure* to assign origins in unrelated individuals from 3 OFC studies: Pittsburgh, PA (US Caucasian, n=102), Madrid, Spain (European Caucasian, n=78), and Guatemala (Mixed, n=38). We utilized genotypes of 31 SNPs, chosen for OFC candidate gene studies. Founder data for these 31 SNPs was obtained from the International HapMap Project [Chinese (CHB) + Japanese (JHP): n=90; Yoruba (YRI): n=60; CEPH people from Utah (CEU): n=60] as prior information to assist in clustering the OFC populations. Each of the 3 OFC populations were added individually and run at K=3. Pittsburgh and Madrid populations clustered closest to the CEU population as expected (93%). The Guatemala population did not cluster with any of the 3 HapMap groups. This population is of interest due to the mixed ancestry primarily from Spain and indigenous Mayan. Substituting the Madrid population for the CEU population showed a shift of the Guatemala population towards the Madrid cluster (86%). Birth prevalence of OFC in the Guatemalan indigenous population is similar to the increased prevalence seen in East Asian populations, but our results do not support similar ancestral origins between the Guatemalan and the HapMap East Asian populations. East Asian populations that were more migratory (i.e. Mongolians) may be a better reference group. Our results suggest that we can successfully generate individual ancestral information in admixed groups by using relatively small, non-random genotyping data. Supported by NIH Grants P50-DE016215, R01-DE016148, R21-DE016930.

A comparison of robust methods for QTL mapping in nuclear families. *S. Bhattacharjee[1], C. Kuo[2], N. Mukhopadhyay[1], D.E. Weeks[1,2], E. Feingold[1,2]* 1) Dept of Human Genetics, GSPH, Univ of Pittsburgh, Pittsburgh, PA; 2) Dept of Biostatistics, GSPH, Univ of Pittsburgh, Pittsburgh, PA.

Recently, a number of new methods have been developed for quantitative trait locus (QTL) mapping in humans using small pedigrees. Most of the new methods are based on score statistics or linear regression statistics, and thus they are at least potentially robust to non-normality of the trait distribution and also to selected sampling. Whereas the theoretical development of these statistics is more or less complete, some practical issues concerning their implementation still need to be addressed. Here we study some of these issues, such as choice of denominator variance estimates, weighting of pedigrees, parameter misspecification and non-normality of the trait distribution. We consider a number of recently-developed statistics, primarily score statistics, including some variations of our own. We investigate the differences in power and robustness among the statistics analytically, and then verify those properties with extensive simulation studies using nuclear families. We give particular attention to appropriateness of the statistics for highly-selected samples such as sibships containing a discordant or affected pair.

Candidate genes for congenital diaphragmatic hernia from animal models: Mutation screening of FOG2, SIX1 and PDGFRA in 96 patients reveals rare variants. *S.B. Bleyl[1], A. Moshrefi[2], G. Shaw[3], Y. Saijoh[1], G.C. Schoenwolf[1], L. Pennacchio[4], A.M. Slavotinek[2]* 1) Dept Pediatrics, Dept Neurbiol Anat Univ Utah, Salt Lake City, UT; 2) Dept Pediatrics, UCSF, San Francisco, CA; 3) California Birth Defects Monitoring Program, Berkely, CA; 4) Genomics Division, Lawrence Berkley National Laboratory, Berkley, CA.

Congenital diaphragmatic hernia (CDH) is a life threatening birth defect that can be isolated or occur with other anomalies. Although isolated CDH is usually sporadic, recent reports have implicated chromosome deletions at 15q26, 8p23.1, 4p16.3-4pter, and 1q41-1q42.1 in CDH patients, but no causative genes have been identified from these studies. We selected three candidate genes involved in diaphragm formation from animal models - *FOG2, SIX1* and *PDGFRA* - and hypothesized that mutations in these genes could cause CDH in humans. Mice homozygous for a hypomorphic *fog2* allele have diaphragmatic eventration, a defect related to CDH. Homozygous null mice for *Six1* have selective loss of muscles including the diaphragm and limbs. Null and conditionally inactivated alleles of *Pdgfra* in mice result in diaphragmatic defects and other anomalies resembling Fryns syndrome. We therefore sequenced *FOG2*, *SIX1* and *PDGFRA* in 96 patients with CDH of which 53 (55.2%) had isolated CDH, 36 (37.5%) had CDH and additional anomalies and 7 (7.3%) had CDH and known chromosome aberrations. For *FOG2*, we identified novel sequence alterations predicting p.M703L and p.T843A that were absent in more than 100 control chromosomes in two patients with isolated CDH. These altered amino acids are highly conserved, but we were not able to determine if they were de novo. For *PDGFRA*, we found an alteration predicting p.L221F in two patients, one with isolated CDH and the other with CDH and preauricular tags. *SIX1* sequencing did not reveal any novel alterations. In conclusion, our data found no evidence that CDH *commonly* results from mutations in these three candidate genes. We did identify rare variants of unknown significance in both *FOG2* and *PDGFRA* that could play a role in the pathogenesis of isolated CDH and further evaluation of these variants is proceeding.

IL-10 and TNF are associated with airflow obstruction in severe Alpha 1-Antitrypsin Deficiency. *D.L. DeMeo[1], E.J. Campbell[2], A.F. Barker[3], M.L. Brantly[4], E. Eden[5], N.G. McElvaney[6], R.A. Sandhaus[7], J.M. Stocks[8], J.K. Stoller[9], C. Strange[10], G. Turino[5], E.K. Silverman[1]* 1) Channing Laboratory, Brigham & Women's Hosp, Boston, MA; 2) Univeristy of Utah; 3) Oregon Health and Science University; 4) University of Florida; 5) St. Luke's/Roosevelt; 6) Beaumont Hospital, Dublin; 7) National Jewish Medical and Research Center; 8) University of Texas; 9) Cleveland Clinic; 10) Medical University of South Carolina.

Severe alpha 1-antitrypsin (AAT) deficiency is a proven genetic risk factor for chronic obstructive pulmonary disease(COPD). There is marked variability in the development of lung disease in individuals homozygous(PI ZZ) for this recessive Mendelian condition, suggesting that modifier genes are important.We hypothesized that asthma and other COPD genetic determinants may be modifier genes of lung function in individuals with severe AAT deficiency.In 378 PI ZZ individuals in the AAT Genetic Modifier Study,we observed that a clinical history of asthma is an important predictor of the presence and severity of lung disease.To identify modifier genes, we have performed association analyses for 10 asthma and/or COPD candidate genes as follows:IL10, TNF, GSTP1, NOS1, SERPINA3, SERPINE2, SFTPB, TGFB1, XRCC5 and EPHX1.All analyses were performed using the pedigree-based association test (PBAT) with covariates for cigarette smoking. Spirometric phenotypes included pre- and post-bronchodilator forced expiratory volume in one second(FEV1) as a percent of predicted and the ratio of FEV1/Forced vital capacity(FVC), both of which are key intermediate phenotypes of COPD. IL10 and TNF demonstrated the most significant associations among the 10 candidate genes; 5 of 11 SNPs in IL10 were associated with FEV1 and FEV1/FVC phenotypes (p=0.0008-0.03) and 3 of 5 SNPs in TNF were associated (p=0.006-0.05). We conclude that IL10 and TNF, two candidate genes frequently associated with risk for asthma, are important modifier genes for the development of lung disease in subjects with severe AAT deficiency. These genetic association findings provide biological support for the observation that features of asthma are important modifiers of COPD in AAT deficiency. Funding:HL072918,HL68926,ALA.

TRMU related to tRNA modification is a nuclear modifier gene for the phenotypic expression of the deafness-associated mitochondrial 12S rRNA mutation. *M. Guan[1], Q. Yan[1], X. Li[1], Y. Bykhovskaya[2], I. del Castillo[3], P. Hajek[4], T. Suzuki[5], M. Shohat[6], X. Estivill[7], J. Lu[8], N. Fischel-Ghodsian[2]* 1) Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Steven Spielberg Pediatric Research Center, Cedars-Sinai Medical Center, Los Angeles, CA; 3) Unida de Genetica Molecular, Hospital Ramon y Cajal, Madrid, Spain; 4) Division of Biology, California Institute of Technology, Pasadena, CA; 5) Department of Integrated Biosciences, Graduate School of Frontier Sciences, University of Tokyo, Chiba, Japan; 6) Department of Pediatrics and Medical Genetics, Basil and Gerald Felsenstein Medical Research Center, Tel Aviv University Medical School, Petah Tikva, Israel; 7) Genes and Disease Program, Center for Genomics Regulation, Barcelona Biomedical Research Park, Barcelona, Spain; 8) School of Life Sciences, Wenzhou Medical College, Wenzhou, China.

Nuclear modifier genes have been proposed to modulate the phenotypic manifestation of the deafness-associated mitochondrial 12S rRNA mutations. We identified the nuclear modifier gene TRMU encoding a highly conserved mitochondrial protein related to tRNA modification. Genotyping analysis of TRMU in 613 subjects of 242 Arab-Israeli, Spanish, Italian and Chinese pedigrees with nonsyndromic deafness revealed a missense mutation (A10S) in evolutionarily conserved N-terminal region of Trmu protein. All eighteteen Arab-Israeli/Italian/Spanish matrilineal relatives carrying bothTRMU A10S and A1555G mutations exhibited congenital profound deafness. Functional analysis showed that this mutation did not affect importing of Trmu precursors into mitochondria. However, the homozygous A10S mutation cause a failure in mitochondrial tRNA metabolisms, specifically reducing the steady-state levels of mt tRNAs. As a consequence, these defects contribute to the impairment of mitochondrial protein synthesis. Resultant biochemical defects aggravate the mitochondrial dysfunction associated with the A1555G mutation, exceeding the threshold for expressing the deafness phenotype. These indicate that the mutated TRMU modulates the phenotypic manifestation of the deafness-associated mitochondrial 12S rRNA mutations.

An association study of a glutamate receptor gene (GRIN2A) in obsessive-compulsive disorder. *P.D. Arnold[1], T. Sicard[1], E. Burroughs[1], G.L. Hanna[2], M. Pato[3], C. Pato[3], M.A. Richter[1], J.L. Kennedy[1]* 1) Dept Psychiatry, CAMH-Univ Toronto, Toronto, ON, Canada; 2) University of Michigan at Ann Arbor, MI; 3) University of Southern California.

Purpose: Recent investigations suggest a role for glutamate in the pathogenesis of obsessive-compulsive disorder (OCD), and our group has previously reported a preliminary positive association with a glutamatergic N-Methyl-D-Aspartate (NMDA) receptor gene in OCD (GRIN2B). The purpose of the study was to perform candidate gene testing of the glutamate receptor ionotropic NMDA 2A (GRIN2A) subunit gene in OCD. Methods: We genotyped 255 nuclear families of adult (n=191) or child (n=64) probands collected from 3 North American centres. Five GRIN2A variants were genotyped including one GT repeat polymorphism and 4 single nucleotide polymorphisms. The analysis for genetic association was conducted using the Family Based Association Test (FBAT) under the additive model of inheritance. Results: A statistically significant association was identified with the intronic SNP rs4782053, with the more common T allele over-transmitted to OCD-affected individuals (z=2.00, p=0.04). This association was also found in the subset of families ascertained through a proband with an early onset (less than 15 years old) of OCD. These results were not corrected for multiple comparisons. Significantly increased transmission of the minor C allele of rs727605 (z=2.04, p=0.04) was identified in transmissions to males with OCD but not in the total sample or in transmissions to females. Conclusions: Overall, these findings provide preliminary evidence that variation in GRIN2A may be associated with OCD. Further study of additional variants in GRIN2A and other glutamate genes in larger samples is needed.

XIST-dependent silencing following expression of an inducible human XIST transgene in human somatic cells.
C.J. Brown, J.C. Chow, S. Sidhu Dept Medical Genetics, Univ British Columbia, Vancouver, BC, Canada.

XIST is a large alternatively spliced nuclear RNA involved in the initiation of X chromosome inactivation (XCI) in female mammals. Ectopic expression of Xist in mice will induce silencing of flanking genes when expressed during an early developmental window. In order to model the events occurring in human XCI we have generated single copy integrations of an inducible human XIST cDNA construct in male (HT1080) and female (293) transformed human cell lines. Localization of the induced RNA is observed by RNA FISH, and silencing has been demonstrated by three alternative approaches. We first demonstrate global silencing by the loss of CoT1 hybridization to heteronuclear RNA in the region of the XIST RNA. Second, to characterize expression of individual genes we analysed cSNPs in autosomal genes on the same chromosome as the integration sites. Reduction in biallelic expression was observed for a subset of these genes. Third, we have integrated an EGFP reporter gene adjacent to the inducible XIST gene and observed loss of GFP expression upon induction of XIST. This silencing is XIST-dependent as removal of XIST expression results in re-expression of the GFP gene. While GFP is reduced to ~20% within 4 days of XIST expression, ongoing XIST expression continues to reduce the level of fluorescence, suggestive of the gradual acquisition of chromatin marks, an observation supported by chromatin immunoprecipitation at the GFP promoter. We observed rapid loss of histone acetylation, slower acquisition of H4K20m1 and HP-1 and slow loss of H3K4m2. Unlike the Xi, ectopic XIST expression in these cells does not lead to H3K9/27 methylation, and no observable focus of H3K27m3 or macroH2A was detected. In conclusion, this model system allows us to examine the events involved in human XIST-induced silencing. XIST expression in human somatic cells can induce transcriptional inactivation and recruit chromatin modifications, but not factors required for stable maintenance of silencing. By examining different integration sites and genes that escape XIST-induced silencing this system also allows us to examine the role of cis-acting DNA elements in the spread of X inactivation.

BRCA2 mutations in Utah high-risk prostate cancer pedigrees. *K. Allen-Brady[1], J.M. Farnham[1], N.J. Camp[1], E.A. Ostrander[2], L.A. Cannon-Albright[1]* 1) Dept Genetic Epidemiology, Univ of Utah, Salt Lake City, UT; 2) National Human Genome Research Institute, Bethesda, MD.

Germline mutations in the BRCA2 gene have been suggested to account for about 5% of familial prostate cancer; mutations have been reported in 2% of early onset (i.e., 55 years) prostate cancer cases and a founder mutation has been identified in Iceland (999del5). However, the role of BRCA2 in high risk prostate cancer pedigrees remains unclear. We examined the potential involvement of BRCA2 in Utah prostate cancer pedigrees. Using the Utah Population Database, we identified 59 high-risk prostate cancer pedigrees (N = 464 cases and an additional 1,261 unaffected relatives), in which all prostate cases were no more distantly related than two meioses from another case, and the resulting cluster contained at least four prostate cancer cases [see Prostate 2005 65(4):365-74]. We genotyped these pedigrees using a panel of 404 fluorescent microsatellite markers spaced ~10 cM apart across the genome. We performed linkage analyses using MCLINK and the Smith et al prostate cancer inheritance model [Science 1996 274: 1371-1374]. We identified five pedigrees with at least nominally significant linkage evidence (LOD score 0.588, $p < 0.05$) within 10 cM of the BRCA2 gene locus on chromosome 13. The LOD scores ranged between 0.95 ($p=0.018$) and 1.42 ($p=0.005$). The number of prostate cancer cases in each of these pedigrees ranged from 5 to 12 and the earliest age at diagnosis ranged from 52 to 60 years. None of the 5 linked pedigrees had a significant excess of breast cancer cases among the descendants of the founder, nor any known male breast cancer cases. There are no special identifying prostate cancer characteristics evident in these pedigrees. We are performing BRCA2 mutation screening in the youngest prostate cancer cases who carry the segregating chromosome 13 haplotype in each pedigree. If BRCA2 germline mutations are found to explain the linkage evidence in these pedigrees, the BRCA2 gene may account for up to 8% (5/59) of Utah high-risk prostate cancer pedigrees.

Strong selection pressures have acted in the evolution of forkhead gene family members. *C.D. Fetterman, B. Rannala, M. Walter* Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

Members of the forkhead gene family act as transcription factors in biological processes including development and metabolism, and have been associated with a variety of human diseases. Forkhead genes contain a highly conserved DNA binding domain originally termed 'forkhead' due to the physical appearance of *Drosophila fork head* mutants. *In silico* methods were used to examine selection pressures acting on the entire coding sequence of six multi-species FOX protein clusters. Of the six clusters analyzed, only one, FoxC, was found to be under positive selection. A single amino acid site, within the inhibitory domain of FOXC1, was under positive selection in the FoxC cluster. A positively selected site may be key to protein function and/or differentiating among species. The remaining five clusters analyzed, FoxA, FoxD, FoxI, FoxO and FoxP were under neutral and negative selection. Neutral selection of an amino acid site suggests that the composition of amino acids at that site is unimportant for protein function whereas negative selection of a site suggests that the amino acid composition that occurs at that site is highly important for protein function. These results have allowed predictions to be made regarding potential functional and non-functional amino acids in FOX proteins. This analysis has also provided insight into forkhead gene family evolution. Features that differentiate different species lineages have been identified in the FoxA and FoxC clusters while features that differentiate paralogs were identified in the FoxO cluster. Analysis of the FoxD cluster suggested that the FOXD proteins are either not related outside of the forkhead domain or are still diverging from one another.

Investigation of Subjective Social Status in orofacial cleft Case families versus Controls. *K.M. Bardi[1], M.E. Cooper[1], D.E. Polk[2], C.A. Brandon[1], M.L. Marazita[1]* 1) Ctr for Craniofacial & Dental Genetics, Univ of Pittsburgh, Pittsburgh, PA; 2) Dept of Dental Public Health, Univ of Pittsburgh, Pittsburgh, PA.

Cleft lip with or without cleft palate (CL/P) is a physical birth defect that involves many factors influencing physical and psychological health. Strong evidence indicates that subjective social status (SSS) is determined in part by objective criteria including education, income, and occupation; other findings suggest that higher SSS may be associated with better physical and psychological health. We hypothesized that parents of CL/P affected children would have lower SSS than controls due to psychological and emotional stresses associated with having a child with CL/P. We used the MacArthur Scale of SSS to assess participants drawn from the Pittsburgh Oral-Facial Cleft (POFC) study of CL/P. In the MacArthur Scale, subjects are asked to place themselves on one of 10 rungs on a diagram of a ladder. In addition, education and income data was acquired during the POFC demographic interview. A total of 185 families participated in this study. The study subjects for these analyses were drawn from 77 control families and 49 case families; each case family was ascertained because there were two or more individuals with CL/P (i.e. each family was multiplex). From those families, we analyzed data from 82 parents of children with CL/P and 91 proportionately matched controls. We used multilevel regression nesting spouses within families and controlling for age and marital status. We regressed SSS on education, income, gender, and case status simultaneously and including interaction terms. Although of borderline statistical significance (p=0.055), the model that best predicted SSS included case status, gender and the interaction of case and gender, therefore supporting our hypothesis that parents of individuals with CL/P have different SSS than controls. Supported by NIH Grants P50-DE016215 and R01-DE016148.

De novo direct duplication of 9(p12p24): a case presentation, review of literature, and possible mechanisms of duplication. *P.C. Cosper, A.J. Carroll, M. Descartes, L. Messiaen* Genetics, University of Alabama at Birmingham, Birmingham, AL.

Since the first reported case in 1970, duplications of 9p have been described in a number of patients. Most of these patients have had a partial duplication of 9p as a result of adjacent I segregation of a balanced translocation carried by one of the parents. There have been very few patients reported to have de novo direct duplications of all or almost all of the 9p. We report a patient who has a de novo duplication of 9(p12p24) including duplication of the subtelomere region of 9p; 46,XY,dup(9)(p12p24).ish dup(9p)(pter++). Trisomy 9p is associated with developmental delay, mental retardation, short stature, prominent bulbous nose, downward-slanting palpebral fissures, downturned corners of the mouth, micrognathia, short stature, abnormal low set ears, abnormal philtrum, clinodactyly, abnormal fingers and toes with abnormal nails, and syndactyly. Clinical findings in our patient that are associated with trisomy 9p include developmental delay, mental retardation, lowset bulbous nose, epicanthic folds, micrognathia, and cup shaped, prominent ears. His hand abnormalities include clinched position, short fifth finger with clinodactyly and hypoplasia of the middle phalanx; the nails are mildly dysplastic. Previously reported cases report similar findings. Studies to determine the parental origin of the duplication are planned. The most likely mechanism of these duplications is unequal homologous or sister chromatid exchange. This mechanism will be discussed.

CFH and LOC387715 genes and susceptibility to Age-Related Maculopathay: AREDS cohort and a meta-analysis. *Y. Conley[1, 2], J. Jakobsdottir[3], T. Mah[4], D. Weeks[2, 3], R. Ferrell[2], M. Gorin[2, 4]* 1) Department of Health Promotion & Development, Univ Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 4) Department of Ophthalmology, University of Pittsburgh, Pittsburgh, PA.

Age-related maculopathy (ARM) is an important cause of visual impairment in the elderly population. It is of crucial importance to identify genetic factors and their interactions with environmental exposures for this disorder. This study was aimed at investigating the CFH and LOC387715 genes, previously reported in ARM susceptibility, in an independent cohort as well as conducting a meta-analysis. The study used a case-control design with subjects originally recruited through the Age-Related Eye Disease Study (AREDS). The meta-analysis encompassed nine reports for CFH and four reports for LOC387715, both of which included the AREDS population presented. CFH was significantly associated with ARM in the AREDS cohort (P 0.00001). A meta-analysis confirmed that the risk allele in the heterozygous or homozygous state (OR, 2.5 and 6.4; 95% CI, 2.2-2.8 and 5.5-7.4, respectively) confers susceptibility. LOC387715 was also significantly associated with ARM in the AREDS cohort (P 0.00001) and a meta-analysis confirmed that the risk allele in the heterozygous and homozygous state (OR, 2.7 and 8.0; 95% CI, 2.3-3.1 and 6.1-10.5, respectively) confers susceptibility. Both CFH and LOC387715 showed an allele-dose effect on the ARM risk, homozygotes at either locus were at more then twofold risk compared to heterozygotes. Joint action of CFH and LOC387715 was best described by independent multiplicative effect without significant interaction in the AREDS cohort. Interaction of both genes with cigarette smoking was insignificant in the AREDS cohort. This study provides additional support for the CFH and LOC387715 genes in ARM susceptibility via the evaluation of the AREDS cohort and through the meta-analyses.

TCF7L2 polymorphisms are associated with type 2 diabetes(T2DM) and reduced insulin sensitivity in U.S. Caucasians. *S.K. Das[1,2], W.S. Chu[1,2], S.C. Elbein[1,2]* 1) Department of Internal Medicine and Research Service, Central Arkansas Veterans Healthcare System, Little Rock,AR; 2) University of Arkansas for Medical Sciences, Little Rock, AR.

Recent studies demonstrated an association of both single nucleotide polymorphisms (SNPs) and a microsatellite in introns of the TCF7L2 gene on chromosome 10q with T2DM in Caucasian populations from Iceland, Denmark, and the United States. The combined relative risk was 1.56, but the mechanism by which the noncoding variants in TCF7L2 increased T2DM risk were not explored. We sought to confirm the association in a population of 183 controls and 190 cases of Northern European Ancestry and in which most cases were from families with no linkage to chromosome 10. We also examined 126 nondiabetic members of Utah T2DM families linked to chromosome 1q, and 177 unrelated normoglyemic controls from Arkansas who had undergone frequently sampled intravenous glucose tolerance tests with minimal model analysis of insulin sensitivity (SI). Both SNPs rs12255372 and rs7903146 were associated (MAF 0.32 and 0.35 in cases, 0.25 and 0.24 in controls, p=0.023 and 0.001, respectively) with relative risks of 1.46 and 1.72 for the T allele. Association of these SNPs was not replicated in a cohort of 369 African American cases and 185 controls. Among nondiabetic Utah family members, SI tended to be lower among TT homozygotes, but neither SNP reached significance except in interaction with body mass index (BMI; p=0.02). In contrast, both SNPs were strongly associated with a reduction in SI in euglycemic, unrelated Arkansas Caucasians with means that suggested a recessive inheritance (rs12255372 p=0.002; rs7903146 p=0.008; means 3.36 in nonrisk homozygotes, 2.93 heterozygotes, 1.41 in TT homozygotes). Beta cell compensation for insulin resistance (SI * acute insulin response) was also reduced (p=0.025), but measures of insulin secretion (AIRglucose and maximal secretory response, AIRmax) did not differ by genotype. Our results confirm the reports of TCF7L2 association with T2DM with similar relative risk in Caucasians, and demonstrate a strong association with reduced insulin action but less impact on insulin secretion.

PedGenie 2.0: Meta genetic association testing in mixed family and case-control designs. *K. Curtin, J. Wong, K. Allen-Brady, N.J. Camp* Biomedical Informatics, University of Utah Genetic Epidemiology Division, Salt Lake City, UT.

In the study of common diseases and genes with modest effects, large consortium and multi-center efforts hold the promise of increased power to detect associations, but present analysis challenges. Studies differ geographically and ethnically, and considerable differences in case-control ascertainment and pedigree structures between resources are likely. Currently, no software package exists that allows association testing in mixtures of family-based and independent resources, between or within studies. PedGenie 2.0 (beta-version) extends the functionality currently available in PedGenie 1.2 (Allen-Brady et al. 2006) by incorporating meta statistics for combined analysis of multi-study resources, along with Monte Carlo significance testing which allows for a mixture of pedigree members and independent individuals. Briefly, study-specific allele or haplotype frequencies for markers of interest are used within studies. A Mendelian gene-drop simulation is performed independent of trait; each possible null genotype configuration is used to create an empirical null distribution for the significance testing of meta statistics. The currently incorporated meta statistics for genotype, composite genotype or haplotype analysis across studies are based on Cochran-Mantel-Haenszel (CMH) techniques to calculate odds ratios, chi-squared test of independence, and chi-squared test of trend. Future efforts will include meta-extensions for other quantitative and transmission statistics, such as the transmission-disequilibrium test (TDT). PedGenie is a flexible, easily implemented analysis tool that is enhanced significantly in beta version 2.0 by the incorporation of meta-statistics to allow valid combined analysis of multiple studies in the detection of genetic association with common disease. Reference: Allen-Brady K, Wong J, Camp NJ (2006) PedGenie: an analysis approach for genetic association testing in extended pedigrees and genealogies of arbitrary size. BMC Bioinformatics 7:209.

Quantifying the distribution of selective effects among newly arising mutations in the human genome. *C.D. Bustamante[1], A.R. Boyko[1], S. Williamson[1], K. Lohmueller[1], R. Hernandez[1], A. Indap[1], J. Pillardy[1], A. Fledel-Alon[2], R. Nielsen[3], A.G. Clark[1,4]* 1) Dept Biol Stats & Comp Bio, Cornell Univ, Ithaca, NY; 2) Dept Human Genetics, Univ of Chicago, Chicago, IL; 3) Univ of Copenhagen, Copenhagen, Denmark; 4) Dept of Mol Biol & Genetics, Cornell Univ, Ithaca, NY.

Quantifying the amount of human genetic variation that is moderate to slightly deleterious is an important problem in both evolutionary and medical genomics. Here we report a novel statistical approach for addressing this issue and apply the method to a data set of 30,000 coding SNPs identified by direct resequencing of over 11,000 known human genes in 39 individuals (19 African Americans and 20 European Americans). Specifically, we will present a method for modeling SNP frequencies, the number of invariant sites in the sample as well as the number of fixed differences between humans and chimpanzees based on a population genetic model with natural selection that can jointly handle population growth, bottlenecks, and migration. We investigate several models for the distribution of selective effects among newly arising mutations (Normal, Gamma, mixture of Normals, etc.) and investigate the relationship between physicochemical measures of amino acid distance and evolutionary exchangeability. By using the draft build of the Macaque genome we are also able to polarize fixed differences along the human and chimpanzee lineages and assess the selective impact of specific types of changes. For example, we can quantify the average selective effect of substituting a small for a large amino acid and vice versa. We also demonstrate that various structural features such as solvent accessibility, breaking of hydrogen or disulfide bonds, location in secondary structure, and location in a known domain strongly impact the distribution of selective effects. Lastly, we demonstrate that there is significant variation in the distribution of deleterious mutations among different individuals and hypothesize how bottlenecks in the distant past may have contributed to present-day patterns of deleterious variation.

Behavioral phenotype of Cornelia de Lange Syndrome (CdLS). *B.W. Clark[1], C. Landy[2], G. Jabbar[3], A.D. Kline[4], M.A. Grados[5]* 1) Dept. of Behavioral Psychology, Kennedy Krieger Institute, Baltimore, MD; 2) Genetic Counseling, University of Maryland, Baltimore, MD; 3) Dept. of Psychology, Notre Dame University of Maryland, Baltimore, MD; 4) Harvey Institute of Human Genetics, Greater Baltimore Medical Center, Baltimore, MD; 5) Dept. of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD.

Background: The behavioral phenotype of CdLS is poorly defined and variable. Given the discovery of genes for CdLS, a defined behavioral phenotype would be useful for genotype-phenotype correlation studies. **Methods**: 31 children and adolescents with CdLS underwent parental self-report on physical and behavioral measures. The Aberrant Behavior Checklist (ABC) for maladaptive behaviors, the CdLS Diagnostic Checklist (DC) for physical features of CdLS, the Childhood Autism Rating Scale (CARS) for autism, the Childrens Yale-Brown Obsessive-Compulsive Scale for Pervasive Developmental Disorders (CY-BOCS PDD) for compulsive behaviors, and the Dunn Sensory Profile for abnormal sensory patterns were completed. **Results**: The ABC suggests a bimodal distribution of irritability, aggression, self-injury, stereotypies and hyperactivity. 2,3 toe syndactyly is associated with higher irritability-aggression-SIB and hyperactivity ($p < 0.001$), more touch hypersensitivity ($p < 0.01$) (Dunn Profile) and higher CARS autism scores ($p < 0.02$). 2,3 toe syndactyly may correspond to homeobox gene alterations associated with the CdLS NIPB-L gene function. Autism scores are correlated with the CY-BOCS PDD compulsions scores (Pearson correlation = 0.38, $p < 0.05$), suggesting that a subgroup has both autism features and compulsive behaviors. Greater abnormal auditory and touch sensitivity are also present with increasing autism and compulsive scores ($p < 0.001$). Approximately 30% of the sample had high autism, compulsive, touch sensitivity scores and more frequent 2,3 toe syndactyly. **Conclusions**: Behavioral and physical markers identify a subgroup of children with CdLS with 2,3 toe syndactyly, high maladaptive behaviors, autistic features, compulsive behaviors and sensory abnormalities. These measures may be useful in studying genotype-phenotype correlations.

***VLDLR* common genetic variation is associated with very low-density lipoprotein (VLDL), high-density lipoprotein (HDL), and low-density lipoprotein (LDL) particle density.** *D.C. Crawford[1], A.S. Nord[2], M.D. Badzioch[2], J. Ranchalis[2], M. Ahearn[1], C. Bertucci[1], E.M. Wijsman[2], M.J. Rieder[1], D.A. Nickerson[1], G.P. Jarvik[2]* 1) Department of Genome Sciences, Univ Washington, Seattle, WA; 2) Division of Medical Genetics, Univ Washington Medical Center, Seattle, WA.

Carotid artery disease (CAAD) is a major risk factor for stroke. Those with CAAD also suffer from coronary heart disease and hyperlipidemia. A 10-cM genome scan of LDL particle size conducted on a family with familial combined hyperlipidemia yielded evidence for linkage on chromosome 9p24 in the region of very low-density lipoprotein receptor (*VLDLR*). To identify SNPs associated with CAAD and hyperlipidemia, *VLDLR* (37kb) was re-sequenced in 46 U.S. Caucasian male military veterans who had >80% internal bilateral or unilateral carotid artery stenosis or had a carotid endarterectomy. These patients, who are a subset of a larger CAAD study, were selected to represent the extremes of the LDL particle density (Rf) distribution: 23 with low LDL-Rf (cases) and 23 not on lipid lowering medication with high LDL-Rf (controls). 157 SNPs were annotated in *VLDLR*, and 66% were shared between cases and controls. Twenty tagSNPs (r^2>0.64; minor allele frequency >10%) were identified among controls, and univariate analyses were performed to identify tagSNPs associated with case status. Eight tagSNPs were associated with case status at p <0.0025, of which five had a p-value <0.001. To replicate the pilot study findings, we genotyped *VLDLR* tagSNPs in an additional 81 cases (>80% internal bilateral or unilateral carotid artery stenosis or had a carotid endarterectomy) and 320 age-matched controls (<15% internal, bilateral carotid artery stenosis on carotid duplex ultrasound). Nine tagSNPs were evaluated using models adjusting for sex, age, and triglycerides (LDL-Rf model only). Results suggest several *VLDLR* tagSNPs demonstrate strong evidence of association with VLDL (R^2_{adj}=0.04; p=0.001), HDL (R^2_{adj}=0.16; p<0.0001), cholesterol (R^2_{adj}=0.06; p=0.0005), and LDL-Rf (AIC=308.64) among Caucasians not on lipid lowering medication. We are genotyping an additional 11 tagSNPs to better define these associations.

MC1R gene mutations in Jewish malignant melanoma patients. *E. Friedman[1], G. Galore[1], E. Azizi[2], A. Scope[2], F. Pavlotsky[2], E. Yacobson[3]* 1) Oncogenetics Unit, Chaim Sheba Medical Ctr (CSMC), Tel Hashomer, Israel; 2) Department of Dermatology, CSMC, Tel-Hashomer, Israel; 3) Laboratory for Molecular Cell Biology, Sheba Medical center, CSCM, Tel-Hashomer, Israel.

To assess the putative role of Melanocrtin 1 receptor (MC1R) gene sequence variants in conferring malignant melanoma (MM) risk, we genotyped 79 Jewish Israeli MM patients for germline sequence variants by direct sequencing of the gene, and compared the rates of sequence variants with those of other populations. Two MM patients, an Ashkenazi male with two MM and non-Ashkenazi female with familial MM harbored an identical truncating mutation - Y152X. Haplotype analysis showed that both patients shared an identical haplotype using 8 intra and flanking MC1R markers spanning 400 Kb of genomic DNA. A missense mutation (Val60Leu) was detected in 24 of the 79 patients (30.3%), a rate that far exceeds the rate of this mutation in Italian, Dutch and French MM patients - 10-18%. Whether this is sequence variant is more prevalent in MM patients than in the general Jewish population is being tested. We conclude that rare truncating mutations occur in the MC1R gene and confer MM risk and that a single missense mutation is the same gene is more prevalent among Jewish MM patients than among non Jewish MM patients.

VLCFA in patients with different clinical forms of X-linked adrenoleukodystrophy treated wiht Lorenzos oil. *M. Deon[1,3], A.G. Barschak[1,3], A. Sitta[1,3], M.P. Garcia[2], G.O. Schmit[1], T.F. Brizolari[1], M.H. Oliveira[1], D.M. Coelho[1], J. De Mari[1], M. Wajner[1,3], R. Giugliani[1,3], C.R. Vargas[1,2,3]* 1) Medical Genetics Service, HCPA, Porto Alegre, Brazil; 2) Dep. of Clinical Analysis, Pharmacy Faculty, UFRGS, Porto Alegre, Brazil; 3) Dep. of Biochemistry, ICBS, UFRGS, Porto Alegre, Brazil.

The X-linked adrenoleukodystrophy (X-ALD) is an inherited disease biochemically characterized by the accumulation of VLCFA (very long chain fatty acids) in tissues and biological fluids, particularly hexacosanoic (C26:0) and tetracosanoic (C24:0) acids. This disorder present predominantly central and peripheral demyelination in addition to adrenocortical insufficiency and hypogonadism. At least seven phenotypes can be made out in this illness. The most common clinical forms are the childhood cerebral (cALD) and adrenomyeloneuropathy (AMN). The recommended therapy consists of the use of the glyceroltrioleate/glyceroltrierucate (GTO/GTE) mixture known as Lorenzos Oil (LO), combined with a VLCFA-poor diet. In the present work it was studied the biochemical profile of VLCFA in 15 patients with different clinical forms of X-ALD (5 AMN, 5 cALD and 5 asymptomatic) in the diagnosis and during treatment with LO. It was verified that C26:0 plasma levels were statistically different between the three clinical forms studied during the treatment. Asymptomatic patients were the only ones who had normal plasma levels of C26:0, during treatment. Thus, our results confirm the main biochemical effect of LO and reinforce that this therapy is efficacious in asymptomatic patients.

Proteomic Analysis of Retinoic Acid-induced Clubfoot-like Deformity in Rat Fetuses. *W.N. Fu[1], K.L. Sun[1], Z.G. Li[1], H. Ji[1], H.T. Zhou[1], S.J. Ji[2], Y.Y. Zhao[1], C.L. Jin[1]* 1) Department of Medical Genetics, Basic Medical College, China Medical University, Shenyang 110001, P.R. China; 2) Department of Pediatric Surgery, the Second Affiliated Hospital of China Medical University, Shenyang, 110003, P. R. China.

Proteomic Analysis of Retinoic Acid-induced Clubfoot-like Deformity in Rat Fetuses Wei-Neng Fu1, Kai-Lai Sun1, Zeng-Gang Li1, Hong Ji1, Hai-Tao Zhou1, Shi-Jun Ji2, Yan-Yan Zhao1, Chun-Lian Jin1 1. Department of Medical Genetics, Basic Medical College, China Medical University, Shenyang 110001, P.R. China; 2. Department of Pediatric Surgery, the Second Affiliated Hospital of China Medical University, Shenyang, 110003, P. R. China. To explore the expression profiling of clubfoot proteome and the clubfoot-related genes in the development of clubfoot. Clubfoot-like deformity model in rat fetuses were established with ATRA (135mg/kg) in E10 pregnant Wister rats. 2-DE was applied to separate the total proteins of related tissues of the animal models. The peptide mass fingerprints of the interesting protein spots were identified based on MALDI-TOF-MS and database searching. Apoptosis study was performed by terminal deoxynucleotidyl transferase nick end labeling. Some clubfoot-related genes were analyssed by RT-PCR. The expression profiling of clubfoot proteome from spinal cord, tibia-fibulae musculature, ankle joint tissue and ankle joint bone of the animal models were presented, in which the peptide mass fingerprint of 23 protein spots differential expressed in the model fetuses were obtained and analyzed. RT-PCR results showed that XIAP, TNNT1 and Col21 were confirmed to be significantly down-regulated in correspondence to the results of 2-DE.The rates of the apoptosis in the spinal, vertebra and muscle from model fetuses were 5.4, 10 and 3.7 times higher than those from the normal fetuses, respectively. The result implies that apoptosis and certain differentially expressed proteins identified in this study might play a role in the development of Clubfoot.

Efficient Analysis of Associations between Haplotypes and Quantitative Traits in Family Studies. *G. Diao, D.Y. Lin* Dept Biostatistics, Univ North Carolina, Chapel Hill, NC.

The associations between haplotypes and quantitative traits provide valuable information about the genetic basis of complex human diseases. Two major challenges arise in haplotype association analysis in family studies. First, the haplotype phases may not be determined with certainty from the genotype data. Second, the trait values within a family tend to be correlated because of common genetic and environmental factors. We present an efficient likelihood-based approach to investigating the associations between haplotypes and quantitative traits. This approach accounts for within-family trait correlations and can handle arbitrary pedigrees with missing genotypes. We characterize the effects of haplotypes on quantitative traits by regression models with random effects and derive appropriate likelihood functions. We develop efficient numerical algorithms to implement the corresponding likelihood-based methods. Extensive simulation studies showed that the proposed methods perform well in realistic situations. A real example is provided. A computer program is freely available.

FFU complex associated with agenesis of kidney, a case report. *G. Contreras[1], J.C. Prieto[1,2]* 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Cundinamarca, Colombia; 2) Departamento de Genetica, Hospital la Victoria, Bogota, Colombia.

The original description the femur-fibular-ulna complex mentioned the absence of the proximal part of the femur, absence of the fibula and malfomations of the ulnar side on the upper limb. Later, cases of bilateral femur and fibula defects with normal arms were included en the same category. The main reason for summarizing defects of femur, fibula and ulna is their tendency to occur together in the same patient much more frequently than could be expected on the basis of chance combinations of the single defects. This malformation syndrome that usually occurs sporadically. It has been described aplasia of ulna and fibula with renal malformation without femur anomalies. We present a new case of a three day-old boy born in Bogotá (Colombia) of non consanguineous parents product of the mother's first term 37-week pregnancy and cesarean delivery. The birth height: 49 cm., and weight: 2660 gr. Prenatal ultrasonographic study showed amelia of right upper limb right and hemimelia of right lower limb. The positive findings found on the physical examination were: short neck, amelia of right upper limb, the rhizomesomelic shortening of right lower limb, varo feet, hypoplasia of the hallux. X-ray studies report: absence of structures the right upper limb, hypoplasia of femur and absence of fibula right with hypoplasia of tibia. In column we observed sacral left hemivertebral. Postnatal ultrasonographic showed associated agenesis of right kidney. Here we report a case with additional phenotypic manifestations mainly in kidney and limbs.

A strong signature of balancing selection on Succinate Dehydrogenase Subunit A gene (*SDHA*) in the African-American population. *B.E. Baysal[1], E.C. Lawrence[2], R.E. Ferrell[2]* 1) OB/GYN & Reproductive Sci, Magee-Womens Research Inst, Pittsburgh, PA; 2) Dept. Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Mitochondrial complex II (succinate dehydrogenase; SDH) is an essential enzyme complex in the Krebs cycle and in the electron transport chain. Mutations in *SDHB*, *SDHC* and *SDHD* subunit genes cause hereditary paraganglioma (PGL), whereas those in *SDHA* lead to neuronal and muscular pathologies. 3-Nitropropionic acid (3-NP), a widely distributed plant and fungal neurotoxin, inhibits the *SDHA* gene product and can cause severe central nervous system defects and death. To gain further insights into mitochondrial complex II function, we analyzed variation patterns in its subunit genes by sequencing a total of 10.8 kb coding and non-coding DNAs in 24 African-American and 24 European-American samples.

In total, 3,828 coding and 7,013 non-coding nucleotides were sequenced for each sample and a total of 52 polymorphisms were detected. Increased sequence diversity distinguished *SDHA* from the PGL genes and refuted the previous suggestions that *SDHA* missense variants originate from two different genetic loci. The *SDHA* variation pattern showed statistically significant deviations from neutral expectations in both racial groups. The elevated values of the nucleotide diversity (% = 0.231) and the Tajimas statistics (D= 1.954) in the *SDHA* gene were comparable to the most prominent cases for balancing selection in the African-American population. *SDHA* nucleotide diversity was higher than 274 ($p<0.011$) and Tajimas D statistics was higher than 276 ($p<0.0036$) of the 277 fully-sequenced genes in the African-American ppopulation in the Seattle SNP database. Two distinct *SDHA* haplotype clusters were present in intermediate frequencies in both racial groups. The unexpectedly high sequence diversity in *SDHA* has revealed one of the most outstanding cases for balancing selection in the African-American population. These findings suggest that a balancing selection mechanism, such as 3-NP toxicity or an infectious agent, has shaped the *SDHA* variation pattern in Africa and that PGL and *SDHA* gene products are under distinct functional constraints.

Gene-Gene Interaction Analysis with Models Based on Entropy Method. *C. Dong[1, 2, 4], Y. Li[1, 4], X. Chu[2], Y. Wang[2], T. Shi[1, 4], Y. Wang[3], L. Jin[3], W. Huang[2]* 1) Bioinformatics Center, SIBS, CAS, Shanghai, China; 2) Chinese National Human Genome Center at Shanghai, Shanghai, China; 3) Fudan University, Shanghai, China; 4) Shanghai Center for Bioinformation Technology, Shanghai, China.

Gene-gene interaction may play important roles in complex disease studies, in which, however, individual genes cant be detected through association analysis. The current approaches including statistical or epidemiological methods and data mining rarely consider the effect of genetic interaction. In this study, we develop an entropy-based method to explore such interaction. This method includes a model-free option and a model-based one. The former aims to explore the joint effect of two SNPs and the latter fits the data to a potential interaction model. Simulation results show that this method is effective to detect gene-gene interaction and furthermore, fit the interaction to various models. Furthermore, the application of the method to malaria data revealed negative epistatic effect between HbAA and $^{+}$-thalassemia against malaria.

Neonatal Asymmetric Crying Facies: phenotype in monozygotic twins associated with preaxial polydactyly, a case report. *C. Duran[1], G. Contreras[1], J.C. Prieto[1,2]* 1) Inst de Genetica Humana, Univ Javeriana, Bogota Cundinamar, Colombia; 2) Departamento de Genetica, Hospital la Victoria, Bogota, Colombia.

Unilateral neonatal facial asymmetry, an age-old problem, is a generic heading for several clinical phenotypes. The neonatal asymmetric crying facies (NACF) indicates that the condition is present at birth, and it allows for multiple etiologies. The clinical hallmark of NACF is a symmetric appearance of the oral aperture and lips at rest, but significant depression of one side of the lower lip with crying. One etiology is due to congenital hypoplasia of the depressor anguli oris muscle and reported other associated anomalies, it has an autosomal dominant pattern of inheritance. The effect is asymmetry of the lower lip, especially evident in smiling or crying. In 70%, children with hypoplasia of the depressor anguli oris muscle found accompanying anomalies. These included anomalies of the head and neck (48%), heart (44%), skeleton (22%), genitourinary tract (24%), central nervous system (10%), gastrointestinal tract (6%), and miscellaneous minor anomalies (8%). Deletion of 22q11.2 was observed in cases fitting into the spectrum of Cayler syndrome and has considered to be part of the CATCH22 phenotype. Monozygotic twins who were concordant for 22q11.2 deletion and Cayler syndrome described. Both had tetralogy of Fallot, as well as hypoplasia of the depressor anguli oris muscle, bifid uvula, and T-cell anomalies. These twins were diamniotic and dichorionic. In monochorionic twins, discordant malformation may be related to the twinning process itself. We report monozygotic twins 14 months old girls born in Bogotá (Colombia) of nonconsanguineos parents, the patients were the product of the mother's first unterm 34-week pregnancy and cesarean delivery. No teratogenic exposure. The birth height: 43 cm., and weight: 1600 gr., with asymmetric crying facies. Face was symmetrical except for marked depression of left lower lip with crying, associated in one the twins preaxial polydactyly of the right hand. To the best of our knowledge, this association has not been previously published.

A novel chimeric gene formed by exon-shuffling and retrotransposition in the hominoid lineage. *D.V. Babushok[1], K. Ohshima[2], X. Chen[3], Y. Wang[3], E.M. Ostertag[1,4], N. Okada[5], C.S. Abrams[3], H.H. Kazazian[1]* 1) Dept Genet, Univ PA, Philadelphia, PA; 2) Nagahama Inst Bio-Sci Tech, Nagahama, Japan; 3) Dept Medicine, Univ PA, Philadelphia, PA; 4) Dept Path Lab Medicine, Univ PA, Philadelphia, PA; 5) Tokyo Inst Tech, Yokohama, Japan.

The structure of most cellular genes, with exons often containing separate domains, has long led to speculation on the role of exon (and domain) shuffling in new gene formation. Such exon shuffling was observed in cases of illegitimate recombination, and can also occur by retrotransposon-mediated transductions of host sequences. Recent studies of intergenic RNA splicing have suggested another important way to form new genes, whereby genes can undergo exon-shuffling at the RNA level by splicing from one gene to another, followed by reverse-transcription and insertion into a new location by the LINE-1 (L1) retrotransposon. To further study this novel mechanism of gene formation, we analyzed the structural features and evolutionary history of the PIP5K1A-PSMD4 chimeric gene. We found that PIP5K1A-PSMD4 chimera was formed roughly 17 MYA in the hominoid lineage by L1-mediated retrotransposition of a rare intergenically-spliced transcript between the phosphatidylinositol-4-phosphate 5-kinase (PIP5K1A) gene and its neighbor, the 26S proteasome subunit 4 (PSMD4) gene. This retrogene has testes-specific transcription starting within the 5UTR of PIP5K1A, contains a moderate Kozak consensus, and is likely translated to make an 862 aa protein. The novel protein is localized predominantly in the cytoplasm, with an apparent loss of membrane localization of PIP5K1A protein and proteasome interaction of PSMD4 protein. The chimera is undergoing rapid evolution in its PSMD4 region, and has functionally diverged from parental proteins. It lacks significant PIP5 kinase activity, but is able bind to endogenous ubiquitinated proteins through its PSMD4 region. Future studies will determine if this evolutionarily young gene is important in ubiquitin signaling in the testis. Novel gene formation by retrotransposition of unusually spiced transcripts likely represents a significant mechanism for exon shuffling.

Partial tandem duplication of *GRIA3* in a male with mental retardation. *T. Chiyonobu[1,2], S. Hayashi[3], M. Morimoto[2], Y. Miyanomae[4], A. Nishimura[2], A. Nishimoto[1], C. Ito[1], I. Imoto[3], T. Sugimoto[2], Z. Jia[5], J. Inazawa[3], T. Toda[1]* 1) Division of Clinical Genetics, Osaka University Graduate School of Medicine, Suita, Osaka, Japan; 2) Department of Pediatrics, Kyoto Prefectural University of Medicine, Kyoto, Japan; 3) Department of Molecular Cyotogenetics, Tokyo Medical and Dental University, Tokyo, Japan; 4) Department of Pediatrics, Kyoto City Child Wellbeing Center, Kyoto, Japan; 5) Program in Brain and Behavior, the Hospital for Sick Children, Toronto, Canada.

The genetic factors underlying mental retardation (MR) are very heterogeneous. Recent studies have identified a number of genes involved in MR, several of which lie on the X chromosome, but the current understanding of the monogenic causes of MR is far from complete. Investigation of chromosomal rearrangements in patients with MR has proven particularly informative in the search for novel genes. Using array-based comparative genomic hybridization analysis, we identified a small copy number gain at Xq25, which was undetectable by conventional G-band analysis, in a boy with unexplained MR. Further characterization revealed a partial tandem duplication of *GRIA3*, an alteration also present on one allele in his mother. RT-PCR analysis of lymphoblastoid cell RNA revealed remarkably reduced *GRIA3* transcript levels in the patient. The mother, whose cognitive level is normal, also demonstrated remarkably reduced *GRIA3* transcript levels in lymphoblastoid cells, and X-chromosome inactivation (XCI) was completely skewed in her peripheral lymphocytes. It is possible that XCI in the brain is not completely skewed and that *GRIA3* expression from the normal allele may account for the mothers normal cognitive function. Taken together with previous findings of *GRIA3* disruption by a balanced translocation and severely reduced *GRIA3* transcript levels in a female with MR, our study strengthens the idea that *GRIA3* is a candidate gene for X-linked MR and that severely reduced *GRIA3* expression results in MR.

A hybrid approach to genetic studies - Genome wide association study and comprehensive candidate gene analysis of nicotine dependence. *L. Bierut[1], P. Madden[1], N. Breslau[2], E. Johnson[3], D. Hatsukami[4], O. Pomerleau[5], G. Swan[6], J. Rutter[7], A. Goate[1], A. Hinrichs[1], K. Konvicka[8], N. Martin[9], G. Montgomery[9], N. Saccone[1], S. Saccone[1], J. Wang[1], G. Chase[10], J. Rice[1], D. Ballinger[8], NICSNP Consortium* 1) Washington University School of Medicine, St Louis, MO; 2) Michigan State University, East Lansing, MI; 3) Research Triangle Institute International, Research Triangle Park, NC; 4) University of Minnesota, Minneapolis, MN; 5) University of Michigan, Ann Arbor, MI; 6) SRI International, Menlo Park, CA; 7) National Institute on Drug Abuse, Rockville, MD; 8) Queensland Institute of Medical Research, Herston QLD Australia; 9) Perlegen Sciences, Mountain View, CA; 10) Penn State College of Medicine, Hershey, PA.

Smoking is the leading source of preventable death in the U. S., and twin studies consistently demonstrate strong genetic contributions to smoking. The NICSNP Project is a hybrid study of a genome wide association (GWA) study in tandem with the systematic coverage of biologically relevant candidate genes. The sample consisted of 1050 nicotine dependent cases and 879 non-dependent smokers as controls. All participants were selected from two community-based studies, the Collaborative Genetics Study of Nicotine Dependence (U.S.) and the Nicotine Addiction Genetics Project (Australia). The GWA study performed pooled genotyping of 2.4 million single nucleotide polymorphism (SNPs) followed by individual genotyping of the top 40,000 signals. The second arm of the study was a comprehensive candidate gene study, where individual genotyping was conducted in over 300 genes chosen for their biological significance by experts in the field of addiction. There were convergent findings in these complementary approaches. Common variants in candidate genes exhibited the highest level of statistical significance and are among the top 25 signals from the GWA study. In addition, the GWA study results identified novel loci not previously associated with the risk for nicotine dependence. These findings are a major advance in the genetics of complex human disease, and data will be available upon publication for further analyses by the scientific community.

Deficiency of ^{1}-pyrroline-5-carboxylate synthase (P5CS) in a consanguineous New Zealand family. *L.S. Bicknell[1], J. Pitt[2], M. Maw[3], R. Ramadas[4], C. Wilson[5], S. Aftimos[5], S.P. Robertson[1]* 1) Dept of Paediatrics & Child Health, University of Otago, Dunedin, New Zealand; 2) Genetic Health Services Victoria, Melbourne, Australia; 3) Dept of Biochemistry, University of Otago, Dunedin, New Zealand; 4) Whakatane Hospital, New Zealand; 5) Northern Regional Genetics Service, Auckland, New Zealand.

We have characterised a consanguineous family segregating a connective tissue disorder (joint dislocations, lax skin) associated with severe global developmental delay, and choreoathetosis. An MRI scan showed underdevelopment of the white matter. Metabolic testing demonstrated no abnormalites of urea cycle intermediates, amino acids or organic acids. We performed a 400 microsatellite genome screen under an assumption of homozygosity for a common ancestral disease allele. Multipoint analysis identified a 50 cM region (~47 Mb) at 10q23.1-23.4 with a peak LOD of 2.99. Fine mapping further refined this interval to a 12 Mb critical region which demonstrated homozygosity by descent with a maximal LOD of 3.25. Of the 85 genes located within this interval, one gene *ALDH18A1,* encoding ^{1}-pyyroline-5-carboxylate synthase (P5CS), was identified as a candidate since a missense mutation had previously been shown to cause progressive neurodegeneration, cataracts, skin laxity, joint dislocations and metabolic derangement in a consanguineous Algerian family. A mutation in *ALDH18A1*, 2350C>T, predicting the substitution H784Y was identified at a residue conserved across all phyla. P5CS is a catalytic bifunctional enzyme that converts glutamate to proline and ornithine prior to ornithine incorporation in the urea cycle. Proline, a major constituent of connective tissue, has also been implicated in neurotransmission. Impaired synthesis could therefore account for many features of this phenotype, however, *in vivo* enzymatic assays suggest proline biosynthesis is not perturbed in this family, consistent with normal results from clinical metabolic testing. Moonlighting roles, the evolutionary adoption by an enzyme of an unrelated function, have been found for other metabolic enzymes, and thus P5CS may possess additional uncharacterised functions within the cell.

Polymorphisms in the Activating Transcription factor 6 (ATF6) a candidate gene are associated with Type 2 Diabetes(T2DM) in Utah Caucasians. *W.S. Chu[1,2], S.K. Das[1,2], S.C. Elbein[1,2], International Type 2 Diabetes Chromosome 1q Consortium* 1) Dept Medicine, Univ Arkansas Medical Sci, Little Rock, AR; 2) Research Service, Central Arkansas Veterans Healthcare System, Little Rock, AR.

ATF6 is located under the well replicated linkage peak for T2DM on chromosome1q21-q23, and is a key activator of the endoplasmic reticulum (ER) stress response. ER stress in turn has been implicated in hepatic and peripheral insulin resistance and in impaired insulin secretion in animal models. We evaluated 78 SNPs over 213 kb, from 8 kb upstream through the 3 flanking region. We used linkage disequilibrium (LD) in our population to select 39 SNPs for r2>0.9 to type in 189 unrelated, euglycemic Caucasian controls and 191 Caucasians with T2DM and a T2DM family history. Additionally, 44SNPs were typed by the Chromosome 1q Consortium in a subset of 191 cases and 165 controls. A nonsynonymous coding SNP rs1058405 (M67V) in exon 3 (MAF 0.316 in case, 0.228 in control) and SNP rs1027700 in intron 4 (MAF 0.321 in case, 0.241 in control) were significantly associated with T2DM (p=0.007 and 0.016 respectively). A second nonsynonymous SNP (S157P, exon 5) in the same LD block also showed a trend to association, and 3 other SNPs in the 3 flanking region of ATF6 gene showed a significant association (p<0.05), but no other SNPs were associated. The significantly associated SNPs were not in Hardy Weinberg equilibrium despite assay redesign. Association of the coding or intronic SNPs was not replicated in a cohort of 370 African American cases and 185 controls, nor did any coding SNP significantly effect insulin sensitivity (SI), secretion (AIRg), or disposition index (DI) among two Caucasian populations (n=125 and n=199) that underwent intravenous glucose tolerance tests. Consortium typing of 44 SNPs in Amish, French and UK Caucasian populations, as well as in Pima and Chinese populations failed to find any significant association of ATF6 variants with T2DM, but did not test SNP M67V. Our association data and deviation from HWE suggest a role of for M67V as a causative variant in one population, but the lack of confirmation suggests that additional studies are needed to assess the significance of ATF6 in T2DM.

Genome-wide linkage analysis of components of the metabolic syndrome in the Beaver Dam Eye Study. *C.Y. Cheng[1,2], K.E. Lee[3], P. Duggal[1], R. Klein[3], E.L. Moore[3], J.E. Bailey-Wilson[1], B.E. Klein[3]* 1) Inherited Disease Research Branch, NHGRI/NIH, Baltimore, MD; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Department of Ophthalmology and Visual Sciences, University of Wisconsin Medical School, Madison, WI.

The metabolic syndrome (MS), characterized by obesity, dyslipidemia, hyperglycemia, and hypertension, has become one of the major public-health challenges worldwide. We sought to identify genetic loci with potential influence on components of the MS in the Beaver Dam Eye Study (BDES), a large cohort study of adults in Beaver Dam, Wisconsin. Components of the MS were derived using principal component analysis on 7 MS-related traits, including body mass index (BMI), systolic and diastolic blood pressure, blood glucose, glycosylated hemoglobin, high-density lipoprotein (HDL) cholesterol, and uric acid level. Three component factors were identified and represented glycemia, blood pressure and combined (BMI, HDL and uric acid) factors, respectively. A genome-wide scan with 385 microsatellite marker was conducted on 1,524 sipships from 486 families. Model-free single- and multipoint linkage analyses of the factor scores were performed using Haseman-Elston regression. Estimates of heritability of the MS factors ranged from 40% for the combined factor to 17% for the blood pressure factor. Genome-wide suggestive evidence for linkage of the glycemia factor was found on chromosome 22 at 32cM (LOD = 2.99, P = 0.0001, near marker D22S658). Regions linked to the combined factors were on chromosome 1 at 102cM (LOD = 2.26, P = 0.00063, near marker D1S1665) and chromosome 17 at 82cM (LOD = 2.52, P = 0.00033, near marker D17S1290). Several regions showed suggestive linkage to the blood pressure factors: chromosome 1 at 188cM (LOD = 2.74, P = 0.00019, marker D1S1619), chromosome 10 at 149 cM (LOD = 2.77, P = 0.00018, marker D10S1656), and chromosome 16 at 54cM (LOD = 2.74, P = 0.00019, between marker D16S769 and D16S540). The linkage signals on the three factors did not overlap with each other. Our findings suggest that the MS factors are influenced by multiple distinct loci across the genome, suggesting its complex pathogenesis.

Familial Thoracic Aortic Aneurysms and Dissection: Rapid Identification of Causative Variants in TGFBR3 through Direct Sequencing of Genes in the TGF- Pathway. *N. Avidan[1], J. Kao[1], D. Divecha[1], H. Pannu[1], D.C. Guo[1], V.T. Tran-Fadulu[1], D.H. Kim[3], S.E. Scherer[2], R. Gibbs[2], D.M. Milewicz[1]* 1) Dept Medical Genetics, Univ Texas Medical Sch, Houston, TX; 2) Human Genome Center, BCM, Houston, TX; 3) Department of Neurosurgery, Brigham and Women's Hospital, Boston, MA.

Familial thoracic aortic aneurysms and dissections (FTAAD) is inherited in an autosomal dominant manner. Mapping studies indicate significant genetic heterogeneity for FTAAD, with 5 loci mapped to date. Mutations in type II transforming growth factor receptor (*TGFBR2*) have been identified as causing disease at the TAAD2 locus. Moreover, the TGF- signaling pathway was activated in smooth muscle cells explanted from TGFBR2 mutation negative FTAAD patients. To test the hypothesis that we could identify defective genes causing familial TAAD more rapidly through direct sequencing of genes in the TGF- pathway, 12 genes encoding proteins in the pathway were sequenced from 200 unrelated FTAAD families. Four novel non-synonymous mutations that segregated with disease in 6 unrelated families and were not present in 384 control chromosomes were identified in type III TGF- receptor (*TGFBR3*). TGFBR3 presents the TGF-2 ligand to TGFBR2 on the cell surface, and enhances TGF- signaling. One of the alterations, Ile790Pro, found in three unrelated families, was predicted to disrupt a cleavage site responsible for shedding the receptor from the cell surface and to increase TGF- signaling. Immunoblot analysis of TGFBR3 using mutant fibroblasts from 2 patients revealed increased receptor in the cell membrane and decreased receptor in the media when compared to control fibroblasts, suggesting the mutation prevented proteolytic shedding of the receptor. Furthermore, when stimulated with TGF-2, the patients fibroblasts had enhanced phosphorylation of Smad2 when compared with controls. The results indicate that the Ile790Phe substitution has functional consequences, including increased TGFBR3 on the cell surface and enhanced TGF-2 signaling. FTAAD is the first phenotype genetically and functionally linked to mutations in TGFBR3 and may account for 3% of affected familial cases.

Replication of candidate regions for familial idiopathic scoliosis with model-independent linkage analysis. *D. Behneman[1], C. Justice[1], D. Fallin[2], T. Beaty[2], B. Marosy[3], N.H. Miller[3], A.F. Wilson[1]* 1) Genometrics Section, Inherited Disease Research Branch, NHGRI/NIH, Baltimore, MD; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Department of Orthopaedic Surgery, Johns Hopkins University, Baltimore, MD.

Idiopathic scoliosis (IS) is a structural lateral curvature of the spine that develops in late juvenile or adolescent period in otherwise normal individuals. Linkage analysis has been used to identify candidate regions on chromosomes: 6, 9, 10, 16, 17, 18, 19, and X [Wise et al. 2000; Chan et al. 2002; Salehi et al. 2002; Justice et al. 2003; Miller et al. 2005]. In this study, an independent sample of families was used in an attempt to replicate these regions. Seventy-one families with at least 2 affected (lateral curvature 10º) individuals, were ascertained and clinically characterized. A genomic screen with 385 STRPs was performed on 306 individuals. Scoliosis was analyzed as a qualitative trait, with varying thresholds of curvature for affectation status (10, 21, 30 and 40) and as a quantitative trait (the observed degree of lateral curvature). Single-point model-independent sib-pair linkage analysis was carried out with SIBPAL [S.A.G.E. v4.5, 2001]. Regions with 2 or more markers significant at the 0.1 level in the Miller et al. [2005] study were combined with the p-value at the corresponding marker in this replication sample using Fishers combined probability test [Whitlock, 2005]. Replicated regions were defined as markers for which the Fishers combined p-value < 0.01. Five regions corresponded to those reported by Miller et al. [2005] and can be considered true replications: D1S2845 to D1S2660, D1S1660, F13A1 to D6S2434, D8S262 to D8S1130, and D9S938 to D9S1826.

Migraine Linkage Mapping using the Norfolk Island Genetic Isolate. *L.R. Griffiths[1], C. Bellis[1], R.M. Hughes[1], K.N. Begley[1], S. Quinlan[1], R.A. Lea[1], S.C. Heath[2], J. Blangero[3]* 1) Genomics Res Ctr, Sch Med Sci, Griffith Univ Gold Coast, Southport, Australia; 2) Centre National de Génotypage, 2 Rue Gaston Cremieux, Evry, France; 3) Southwest Foundation for Biomedical Research, San Antonio, Texas, USA.

Migraine is a common and debilitating neurological disorder with a significant genetic component. Genetic linkage studies in our laboratory have so far revealed migraine susceptibility regions on chromosome 19p13, Xq28, 1q31 and 18p. To aid in migraine gene mapping and identification, we are currently undertaking linkage studies using a unique genetic isolate. The Norfolk Island community is a population of ~1200 permanent residents, the majority of whom are direct descendents of 18th century English Bounty mutineers and Polynesian women who relocated to Norfolk Island from Pitcairn Island in the 1850s. As a genomic study population, Norfolk is of interest because there are strong family groupings and well-documented family histories and the population initially grew in isolation from other communities. We have recruited individuals from this isolate to investigate the genes involved in migraine. DNA samples from two-thirds of the Islands adult permanent population have been prepared for these studies and individuals phenotyped for the disorder. 602 individuals have been collected with information relating to migraine, eg age of onset, severity, triggers and medication response obtained, and affected individuals diagnosed as MA or MO using IHS guidelines. The population has a high prevalence of migraine with 26% affected by the disorder. Most of these individuals fit within a single large, 12-generation (~6500) pedigree extending back to the original founders. Heritability and power estimates have been determined with these studies indicating that the pedigree should provide a unique and powerful resource for disease gene mapping. We are currently investigating migraine implicated loci and a full genome scan is being undertaken. Results implicating vascular related migraine susceptibility variants in the MTHFR gene and investigating the Xq24-28 genomic region in this genetic isolate will be presented.

Strong evidence for gene-gene interactions in rheumatoid arthritis (RA). *L.F. Barcellos[1], P.P. Ramsay[1], E. Madden[1], P.K. Gregersen[2], L.A. Criswell[3]* 1) University of California, Berkeley, CA; 2) North Shore LIJ Institute for Medical Research, Manhasset, NY; 3) University of CA, San Francisco, CA.

Association between MHC genes and RA is well established, and accounts for ~30% of the genetic component in RA. Multiple HLA-DRB1 (shared epitope, SE) alleles largely explain this association; however, exact mechanism(s) by which MHC genes operate in RA are not known. Genome screens have been performed to identify non-MHC loci, but little overlap has been observed between studies, suggesting that the existence of genes with strong individual effects is not likely. Non-parametric tree-based classification methods that accommodate large marker datasets and allow for genetic heterogeneity and interactions among variables are useful for RA studies. Theoretical work has shown that prediction accuracy of classification trees is significantly improved by building a collection of trees, or Random Forests. We analyzed whole-genome screen data (381 markers) for 583 Caucasian RA affected sib pairs from the North American Rheumatoid Arthritis Consortium using a Random Forest approach, to identify evidence for non-MHC loci associated with important RA outcome variables. Genetic sharing (mean IBD) at non-MHC genomic regions, gender distribution, and exposure to smoking within each sib pair (total=383 predictors) were used to predict concordance (both sibs either positive or negative) for the following outcomes: (1) SE status, (2) DRB1*0401 status, (3) carrier status for the PTPN22 R620W variant, (4) RF status, (5) CCP status, (6) age of onset, and (7) exposure to tobacco smoke. In addition, sharing of SE was included as a predictor for CCP status. Several non-MHC regions were identified by Random Forest as predictive of age of onset (chr. 1, 7, 12, 14), CCP status (chr. 1, 4, 10), and RF status (chr. 7 and 9). Evidence for gene-gene interactions was also observed; chr. 3, 4, 10, 14 were predictive of PTPN22 status, chr. 7 was predictive of DRB1*0401 status, and chr. 4, 11 were predictive of SE status. Gender and SE status were predictive of CCP status, but were not important for other outcomes. Results suggest that multiple non-MHC loci influence clinical and HLA-associated risk for RA.

Common deletions in Iranian patients with -thalassemia. *F. Esteghamat[1, 2], H. Imanian[1], A. Azarkeivan[1], N. Almadani[1], H. Najmabadi[1, 2]* 1) Kariminejad-Najmabadi Pathology and Genetics Center, Tehran, Iran; 2) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences,Tehran, Iran.

Backgrounds: Hereditary Persistence of Fetal Hemoglobin (HPFH) and -thalassemia are heterogeneous disorders, characterized by increased level of fetal hemoglobin (HbF) in adult life. A considerable number of deletions of variable size and position that involve the -globin gene cluster on chromosome 11 are associated with the clinical entities of HPFH and -thalassemia. Here, we studied the most eight common deletions involved in HPFH and -thalassemia in Iranian patients. Materials and Methods: We included 32 patients from 19 families who have referred to our private genetic center since last 3 years with elevated levels of HbF, and low MCV. After obtaining the informed consent, DNA was extracted from whole blood by salting-out method. Detection of 8 deletions including HPFH-1, HPFH-3, Spanish, Sicilian, Chinese, Asian-Indian inversion-deletion G(A)0, and the Turkish form of inversion-deletion ()0 thalassemia, Hb-Lepore was based on PCR method described previously by Craig et al. Results: We found Sicillian, Hb lepore and Asian-Indian inversion-deletion G(A)0 deletions causing -thalassemia in 10(52.62%), 3(15.78%) and 5(26.31%) of patients, respectively. We could not find any of eight deletions in one of the patients. Conclusion: Taken together, this is the first study of deletions involved in HPFH and -thalassemia in Iranian patients with -thalassemia that highlight the heterogeneity of the genetic background of Iranian population and importance of screening this deletions in prenatal diagnosis.

TMEM16A is amplified and overexpressed in head and neck cancer. *U. Duvvuri[1, 2], B.J. Henson[2], X. Huang[2], J.S. White[2], R.A. Parikh[2], R. Seethala[3], A. El-Naggar[5], J.R. Grandis[1, 4], S.M. Gollin[1,2,3,4]* 1) Otolaryngology, University of Pittsburgh, Pittsburgh, PA.,; 2) Department of Human Genetics Graduate School of Public Health; 3) Pathology; 4) University of Pittsburgh Cancer Institute; 5) Pathology, MD Anderson Cancer Center.

TMEM16a is a novel gene that we recently identified by high-resolution physical mapping of chromosomal band 11q13 in squamous cell carcinoma of the head and neck (SCCHN). We prepared and validated a polyclonal antibody against TMEM16A. Immunoflourescence demonstrated the presence of TMEM16a in the cytoplasm, plasma membrane, nuclear membrane and nucleoplasm of SCCHN cell lines. The expression of TMEM16A was evaluated in paired samples of SCCHN and normal adjacent mucosa by immunoblotting. TMEM16A was overexpressed by 500% in 80% of tumors, but not in normal mucosa ($p<0.001$). QuMA was used to determine the gene copy number in SCCHN cell lines. qRT-PCR was used to determine transcript levels. Gene copy number, transcript and protein levels were not directly correlated in cell lines that do/ do not overexpress the 11q13 amplicon. PCR was used to map the genomic sequence of *TMEM16a* in 16 primary tumor samples. No mutations were identified in these tumors. TMEM16a expression in SCCHN was further investigated by immunohistochemical staining of a SCCHN tissue array. Two distinct tumor populations distinguished by differences in the nuclear and cytoplasmic staining were identified. Tumors with a high nuclear to cytoplasmic ratio were more poorly differentiated than those with a lower ratio. *TMEM16a* is a novel gene that is amplified in SCCHN with 11q13 amplification. This gene encodes a protein with an undiscovered function that is predicted to have eight transmembrane domains (TMDs). TMEM16A was found in the nucleoplasm in cell lines and tumor samples, despite the presence of TMDs. The lack of correlation between the gene, mRNA and protein levels suggests that factors other than overexpression at the DNA level may regulate TMEM16a expression. The overexpression of TMEM16A observed in tumors versus normal tissue, when coupled with the lack of mutations suggest that TMEM16a overexpression may be related to carcinogenesis.

Ulcerative colitis and sensorineural hearing loss. Mother and daughter in a Mexican family. *L.Hdez Gomez[1], S.G. Juarez Garcia[2], D.O. Gomez Torres[3], G. Garcia Sanchez[3], M.R. Izquierdo Ortiz[4], L. Acosta Ramos[5]* 1) Servicio de Audiologia, Instituto Nacional de Rehabilitacion Mexico D.F; 2) Servicio de Neuropsicologia infantil, Instituto Nacional de Rehabilitacion Mexico D.F; 3) Depto. Investigacion, Instituto Nacional Rehabilitacion, Mexico, DF, Mexico; 4) Servicio de Otoneurologia, Instituto Nacional de Rehabilitacion Mexico D.F; 5) Servicio de Genetica, Instituto Nacional de Rehabilitacion Mexcio D.F.

Ulcerative colitis (UC) is a polygenic disorder that gives rise to multiple clinical subgroups within UC and Crohn disease (CD) . Genome-wide searches have shown disease-associated loci on chromosomes 16, 12, 7, 5, 3, and 1. The major symptoms of UC are diarrhea, rectal bleeding, tenesmus, passage of mucus, and crampy abdominal pain. The severity of symptoms correlates with the extent of disease. Although UC can present acutely, symptoms usually have been present for weeks to months. Occasionally, diarrhea and bleeding are so intermittent and mild that the patient does not seek medical attention; hearing loss (SHL) was found in 46%; associated with UC, frist described by McCabe in 1973. We report a Mexican family with 2 affected members with UC and SHL in 2 generations, in which mother and her daughter are affected. CASE 1: female patient 79-year-old, mother, hearing loss and UC onset at 40-year-old. Audiometric test showed sensorineural bilateral middle hearing loss. Speech audiometric test showed sensorineural deficit. Timpanogram: curves A of Jerger bilateral. Stapedial reflex: absent bilateral. ABR performed reported response at 50 dB ear right, left at 60 dB. Trascient evoked otoacoustic emissions absent bilateral. Vestibular response to caloric is markedly reduced. Case 2: female patient 54 year old, hearing loss and Ulcerative Colitis onset at 40 year old. Audiometric test showed mild sensorineural hearing loss. Speech audiometric test showed sensorineural deficit. Timpanogram: curves A of Jerger bilateral Stapedial reflex: absent bilateral ABR performed reported bilateral response at 50 dB. Trascient evoked otoacoustic emissions absent bilateral. Vestibular response to caloric is reduced and posturographic testing is normal.

A putatively expressed, imprinted and functional mouse pseudogene proposed to regulate its source gene and cause neonatally lethal disease is actually an inactive relic. *T.A. Gray[1], R.D. Nicholls[2]* 1) Wadsworth Ctr, New York State Dept Health, Albany, NY; 2) Dept of Pediatrics, Children's Hospital of Pittsburgh, Pittsburgh, PA.

A recently promoted genome evolution model posits that mammalian pseudogenes can regulate their founding source genes, and it thereby ascribes an important function to junk DNA, an idea that has also gained significant support by the intelligent design community. This model arose from analysis of a serendipitous mouse mutant in which a transgene insertion/deletion caused severe polycystic kidney disease and osteogenesis imperfecta with ~80% neonatal lethality, when inherited paternally (Hirotsune et al. *Nature* 423:91-96, 2003). The authors concluded that the transgene reduced the expression of a nearby robustly transcribed and imprinted pseudogene named *Mkrn1-p1*. This reduction in chromosome 5 imprinted *Mkrn1-p1* transcripts was proposed to destabilize the cognate chromosome 6 *Mkrn1* source gene mRNA, with a partial reduction in one of two full-length *Mkrn1* isoforms leading to the imprinted phenotype. In contrast to this and two ensuing evolutionary claims (Podlaha & Zhang, *Mol Biol Evol* 21, 2202-9, 2004; Kaneko et al. *Genetics* 172, 2421-9, 2006), we find that 5 *Mkrn1-p1* is fully methylated on both alleles, a pattern indicative of silenced chromatin, and that *Mkrn1-p1* is not transcribed and therefore cannot stabilize *Mkrn1* transcripts in *trans*. Moreover, the short mRNA erroneously attributed to *Mkrn1-p1* is a *Mkrn1* isoform. Additionally, *Mkrn1* is not imprinted and the 5 promoter is fully unmethylated. Finally, mice that produce 50% or 0% of normal *Mkrn1* mRNA amounts due to a gene-trap mutation show none of the phenotypes claimed for mice having ~ 75% normal levels of *Mkrn1* mRNA. These data annul previous assertions that *Mkrn1-p1* is imprinted and that either it or its source *Mkrn1* gene relates to the original imprinted transgene phenotype. We conclude that the *Mkrn1-p1* pseudogene is a typical evolutionary relic, negating the pseudogene *trans* regulation model.

Beckwith-Wiedemann syndrome: report of a new case. *G.Juarez Garcia[1], L. Hernandez Gomez[2], L. Acosta Ramos[3], D.O. Gomez Torres[4], T. Gomez Torres[4]* 1) Neuropsicologia Infantil, Instituto Nacional de Rehabilitacion, Mexico, DF; 2) Servicio de Audiologia, Instituto Nacional de Rehabilitacion, Mexico, DF; 3) Servicio de Genetica, Instituto Nacional de Rehabilitacion, Mexico, DF; 4) Depto Investigación, Instituto Nacional de Rehabilitacion, Mexico, DF.

Beckwith-Wiedemann syndrome (BWS) is a common genetic overgrowth syndrome that is associated with visceromegaly, macroglossia, abdominal wall defects, pre and postnatal overgrowth, neonatal hypoglycemia, exomphalos, macroglossia, and gigantism, are considered the characteristic diagnostic triad of findings; due to this it , earlobe creases and pits,facial nevus flammeus,and prominent eyes with infraorbital creases,is also known as EMG-syndrome. Recognition of BWS is important because of the associated risk for development of embryonal neoplasms affecting abdominal organs, the need for prompt treatment of neonatal hypoglycemia, and for purposes of genetic counseling. Overall, intelligence is usually normal, although BWS has previously been reported in association with mild to moderate mental deficiency (due to hypoglycemic episodes or to subtle cytogenetic alterations) Although most cases appear to be sporadic (85%). Present autosomal dominant inheritance of BWS, with reduced penetrance and variable expressivity that may relate to the effects of genomic imprinting. Families with more than one relative affected, have been reported, and linkage studies in these familial cases have located the gene for BWS on the chromosome 11 (11p15.5). It is estimated the BWS occurs in between one in 14 000 births, with approximately equal incidence in males and females. We present a new case of Beckwith-Wiedemann in a female, mexican 2 years old child, that presents inconvenience of language, characterized by being found to level of dissyllables, basing its communication with signs and carrying al object desired. Two maternal cousins with congenital tumors. Geste product I, both parents of 20 years old, obtained pretermino. She presented onfalocele, macroglosia, visceromegaly, palate cleft and cardiac puff. EEG normal. ABR performed reported response at 30 dB ear right, left at 40 dB. Two years average mental age.

Screening ARX Gene in Iranian Families with X-linked Mental Retardation. *S. S. Abedini[1], K. Kahrizi[1], S. Esmaeeli Nieh1[1], F. Behjati[1], A. Aghajani[1], S. Ghasemi Firoozabadi1[1], L. Abbasi[2], S. Banihashemi[1], A. Tzchach[2], H.H. Ropers[2], H. Najmabadi[1]* 1) University of Social Welfare and Rehabilitation Sciences , Genetics Research Center, Tehran, Tehran, Iran; 2) Max Planck Institute for Molecular Genetics, Berlin, Germany.

The recently identified gene ARX (Aristalles-Related Homeobox), codes the ARX protein, an important transcription factor that belongs to one of the three largest classes of homeoproteins, the paired (Prd) class. Several mutations have been identified in ARX gene, which are responsible for a wide spectrum of phenotypes, including both nonsyndromic X-linked mental retardation (MRX), and syndromic (MRXS) forms such as X-linked lissencephaly with abnormal genitalia (XLAG), Partington syndrome and X-linked infantile spasm syndrome. The most common mutation in ARX gene identified is a duplication 24 bp (24 bp dup) in exon 2. This duplication leads to an expansion of the second polyalanine tract of ARX protein. The aim of this study is to obtain the relative prevalence of ARX mutations in the Iranian population. We have collected 65 probands from 65 families with two or more individuals with X-linked mental retardation (XLMR) inheritance pattern after obtaining informed consent form from the parents of probands. Each propband was subjected for molecular FMR1 gene mutation and karyotyping .The result of these tests for all probands were negative. In the first step these families were screened for the most common form of mutation, 24 bp duplication and if the result of each sample was negative, SSCP (Single Strand Conformation Polymorphisms) analysis performed. Consequently, we identified one family with 24 bp dup. We have also identified numbers of shifts in our families and DNA sequencing is on the way. Hence, we suggest that the molecular analysis of ARX mutations as the second cause of MR should be considered for any male which is negative FMR1 mutation as a part routine diagnostic test.

Kawasaki disease is strongly associated with common ancestral haplotypes of the major histocompatability complex in Australian Caucasoids. *D. Burgner[1], B. Edel[2], M. Odam[1], C. Witt[2], D. Sayer[2], S. Davila[3], M. Hibberd[3], F. Christiansen[2]* 1) School of Paediatrics, University of Western Australia; 2) Dept. of Clinical Immunology and Biochemical, Royal Perth Hospital, Australia; 3) Infectious Disease, Genome Institute of Singapore, Singapore.

BACKGROUND: Kawasaki disease (KD) is the commonest cause of pediatric acquired heart disease and a potential paradigm for identifying common mechanisms in atherosclerosis. Epidemiologic data supports a substantial genetic contribution to KD susceptibility. The Major Histocompatability Complex (MHC) contains over 30 immune genes, including The Human Leucocyte Antigens (HLA) and is a prime candidate region for inflammatory and infectious diseases. HLA data in KD suggest an association with class I, but not class II, regions, but studies are underpowered, admixed and may reflect inaccuracies with older HLA typing methodologies. We analysed the MHC in a carefully defined ethnically-matched Australian population using state-of-the-art molecular methods. METHODS: 70 Australian Caucasoid KD cases and 120 Australian Caucasoid population controls were typed for HLA A, B, C and DR loci using sequence-based methods. Recombinant mapping, using published and private markers within the central MHC, defined the associated genetic regions. RESULTS: KD susceptibility was associated with HLA-B*702 and HLA-DRB1*1501 (OR = 3.2; P=0.007), which lie on the 7.1 ancestral haplotype (AH). Fine-mapping defined a central MHC susceptibility region centromeric to the complement genes and telomeric to HLA-B (OR=9.5; P=0.0016). Protection from KD was associated with HLA-B*4403 and HLA-C*1601, which lie the 44.2 AH (OR = 0.2; P =0.01). DISCUSSION: Susceptibility and protective loci for KD are located within the MHC and are likely to be in linkage disequilibrium (LD) with markers defining common ancestral haplotypes. Further mapping, using genome-wide studies and both case-control and family-based methods, and with trans-racial mapping in areas of high LD, are on-going. Significantly associated KD variants will be assessed in large atherosclerosis cohorts to identify common determinants.

No effect of folic acid and methionine on D4Z4 methylation in facioscapulohumeral muscular dystrophy. *J.C. de Greef[1], E.L. van der Kooi[2], M. Wohlgemuth[2], R.R. Frants[1], R.J.G.P. van Asseldonk[2], H.J. Blom[3], B.G.M. van Engelen[2], S.M. van der Maarel[1], G.W. Padberg[1]* 1) Department of Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Neuromuscular Center Nijmegen, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands; 3) Laboratory of Pediatrics and Neurology, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is associated with contraction of the polymorphic D4Z4 repeat on chromosome 4qter. In healthy individuals, D4Z4 consists of 11-100 units on both chromosomes, whereas FSHD patients carry one 4q array of 1-10 units. This contraction is associated with significant hypomethylation of the shortened D4Z4 allele. In phenotypic FSHD cases in which patients do not have a contraction of D4Z4 on chromosome 4q, both their D4Z4 alleles show hypomethylation. These findings suggest a central role of D4Z4 hypomethylation in the pathogenesis of FSHD. As DNA methylation and demethylation are reversible processes, DNA methylation levels can potentially be influenced. Folic acid is essential for the synthesis of methione and S-adenosyl methionine (SAM), the common methyl donor required for DNA methylation maintenance. Intervention studies in humans taking folic acid supplements show that DNA hypomethylation, chromosome breaks, and uracil misincorporation are minimized when serum concentration of folate is higher than 34 nmol/l. We therefore performed a pilot study to evaluate the effect of supplemental folic acid and methionine on the methylation level of D4Z4 alleles on chromosome 4qter in peripheral blood lymphocytes (PBLs) of FSHD patients, including phenotypic FSHD patients, and healthy controls in order to decide if a larger clinical trial is warranted. Despite the fact that the recommended serum folate level to minimize DNA hypomethylation was reached in all subjects and total DNA methylation levels increased in the majority of subjects, D4Z4 methylation levels did not change in PBLs of FSHD patients and controls. At present, there is insufficient ground for a larger clinical study on folic acid supplements in FSHD.

SCNN1G variants are associated with systolic blood pressure in the Victorian Family Heart Study. *C.J. Büsst, K.J. Scurrah, J.A. Ellis, S.B. Harrap* Department of Physiology, University of Melbourne, Melbourne , Australia.

The -subunit of the epithelial sodium channel, encoded by SCNN1G, has been implicated in the Mendelian blood pressure diseases Liddles syndrome and pseudohypoaldosteronism type 1 - severe. SCNN1G is located on a region of chromosome 16 that has been linked to systolic blood pressure (SBP) by a number of independent studies, including our Victorian Family Heart Study (VFHS). To assess the impact of SCNN1G variation on SBP in the Caucasian VFHS population, 26 single nucleotide polymorphisms (SNPs) throughout SCNN1G were genotyped in 190 unrelated VFHS subjects selected for high SBP (n=96, SBP: 160.5, SD: 12.7) or low SBP (n=94, SBP: 98.4mmHg, SD: 5.2). Genotyping was carried out using a combination of single nucleotide primer extension and sequencing on the MegaBACE DNA Analysis Platform. Association of individual SNPs was assessed by logistic regression analysis in the statistical package R, with adjustments made for the covariates age, sex and body mass index. Haplotype estimation and association testing was performed within the Haplo.Stats software package. Four intronic SNPs displayed modest individual associations with SBP (P between 0.01 & 0.03), three of which formed a haplotype with evidence of strong association to SBP (global p-value = 0.00006). In summary, we have found evidence that common variants within SCNN1G are associated with SBP in the Victorian population. In order to validate the role of SCNN1G in SBP variation in the general population, it will be necessary to confirm these results in a larger population and to identify the causative functional variant.

Molecular analysis of Tumor Suppressor genes in synchronous and metachronous secondary carcinomas of the upper aerodigestive tract. *R. Birkenhager, W. Maier, G. Ridder, R. Laszig, J. Schipper* Otorhinolaryngology H&N Surg, Univ Freiburg, Freiburg, GermanyDep. ORL&HN Surg, Medical School, University of Freiburg, Killianstrasse 5, D-79106 Freiburg, Germany.

Genomic instability, reflecting the propensity and the susceptibility of the genome to acquire multiple alterations, might be considered a driving force behind multiple carcinogenesis. Head-and-neck cancer (HNC) patients have a risk of 10-15 % of developing second tumors of the upper aerodigestive tract. Due to the identical histological tumor entity of secondary carcinomas, their appearance cannot be explained exclusively by somatic mutations. Therefore an additional genomic predisposition for the development of synchronous and metachronous secondary carcinomas of the upper aerodigestive tract by this patient collective must be postulated. The genetic reason for this appearance of this special type of secondary carcinomas on genomic level has not been analyzed and investigated up to now. This patient collective demonstrates an inimitably homogenous gene pool for the analysis for such genomic predisposition. In our project we investigated a group of clinically consistently characterized patients who developed synchronous or metachronous secondary carcinomas of the mucosa in the upper aerodigestive tract with a SNP array-based analysis. By utilizing the Affymetrix GeneChip Chromosome Copy Number Tool, the allelic imbalance profiles on genomic level of these patients with secondary tumors were generated based on 10 K and 100 K XbaI/HindIII SNP mapping array. With this method it was possible to identify different loss of heterozygosity (LOH) areas specially on chromosome one and six. The aim of our project is to analyze the whole genomic background of these patients for identification of genomic alterations loss of LOH's areas and suppressor genes, responsible for the development of this special kind of secondary tumors in the upper aerodigestive tract.

***POLG1* GENE MUTATIONS ARE NOT A COMMON CAUSE OF SPORADIC ATAXIA IN ITALY.** *C. Cagnoli[1], A. Brussino[1], E. Di Gregorio[1], E. Dragone[2], M. Ferrone[1], S. Padovan[1], N. Migone[1, 2], A. Brusco[1, 2]* 1) Dept Genetics, Biol & Biochem, Univ Torino, Torino, Italy; 2) San Giovanni Battista Hospital, Medical Genetics Unit, Turin, Italy.

Mutations in the *POLG1* gene, encoding the catalytic subunit of the mitochondrial DNA polymerase , have recently been reported in autosomal recessive and sporadic cases with syndromic ataxia. The frequency of the Trp748Ser allele seems to be high among Finnish (1:125), and, due to a common haplotype of ancient origin, it has been suggested to be an important cause of ataxia also in other populations of European descent. We studied 257 consecutive Italian probands referred to our diagnostic center for a SCA testing (227 sporadic, and 30 with a possible familiarity). The screening for Trp748Ser and four other mutations reported in ataxic patients (Ala467Thr, Arg627Trp, His932Tyr, and Gly1051Arg) did not identify any carrier. Our findings suggest that *POLG1* mutations do not represent a major determinant for the pathogenesis of cerebellar ataxias in our population.

Effect of deferiprone on cerebellar iron accumulatio in Friedreich's ataxia. *N. Boddaert[1], K.H. LE QUAN SANG[2], A. Rotig[3], A. LEROY-WILLIG[4], S. GALLET[5], F. BRUNELLE[1], D. SIDI[6], J.C. THALABARD[2], I.Z. CABANTCHIK[7], A. MUNNICH[3]* 1) Dept Radiology, Hosp Necker, Paris, France; 2) Clinical Research Unit, Hôpital Necker-Enfants Malades, 75015 Paris France; 3) Medical Genetic Clinic and Research Unit INSERM 781. Department of Biological Chemistry and Charles E. Smith Laboratory of Psychobiology, Institute of Life Sciences, Hebrew University, Jerusalem 91904 Israel.

Friedreichs ataxia results from deficient frataxin levels causing reduced iron-sulphur-cluster formation, respiratory chain deficiency, mitochondrial iron accumulation and ensuing oxidative damage. We aimed at dissipating the allegedly toxic iron in the brain by using an orally active chelator that removes labile cell iron in clinical iron overload. An efficacy-toxicity phase I-II open trial was conducted with deferiprone on 11 adolescents who were already on the antioxidant Idebenone. Compared to age-matched controls, brain magnetic resonance imaging revealed relatively small and irregularly shaped dentate nuclei and significant ($p<0.027$) increase in iron content reflected in proton relaxation rates R2-star. Intake of 20-30mg/kg/d deferiprone for 6 months led to a progressive decrease in R2-star from 18.31.6msec-1 to 15.70.7msec-1 linearly related to the initial iron content ($r=0.90$). The chelation treatment was substantially milder than used for hemosiderosis and seemingly safe in the study period. Patients showed cessation of constipation and incontinence and improvements in manipulative dexterity and speech fluency and reduced signs of neuropathy and ataxic gait in the youngest treated patients. This is the first clinical demonstration of removal of labile iron accumulated in brain areas implicated in neurodegenerative disorders. The modest neurological improvements attained by chelation warrant future controlled prospective studies.

Splicing Sequences Finder: a bioinformatics resource to identify sequences involved in splicing. *C. Beroud, D. Hamroun, S. Tuffery-Giraud, O. Leroy, G. Collod-Beroud, M. Claustres* Laboratoire de génétique moléculaire, IURC, Institut Universitaire de Recherche Clinique UFR Médecine Site NORD UPM/IURC Montpellier, France.

Today thousands of intronic variations are identified yearly in molecular diagnostic laboratories. To assess the pathogenicity of these mutations, their impact on the well-characterized motifs acceptor and donor splice sites is usually evaluated. It is also important to identify branch point sequences (BP) whose key role in splicing can also explain the pathogenicity of some intronic mutations. Parallel to these motifs, which allow the cellular machinery to recognize an exon, it has recently been shown that exonic and intronic sequences are able to reinforce or inhibit these signals. These sequences are named ESE and ESS (exonic splicing enhancer or silencer), ISE and ISS (intronic splicing enhancer or silencer). Their identification was mainly based on bioinformatics and functional analyses. Therefore, many matrices are today available to predict these auxiliary-splicing sequences and to evaluate the pathogenic impact of not only intronic but also exonic missense mutations. The diversity of bioinformatics resources necessary to an exhaustive evaluation of these various elements as well as the need for new algorithms led us to develop the Splicing Sequences Finder (SSF) tool, which allows the identification of the various splicing elements from a crude sequence. To identify enhancer and silencer motifs various matrices (Cartegni and Krainer, Fairbrother and Burge, Zang and Chasing, Sironi and Pozzoli and Wang and Burge) were used. We also developed a specific algorithm to identify BP sequences. It was confronted to all mutations known to involve a BP sequence and was found reliable in all cases. The SSF tool could give valuable information for molecular diagnostic laboratories to evaluate the pathogenicity of a mutation. It can also be used to identify potential targets for antisens oligonucleotides to silence ESE or BP and therefore lead to exon skipping. This tool is freely accessible at: http://www.umd.be/SSF.

Mutations in the ND5 subunit of complex I of the mtDNA are a frequent cause of OXPHOS disease. *M.J. Blok[1], L. Spruijt[2], I.F.M. DeCoo[3], K. Schoonderwoerd[3], A. Hendrickx[1], H.J.M. Smeets[1,2]* 1) Clinical genetics, Academic Hospital Maastricht, Maastricht, Netherlands; 2) Department of Genetics and Cell Biology and Research Institute Growth & Development (GROW), University of Maastricht, the Netherlands; 3) Department of Child Neurology, Department of Clinical Genetics, Erasmus Medical Centre Rotterdam, the Netherlands.

Objective: To investigate if regions in the mtDNA are preferentially mutated in patients with OXPHOS disease. Background: Mutation detection in the mitochondrial genome is usually limited to common mutations and the tRNA genes. However, mutations in other mtDNA regions can be an important cause of OXPHOS disease as well. **Methods**: Screening of the mtDNA for heteroplasmic mutations was performed by DHPLC-analysis of 116 patients with OXPHOS disease but without the common mtDNA mutations. Heteroplasmy levels in different tissues were determined using PCR with fluorescently labeled primers and mutation specific restriction enzymes. **Results**: A mtDNA mutation was detected in 15 patients, five of which were present in the ND5 gene. Two mutations were new and two were known, one of which was found twice. The novel mtDNA point mutation, 12622G>A, was identified in three brothers, all with infantile encephalopathy (Leigh syndrome) fatal within the first 15 days of life. The other novel point mutation, 13511A>T, occurred in a patient with a Leigh-like syndrome. The known 13513G>A mutation, associated with MELAS and MELAS/Leigh/Leber hereditary optic neuropathy overlap syndrome, was found in a relative low percentage in two patients from two different families, one with a MELAS/Leigh and one with a MELAS/CPEO phenotype. The 13042G>A mutation, once detected in a patient with a MELAS/MERRF phenotype, was now found in a patient with a Leigh-like phenotype. **Conclusions**: Mutation screening of the ND5 gene is advised for routine diagnostics of patients with OXPHOS disease, especially MELAS- and Leigh(-like) patients.

Clinic and genetic study in a family with a clinical picture of pantothenate kinase-associated neurodegeneration.
I.C. Ciro Candiano, F. Annesi, S. Carrideo, E.V. De Marco, D. Civitelli, P. Tarantino, F.E. Rocca, M. Caracciolo, G. Provenzano, G. Annesi Inst Neurological Sciences, National Research Council, Mangone, Cosenza, Italy.

Pantothenate kinase-associated neurodegeneration (PKAN) is a disorder characterized by dystonia, parkinsonism, and iron accumulation in the brain. Many patients with PKAN have mutations in the gene encoding pantothenate kinase2 (PANK2) and a specific MRI pattern of hyperintensity within the hypointense medial globus pallidus (eyes of the tiger). Abnormal accumulation of iron in the brain is detected also in other neurodegenerative diseases such as neuroferritinopathy, characterized by extrapyramidal symptoms and low serum ferritin levels. Neuroferritinopathy is associated with mutations in the ferritin light polypeptide (FTL) gene whereas mutations in the ferritin heavy polypeptide (FTH1) gene are associated with a disorder presenting with iron overload. In this study, we performed a molecular study of the PANK2, FTL and FTH genes in a family with PKAN classic phenotype. The patient originated from Southern Italy. Her parents were healthy and consanguineous. Progression of disease was severe, with appearance of progressive dystonia, rigidity and spasticity of the four limbs. Brain MRI study revealed the presence of the eyes of the tiger. Serum ferritin was 16 ng/mL (N= 20 to 300). The exons of the PANK2, FTL and FTH genes were sequenced on ABI 3130xl. All members of the family were genotyped for 7 microsatellite markers from the PANK2 region (20p12.3-p13); linkage analysis was performed by GeneMapper software. Sequencing analysis of the PANK2, FTL and FTH genes excluded presence of mutations. Microsatellite analysis excluded linkage with PANK2 locus. On the basis of the clinical and neuroimaging features, a diagnosis of classic PKAN was made in our patient but the molecular analysis excluded linkage with this locus. Considering the abnormally low levels of ferritin in the serum of the patient, we supposed a ferritin-related neurodegeneration but the sequences of the FTH1 and FTL genes were found to be normal. These findings suggest a probable involvement of other iron regulatory proteins.

EURExpress, a web-based transcriptome atlas of the developing mouse embryo. *G. Diez-Roux, EURExpress Consortium* Telethon Institute of Genetics and Medicine, Naples, Italy.

Genome-wide expression analyses have a crucial role in functional genomics. RNA in situ hybridization (ISH) provides an accurate spatio-temporal description of the distribution of transcripts at cellular resolution. The EU-funded EURExpress consortium is generating a transcriptome-wide acquisition of expression patterns by means of ISH with non-radioactive probes and using this data to establish a web-linked, interactive digital transcriptome atlas (www.eurexpress.org). An initial phase of the project led to the generation of the Human Chromosome 21 Atlas (Nature 420, 582-586 (2002)). The goal of this 4 year project is to build on this success and generate the expression data of > 20,000 genes on sagittal sections from E14.5 wild type murine embryos. Since its establishment in 2005, EURExpress has generated over 3500 expression patterns, which have been thoroughly annotated using a special interface for high-throughput annotation. This interface includes 1420 anatomical structures and correlative trees regarding ontological (embryological) and topological relations allowing advanced queries. The analysis of the data produced so far has determined that 30-40% of genes show a specific/restricted pattern of expression at E14.5. Interestingly, 20% of these are uncharacterized genes of which a large percentage show restricted expression patterns in organs such as the central nervous system, ear, eye, skin, liver, skeletal muscle, mesenchyme and salivary glands. Among the high priority genes, we analyzed the expression pattern of 150 murine counterparts of genes located within the ENCODE regions, which will allow determining potential expression clustering and /or long distance tissue specific enhancers or promoters. To gain maximum leverage from the transcriptome atlas, the database will be linked to other bioinformatics resources. Our future plans include adding other developmental stages and adult tissues as well as analyzing the mutant mice resources being generated by the mutagenesis projects in USA and Europe.

Whole genome scanning for inversion polymorphisms based on population substructural patterns. *L. Deng[1], J. Kang[2], T. Liu[3], Y. Zhang[1], Q. Wang[4], H. Yang[1], C. Zeng[1], BGI HapMap Group* 1) Beijing Genomics Institute, Beijing, Beijing, China; 2) Department of Mathematical Sciences, Tsinghua University, Beijing, China; 3) Institute of Biophysics, Chinese Academy of Sciences, Beijing, China; 4) College of Mathematics, Beijing Normal University, Beijing, China.

Submicroscopic inversion is usually hard to detect, as it is commonly very large at the genomic level and gene structures are often left undisturbed. However, recent reports suggest that such inversions might be widespread in the human genome. Based on the unusual population substructure patterns generated from HapMap data, we developed an algorithm to discover stuctural polymorphisms. Here we present the application of this statistical method in the identification of inversion polymorphisms in human genome and the distinctive genetic structures of the rearrangement regions. Scanning of HapMap genotyping data on autosomes revealed numerous candidates of large scale inversion polymorphisms, covering more than 1% of human genome. Among them, several previously reported inversions also shown as strong signals of polymorphism. Further population genetic analysis revealed great differentiation and non-equilibrium haplotype distributions among geographic populations (African, Asian and European) in these candidate regions. Particularly, at our previously identified three hyplotype clades in the 3.8 Mb inversion region of 8p23, allele sharing distance (ASD) analysis showed that most of YRI haplotypes located in Clade_1 and most CHB and JPT haplotypes were in Clade_3. In CEU samples, however, divergent population subgroups were resolved whose haplotypes distributed in both Clade_2 and Clade_3. As determined by our statistical computation and confirmed by fluorescent in situ hybridization (FISH), Clade_2 are non-inverted chromosomal alleles, and Clade_3 corresponds to inverted structure. Taken together, our results provide a practical method to resolve structural polymorphisms on human genome and a panoramic view on haplotype structural and features of the candidate regions, including the inversion at 8p23.

Maternal serum screening in Abruzzo using triple test. *P. Guanciali Franchi[1,2], I. Iezzi[1], C. Palka[1], G. Calabrese[1,2,3], E. Morizio[2], M. Di Zio[2], G. Castriota[2], C. Nuzzi[1], G. Palka[1,2,3]* 1) Sci Biomed, Univ Chieti, Chieti, Chieti, Italy; 2) U.O. Genetica Umana, Pescara Hospital, Pescara, Italy; 3) CESI, Center for Aging, D'Annunzio Foundation, Chieti, Italy.

From January 1995 to December 2005, 17909 pregnant women were submitted to triple test screen in Abruzzo, a region in the middle of Italy. Women with age 35 yrs were 3617 (21%) while those ageing <35 yrs were 14302 (79%). Mean age was 30.6 yrs. Complessively 1295 women had a positive triple test for Down syndrome (DS) (7.2%) and 211 for neural tube defects (NTD) (1.18%). After genetic counseling, all the women with positive triple test for DS underwent to amniocentesis while those positive for NTD were screened by ultrasonographic scan at 20 weeks of gestation. Sixty three pregnant women had a fetus with abnormal karyotype consisting in 32 DS, 12 trisomy 18, 8 Turner syndromes, one triploidy, one partial trisomy 10p, one i(18p), one complex karyotype with inv(12) and der(16)t(12;16)mat, and one 46,XX male resulted from the SRY gene translocation onto a Xp chromosome. Among the women at risk for NTD, ultrasonographic scan showed 5 NTD and one abdominal wall defect. As a whole, the total detection rate for chromosome abnormalities was 88%, specifically for DS 80%, false positive cases were 1232 (6.8%), while false negative 8 (0.04%). The detection rate for NTD was 100%. Finally, 490 women showed a negative triple test and isolated hCG 2.5MoM. Forty nine of these women, all ageing <35yrs, presented a sonographic (soft) marker consisting in pielectasy, short femour, cardiopathy, cystic hygroma, or duodenal atresia. In 9 of these patients (18%), amniocentesis disclosed a chromosome abnormality consisting in 6 DS, and 3 Turner syndromes.

Linkage disequilibrium between polymorphisms at the IRF6 locus and nonsyndromic cleft lip with or without cleft palate in the Italian population. *P. Carinci[1], L. Scapoli[1], A. Palmieri[1], M. Martinelli[1], F. Pezzetti[1], F. Carinci[2]*
1) Department of Histology, Embryology, and Applied Biology; Center of Mol. Genetics, CARISBO Foundation, University of Bologna, Italy; 2) Chair of Maxillo-Facial Surgery, University of Ferrara, Italy.

Cleft lip with or without cleft palate (CL/P) is one of the commonest birth defects but its etiology is largely unknown. Very likely both genetic and environmental factors contribute to this malformation. Mutations in interferon regulatory factor 6 (IRF6) gene have been shown to be the cause of Van der Woudes syndrome, a dominant disorder that includes CL/P as a common feature. Recently, it has been reported that genetic polymorphisms at the IRF6 locus are associated with nonsyndromic CL/P with stronger signals in Asian and South American populations. We investigated four markers spanning the IRF6 locus using the transmission disequilibrium test. A sample of 219 patient/parents triads from Italy were enrolled for the study. Strong evidence of linkage disequilibrium was found between markers and disease in both single alleles (P=.002 at rs2235375) and haplotype analyses (P=0.0005). These findings confirm the contribution of IRF6 in the etiology of nonsyndromic CL/P and strongly support its involvement in populations with European ancestry.

Association study of the locus 19q13 in the Cystic Fibrosis liver disease. *S. Gambardella[1], M.R. D'Apice[1], S. Ciacci[1], S. Petrocchi[1], T. Santostasi[2], L. Narzi[3], S. Quattrucci[3], G. Castaldo[4], F. Salvatore[4], C. Colombo[5], G. Novelli[1]*
1) Department of Biopathology, Tor Vergata University, Rome, Italy; 2) Departiment di Biomedicine, Bari University, Bari, Italy; 3) Center for Cystic Fibrosis of Lazio, University La sapienza, Rome, Italy; 4) Department of Biochemistry and Medical Biotechnology, Federico II University, Naple, Italy; 5) Center for Cystic Fibrosis of Lombardia, Milan, Italy.

Cystic fibrosis (CF; #219700) is a disorder caused by mutations in the CFTR gene that encodes a chloride conducting channel expressed in the apical plasma membrane of the epithelial cells. The disease is characterized by a wide variability of clinical expressions which include pancreatic insufficiency, lung disease, hepatic manifestations, meconium ileus (MI) and male infertility. Even though CF is principally a monogenic disease, its wide phenotypic spectrum is influenced by secondary genetic factors, that can modulate the severity. Previous results through trasmission disequilibrium test in CF sibpairs, demonstrated the presence of a genetic modifier locus, CFM1 (Cystic Fibrosis Modifier 1) for MI on chromosome 19q13. In this study, we performed an association analysis by three microsatellite markers to test the role of this region as possible modifier of the hepatic involvement in Cystic Fibrosis. We genotyped a cohort of 90 CF patients (E) with hepatic involvement and pancreatic insufficiency, carrying two class I mutations, homozygous F508del, or compound heterozigous for a class I allele and F508del. We selected as control subject 75 CF patients with pancreatic insufficiency without hepatic involvement (CFC) and 100 unaffected individulas (C). We scanned the region on 19q13 by microsatellite D19S903- D19S219-D19S112, spanning 1.1 Mb. There was no particular allele or haplotype associated with the hepatic involvement compared with CFC and control subjects. These rules out the possibility that genes mapping in this region act as modifier genes of the CF hepatic manifestation.

Linkage study in three Italian families with autosomal dominant nocturnal frontal lobe epilepsy. *S. Carrideo[1], E.V. De Marco[1], A. Gambardella[2], A. Labate[2], F. Annesi[1], I.C. Cirò Candiano[1], P. Tarantino[1], F.E. Rocca[1], D. Civitelli[1], M. Caracciolo[1], G. Annesi[1]* 1) Inst Neurological Sciences, CNR, Mangone, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Mutations in the genes encoding the 4 and 2 subunits of the neuronal nicotinic acetylcholine receptor (nAChR) play a causative role in autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE). A third ADNFLE locus (15q24) has been identified but mutations linked to the disease have not yet been found. Recently, variations in the promoter of the corticotropic-releasing hormone gene (CRH) were reported in patients with NFLE. However, only a minority of ADNFLE families carry a mutation of these genes. Here, we investigated whether nine brain-expressed genes, encoding distinct nAChR subunits, or CRH gene are associated with the disease in three ADNFLE families from Southern Italy. We performed a linkage study on 11 affected and 29 unaffected individuals of these families with microsatellite markers and RFLPs encompassing the chromosome localization of the nAChR subunits and the CRH genes. We examined the following chromosome regions: 1q21 (CHRNB2), 8p21 (CHRNA2), 8p11.2 (CHRNA6, CHRNB3), 15q14 (CHRNA7), 15q24 (CHRNA5/A3/B4), 20q13.2 (CHRNA4), 8q13 (CRH). Two point and multipoint linkage analysis were performed by LINKAGE and GENEHUNTER. In two families, most markers were not informative for CHRNB2 and CRH, respectively. Mutational analysis of these two genes were therefore performed in the probands. Negative LOD scores values (less than -2) at theta 0 were obtained for all the informative markers related to nAChR subunits or CRH genes. No mutation of CHRNB2 and CRH genes was detected in the probands of the families with non informative markers. The results of this study illustrated no association between nAChR subunits or CRH genes and ADNFLE in our families. It is therefore reasonable to hypothesize that further genes are involved in the disease. These results confirm the considerable genetic heterogeneity of ADNFLE, despite the quite homogeneous clinical picture. Supported by FIRB-MIUR, year 2001 RBNEO1XP4.

Impact of *DNAI1* and *DNAH5* pathogenic mutations in a cohort of unselected PCD patients. *M. Failly[1], A. Saitta[1], M. Alvarez[1], C. Ramos[1], L. Gilbert[1], S.E. Antonarakis[1,2], L. Bartoloni[1], J-L. Blouin[2]* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Switzerland; 2) Medical Genetics, University Hospitals of Geneva, Switzerland.

Primary Ciliary Dyskinesia (PCD) is a rare congenital disorder (affecting 1/20'000) mainly inherited on autosomal recessive mode and caused by ciliary/flagellar dysmotility due to ultrastructural/functional defects of the axoneme. Symptoms are respiratory infections, with chronic sinusitis, nasal polyps, bronchiectasis, and male subfertility. In addition, 50% of cases show a situs inversus (Kartagener syndrome). To date, 4 genes have been found to be mutated in PCD: *DNAI1*, *DNAH5*, *DNAH11*, and *RPGR* in a X-linked form always associated to Retinis Pigmentosa. In order to determine the impact of the known disease genes, we screened for mutations in 96 unrelated affected individuals without any preselection of phenotype subtype. All exons and splicing sites of *DNAI1* were investigated by DHPLC and sequencing. In the *DNAI1* gene we found 1 novel missense variant (E174K) and 2 previously described mutations (IVS1+3insT, c.1703C>G). The impact of *DNAI1* mutations in our large cohort of unselected patients represents only 4.2%. We have also screened exons with previously reported mutations as well as exons coding for the 4 P-loop domains of gene *DNAH5* (15 of the 79 exons). One published mutation S2264N, in P-loop 2 domain, has been identified in heterozygosity. In addition a new heterozygous non-sense (K1853X) was found in exon 34 in one patient. The mutation search in these *DNAH5* exons among those coding for important functional domains of this heavy chain dynein is not compatible with a large impact of this gene in PCD patients without subphenotype selection. We conclude from our preliminary results that mutations in the *DNAI1* and *DNAH5* genes are not the main contributors of PCD. Additional PCD genes, remain to be characterized.

The Spine and the Craniocervical Junction in Ehlers-Danlos Syndrome. *C.A. Francomano[1,2], R. Razza[3], B. Griswold[2], P. Bolognese[4], T. Milhorat[4], N.B. McDonnell[2]* 1) Greater Baltimore Med Ctr, Harvey Inst Human Gen, Baltimore, MD; 2) National Institute on Aging, Baltimore, MD; 3) Harbor Hospital, Baltimore, MD; 4) The Chiari Institute, NS-LIJHS, NY.

The Ehlers-Danlos syndromes (EDS) are a heterogeneous group of hereditary disorders of connective tissue characterized by joint, skin and vascular abnormalities. Joint laxity and dislocations are commonly recognized musculoskeletal features of EDS. However, the frequency of spinal involvement, including degenerative disc disease and dural ectasia, is unknown. Previous anectodal reports have described spinal abnormalities including spondylolisthesis, lumbar platyspondyly and scoliosis. We assessed images of the lumbar spine by Magnetic Resonance Imaging (MRI) in 58 consecutive patients with a diagnosis of EDS. The cohort included patients with hypermobile, classical and vascular forms of EDS, and the age range was 12-67. The abnormalities observed included degenerative disc disease, disc herniation, facet arthrosis, dural ectasia and dural cysts. The abnormalities were observed in all age groups, including patients as young as 15 years of age. All patients over the age of 45 had significant disc disease. 45/58 patients were found to have some degree of disc disease. 15/58 patients had dural ectasia. Degenerative disc disease was highly correlated with the presence of back pain. During the course of the clinical evaluation, it was noted that twelve patients in the cohort had a previous diagnosis of Arnold Chiari I malformation, or received the diagnosis during longitudinal follow-up. Two patients had a history of previous decompression surgery; four others were operated after enrollment in the study. The remaining patients were treated conservatively. Several additional patients had evidence of a retroflexed odontoid or pannus formation around the odontoid that was felt to contribute to complaints of head and neck pain. The results indicate that pathology in the spine and the craniocervical junction is a frequent cause of morbidity in EDS. The data suggest that it is advisable to pursue appropriate radiological evaluations in the presence of back, head and neck pain in this group of patients.

Association of the *FCRL3* gene with rheumatoid arthritis: a further example of population specificity of disease loci? *A. Barton, S. Eyre, J. Worthington* ARC-EU, The University of Manchester, Manchester, United Kingdom.

Background: Association of a functional promoter polymorphism mapping to the Fc receptor-like 3 (*FCRL3*) gene has recently been reported and replicated with rheumatoid arthritis (RA) in independent Japanese populations, but not in a population from North America.

Aim: To investigate association of the *FCRL3* gene with RA in UK subjects.

Methods: DNA was available from 1065 patients with RA and 2073 population controls from the UK. Four single nucleotide polymorphism (SNP) markers (FCRL3-169C/T (fclr3_3, rs7528684), fclr3_4 (rs11264799), fclr3_5 (rs945635), fclr3_6 (rs3761959)) all previously associated with RA in a Japanese population were genotyped in 761 RA samples and 484 controls. In the remaining samples, only the putative disease causal polymorphism, FCRL3-169C/T, was tested. Genotyping was performed using either the Sequenom MassArray iPlex platform (www.Sequenom.co.uk) or a 5 Allelic discrimination assay (Taqman, ABI).

Results: Extensive linkage disequilibrium was present across the promoter SNPs genotyped (r^2 values = 0.60-0.98). Allele frequencies did not differ between RA cases and controls either for the putative disease causal polymorphism (odds ratio FCRL3-169C allele = 0.97 (0.87-1.07), p = 0.51) or for the other SNPs tested. Similarly, no association was detected with RA when stratification by shared epitope carriage or by presence of rheumatoid factor was undertaken. Of the 16 possible estimated haplotypes, only 3 existed at a population frequency greater than 1% but no difference in their frequencies were observed between cases and controls (p = 0.97).

Conclusion: This study was powered to detect an effect size of 1.24 or greater for the FCRL3-169C/T functional promoter polymorphism but no evidence for association was detected, suggesting that this gene will not have a substantial effect in determining susceptibility to RA in populations of Northern European descent.

Exon resequencing and mutation detection in syndromic oesophageal atresia. *A. Coffey[1], E. Howard[1], K. McLay[1], A. Dunham[1], S. Hunt[1], S. Leonard[1], J. Burton[1], J. Rogers[1], C. Shaw-Smith[2]* 1) Human Genetics, Sanger Institute, Cambridge, United Kingdom; 2) Department of Medical Genetics, University of Cambridge, Addenbrooke's Hospital, Cambridge, UK.

Oesophageal atresia and/or tracheo-oesophageal fistula are common malformations occurring in approximately 1 in 3500 births. In around half of cases (syndromic oesophageal atresia), there are other associated anomalies, with cardiac malformations being the most common. Oesophageal atresia is regarded as a sporadic entity with a low recurrence risk, but there are well-defined instances of this malformation where genetic factors clearly are important. This is highlighted by the recent identification of no fewer than four separate genes with a role in its aetiology. The genes identified to date are the genes for Feingold syndrome (N-MYC), anophthalmia-oesophageal-genital (AEG) syndrome (SOX2), CHARGE syndrome (CHD7) and X-linked Fanconi anaemia (FANCB). We are actively collecting DNA samples from patients with syndromic forms of oesophageal atresia and resequencing all exons from a set of 25 candidate genes using a stratified approach. These genes have been sequenced in a panel of 48 unrelated Caucasian samples and novel single nucleotide polymorphisms identified, approximately 40% of which are rare. In the first phase of the stratified approach to mutation detection, we have sequenced exons from 4 genes in the patient samples collected to date. The results of this analysis will be presented.

Molecular genetic basis of the disease in a Spanish family with Usher syndrome type 1 and non-syndromic deafness. *E. Aller[1,2], T. Jaijo[1], M. Beneyto[1], C. Vilela[3], C. Nájera[2], C. Ayuso[4], J.M. Millán[1]* 1) Unidad de Genética, Hospital La Fe, Valencia, Spain; 2) Departamento de Genética, Universidad de Valencia, Valencia, Spain; 3) Sección de Neurofisiología, Hospital La Fe, Valencia, Spain; 4) Departamento de Genética, Fundación Jiménez Díaz, Madrid, Spain.

INTRODUCTION: Usher syndrome type I (USH1) is an autosomal recessive hereditary disease characterized by the association of retinitis pigmentosa (RP), congenital severe-profound sensorineural deafness and vestibular dysfunction. Up to date, five genes have been identified as disease-causing for USH1, being the MYO7A (corresponding to USH1B), the gene responsible in most of cases (about 50%). Mutations located in this gene have also been shown to be responsible for some non-syndromic deafness cases, in both dominant (DFNA11) and recessive (DFNB2) forms. AIMS: The aim of the present work is to elucidate the genetic basis of the disease in a Spanish family with some affected members displaying USH1 and some others displaying non-syndromic sensorineural deafness. PATIENTS and METHODS: The paternal family showed non-syndromic deafness compatible with an autosomal dominant hereditary pattern. The maternal family displayed USH1. The two affected sibs of this couple suffered from USH1. DNA samples were obtained from all family members. The maternal family and the affected sibs were screened for mutations in MYO7A gene by SSCPs analysis. Coding regions of MYO7A gene were directly sequenced in the father. The father was also screened for the most prevalent deafness-causing mutations in the Spanish population. RESULTS: Affected sibs were compound heterozygous for 2 MYO7A mutations: (p.Q821X/c.9_10dupGATT). The mother was homozygous for p.Q821X. The father was heterozygous for c.9_10insGATT. A second mutation in the father was not found after the direct MYO7A sequencing. None of the deafness-causing mutations studied were detected in the father. DISCUSSION: USH1 in this family is caused by mutations in MYO7A. The genetic basis of deafness in paternal family is still unclear. The haplotype study of paternal family members will be useful to elucidate this question.

Truncation of Cernunnos/XLF in a patient with polymicrogyria. *V. Cantagrel[1], A-M. Lossi[1], S. Lisgo[2], C. Missirian[1,3], A. Borges[1], N. Philip[1,3], C. Fernandez[4], C. Cardoso[1], D. Figarella-Branger[4], A. Moncla[1,3], S. Lindsay[2], W.B. Dobyns[5], L. Villard[1]* 1) INSERM U491, La Timone, Marseille, France; 2) Institute of Human Genetics, International Centre for life, Newcastle, UK; 3) Departement de genetique medicale, La Timone, Marseille, France; 4) Biopathologie nerveuse et musculaire, La Timone, Marseille, France; 5) Departements of human genetics, Neurology and pediatrics, Chicago, IL, USA.

Polymicrogyria (PMG) is a common malformation of the human cerebral cortex for which both acquired and genetic causes are known. Although genetic heterogeneity is documented, only one gene is currently known to cause isolated PMG. In order to clone new genes involved in this type of cerebral malformation, we studied a fetus presenting a defect of cortical organization consisting of a polymicrogyric cortex and neuronal heterotopia within the white matter. Karyotype analysis revealed that the fetus was carrier of a balanced, de novo, chromosomal translocation t(2;7)(q35;p22). Cloning and sequencing of the two translocation breakpoints reveals that the chromosomal rearrangement disrupts the coding region of a single gene, called Cernunnos or XLF, in 2q35. The Cernunnos gene was recently identified as being responsible for autosomal recessive immunodeficiency with microcephaly and as a member of the NHEJ pathway. Using quantitative PCR experiments, we show that a truncated transcript is expressed in the polymicrogyric patient cells suggesting a potential dominant negative effect possibly leading to a different phenotype. We performed in situ hybridization on human embryos and show that the Cernunnos transcript is preferentially expressed in the telencephalic ventricular and subventricular zones, consistent with the phenotype of the affected individual. In the human adult central nervous system, Cernunnos is mainly expressed in the cerebral cortex and in the cerebellum. The association of polymicrogyia with the disruption of its transcript suggests that, in addition to its recently uncovered function in the development and maturation of the adaptative immune system, the Cernunnos protein may also play a role during development of the human cerebral cortex.

Genetic mapping for *RET*-dependent modifiers in Hirschsprung disease (HSCR). *P.Y. Fong[1], M. Garcia-Barcelo[1,2], P. Sham[1,3], P. Ng[1], C. Lau[1], M.T. So[2], W. Mak[1], P. Tam[1,2]* 1) Genome Research Centre, The University of Hong Kong, Hong Kong SAR, China; 2) Department of Surgery, The University of Hong Kong, Hong Kong SAR, China; 3) Institute of Psychiatry, Denmark Hill, London SE5 8AF, UK.

Hirschsprung disease (HSCR, colon aganglionosis) is a non-mendelian, multifactorial, congenital disorder. Mutations have been identified on several genes, and show incomplete penetrance. Although, a high risk common variant has been found in the *RET* gene (main HSCR gene), the low penetrance of this *RET* variant is not sufficient to explain the disorder. This suggests that additional loci are required in the total susceptibility of the disease. A genome scan study in families identified 3p21 and 19q12 loci as *RET*-dependent modifiers. In this study, we conducted a high density region-wide association study on 3p21. To enhance the cost effectiveness of our study, we refined our study to a gene-rich region, which is also in high linkage disequilibrium (LD). In addition, we selected tag SNPs based on a clustering algorithm with data from the International HapMap Project. This tag SNPs were genotyped in 172 cases, 161 parents and 153 unrelated controls. We performed standard allelic and haplotype association analyses of the case-control and trio data, as well as correlational analyses between alleles and the high risk *RET* variant, as a way of examining for epistasis. Our study demonstrates a systematic approach to map susceptibility loci in multifactorial disease.

Elevated levels of Low Density Lipoprotein are frequently seen in patients with Ehlers Danlos Syndromes. *M. Burchett[1], A. Gustafson[1], B. Griswold[1], N.B. McDonnell[1], C.A. Francomano[1,2]* 1) National Inst on Aging, Baltimore, MD; 2) Harvey Inst Hum Genetics, GBMC, Baltimore, MD.

The Ehlers-Danlos syndromes (EDS) are a heterogeneous group of hereditary disorders of connective tissue characterized by joint, skin and vascular abnormalities. There have been no previous reports on abnormalities of cardiovascular risk biomarkers in patients with EDS. Complete lipid profiles as well as fibrinogen and C-Reactive protein (CRP) levels were obtained on 63 consecutive patients, ages 12-61, with a diagnosis of EDS enrolled in the National Institutes of Aging protocol 2003-086 entitled Clinical and Molecular Manifestations of Heritable Disorders of Connective Tissue. There were 50 females and 13 males in the cohort. An elevated low density protein (LDL) was seen in 37/50 females, and in 10/13 males, whereas elevated total cholesterol was seen in 7/50 females and 3/13 males. Only three persons in the cohort had a BMI > 30, suggesting that obesity was not a pervasive cause of dyslipidemia in this group of patients. Elevated triglycerides were seen in 9 subjects. There were 7 females with elevated CRP and 5 with elevated fibrinogen. The female cohort was broken down to age groups in line with National Health and Nutrition Examination Survey (NHANES III) and age specific comparisons were performed using age specific national averages for the LDL profiles. All age groups in the EDS female cohort showed a skewed distribution pattern of LDL values. The skewed pattern was most remarkable in the younger age groups: In the 12-44 age range, 50% of the patients had LDLs in the greater than 75th centile. The mean LDL for females over 20 was 128 mg/dL, which plots at 70% percentile of the national mean. These data suggest that persons with EDS are at higher than population risk for having an elevated LDL. We suggest that patients with the diagnosis be screened with a complete lipid profile starting in teenage years. The etiology and prognosis for isolated elevated LDL without elevated total cholesterol in EDS patients is unclear. Further studies, including pedigree analysis, are necessary to determine if increased cardiovascular morbidity and/or mortality segregate with EDS.

Collection of human genome variation: The Human Variome Project? *R. Cotton, Collaborators* Dir, Genomic Disorders Res Ctr, St. Vincent's Hospital, Fitzroy, Australia.

Mutation is estimated to affect 60% of humans directly in a lifetime, excluding cancer, members of the extended family and carers, representing billions worldwide. However, little formal attention has been given to collecting human variation causing disease and potentially causing disease.

Collection of inherited disease began with Victor McKusick, later collecting mutations in each disease www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM. In parallel, many individuals began collecting mutations in the genes of clinical and research interest. David Cooper began collecting mutations in genes to see which mutational change was predominant www.hgmd.org/.

As there was no systematic or structured effort to collect mutations, a 1994 Montreal meeting, of a group of the worlds prominent geneticists resolved that collection and curation of mutation data is best done by a federation of LSDB curators, each experts in their gene rather than informatics/database experts centrally. This led to the formation of the HUGO-MDI and subsequently, the Human Genome Variation Society (www.hgvs.org) with Human Mutation as its society journal.

Enormous progress has been made by members of the Society and others despite limited funding. Outcomes include recommendations on nomenclature of mutations, quality control of mutation data, entry form for mutation databases, recommended content of mutation databases, software for LSDBs, a collection facility for mutations (the WayStation www.centralmutations.org), twice yearly scientific meetings, comprehensive listing of LSDBs etc. The SNP community has made more progress due to good funding, but there is still much to be done.

The projects nature makes it difficult to obtain funding for this reason, we have attempted to obtain a focus for the effort by initiating The Human Variome Project Meeting obtaining the World Health Organizations co-sponsorship for this meeting in Melbourne, June 2006. Progress, problems, plans and the meeting outcome will be outlined.

Polymorphisms In Cell Cycle Genes And Predisposition To Ovarian Cancer. *S. Gayther[1], H. Song[2], S. Ramus[1], A. Whittemore[3], S. Krüger Kjær[4], P. Pharoah[2], Ovarian Cancer Association Consortium* 1) Dept Gyn. Oncology, Windeyer Inst, London, United Kingdom; 2) Strangeways Research Laboratories, Cambridge, United Kingdom; 3) Stanford University School of Medicine, Stanford, USA; 4) Danish Cancer Society, Copenhagen, Denmark.

High-risk susceptibility genes explain less than 30% of the excess risk of familial ovarian cancer. Other ovarian cancer susceptible gene are likely to exist. We have used a SNP tagging approach to evaluate common variants in 13 genes involved in cell cycle control - CCND1, CCND2, CCND3, CCNE1, CDK2, CDK4, CDK6, CDKN1A, CDKN1B, CDKN2A, CDKN2B, CDKN2C, and CDKN2D - and risks of invasive epithelial ovarian cancer. We used a two-stage, multi-centre, case-control study. SNPs that tag common variation in these genes were initially genotyped in three studies from UK, USA, and Denmark (~1500 cases and 2500 controls). Seven other studies from Australia, Poland, and USA (~2500 cases and ~3500 controls) were used for replication of the most significant results. Genotype frequencies in cases and controls, were compared using a logistic regression model. In the first stage we genotyped 87 SNPs in 13 genes. Eight SNPs in 4 genes were associated with P greater than 0.05. The five most significant SNPs were then genotyped in the second stage. After adjusting for 5 hypotheses tested no SNP was significantly associated with disease (most significant unadjusted P = 0.045 for CDKN2A rs3731257). Using the full dataset, the same SNP was most significant (unadjusted P = .004), but again not significant after adjusting for multiple testing (87 hypotheses). In conclusion, we have found evidence that a SNP in the CDKN2A gene may be associated with increased risk of ovarian cancer. This study highlights the need for multi-centre collaborations in order to validate and refute preliminary data generated by genetic association studies.

Haplotype Analysis In Patients With Chromosome 16q22.1-linked Autosomal Dominant Cerebellar Ataxia. *T. Amino[1], N. Sato[1], T. Ishiguro[1], T. Tsunemi[1], S. Toru[1], T. Toda[2], H. Mizusawa[1], K. Ishikawa[1]* 1) Neurology and Neurological Science, Tokyo Medical and Dental University, Tokyo, Japan; 2) Department of Clinical Genetics, Osaka University Graduate School of Medicine, Suita, Osaka, Japan.

Background, Purpose We have previously mapped mutations in Japanese families with autosomal dominant cerebellar ataxia (ADCA) to Chromosome 16q22.1,which is the gene locus for SCA4. Last year we reported that Chromosome 16q22.1-linked ADCA(16q-ADCA) patients share a common haplotype in the 600kb genomic region, and the heterozygous single nucleotide substitution in the *puratrophin-1* gene is strongly associated with the disease (Ishikawa et al, AJHG 2005). In this study, newly diagnosed families were additionally enrolled and their haplotypes were determined in more detail.

Methods Cerebellar ataxic patients were diagnosed as 16q-ADCA based on the presence of the single nucleotide substitution in the *puratrophin-1* gene. We have identified multiple single nucleotide polymorphisms(SNPs) on the disease allele. Haplotypes were determined for the 16q-ADCA families with these SNPs in addition to microsatellite markers.

Results We found 61 families of 16q-ADCA. They all had the possibility of harboring the disease allele within the 600kb genomic region for the SNPs as well as the microsatellite markers.

Discussion, Conclusion This study confirmed that 16q-ADCA patients may share a common founder haplotype. Detailed haplotype analysis with SNPs can lead to more accurate diagnosis.

Cutaneous Signs in Ehlers-Danlos Syndromes: The role of skin findings in determining the clinical diagnosis and predicting the genotype. *W. Chen[1], J. Yang[1], B. Griswold[1], A. Gustafson[1], M. Burchett[1], C.A. Francomano[1,2], N.B. McDonnell[1]* 1) Lab Clinical Investigation, Nat Institute on Aging/NIH, Baltimore, MD; 2) Harvey Inst Hum Genetics, GBMC, Baltimore, Maryland.

Ehlers-Danlos Syndomes (EDS) are a group of genetically heterogeneous hereditary disorders of connective tissue manifesting with joint hypermobility, tissue and vessel fragility, and skin involvement. Differentiation between subtypes of EDS has proven to be a challenge on a clinical basis. We present a summary of skin findings in 100 consecutive patients with a diagnosis of EDS enrolled in a natural history study at the NIH. Skin findings were notable for intra-familial variability. Presence of atrophic scars and skin hyperextensibility were variable not only between members of a family, but also on different body parts of the same person. Smooth and velvety skin, which is highly subjective, was noted in many patients, however unaffected members of some families were found to have the velvety skin, casting doubt in the clinical utility of this finding. Bruising, translucent skin, subcutenous venous patterns, and poor wound healing were seen to varying extents in patients with vascular EDS, but were also noted in other subtypes. Patients with a clinical history consistent with the hypermobile form were found to have a youthful appearance, a non-quantifiable finding. Molecular studies of COL5A1 and COL5A2 were completed on a research basis on patients who had skin features suggestive of the classical form of EDS (29/100), such as the presence of skin hyperextensibility, widened atrophic scars, and poor wound healing. Five mutations were found in COL5A1 and no mutations were found in COL5A2. By contrast, a sixteen year old girl, and a sixty year old woman, both with joint hypermobility, chronic joint pain and extensive striae similar to that seen in Marfan syndrome were found to have mutations in N-terminal propeptide of COL5A1. Our results suggest that while the presence of a skin abnormality can help to point to the diagnosis of EDS, skin findings from a single affected family member are often not helpful in determining the clinical subtype or predicting the molecular defect involved.

Genotype/Phenotype correlations with Col2A1 and Col11A1 mutations in Stickler Syndrome. *B. Griswold[1], M. Männikko[2], J. Wells[2], M. Majava-Elo[2], K. Mandel[1], J. Tran[1], P. Rose[3], H. Levy[4], R. A. Liberfarb[5], J. Davis[6], B. Rubin[6], Y. Szymko[6], E. Tsilou[6], M. Kaiser[6], A. Griffith[6], L. Ala-Kokko[2], N.B. McDonnell[1], C.A. Francomano[1,7]* 1) National Inst Aging, NIH, Baltimore, MD; 2) Dept Med Biochem Mol Bio, Univ Oulu, Oulu, Finland; 3) Mayo Clinic, Rochester, MN; 4) Johns Hopkins University Sc of Medicine, Baltimore, MD; 5) Mass Gen Hospital, Boston, MA; 6) National Institutes of Health, Bethesda, MD; 7) Harvey Inst Hum Gen, GBMC, MD.

Stickler Syndrome is estimated to be the most common autosomal dominant connective tissue dysplasia in North America. Mutations in procollagen genes COL2A1, COL11A1 and COL11A2 have been implicated in 35-50% of affected families. Mutation analysis for COL2A1 and COL11A1 was performed on 48 probands with Stickler syndrome using Conformation Sensitive Gel Electrophoresis (CSGE) and direct sequencing. Sixteen mutations in COl2A1 and four mutations in COL11A1 were detected. Six mutations in COL2A1 involved an altered splice site, and 9 mutations created premature termination codons, consistent with previous observations that haploinsufficiency is the predominant mechanism of disease. No mutations in COL2A1 involved substitutions of a glycine in the collagen helix with a bulkier amino acid, which is frequently seen in type II collagenopathies that lead to dwarfism. COL11A1 mutations consisted of a glycine substitution, an insertion leading to a frameshift in the helical domain, and two splice site mutations. Genotype/phenotype analysis of 35 affected persons from the 20 families with the COL2A1 or COL11A1 mutations revealed that all patients met the recently developed Stickler diagnostic criteria. Facial characteristics such as malar hypoplasia, broad nasal bridge or flat facial profile were seen in all affected persons. Cleft palate showed inter and intra-familial variability. All patients had ocular manifestations, with vitreous and/or retinal changes. Hearing loss, failure of femoral head development, skeletal manifestations and premature osteoarthritis were variable but common findings. Efforts are underway to determine the underlying mutations in the remaining 28/48 families.

Do abnormalities of extracellular matrix elements lead to autoimmune disorders? Unexpectedly high incidence of rheumatologic disorders in persons with Ehlers Danlos Syndrome. *A. Gustafson[1], B. Griswold[2], M.E. Burchett[2], S.H. Schurman[2], S. Ling[2], C.A. Francomano[2,3], N.B. McDonnell[2]* 1) Brown Univ, Providence, RI; 2) National Institute on Aging, Baltimore, MD; 3) Harvey Inst Hum Genetics, GBMC, Baltimore, MD.

The Ehlers-Danlos syndromes (EDS) are characterized by joint, skin and vascular abnormalities. Non-inflammatory joint pain is a common feature in many patients with EDS. Rheumatoid Arthritis(RA),Systemic Lupus Erythematosus(SLE), and Sjogren's syndrome(SS) are inflammatory acquired rheumatologic conditions. Raynauds phenomenon consists of vasospastic attacks in the digits, and may be found associated with an autoimmune disorder. We have found a high incidence of the above autoimmune disorders in a cohort of 72 consecutive EDS patients enrolled at the National Institute on Aging study 2003-086. In longitudinal follow-up 5/25 adults 40 years or older developed RA. One adult over 40 presented with a diagnosis of EDS and SLE. A 15 year old girl had a positive ANA, joint swelling and unexplained fevers, and later met the diagnostic criteria for SLE. Another young girl, age 16, in whom a COL5A1 mutation was found, presented with Raynauds phenomenon and joint swelling at the time of initial visit, and was later diagnosed with Juvenile Rheumatoid Arthritis (JRA). The total number of patients who exhibited Raynauds phenomenon in our cohort was 7/72. A 39 year old woman was found to have SS, diagnosed by biopsy of the oral mucosa. In total, there were 12/72 patients in our cohort who either presented with a rheumatologic disorder in addition to EDS, or developed one during follow-up. The number of RA patients, 5/72 (7%) in the total cohort, and 5/25 (%20) in patients over 40, far exceeds the predicted co-occurrence of this disorder with EDS. The same is true, albeit to a lesser extent, for the number of patients with Raynauds phenomenon, 7/72 (10%) and SLE, 2/72 (3%). This raises the possibility that abnormalities of the extracellular matrix might contribute to the development of autoimmunity in the presence of other environmental or genetic influences.

Phenotypic Variation of Congenital Diaphragmatic Defects. *K.G. Ackerman[1,2,3], S.O. Vargas[3,4], H.P. Kozakewich[3,4]* 1) Division of Genetics, Brigham and Women's Hospital, Boston, MA; 2) Division of Emergency Medicine, Children's Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Department of Pathology, Children's Hospital, Boston, MA.

Congenital diaphragmatic defects are common and serious, yet we do not understand why they occur. Definition of the range of both normal and abnormal diaphragmatic development in humans is critically important for understanding the pathogenesis of developmental diaphragmatic disorders. Diaphragmatic pathology was systematically reviewed from autopsies performed at Childrens Hospital, Boston on 48 patients diagnosed with a diaphragmatic defect between1990-2006 and from 94 patients diagnosed with unrelated conditions. Among these recent autopsy cases (collected during a time period of aggressive therapy and improved outcomes), 58 defects were identified in 48 patients (10 cases had bilateral defects). Of these 58 defects, 24 were posterolateral,11 were diaphragms with complete hemi-aplasia or diffuse unilateral muscularization defects, 11 had primarily lateral defects, 5 had anterior defects, and 7 were not able to be classified to a precise location. Of the anterior defects, one fit the description of a Morgagni hernia, while the other 4 had phenotypes that have not been previously defined. In the 10 cases with bilateral defects, most had a different type of defect (hernia vs. muscularization defect without herniation) in each hemi-diaphragm, but these different phenotypes tended to occur symmetrically. There is significant variation among the congenital diaphragmatic defects presenting in the neonatal period. Many of these defects are lateral or anterolateral with preservation of the posterior muscular rim and do not fit the classic description or proposed mechanism of Bochdalek hernia. A more rigorous anatomic classification system is warranted so that we can better understand the developmental biology of these disorders. We suggest that a new anatomic classification system be established to prospectively evaluate these defects. This fist step would help achieve the ultimate goal of a classification based on embryonic and genetic mechanisms.

Association of systemic lupus and lupus glomerulonephritis and copy number variation in *FCGR3B*: a follow-up study. *M. Fanciulli, E. Petretto, P. Norsworthy, M.K. Kumaran, T. Cook, T. Vyse, T. Aitman* Physiological Genomics and Med, MRC Clinical Sciences Centre , London, United Kingdom.

Systemic lupus erythematosus (SLE) is a chronic multi-system disease with an autoimmune aetiology. Clinical manifestations of SLE include glomerulonephritis, dermatitis, thrombosis, arthritis and CNS involvement. We recently reported an association between *FCGR3B* copy number variation (CNV) and glomerulonephritis in SLE in a small sample of UK nuclear families. *FCGR3B* is one of a number of immunoglobulin G Fc receptors with a key role in the initiation and regulation of the immune response. SNP variants in *FCGR3B* have previously been associated with numerous autoimmune and infectious diseases. Here, we investigated the association of CNV in *FCGR3B* with glomerulonephritis and SLE in a larger and separate sample including 375 SLE cases, 161 SLE patients with glomerulonephritis and 312 non-family controls from the UK 1958 birth cohort. Copy number was estimated by quantitative real-time q-PCR with SYBR Green. Association analyses were carried out by Mann-Whitney and Chi-square tests. Risk estimates were made using multivariate logistic regression models. We confirmed and strengthened our previous association between glomerulonephritis in SLE and CNV at *FCGR3B* (Mann-Whitney U-test P= $1.4*10^{-8}$, Pearson Chi-Square P= $6.2*10^{-7}$). Furthermore, we found that low copy number at *FCGR3B* is independently associated with SLE (Mann-Whitney U-test P= $1.4*10^{-5}$, Pearson Chi-Square P= $1.4*10^{-5}$). Odds Ratios indicated an increased risk for development of both SLE (OR=2.21, 95% CI 1.43-3.40, P=$3*10^{-4}$) and glomerulonephritis (OR= 2.43, 95% CI 1.47-4.03, P=$5*10^{-4}$). However, no significant increased risk of acquiring glomerulonephritis was observed in SLE subjects who possessed low copy number at *FCGR3B*. These data strongly suggest that *FCGR3B* is a susceptibility gene for both SLE and glomerulonephritis, and highlight implication of CNV in the genetics of complex traits.

Hemangioblastoma as a part of Tenascin-X deficiency spectrum. *P. Blanchet[1], C. Coubes[1], J. Puechberty[1], L. Pinson[1], J. Schalkwijk[2], G. Lefort[1], P. Sarda[1]* 1) Medical Genetics Center, Arnaud de Villeneuve Hosp, Montpellier, France; 2) Dept of Skin Biology and Experimental Dermatology, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands.

Tenascin-X deficiency leads to an autosomal recessive form of Ehlers-Danlos (ED) syndrome, a connective tissue disorder characterized by hyperextensible skin, hypermobile joints, and tissue fragility. The phenotype of patients with tenascin-X deficiency includes skin hyperextensibility, easy bruising, and joint laxity but in contrast to classic ED, patients have soft skin, no atrophic scarring and no poor wound healing. Also, particular medical problems occur in these patients : diverticular intestinal disease, rectal prolapse, mitral valve prolapse and obstructive airway disease. In a family of 9 sibs, 2 brothers and one sister presented ED syndrome with an autosomal recessive inheritance and typical findings of Tenascin-X deficiency. This diagnosis was confirmed in the serum with a complete deficiency for Tenascin-X protein as determined by ELISA. At the age 44, a brother with Tenascin-X deficiency presented neurological problems due to cervical spine hemangioblastoma. After surgery, diagnosis of hemangioblastoma was confirmed by histology. Tenascins are a family of extracellular matrix glycoproteins. In mouse models, data suggest the role of TNX in the regulation of vasculogenesis and angiogenesis, with an important role in the control of endothelial cell proliferation. Tenascin-C, the most well-known member of this family, is expressed in various tumors including human astrocytomas, carcinomas and gliomas. Tenascin-X is also expressed in glioma cell lines and human astrocytomas but expression is mainly localized in the perivascular stroma around tumor vessels. These findings indicate that Tenascins could be involved in tumoral neovascularization. Considering the observation of hemangioblastoma in our patient and the data on the implication of Tenascin-X in vasculogenesis and angiogenesis, we suggest that hemangioblastoma be included in the spectrum of Tenascin-X deficiency.

Mutational analysis of the presenilin 2 gene in a group of Italian patients with familial Alzheimer's disease. *V. Andreoli, M. Liguori, F. Trecroci, A. La Russa, R. Cittadella* Institute of Neurological Sciences, National Research Council, Piano Lago di Mangone, Cosenza; Italy.

Alzheimer's disease (AD) is a genetically heterogeneous condition characterized by an early onset (EOAD) and a late onset (LOAD). Family history of dementia is the second major risk factor for AD after age and it has been proposed that several genetic determinants influence the development of the pathology. To date, three genes have been implicated: the amyloid precursor protein gene (APP) and the presenilin (PSEN) 1-2 genes. Mutations in these genes cause autosomal dominant familial AD (FAD). At present only eleven mutations have been described in the PSEN2 gene. We initiated the present study in order to identify mutations in the PSEN2 gene in 25 patients with early and late FAD, to determine whether these mutations were present in this group. We did not find pathogenic mutations in the PSEN2 gene but we found a novel and rare single-nucleotide polymorphism (SNPs) in the PSEN2 gene in a patient having familial early-onset AD, consisting of a heterozygous G->A substitution on exon 6. This variation in the coding region results in a Met to Val substitution in the first position of the codon 174 within the predicted transmembrane 3 (TM3) domain of the PSEN2 protein. The patient was a 51-year-old woman suffering from dementia; she presented a 6-year history of mild memory deficit with problems in spatial orientation and word finding difficulty. We have therefore analyzed TM3 domain in a group of age-matched healthy controls and this change was also detected in one of 125 unrelated individuals tested, suggesting that it was a non-pathogenic SNPs. The M174V change reported herein has a very low frequency compared with other reported polymorphisms, since it was detected in only two of the 150 individuals studied (1/125 healthy controls and 1/25 AD patients). On the other hand, the lack of PS2 mutations in the analyzed subjects confirms their rare occurrence in patients with familial AD. The uncommon SNPs should be always taken into account in the genetic testing of AD, because it may have important implications as genetic marker in FAD.

Type 2 diabetes *TCF7L2* risk alleles reduce beta-cell function and increase birth weight. *R.M. Freathy[1], M.N. Weedon[1], M.I. McCarthy[2], M. Walker[3], G.A. Hitman[4], Y. Ben-Shlomo[5], G. Davey Smith[5], S.M. Ring[5], A.T. Hattersley[1], T.M. Frayling[1]* 1) Peninsula Medical School, Exeter, UK; 2) Oxford, UK; 3) Newcastle, UK; 4) London, UK; 5) Bristol, UK.

The transcription factor *TCF7L2* is the most important type 2 diabetes gene found to date. Heterozygotes and minor allele homozygotes for rs12255372, which constitute 41% and 9% of the population, have odds ratios for type 2 diabetes of 1.30 and 1.66 respectively, and this association has been replicated in multiple studies. The mechanism by which variation in *TCF7L2* predisposes to diabetes is unknown. Identifying intermediate traits in the non-diabetic population will help define the mechanism of action but is notoriously difficult. We studied the role of common variation in the *TCF7L2* gene in diabetes-related intermediate traits in the general population. We assessed the role of *TCF7L2* in beta-cell function using 1053 non-diabetic subjects from two studies (Barry Caerphilly Growth Study, n=631, mean age 25; Warren 2 Extension, n=422, mean age 39) with oral glucose tolerance test data available, and in birth weight using 7211 children and 6573 mothers from the ALSPAC study. All subjects were UK whites. Each copy of the type 2 diabetes predisposing allele of rs12255372 (frequency 0.29) decreased beta-cell function (early insulin response) by 0.15 (0.06-0.24) SD (P=0.001). Each copy of the diabetes risk allele in the fetus was associated with a 21g (3g-40g) increase in birth weight (ANOVA P=0.004), while each copy of the diabetes risk allele in the mother was associated with a 32g (12g-52g) increase in offspring birth weight (ANOVA P=0.0006). There was no association with fasting glucose, insulin or BMI (all P>0.05). Our results suggest that prior to the development of type 2 diabetes, common variation in *TCF7L2* is associated with reduced beta-cell function and increased birth weight. Our results indicate that with large sample sizes it is possible to identify subtle effects of established disease risk alleles in the general population.

Analysis of P2RY12 gene H2 haplotype in coronary artery disease and myocardial infarction. *U. Cavallari[1], E. Trabetti[1], M. Biscuola[1], G. Malerba[1], D. Girelli[2], O. Olivieri[2], N. Martinelli[2], R. Corrocher[2], P.F. Pignatti[1]* 1) Department of Mother-Child & Biol-Genetics, Univ Verona, Verona, Italy; 2) Department of Clinical and Experimental Medicine, University of Verona, Verona, Italy.

BACKGROUND: Platelet activation and aggregation are key elements in coronary atherosclerosis. Platelet receptor P2Y12 stimulated by adenosin diphopsaphate (ADP) modulates affinity of glycoprotein IIb/IIIa for fibrinogen, resulting in fibrinogen binding and platelet aggregation. A haplotype of the P2RY12 gene (H2 haplotype) was found to be associated with maximal aggregation response to ADP in the general population and to increase risk of peripheral arterial disease (Fontana P. et al. Circulation 2003;108:2971-2973). Aim of this study was to test the association of the H2 haplotype with coronary atherosclerosis and myocardial infarction. METHODS AND RESULTS: We studied 1422 unrelated consecutive Italian patients of both sexes. They were diagnosed by coronary angiography as affected by coronary artery disease (CAD or cases, n=1033) or not (CAD-free controls, n=389). In the CAD group 616 patients had a history of myocardial infarction (MI). All patients were genotyped for the H1/H2 haplotype tag SNP of the P2RY12 gene by melting curve analysis of fluorescent real time PCR. We observed a significant difference in genotype distribution between CAD and CAD-free groups (p=0.024). H2 haplotype carriers were more frequent in the CAD group than in the CAD-free group (p=0.041, OR=1.35, CI=1.00-1.83). No significant difference in H2 haplotype frequency was observed between MI and MI-free groups within CAD population. CONCLUSIONS: These results suggest an association of the H2 haplotype of the P2RY12 gene with coronary artery disease. No significant association was observed between the H2 haplotype and history of myocardial infarction in the studied population.

Lysosomal stabilization of -glucocerebrosidase and -galactosidase-A by competitive inhibitors: Implications for chaperone therapy. *T. Edmunds, J. Jaworski, Q. Zhou, A. Park, D. Honey, S. VanPatten* Therapeutic Protein Research, Genzyme Corp, Framingham, MA.

Gaucher disease and Fabry disease are caused by mutations in the genes encoding the lysosomal enzymes -glucocerebrosidase (GC) and -galactosidase-A (Agal), respectively. The standard of care is enzyme replacement therapy with recombinant GC or Agal. Recently, a therapeutic strategy has been postulated in which competitive inhibitors chaperone the trafficking of misfolded enzymes from the endoplasmic reticulum (ER) to the lysosome. Since competitive inhibitors are more likely to bind enzymes in the lysosome than in the ER, it is essential to distinguish between their effect on transport to the lysosome and effects within the lysosome. To do this we evaluated their effect on recombinant enzymes delivered directly to the lysosome. Macrophages were incubated with recombinant GC (rGC) in the presence and absence of derivatives of the competitive inhibitor deoxynojirimycin. Uptake of rGC into macrophages does not involve trafficking from the ER, but occurs via receptor-mediated enzyme delivery to the lysosome. In the absence of competitive inhibitors the lysosomal half-life of rGC was ~15 hours. In the presence of competitive inhibitors the lysosomal half-life of rGC was extended up to 3-fold. rGC containing the N370S mutation was also stabilized within the lysosome, but the concentrations of competitive inhibitor required were 10-fold higher than those required to stabilize wild-type rGC. Similar results were obtained with fibroblasts incubated in the presence of recombinant Agal and the competitive inhibitor deoxygalactonojirimycin. These results suggest that the increased level of normal and mutant enzymes observed in the presence of competitive inhibitors is due to decreased lysosomal degradation, rather than increased transport from the ER to the lysosome. Although enzyme levels are elevated in the lysosome, the enzyme will be non-functional since the stabilization is dependent on the binding of the competitive inhibitor to the enzyme. Thus the increased enzyme level seen in the presence of competitive inhibitors is unlikely to provide any therapeutic benefit.

Hominoid lineage specific evolution of low-copy repeats on 22q11.2 (LCR22s) provides mechanisms for genome plasticity. *M. Babcock[1], S. Yatsenko[2], J. Hopkins[3], M. Brenton[3], Q. Cao[4], P. de Jong[4], P. Stankiewicz[2], J.R. Lupski[2], J.M. Sikela[3], B.E. Morrow[1]* 1) Department of Molecular Genetics, Albert Einstein College of Medicine, Bronx, NY; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Pharmacology and Human Medical Genetics Program, University of Colorado Health Sciences Center, Denver, CO; 4) Children's Hospital of Oakland Research Institute, Oakland, CA.

Low-copy repeats (LCRs) or segmental duplications, constitute roughly 5 percent of the human genome and are associated with many human congenital anomaly disorders. The LCRs on chromosome 22q11.2 (LCR22s) mediate chromosomal rearrangements leading to deletions, duplications, and translocations. Four genes, *USP18*, *BCR*, *GGTLA* and *GGT*, map adjacent to the LCR22s and pseudogene copies are located within them. We hypothesize that gene duplication occurred during primate evolution, followed by recombination events, forming pseudogene copies. To test whether gene duplication could be detected in non-human hominoid species, FISH mapping was performed using probes to the four functional gene loci, avoiding LCR22 sequences. A single copy of each was present in humans but one to five additional copies were found in hominoid species. We then compared LCR22 copy number and organization using LCR22 specific FISH probes. Lineage specific LCR22 variation in structure and copy number was detected all hominoid species examined (chimpanzee, bonobo, gorilla, orangutan, gibbon). To independently validate and extend initial findings, array comparative genome hybridization, real time PCR, and physical mapping was performed. The most striking discovery was a dramatic amplification of LCR22 copies in gorilla. Interestingly, they localized to the telomeric bands of many gorilla chromosomes. The most parsimonious explanation is that the LCR22s became amplified by inter-chromosomal recombination between chromosome termini. In summary, our results are consistent with a lineage specific coupling between gene and LCR22 duplication events. This underscores the instability and dynamic nature of LCRs in the genome and provides a model to study genome evolution and variation.

Homozygous silencing of the TBR2 locus by position effect results in severe neuronal proliferation defect and corpus callosum agenesis. *L. Baala[1,2], S. Briault[3], A. Assermouh[4], F. Laumonnier[3], T. Attie-Bittach[1], F. Encha-Razavi[1], M. Clément-Ziza[1], S. Romana[1], J. Amiel[1], G. Goudefroye[1], A. Sbiti[2], H. Natiq[2], A. Munnich[1], A. Sefiani[2], S. Lyonnet[1]* 1) Génétique INSERM U781, Necker Hospital, Paris 15, France; 2) INH,Rabat, Morocco; 3) INSERM U619, Université Rabelais, Tours, France; 4) Hôpital d'Enfants, Rabat, Morocco.

In accordance with the importance of the regulation of cell division during neuronal proliferation, all genes known to be mutated in human primary microcephaly so far, encode proteins involved in mitosis and, mostly, centrosome formation. We report an autosomal recessive primary microcephaly syndrome co-segregating with a balanced translocation between chromosomes 3p and 10q in a large inbred family. The translocation was found at the homozygous status in all affected individuals (46,XY,t(3;10)(p24;q23)2x), while unaffected parents were heterozygous. Accordingly, homozygosity linkage analysis between the disease trait and polymorphic markers of chromosomes 3p and 10q defined 2 homozygous regions of 27 and 11.4 Mb respectively. We established a physical and characterized the BACs that encompassed the breakpoints on 3p24 and 10q23 (BAC RP11-9a14 and RP11-104H24). Interestingly, neither of the two translocation breakpoints disrupted a known or predicted gene coding sequence. However, we showed that position effect at the breakpoint on chromosome 3, located 200 kb upstream, silences the TBR2 locus with monoallelic expression in heterozygous parents. These data support the involvement of TBR2, a transcription factor of the T-box family, in neuronal proliferation and in the severe syndromic microcephaly observed in this family, in agreement with our data on its expression pattern in early developing human telencephalon. Our findings provide evidence that not only mitotic and apoptotic proteins but transcription factor mutation also, may be responsible for severe proliferation defect of the human brain.

Phelan-McDermid Syndrome: Deletion 22q13 characterized by comparative genomic hybridization microarray analysis and FISH with locus specific probes. *P.I. Bader[1], S.C. Newman[1], F.J. Bader[1], S.-H.L. Kang[2], S.W. Cheung[2]*
1) Northeast Indiana Genetic Counseling Center, Parkview Hospital, Fort Wayne, IN; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Phelan-McDermid Syndrome (PMS) is characterized by normal to increased growth, severe mental retardation (MR), severe speech deficiency, hypotonia, mouthing/chewing objects, dolicocephaly, prominent/dysplastic external ears, pointed chin, large and fleshy hands, and dysplastic toenails. PMS is caused by deletion 22q13. SHANK3 or PROSAP2 (Proline-rich synapse associated protein 2) which codes for a structural protein found in the postsynaptic density is deleted, and this may lead to neurological abnormality in PMS. We report a 29-year-old female with MR, little speech, autistic features, seizures, keloid formation, hypotelorism, long lashes, inner epicanthal folds, abnormal philtrum without markings, high palate, prominent nose, ears with prominent anthelix, fleshy and large hands, low-set and broad thumbs, clinodactyly of 5th fingers, variant palmar creases including extra creases on thenar and antithenar eminences, edematous feet with dysplastic toenails, cutis marmarata, hirsuitism, hyperextensible joints, poor balance. Height, weight, and OFC were at the 50%ile. Evaluations and chromosome analysis at (IU medical center) at age 1 and 22 resulted in no diagnosis for a specific genetic syndrome. Head MRI was normal. Re-evaluation by FISH analysis for DiGeorge syndrome showed absent control signal at band 22q13.

Chromosomal microarray analysis designed to interrogate clinically relevant genomic regions revealed haploinsuffiency at 22q13.3 with the following clones: RP11-93F4, RP11-66M5, RP5-92517, RP3-402G11, RP11-164E23, GS-99K24 encompassing approximately 5 Mb of the subtelomeric region. This deletion was subsequently confirmed by high resolution banding showing a subtle deletion at band 22q13.3. Although PMS is believed to be caused by deletion of SHANK3/PROSAP2, haploinsuffiency for other contiguous candidate genes in the area may explain the variation seen in the syndrome and could lead to determination of a critical region of deletion overlap.

Detection of an interstitial deletion of 3q21 by Comparative genomic hybridization in a child with multiple congenital abnormalities and pancytopenia with myelodysplasia. *P. Callier, M. Nathalie, J. Guy, C. Thauvin-Robinet, AL. Mosca, F. Huet, L. Faivre, F. Mugneret* Cytogenetics Laboratory, CHU Le Bocage, Dijon, France.

Comparative genomic hybridization (CGH) is a rapid molecular cytogenetic technique, which can detect chromosomal abnormalities in the range of 3-20Mb. This method have been performed in 44 patients with multiple congenital abnormalities and mental retardation with normal standard, high resolution and subtelomeric FISH cytogenetic analyses. We present here the first child of healthy non-consanguineous parents presenting with features overlapping with Townes-Brocks and Baller-Gerold syndrome and an interstitial deletion 3q detected by CGH studies. She had a healthy sister. Examination at birth revealed a length of 43.5 cm, dysmorphism with cranial and facial asymmetry, unilateral right hypoplastic and low-set ear, left preauricular tags and duplication of the right thumb. A right coronal craniosynostosis was evidenced and surgically treated at 6 months of life. She also had posterior agenesis of the corpus callosum, persistent ductus arteriosus, unilateral deafness secondary to external ear canal stenosis and chronic constipation. Follow-up revealed severe mental retardation with hyperactivity and abnormal behaviour, precocious puberty at the age of 8 years with a height at -2SD and pancytopenia with myelodysplasy at the age of 11 years with normal chromosomal breakage studies. CGH revealed an interstitial deletion 3q21 and FISH study with BAC RP11-205A6 (3q21.2) confirmed the deletion. Molecular cytogenetics studies with BACs located in the 3q21 region are in progress to better define the size of the deletion. The clinical features did not overlap with the other rare cases with interstitial 3q deletion including the q21 band. This deletion does not comprise the Townes-Brocks and Baller-Gerold syndromes loci. This study demonstrates the importance of CGH technology to detect interstitial deletions. Interestingly, the RPN1 (Ribophorin 1) gene implicate in myelodysplasia is locate in the 3q21 region.

Familial amniotic band sequence with mutation of FOXC2 gene. *C. Coubes[1], P. Blanchet[1], J. Puechberty[1], L. Pinson[1], S. Jeffery[2], G. Lefort[1], P. Sarda[1]* 1) Dept of Medical Genetics, Arnaud de Villeneuve Hospital, Montpellier, Herault, France; 2) Medical Genetics Unit, St. George's Hospital Medical School. London United Kingdom.

Amniotic band sequence is a common anomaly with an incidence estimated between 1/1200 and 1/15000. It is considered to be an isolated and sporadic defect due to early rupture of the amnion. However, cases with additional anomalies such as cleft lip and palate, congenital heart defects or renal anomalies have been reported. Rarely, familial amniotic band sequence has been described, sometimes associated with connective tissue disorders such as Ehlers-Danlos syndrome type IV or osteogenesis imperfecta. We report a familial case of amniotic band sequence in a mother and her son. The two patients had digital amputations and constriction rings. The mother also presented microretrognathia, duplex kidney, bicornuate uterus, lymphedema and distichiasis. The boy, 12-year-old, had dysmorphic facial traits, bilateral rocker bottom feet, spinal arachnoid cyst and distichiasis. Mutation 1061ins GCCC in the FOXC2 gene was found in the two patients. FOXC2 is a transcription factor gene expressed in many embryonic tissues such as brain, kidney, cardiovascular and skeletal systems. To date, we have no data on the expression of FOXC2 in placenta and amnion. The observation of a family with cosegregation of amniotic band sequence and distichiasis-lymphedema syndome suggests that amniotic band sequence is probably a part of the large spectrum of syndromes due to mutations of the FOXC2 gene.

Epistatic Effects of Polymorphisms in Genes from the Renin-Angiotensin, Bradykinin, and Fibrinolytic Systems on Plasma t-PA and PAI-1 Levels. *F.W. Asselbergs[1], S.M. Williams[2], P.R. Hebert[3], C.S. Coffey[4], H.L. Hillege[1], G. Navis[1], D.E. Vaughan[2], W.H. van Gilst[1], J.H. Moore[5]* 1) University of Groningen, Groningen, Netherlands; 2) Vanderbilt University, Nashville, TN; 3) Yale University, New Haven, CT; 4) University of Alabama Birmingham, Birmingham, AL; 5) Dartmouth Medical School, Lebanon, NH.

Tissue plasminogen activator (t-PA) and plasminogen activator inhibitor 1 (PAI-1) directly influence thrombus formation and degradation and thereby risk for arterial thrombosis. Activation of the renin-angiotensin system has been linked to the production of PAI-1 expression via the angiotensin II type 1 receptor (AT1R). In addition, inhibition of the angiotensin converting enzyme (ACE) augments bradykinin that can induce the acute release of t-PA from the endothelium through a B2 receptor mechanism. In the present study, we investigated the epistatic or synergistic effects of polymorphisms in genes from the renin-angiotensin, bradykinin and fibrinolytic systems on plasma t-PA and PAI-1 levels. We used two-way ANOVA to model epistatis between polymorphisms in the *ACE*, *AT1R*, *bradykinin B2 receptor*, and *PAI-1* genes and their effects on plasma levels of t-PA and PAI-1 in a large population-based sample from the PREVEND study in Groningen, The Netherlands (n=2,527). After correction for multiple testing using a permutation distribution, we demonstrated strong interactions between *bradykinin B2* polymorphisms (p=0.002) and between *ACE* and *bradykinin B2* polymorphisms (p=0.003) that predict plasma t-PA levels in females. In males, polymorphisms in the *bradykinin B2* and *AT1R* genes showed the strongest interactive effects on t-PA levels (p=0.006). In both females and males, the *bradykinin B2* polymorphisms interacted with the *AT1R* polymorphism on plasma PAI-1 levels (p=0.026 and p=0.039, respectively). In addition, we found a borderline significant interaction between *PAI 4G5G* and *ACE I/D* on plasma t-PA and PAI-1 levels. These results support the idea that the relationship between the genome and t-PA and PAI-1 levels is complex involving synergistic interactions among genes from multiple biochemical systems.

Modeling of twin growth during gestation and quantification of the genetic and environmental factors involved.

M. Gielen[1,2], P.J. Lindsey[1,2], C. Derom[3], H.J.M. Smeets[1], R. Derom[3], J.G. Nijhuis[4] 1) Population Genetics, Genomics and Bioinformatics, Maastricht University, Maastricht, Netherlands; 2) NUTRIM, Maastricht University, Maastricht, the Netherlands; 3) Human Genetics, Faculty of Medicine, Catholic University of Leuven, Leuven, Belgium; 4) Obstetrics and Gynecology, University Hospital Maastricht, Maastricht, The Netherlands.

Structural equation modeling of birth weight has given inconsistent results with heritability estimates between 10 and 40%. One explanation could be that the heritability changes during gestational age or that different covariates explain different parts of the variance covariance structure. The aim of this study was to model prenatal growth as well as to quantify the genetic and environmental components to explain the effects of several covariates. Perinatal data were obtained from 4232 live-born twin pairs from the East Flanders Prospective Twin Survey, Belgium. Heritability of birth weights at different gestational ages was estimated using a non-linear multivariate Gaussian regression with covariates in the mean model as well as in the variance and the covariance components. Following covariates were considered: gestational age, sex, chorionicity, placental type, insertion of the umbilical cord, birth order, the origin of the pregnancy (spontaneous, in-vitro-fertilization, induction of ovulation), maternal age, parity, and neonatal death. During gestation, heritability dropped from 37% at 25 weeks to 14% at 42 weeks. After adjusting for covariates the heritability increased: from 58% at 25 weeks to 26% at 42 weeks. The origin of the pregnancy did not contribute to the model. Chorionicity explained part of prenatal growth but had almost no influence on the covariance structure. All other covariates influenced the genetic and environmental components of the covariance structure in different ways. For complex traits such as growth, it is important to explain a large part of the variance and covariance, as it will help to find genes in linkage and association studies. Thus, explaining (birth) weight by modeling the genetic and environmental factors gives a better inside in factors influencing growth during gestation.

Expression profile study of atherosclerosis: microarray analysis in human coronaries with atheromas. *M. Biscuola[1], S. Cagnin[2], C. Patuzzo[1], E. Trabetti[1], M. Iafrancesco[3], A. Forni[3], G. Faggian[3], A. Mazzucco[3], G. Lanfranchi[2], P.F. Pignatti[1]* 1) Department of Mother & Child & Biol-Genetics, University of Verona, Verona, Verona, Italy; 2) CRIBI Biotechnology Centre and Department of Biology, University of Padova, Italy; 3) Division of Cardiac Surgery, University of Verona Medical School, Italy.

Atherosclerosis is a progressive disease characterized by the accumulation of lipids and fibrous elements in the large arteries and it constitutes the single most important cause of cardiovascular disease. Genetic susceptibility, mechanical shear stress, diet and smoke have been involved in the pathogenesis of atherosclerosis but the causal mechanisms are not yet understood. Changes in the expression levels of several genes have been described in animal models. Segments of Left Anterior Descending (LAD) coronary artery were obtained from a total of 13 patients undergoing graft surgery. Coronarography was used to classify individuals into occluded or not. 3 patients with acute myocardial infarction with atherosclerosis were cases. 10 patients presenting with dilatative cardiomyopathy and no atheromas were controls. We performed a preliminary study using the RNA extracted from all the samples. RNA obtained from 6 of the 10 controls was used to create a control pool and this pool was compared with 2 of the 3 cases. Using an oligo DNA microarray carrying 22.000 human genes we looked at differential gene expression profiles. Data were analyzed with a modified t-test using the SAM program (Significance Analysis of Microarrays). We found 6 classes of genes differentially expressed in both cases. They represent genes involved in the pathway for the eicosanoid synthesis, complement and coagulation cascades, response to wounding, innate immunological response, actin binding and cytoskeleton activities, blood and lymph tissue proliferation. After an extension of the number of samples analyzed by microarray, we will perform qRT-PCR in order to confirm the suggested results.

Autosomal dominant early onset Alzheimer disease with cerebral amyloid angiopathy caused by *APP* duplication: clinical and neuropathological study of five French families. *L. Guyant-Maréchal[1,2], L. Cabrejo[1], A. Laquerrière[1], M. Vercelletto[3], F. De La Fournière[4], C. Thomas-Antérion[5], C. Verny[6], F. Letournel[7], F. Pasquier[8], A. Vital[9], F. Checler[10], T. Frebourg[1,2], C. Campion[2], D. Hannequin[1,2]* 1) Departments of Neurology, Genetics, and Neuropathology, University Hospital, Rouen, France; 2) Inserm U614, Faculty of Medicine, Rouen, France; 3) Department of Neurology, University Hospital, Nantes, France; 4) Department of Geriatrics, Pau Hospital France; 5) Department of Neurology, University Hospital, Saint-Etienne, France; 6) Department of Neurology, University Hospital, Angers, France; 7) Laboratory of Cellular Biology, University Hospital, Angers, France; 8) Department of Neurology, University Hospital, Lille, France; 9) Department of Pathology, University Hospital, Bordeaux, France; 10) Institute of Molecular and Cellular Pharmacology, UMR6097 CNRS/UNSA, Valbonne, France.

We recently reported (Rovelet-Lecrux et al. Nature Genetics 2006, 38: 24-26), in 5 French families with autosomal dominant early-onset Alzheimer disease (ADEOAD) and cerebral amyloid angiopathy (CAA), the duplication of the *APP* locus located on chromosome 21, the duplication ranging from 0.58 to 6.37 Mb. The present study describes the phenotype of this new entity. The phenotype was not dependent on the size of the duplication and, remarkably, there was no clinical feature of Down's syndrome (DS). Dementia was observed in all cases (age of onset (AOO): 42-59 years), intracerebral haemorrhage (ICH) was reported in 6 (26 %; AOO: 53-64 years) and seizures occurred in 12 (57%)among 21 affected patients. Neuropathological examination in 5 cases demonstrated AD and severe CAA lesions which were reminiscent from those reported in brains of DS patients. A striking feature consisted in intraneuronal Ax-40 accumulation located in the granular cell layer of the dentate gyrus and in the pyramidal cell layer of the Ammon's horn. It could be speculated that both an overproduction of the A peptide and a possible shift toward a high A40/A42 ratio account for the pathological hallmarks of the disease.

Rare cases from a large sample of Rett syndrome patients, including a MECP2 mutated male and a female with a novel CDKL5 mutation. *F. Cogliati[1], M. Masciadri[1], I. Moroni[2], M. Marchi[1], P. Vigliano[3], R. Gaggero[4], MT. Bonati[1], L. Larizza[5], S. Russo[1]* 1) Ist.Auxologico Italiano,Milano, Italy; 2) Ist.Neurologico C.Besta,Milano,Italy; 3) NPI ASL2,Torino,Italy; 4) Ist.G.Gaslini,Genova,Italy; 5) Polo S.Paolo,Milano University,Italy.

Classical RTT syndrome is a neurodevelopmental disorder predominantly affecting young females which causes retardation with loss in motor and vocal skills and additional problems such as microcephaly,ataxia,growth retardation and scoliosis. 95% percent of classical RTT and 40-50% of atypical cases have been attributed to mutations in the gene coding for methyl CpG binding protein,MECP2.Occurrence of males affected by severe encephalopathy and Rett-like phenotype with mutation in MECP2 is very rare.Recently, mutations in cyclin-dependent kinase-like 5,CDKL5,have been described in atypical variants of RTT including early onset of epileptic seizures and infantile spasms.We addressed the molecular characterization of MECP2 mutations in both the alfa and beta isoforms on over200 females and 30 males,identifying mutations in the isoform MECP2e2 in 42 classical and in 19 atypical RTT girls. Mutational screening of MECP2e1 evidenced the A2V substitution in a girl with Rett classical phenotype not found in her parents and in over100 controls. As regards the males cohort we could identify a maternally inherited C-terminal deletion,1163del44,in a boy affected with severe encephalopaty and early onset of epilepsy. X inactivation test disclosed maternal skewed inactivation. This MECP2 mutated male patient is a tool to investigate MECP2 interactors and underlines the occurrence of maternal transmission of non expressed mutations and their impact on genetic counseling.We also investigated for CDKL5 mutations a cohort of 15 atypical RTT patients selected for the early onset of seizures or infantile spasms and identified a novel IVS4+2 T-C splice mutation.The girl presented with early onset focal seizures and infantile spasms evolved in daily mioclonic seizures.Based on our results we recommend to investigate both MECP2 and CDKL5 genes when there is a suspicious of Rett syndrome and to test males with specific clinical traits.

The G397A (E133K) change in the AGGF1 (VG5Q) gene is a single nucleotide polymorphism in the normal population and not a predisposing mutation for Klippel-Trenaunay syndrome. *S. Gutiérrez[1], L. Magano[1], A. Delicado[1], M.A. Mori[1], M.L. de Torres[1], I. Vallcorba[1], L. Fernández[1], M. Palomares[1], E. Fernández[2], G. Rodriguez Tarduchy[2], J. Molano[1], I. López Pajares[1], P. Lapunzina[1]* 1) Medical and Molecular Genetics, Hospital Universitario La Paz, Madrid, Madrid, Spain; 2) Sequencing Unit, IIB, Madrid, Spain.

Introduction: Klippel-Trenaunay syndrome (KTS) is an unusual, asymmetric overgrowth syndrome (OGS) characterized by vascular malformations and partial overgrowth of the affected region of the body, usually the lower limb. It was recently suggested that the E113K change in the VG5Q (*AGGF1*) gene causes susceptibility to KTS (Nature 2004;427:640-5). In that paper, the authors suggested that this change was responsible of such susceptibility after finding 5 out of 130 KTS patients with heterozygosis for the E113K. **Methods**: We genotyped 768 control DNA samples and 387 DNA samples of patients and/or parents of patients with overgrowth syndromes (OGS): 63 patients and 53 parents with Beckwith Wiedemann syndrome, 97 patients and 130 parents with Sotos, 18 with Simpson-Golabi Behmel, 10 patients and 13 parents with Macrocephaly-Cutis Marmorata telangienctatica and 3 patients with KTS. Genotyping was performed using TaqMan Genotyping Assays (C_25615428_10, Applied Biosystems). **Results**: On 768 normal, age-matched control samples we found that 23 individuals were heterozygous for the E133K change (3 %). In patients with OGS and their relatives, only 3 were heterozygous, 1 Simpson-Golabi-Behmel syndrome and 2 parents of patients with OGS (1 with Sotos syndrome and 1 with Beckwith Wiedemann syndrome). **Conclusions**: the E133K (G397A) change of the *VG5Q* (*AGGF1*) gene seems to be a polymorphism rather than a true predisposing mutation since, similarly to the frequency observed in KTS patients,around 3 % of controls were heterozygous for such a change. The E133K change should not be related to susceptibility to KTS or any other OGS and should be assumed as a normal, infrequent SNP instead.

.

Identification of a Telencephalon preferentially expressed new MicroRNA, exploring its roles in Neurodevelopmental Processes. *P. Carotenuto, L. Garzia, A.M. Bello, V. Maffia, G. Vitale, M. Zollo* Biotecnologie Avanzate SCARL, CEINGE, Naples, Italy.

We have recently isolated 48 new microRNA precursors preferentially expressed in murine telencephalon at embryonic days E14.5 (Zollo et al. 2005). Within this collection a novel microRNA (6.A7), was characterized and found involved in differentiation and apoptosis processes of human neuroblastoma SH-SY5Y cells line, thus regulating the expression of target genes including IAP genes (BIRC1, BIRC4, BIRC5), and Delta/Notch EGF receptor (DNER) pathway related genes. We will present its functional correlation to neurodevelopmental processes such as neural differentiation and apoptosis, being potential a new controlling gene involved in human neurodevelopmental disorders.

Four Different ABCA4 Mutations in a Large Family, With Several Loops of Consanguinity, Affected With Autosomal Recessive Cone-Rod Dystrophy : Further Evidence for a High Frequency of ABCA4 Heterozygote Carriers. *D. Ducroq[1], S. Shalev[2], A. Habib[2], A. Blumenfeld[3], A. Munnich[1], J. Kaplan[1], J.M. Rozet[1]* 1) INSERM U781, Hopital des Enfants Malades, Paris, France; 2) Genetics, Institute of Ha'Emek Medical center, Afula, Israel; 3) Genetic Testing Laboratory, Department of Ophthalmology, Hadassah University Hospital, Israel.

This study aimed to identify the molecular defect responsible for autosomal recessive cone-rod dystrophy segregating in a large multiplex and consanguineous family of Christian-Arab ancestry. This pedigree was made of seven nuclear families gathering 12 affected members and seven healthy relatives. All family members underwent general and ophthalmologic examinations. Among affected patients, 9/12 displayed typical signs of cone-rod dystrophy, 1/10 was affected with a typical Stargardt disease. In 2/10 affected patients the exact diagnosis could not be definitely carried with regard to their young age. Linkage analyses were performed in this pedigree using polymorphic markers flanking each of the three hitherto known arCRD loci: CORD3, CORD8 and CORD9, respectively. Subsequently, all 50 exons of the ABCA4 gene at the CORD3 locus were screened for mutations by direct sequencing. Linkage analyses failed to identify homozygosity in the seven nuclear families of this large pedigree at any of three arCORD loci. However, homozygosity was found at the CORD3 locus for three nuclear families and the segregation of four distinct haplotypes at this locus in the whole pedigree suggested the alteration of the ABCA4 gene. This hypothesis was confirmed by the identification of four distinct mutations leading to cone-rod dystrophy in all patients but one. This last patient, suspected to have the same disease as her relatives, displayed in fact typical sypmptoms of Stargardt disease without extension to the peripheral retina. In conclusion, the results of this study emphasize the trap of the search for homozygosity in patients belonging to highly inbred families when the heterozygote carrier frequency is much higher than the mean frequency of heterozygote individuals in the general population.

Lysinuric protein intolerance is present world-wide and is not a rare disorder. *S. Fecarotta, M.P. Sperandeo, P. Annunziata, P. Piccolo, A. Pepe, G. Andria, G. Sebastio* Department of Pediatrics, Federico II University, Naples, Italy.

Lysinuric protein intolerance (LPI; [MIM 222700]) is caused by mutations of the SLC7A7 gene, encoding the light chain of the cationic amino acid transporter 4F2hc/y+LAT-1. LPI was described in Finland where its frequency was estimated at 1:60,000. LPI was considered a rare disease in other countries, apart from Italy and Japan, where small clusters where identified. LPI patients are usually asymptomatic when breast-fed whereas, after weaning, they present vomiting, diarrhea, growth retardation, hepatosplenomegaly, osteoporosis, episodes of coma, lung and renal involvement. A total of 35 mutations of the SLC7A7 gene were identified by three research groups (Italian, Spanish-Finnish, and Japanese) in 115 LPI patients from all continents. Except for the IVS6-2AT mutation, found in all the Finnish patients, only 5 mutant alleles (1670insATCA, 1471delTTCT, W242X, R410X and IVS4+1GA) were found in more than a single LPI family. Private mutations account for most of the mutant alleles of non-Finnish origin. This mutational heterogeneity reaches the highest level in Italy where 10 different mutant alleles were identified in 17 LPI independent families from Southern Italy. This suggests that LPI is present worldwide and that the relatively higher frequency in Finland is due to a founder effect. The diagnosis of LPI is difficult and it is likely that the disease has been under-recognized in countries other than Finland. Clinical data from LPI patients of non-Finnish origin (18 different countries) underline the wide clinical variability in LPI and the lack of specificity of the clinical presentation. In addition, diagnostic laboratory tools rarely provide an unequivocal LPI diagnosis. As a consequence, most of patients receive misdiagnoses such as celiac disease, hemophagocytic histiocytosis, myopathy, infectious diseases and various metabolic disoders. We propose a diagnostic work-up as a rapid diagnosis of LPI is necessary to avoid hyperammonemic crisis by appropriate therapy. In addition, a well designed follow-up is requested to monitor life-threatening complications.

Usher Syndrome Type 1a: From Myth to Reality. *S. Gerber[1], D. Bonneau[2], A. Munnich[1], J.L. Dufier[3], J.M. Rozet[1], J. Kaplan[1]* 1) INSERM U781, Hopital Necker-Enfants Malades, Paris, France; 2) Service de Genetique Medicale, CHU d'Angers, France; 3) Service d'Opthalmologie, Hopital Necker-Enfants Malades, Paris, France.

The purpose of the present study was to check the reality of the "French variety" of Usher Type 1A, thirteen years after its report, in light of unexpected data that occured since then. The USH1A locus was described in 1992 in eight families originating from the small area of the Poitou-Charentes region around the town of Bressuire in France. Subsequently, an enlarged panel USH1 families was considered including the eight original USH1A families and two additonnal ones hailing from Bressuire. Surprisingly, one of these two additional families appeared unlinked to the USH1A locus on 14q32.1. Besides, an additional affected individual in one of the original USH1A families turned to be haplodifferent to his affected sibs at this locus. Therefore we decided to screen for mutations the major USH1 gene, the myosin VIIA in one affected individual of each family using direct sequencing. Among the 10 families originating from Bressuire, 7/10 harboured mutations in the myosin VIIA gene, 1/10 was compatible with the USH1D and USH1E loci, 1/10 excluded all seven hitherto identified USH1 loci. No DNA was available for further linkage studies in the last family. In conclusion, the recent study of additonal families affected with Usher syndrome type 1 originating from Poitou-charentes clearly showed that i)the USH1A locus does not exist; ii) the myosin VIIA gene is the major USH1 gene and finally iii) that, in our series, one family excluded all USH1 loci suggesting that at least one additional gene should be identified.

Traumatic Brain Injury and APOE-e4 allele: cause or risk of Alzheimers Disease? *R. Cittadella[1], V. Andreoli[1], G. Bono[2], M. Mauri[2], E. Sinforiani[3], F. Boller[4], A. La Russa[1], I. Manna[1], E. Altomare[1], G. Nappi[3], A. Quattrone[5]* 1) Inst Neurological Sci, CNR, Cosenza, CS, Italy; 2) Department of Clinical Medicine, VA, Italy; 3) IRCSS C. Mondino,PV, Italy; 4) INSERM U549,Paris, France; 5) University of Magna Graecia,CZ,Italy.

The hypothesis, that traumatic brain injury (TBI) may influence the development of Alzheimers Disease (AD) in human subjects encouraged several research lines. The link between head injury and dementia/AD is controversial. Recent epidemiological studies have shown that head injury is a risk factor for the development of dementia/AD. The e4 allele of Apolipoprotein E and TBI are both risk factors for the development of AD. Several studies have found that individuals who sustained moderate to severe head injury are more likely to develop dementia and AD. These risk factors appear to act synergistically, in that individuals who are ApoE4+; are even more likely to develop dementia if they sustain TBI at some time in their life. For example, ApoE4-; individuals were 10 times more likely to develop AD after TBI than those who were ApoE4-, whereas ApoE4 in the absence of injury was associated with only twice the risk. We present the results of a cross-sectional and longitudinal study of the relationship between these factors in northern and southern Italy. The study included 337 consecutive patients with probable AD and 63 subjects with Mild Cognitive Impairment (MCI). Information concerning head injuries was collected by interview of multiple informants. Twenty-one patients with dementia and 9 with MCI were found to have a history of TBI with loss of consciousness. AD and MCI patients with TBI, compared with a control group matched by age, sex, education and degree of mental impairment, showed more marked depressive and behavioral disturbances (GDS and NPI $p<0.05$). Among the patients with TBI and cognitive impairment, a high frequency of e4 allele was detected. The higher frequency of TBI and e4 genotype among AD and MCI patients confirms the synergistic interaction of enviromental and genetic factors in the development of dementia. This study has been supported by grant Mini-San 2000 IRCSS-C. Mondino-Pavia.

Genetic characterization of a family with asymptomatic high serum gamma-glutamyltransferase (GGT) concentration. *A. De Grandi[1], B. Taibi[1], F. Marroni[1], I. Pichler[1], S. Pedrotti[1], C. Beu Volpato[1], P.P. Pramstaller[1, 2]* 1) Department of Genetic Medicine, EURAC Research, Bolzano, Italy; 2) Department of Neurology, General Regional Hospital, Bolzano, Italy.

GGT is one of the major enzymes involved in the metabolism of glutathione. In humans, hepatic GGT activity is elevated in some liver diseases and also in liver damage. Patients with cholestasis usually have increased serum GGT concentration, which may be due to certain enzyme-inducing drugs or alcohol abuse. This GGT involvement, in the presence of transition metals like iron, is demonstrated by the production of free radicals which cause oxidative stress. GGT is also independently associated with cardiovascular mortality. Its activity in serum is the sum of the activities of at least four heterogeneous isoenzymes. This study involves an Italian family, already described by Bibas et al. (1994), in which 7 members in 3 generations showed unexplained high (100-fold) elevation of serum GGT. There was no history of drug use, alcohol abuse, or any form of viral hepatitis, and all family members studied were healthy and had normal results on other liver function tests. Inheritance appeared to follow an autosomal dominant pattern. A whole genome wide scan analysis was performed and lead to a peak signal in the 22q11.1-q11.2 region. In this region all 7 individuals shared a common haplotype not present in other family members in a region known to have at least 4 genes in the GGT family. Analysis of the chr22 region identified large repeat sequences involving part of the GGT transcript region. The presence of low copy repeats (LCR22s) hindered the search for mutations in the GGT genes. Rearrangements in this region of chr22 were already reported in some rare genetic diseases like VCFS/DGS and cat-eye syndromes. Real time PCR experiments show the presence of a deletion in the GGT2 locus in the 7 individuals with the condition. Further studies to better understand the genomic organization and transcription regulation in this region on chr22 are in progress.

Simple F-ratio test reveals Gene-Gene Interactions in Case-Control Studies. *G. Chen, A. Yuan, J. Zhou, A. Adeyemo, C. Rotimi* Natl Human Genome Ctr, Howard Univ, Washington, DC.

To analysis the gene-gene interactions in human disease case-control studies, we propose a simple F-ratio non-parameter method to measure these interactions. In this three steps method, first we examine dependence of genes in cases and controls, respectively. Second, F-ratio test is used to evaluate the ratio of dependence in cases than controls. Final, False Discovery rate (FDR) to evaluate the multiple F-ratio tests. Comparing with logistical regression method, we show F-ratio test is an efficient approach to measuring gene-gene interactions.

Molecular diagnosis of hypertrophic cardiomyopathy with a high-throughput 12-gene DNA resequencing chip: the first 38 cases. *S. Fokstuen[1], R. Lyle[2], A. Munoz[2], C. Gehrig[2], R. Lerch[3], M. Beghetti[4], A. Perrot[5], K.J. Osterziel[5], F. Mach[3], J. Sztajzel[3], S.E. Antonarakis[1,2], U. Sigwart[3], J.L. Blouin[1]* 1) Medical Genetics, Univ. Hospitals of Geneva, Switzerland; 2) Genetic Medicine and Development, Univ. of Geneva School of Medicine, Switzerland; 3) Cardiology, Univ. Hospitals of Geneva, Switzerland; 4) Pediatric Cardiology, Univ. Hospitals of Geneva, Switzerland; 5) Charité-Universitaetsmedizin Berlin, Germany.

Hypertrophic cardiomyopathy (HCM) is a primary autosomal dominant disorder of the myocardium with a prevalence of 1/500 showing a wide range of clinical features. Over 300 different mutations in 16 genes have been identified so far. The large allelic and genetic heterogeneity of HCM requires high-throughput, rapid and cheap mutation detection technologies in order to efficiently integrate molecular knowledge into clinical practice. We have developed a custom DNA resequencing array for molecular diagnosis of HCM. Our chip is able to sequence nearly 30 kb in a single experiment and contains both strands of all coding exons (160), splice-site junctions and known promoter regions of 12 genes mutated in HCM. We analysed a first series of 38 unrelated patients with HCM (17 familial, 21 sporadic). The mean base call rate of successfully assigned nucleotide was 96%. Overall we identified 20 different functional variants in 22 patients (58 %). Three functional variants were known mutations (1 nonsense, 2 missenses) and four were known functional SNPs. All the others were novel functional changes in highly conserved regions (3 splice, 2 promoter regions, 8 amino-acid replacements). In order to assess the potential pathological role of the 8 new missense variants, we screened 192 chromosomes of a control population of matched ethnic origin. Five variants were absent in the controls, 2 were found in 4 chromosomes and 1 was found in 10. In conclusion, our results demonstrate the need to screen all coding sequences, splice sites and promotor regions of the entire panel of HCM genes for appropriate clinical genetic testing. Our high-throughput HCM array allows to screen efficiently 12 of the so far 16 known HCM genes in a reliable, fast and cost-effective way.

NTRK2 is a susceptibility gene for obsessive-compulsive disorder, while BDNF involvement is limited to patients with positive family history. *M.P. Alonso[1], M. Gratacos[2,3], J.R. Gonzalez[2,3], J.M. Menchon[1], R. de Cid[2,3], C. Segalas[1], M. Bayes[2,3], J. Labad[1], J. Vallejo[1], X. Estivill[2,3,4]* 1) OCD Clinic, Department of Psychiatry, Hospital Universitari de Bellvitge, Hospitalet de Llobregat, Barcelona, Spain; 2) Genes and Disease Program, Barcelona, Spain; 3) National Genotyping Center (CeGen), Center for Genomic Regulation, Barcelona, Spain; 4) Department of Health and Life Sciences, Pompeu Fabra University, Barcelona, Catalonia, Spain.

Growth factors promote cell survival and neuronal differentiation and are known to be involved in synaptic efficiency and neuronal plasticity. Brain-derived neurotrophic factor (BDNF) pertains to the neurotrophin family and has been involved in several psychiatric disorders. To test the involvement of BDNF and its receptor (NTRK2) in obsessive-compulsive disorder (OCD), we performed an association study of 54 TagSNPs covering both genes in a sample consisting on 134 patients (OCD Clinic of Bellvitge University Hospital) and 342 control samples. TagSNPs were selected from the HapMap project (Phase I data freeze, dbSNP b124) and considering the genotypes corresponding to the 60 individuals from the CEPH-30-trios of European ancestry. Eight TagSNPs were selected that cover BDNF and 46 for coverage of NTRK2. We performed both single case-control association analysis and haplotype analysis. No significant differences in genotype and allele distributions of BDNF, including the functional Val66Met variant, were detected between OCD and the control group. A significant association of an intronic SNP in NTRK2 receptor gene and the presence of OCD was identified ($p = 0.001$). When considering OCD family background, both a single SNP and a composite haplotype was identified for BDNF ($p = 0.0003$ and $p = 0.01$, respectively). Furthermore, an intronic SNP from the NTRK2 gene and OCD with positive family history of OCD emerged ($p = 0.0002$). Our findings suggest that NTRK2 is a susceptibility gene for OCD, while BDNF involvement in OCD vulnerability appears to be limited to the subgroup of patients with positive family history of OCD.

Inhibition of topoisomerase I prevents common fragile site expression. *M.F. Arlt, R.L. Ragland, T.W. Glover*
Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Common fragile sites (CFS) are regions of the genome that exhibit chromosome gaps and breaks after cells are grown under conditions of replication stress. CFSs are frequently deleted or rearranged in cancers, with the most frequently-expressed CFSs (FRA3B, FRA16D) mapping within tumor suppressor genes (FHIT, WWOX). Partial replication inhibition by aphidicolin (APH), an inhibitor of DNA polymerases, is highly effective in inducing chromosome gaps and breaks at these sites. APH has been shown to uncouple the replicative helicase complex from the polymerases in vitro, causing continued unwinding of template DNA without replication, leading to long stretches of single stranded DNA. We hypothesize that the APH-induced uncoupling of the helicase and polymerase functions is an integral part of CFS expression. Under this hypothesis, if the uncoupling of polymerase and helicase activities were attenuated, CFS instability should be reduced, even in the presence of APH. To test this hypothesis, we treated normal lymphoblasts and primary lymphocytes with APH in combination with low doses of the topoisomerase I inhibitor, camptothecin (CPT). Topoisomerase I reduces the torsional stress ahead of the replication fork and is required for continued DNA unwinding by helicase. We found that, in the presence of APH, varying doses of CPT result in up to a five-fold reduction of total gaps and breaks as well as a ten-fold reduction of specific CFS breaks, almost down to levels seen in untreated cells. This reduction in CFS expression is not due to checkpoint induction, as CPT treatment results in a reduction, rather than an increase, of APH-induced phosphorylation of CHK1, a checkpoint protein important in CFS stability. We are currently investigating if the transcription function of topoisomerase I is involved in CFS expression. These results indicate that, unlike most mammalian proteins examined to date, topoisomerase I is required for the induction of CFS instability, rather than for its suppression. Furthermore, they support models for CFSs based on regions of single-stranded, unreplicated DNA.

The effects of SNP genotyping errors on power of the Cochran-Armitage linear trend test for case/control association studies. *K. Ahn[1,2], D. Gordon[3], S.J. Finch[2]* 1) Health Evaluation Sciences, Penn State College of Medicine, Hershey, PA; 2) Applied Mathematics and Statistics, Stony Brook University, Stony Brook, NY; 3) Genetics, Rutgers University, Piscataway, NJ.

The questions addressed in this work are: What single nucleotide polymorphism (SNP) genotyping errors are most costly, in terms of minimum sample size necessary (MSSN) to maintain constant asymptotic power and significance level, when performing case-control studies of genetic association applying the Cochran-Armitage trend test? Which trend test or 2X3 Chi-squared test is more powerful under standard mode of inheritances (MOIs) with genotyping errors? Our strategy is to expand the non-centrality parameter of the asymptotic distribution of the trend test to approximate MSSN using a Taylor series linear in the genotyping error rates. We apply our strategy to example scenarios that assume recessive, dominant, additive, or over-dominant disease MOIs. The most costly errors are recording the more common homozygote as the less common homozygote and the more common homozygote as the heterozygote for each of the trend tests considered, with MSSN that become indefinitely large as the minor SNP allele frequency approaches zero. Misclassifying the heterozygote as the less common homozygote can be indefinitely costly when using the recessive trend test on data from a recessive MOI. The 2X3 Chi-squared test has power close to but less than the optimal trend test and is never dominated over all MOIs studied by any specific trend test.

FOS - the Fabry Outcome Survey - a newly expanded global outcomes database for patients with Fabry disease.

M. Beck[1], J. Clarke[2], A. Linhart[3], A. Mehta[4], G. Sunder-Plassmann[5] on behalf of the FOS Investigators 1) Dept Pediatrics, Univ Mainz, Mainz, Germany; 2) Dept Clinical Genetics, Hosp Sick Children, Toronto, ON, Canada; 3) Dept Internal Medicine II, Charles Univ, Prague, Czech Republic; 4) Dept Haematology, Royal Free Hosp, London, UK; 5) Division of Nephrology and Dialysis, Dept Medicine III, Medical Univ, Vienna, Austria.

Fabry disease is a rare debilitating X-linked lysosomal storage disorder caused by deficiency of the enzyme -galactosidase A. Introduction of enzyme replacement therapy with agalsidase alfa led to the establishment of two multinational outcomes databases: FOS (the Fabry Outcome Survey) based in Europe, and FIRE (the Fabry Information Research Exchange) in the rest of the world. These were recently merged and the expanded database now contains comprehensive information on 1230 patients (604 females, 626 males) from 107 clinical centres in 18 countries. The present analysis of the expanded FOS database was undertaken to assess the compatibility of the two original independent databases and to explore any differences that may exist in patient populations from different regions. The age of patients was 36.017.1 and 36.915.2 years (meanSD) in FOS and FIRE, respectively. In FOS, 48.1% of patients were males vs 56.7% in FIRE. End-stage renal failure was present in 13.4% (95% CI, 10.2-17.1%) of males and 0.7% (0.1-2.0%) of females in FOS and in 14.3% (10.0-19.6%) of males and 1.2% (0.1-4.2%) of females in FIRE. Left ventricular hypertrophy was reported in 41.1% (95% CI, 36.2-46.2%) of males and 25.1% (21.0-29.6%) of females in FOS and in 25.1% (19.6-31.3%) of males and 15.9% (10.7-22.3%) of females in FIRE. In FOS, stroke had occurred in 9.2% (6.6-12.4%) of males and 5.8% (3.8-8.4%) of females; in FIRE, stroke had occurred in 7.6% (4.5-11.9%) of males and 2.9% (1.0-6.7%) of females. Transient ischemic attacks were reported in 8.4% (5.9-11.6%) of males and 7.1% (4.9-10.0%) of females in FOS and in 7.2% (4.2-11.4%) of males and 3.5% (1.3-7.5%) of females in FIRE. We conclude that the two databases are sufficiently similar to be combined for the purposes of further epidemiological investigation of Fabry disease and the effects of agalsidase alfa.

Genome-Wide Study of Isolated Cleft Palate Only (CPO) Using the 50K Affymetrix SNP Chips. *M. Ghassibe[1], B. Bayet[2], N. Revencu[1, 3], Ch. Verellen-Dumoulin[3], Y. Gillerot[3], R. Vanwijck[2], M. Vikkula[1]* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology, Université catholique de Louvain, Brussels, Belgium; 2) Centre Labiopalatin, Division of Plastic Surgery, Cliniques universitaires St Luc, Brussels, Belgium; 3) Center for Human Genetics, Cliniques universitaires St Luc and Université catholique de Louvain, Brussels, Belgium.

Cleft lip and/or cleft palate is the most frequent craniofacial malformation in humans (~ 1/700). Genetic factors involved in cleft lip with or without cleft palate (CL/P) are thought to be different from those having a role in cleft palate only (CPO). There is a significant challenge in identifying the important genetic and environmental causes of complex traits such as isolated clefting, particularly when the numbers of genes and environmental triggers are expected to be large. We carried out a genome-wide study of 65 patients affected with CPO, 34 of which had isolated nonsyndromic cleft palate only, 18 the Pierre Robin sequence, and 12 a syndromic cleft palate. 50K Affymetrix SNP Chip analysis was performed for every patient. In order to detect copy number changes in the human genome, several analysis softwares were used: CNAT (Copy Number Analysis Tool), CNAG (Copy Number Analyzer for GeneChip) and dChip (DNA-Chip Analyzer). The results were compared to human polymorphism databases in order to eliminate all non causative deletions and duplications. Several copy number variations were identified in our cohort, including a 2p12 amplification (the CTNNA2 gene), 3p26.1 and 10q21.1 deletions. This study shows that deletions and/or duplications may be involved in the occurrence of cleft palate. Yet, several copy number changes located in coding regions may be of no pathological significance, since we can find them in non affected individuals as well. The role of these changes needs to be studied more carefully in order to see if they modify the occurrence of cleft palate. (http://www.icp.ucl.ac.be) (vikkula@bchm.ucl.ac.be).

Detection and mapping of DNA copy number alterations in human chromosome 21 using tiling BAC arrays. *F. Béna[1], C. Gehrig[1], G. Lopez[1], S. Gagos[3], J.M. Delabarre[4], A. Schinzel[5], S. Dahoun[1], J. Lespinasse[6], L. Taine[7], M. Doco-Fenzy[8], L. Colleaux[9], E.A.Y. Graison[10], M. Costantine[4], P.M. Sinet[10], S.E. Antonarakis[1], R. Lyle[2]* 1) University of Medical School, Geneva, Switzerland; 2) Institute of Public Health, Oslo, Norway; 3) Foundation for Biomedical Research of the Academy Athens, Greece; 4) EA 3508 University Paris Denis Diderot, France; 5) Institute of Medical Genetics, Schwerzenbach, Switzerland; 6) Cytogenetic Laboratory, General Hospital, Chambery, France; 7) Department of Genetics, CHU Pellegrin , Bordeaux, France; 8) Department of Genetics, IFR53 Reims, France; 9) INSERM U781 Necker-Enfants Malades, Paris, France; 10) CNRS UMR7637,Paris, France.

A major goal of understanding the molecular pathology of Down Syndrome (DS) is genotype-phenotype correlations, that is identification of Hsa21 genes or other functional elements that contribute to specific aspects of the phenotype. Rare cases of partial trisomy 21 associated with DS features could identify genomic regions associated with specific phenotypes. Studies of other rearrangments involving Hsa21 may also provide information on the contribution of Hsa21 genes to DS. In order to establish high resolution mapping of pathogenic partial aneuploidies and unbalanced translocations involving Hsa21, we constructed a BAC microarray covering 21q. The array consists of 411 Hsa21 BACs (from RPCI and CTD libraries) with a mean overlap of 85 kb giving an approximate 2-fold tiling path. The array also includes 100 BACs for normalisation as well as additional controls. We analysed 45 phenotypically well-characterised pathogenic chromosomal aberrations; including 8 complete trisomies and 32 partial aneuploidies of Hsa21. In each case, the size of the segmental aneuploidy has been estimated and in 20 cases confirmed by real-time quantitative PCR. The breakpoints have been mapped to within 200kb on average. We also tested 5 cases with a normal karyotype on the basis of clinical findings indicative of a DS phenotype. Our study contributes to the understanding of genotype-phenotype correlations in DS pathophysiology.

Association of the 4 integrin subunit gene with autism. *C. Correia[1, 2], M. Martins[1, 2], A.M. Coutinho[1], C. Marques[3], T. Miguel[4], A. Ataíde[4], J. Almeida[3], L. Borges[3], L. Gallagher[5, 6], J. Conroy[5], M. Gill[5, 6], G. Oliveira[3], A.M. Vicente[1, 2]*
1) Inst Gulbenkian Ciencia, Lisbon, Portugal; 2) Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisbon, Portugal; 3) Centro de Desenvolvimento da Criança, Hospital Pediátrico de Coimbra, Coimbra, Portugal; 4) Direcção Regional de Educação da Região Centro, Coimbra, Portugal; 5) Department of Genetics, Smurfit Institute, Trinity College, Dublin, Ireland; 6) Department of Psychiatry, Trinity College, Dublin, Ireland.

Autism is a complex behavioral disorder likely determined by interaction of multiple genes, still largely unidentified. The results from several genome scans have provided convincing evidence for the presence of an autism susceptibility locus on chromosome 2q31-q33. One of the functional candidate genes that maps in this region is the *ITGA4* gene, which encodes the Integrin alpha-4 precursor. In this study, we tested eight single nucleotide polymorphisms (SNP) in the *ITGA4* gene for association with autism in a sample of 164 autistic nuclear families. We found significant transmission disequilibrium of alleles at the rs155100 marker (*P=0.019*) and of specific haplotypes containing this SNP. It is reported that 4-integrins play an important role in the recruitment of circulating activated T-cells, monocytes and macrophages to the central nervous system and in the modulation of the behaviour of microglia. In a previous study, we have shown that an autoreactive response to a specific brain protein occurs significantly more frequently in autistic children than in age-matched controls, which may represent the immune systems neuroprotective response to a previous brain injury occurred during neurodevelopment. The finding that *ITGA4* rs1449263 marker is associated with this specific autoreactivity prompt us to suggest that the association found between autism and the *ITGA4* gene is due to a possible involvement of 4 integrin in this process of neuroinflammation. Our study provides new insights in the role of integrins in the etiology of autism, to which little attention has been paid so far.

RET-DEPENDENT AND RET-INDEPENDENT HIRSCHSPRUNG DISEASES. *L. de Pontual, A. Pelet, D. Trochet, S. ANTONORAKIS, R. TOURRAINE,, A. MUNNICH, F. JAUBERT, M. GOOSSENS, J. FEINGOLD, S. LYONNET, J. AMIEL* Dept Genetics, Hosp Necker-enfants Malades, Paris, France.

Hirschsprung disease (HSCR) stands as a model in the study of diseases with a complex mode of inheritance. A multiplicative oligogenic model with 3 loci has been proposed with RET proto-oncogene being the key player. Indeed, almost all HSCR patients harbor either a heterozygous mutation of the coding sequence or, more frequently, a hypomorphic allele located in a conserved non gene sequence in intron 1. In roughly 30% of the cases however, HSCR is associated to other malformations; Ondines Curse (CCHS), Mowat-Wilson (MWS), Waardenburg type 4 (WS4), Bardet-Bield Syndrome (BBS) and Down syndrome . The penetrance of the HSCR phenotype is incomplete in all cases. To test whether RET could be regarded as a modifier gene for the enteric phenotype in these 5 syndromes, we genotyped the RET locus in CCHS (N=143), MWS (N=70), WS4 (N=28), BBS (N=38) and Down syndrome (N=60). Splitting patients into 2 groups (with or without HSCR) for each syndrome showed a statistically significant over representation of the RET hypomorphic allele in CCHS, BBS and Down syndrome patients whereas HSCR is RET independent in MWS ans WS4 syndromes. These data illustrate the concept of a developmental gene being either a major disease-causing gene or a modifier gene. Finally, we also suggest the possibility of RET dependent and RET independent HSCR cases.

Novel genomic rearrangements of *ATM* gene identified in Ataxia-Telangiectasia Italian patients. *S. Cavalieri[1], A. Funaro[1], P. Porcedda[2], V. Turinetto[2], N. Migone[1], R.A. Gatti[3], A. Brusco[1]* 1) Department of Genetics Biology and Biochemistry, University of Turin, and Medical Genetics Unit, S. Giovanni Battista Hospital, Turin, Italy; 2) Department of Clinical and Biological Sciences, University of Turin, Regione Gonzole 10, Orbassano 10043, Italy; 3) Department of Pathology and Laboratory Medicine, The David Geffen School of Medicine at UCLA, Los Angeles, California, USA.

Mutations in the *ATM* gene lead to loss-of-function alleles. Here we report a multi-step mutation screening strategy on the *ATM* gene in 19 unrelated Italian A-T patients which allowed us to identify 37 of the 38 expected defective alleles. Most mutations (21/37) were novel. Standardized SNP and STR haplotyping followed by DHPLC screening of genomic DNA, allowed us to detect all but 5 mutations (~86%). The remaining mutations were initially investigated by RT-PCR analysis of *ATM* transcript and Southern Blotting of genomic DNA. Three large deletions were found: one 8.5-kb and two 18-kb identical deletions, spanning exons 32-36 and 21-29, respectively; both deletions involved regions rich in repetitive elements. The recent development of a Multiple Ligation of Probe Amplification (MLPA) kit covering 33 of the 65 *ATM* exons led us to screen for deletions and duplications in the remaining 3 patients where only one mutation had been found. We discovered a small deletion containing exon 31 and a duplication of exons 4-20. In conclusion this screening strategy, using SNP/STR haplotyping to rapidly identify known founder mutations, followed by analysis of point mutations and large gene rearrangements by DHPLC, MLPA, RT-PCR and Southern Blotting, allowed us to reach 98% sensitivity. Moreover the frequency of genomic rearrangements found in our patients (5/38, 13%) may suggest a full exon screening of *ATM* exons by the MLPA kit, increasing its sensitivity and reliability.

Mutation analysis of pantothenate kinase 2 (PANK2) gene in patients with pantothenate kinase-associated neurodegeneration (PKAN). *E. Battaloglu[1], B. Bilir[1], C. Yalcinkaya[2], Z. Yapici[3]* 1) Dept Molecular Biol & Gen, Bogazici Univ, Istanbul, Turkey; 2) Istanbul University, Istanbul Medical Faculty, Department of Neurology, Istanbul, Turkey; 3) Istanbul University, Cerrahpasa Medical Faculty, Department of Neurology, Istanbul, Turkey.

Pantothenate kinase-associated neurodegeneration (PKAN), formerly known as Hallervorden-Spatz syndrome (HSS), is a rare autosomal recessive neurodegenerative disorder associated with iron accumulation in the brain. Clinical features include dystonia, rigidity, pigmentary retinopathy and mental deterioration. Age of onset is usually in early adolescence (classic form); however, cases with onset in adulthood (atypical form) have also been reported. Prevalence of PKAN is estimated to be 1-3 in 1,000,000 individuals. It is associated with the mutations in the pantothenate kinase 2 gene (PANK2) on chromosome 20p13-p12.3. PANK2 gene is composed of seven exons, covering approximately 3.5Mb of genomic DNA and encodes a 50.5-kDa pantothenate kinase that is a regulatory enzyme in coenzyme A (CoA) biosynthesis. In the present study, the genetic basis of PKAN was investigated in five unrelated Turkish families with PKAN, including a total of eight patients (five males and three females). Mutation analysis using SSCP and subsequent DNA sequencing techniques revealed that a novel homozygous 664CT transition (Q222X) was present in the third exon of the PANK2 gene in all affected individuals of family 1. The members of this family had classic disease and their parents were heterozygous for the mutant allele. No disease causing mutations could be identified in the other four families, two of which were manifesting atypical phenotypes. Furthermore, a homozygous polymorphism (IVS4-9_8insTTCCCC) was present in the intronic region of the gene in family 1 and in heterozygous condition in the two atypical cases.

***In vitro* and *in vivo* effects of farnesyltransferase inhibitors for Hutchinson-Gilford progeria syndrome.** *B.C. Capell[1], M.R. Erdos[1], M. Eriksson[2], R. Varga[1], M. Olive[1], F. Kolodgie[3], H. Avallone[3], H. San[1], X. Qu[1], L.B. Gordon[4], R. Virmani[3], E.G. Nabel[1,5], W.A. Gahl[1], F.S. Collins[1]* 1) NHGRI, NIH, Bethesda, MD; 2) Karolinska Institutet, Huddinge, Sweden; 3) CVPath, Inc., Gaithersburg, MD; 4) Brown University, Providence, RI; 5) NHLBI, NIH, Bethesda, MD.

Hutchinson-Gilford progeria syndrome (HGPS) is a rare genetic disorder of premature aging and accelerated cardiovascular disease. HGPS is almost always caused by a *de novo* point mutation in the lamin A (*LMNA*) gene that activates a cryptic splice donor site, producing a mutant protein, termed progerin. Wild-type prelamin A is anchored to the nuclear envelope by a modification of the C-terminal CAAX motif by a farnesyl isoprenoid lipid. Cleavage of the terminal 15 amino acids and the farnesyl group releases mature lamin A from this tether. This cleavage site is deleted in progerin. We hypothesized that retention of the farnesyl group causes progerin to remain anchored in the nuclear membrane, disrupting the nuclear scaffold and causing nuclear blebbing characteristic of HGPS. If so, blocking farnesylation should decrease progerin toxicity. Blocking farnesylation of progerin in transiently transfected cells with farnesyltransferase inhibitors (FTIs) has been shown to restore normal nuclear architecture. Treatment of early and late passage human HGPS fibroblasts with FTIs also reduces nuclear blebbing. Therefore, we administered the FTI, tipifarnib (R115777, Zarnestra), to a transgenic mouse model of HGPS that was created by recombineering a 164 kb human BAC containing the *LMNA* gene to incorporate the 1824C>T (G608G) mutation. Mice from a stable transgenic line express the mutant *LMNA* RNA and protein (progerin) products, and display a progressive loss of vascular smooth muscle cells, strikingly similar to the cardiovascular disease of HGPS. Early results in 5 month-old animals treated with R115777 suggest little or no dropout of vascular smooth muscle cells in the media of large arteries, providing encouragement that this drug therapy may work. Based on these observations, we believe that there is sufficient evidence to initiate a clinical trial with an FTI for children with progeria later this year.

The level of HER-2/neu gene amplification may correlate with some relevant histopathological features of early stage breast cancer. *D. Bettio[1], G. Gullo[2], G. Masci[2], A. Venci[1], L. Di Tommaso[3], A. Santoro[2]* 1) Cytogenetic Laboratory, Humanitas Clinical Inst, Milan, Italy; 2) Oncology Dept.,Humanitas Clinical Inst, Milan, Italy; 3) Anatomic Pathology Laboratory,Humanitas Clinical Inst, Milan, Italy.

BACKGROUND HER-2/neu gene amplification and/or protein overexpression predict poor outcome in invasive breast cancer and have become crucial determinants in therapeutic decisions. FISH by means of the PathVysion kit was used to investigate HER-2 gene amplification in order to identify different categories of patients with different levels of amplification and correlate this value with histopathological features rather than IHC evaluation of the protein overexpression and looking for a prognostic role of these parameters. METHODS Our study was performed on 28 early stage breast cancer female patients treated with curative surgery randomly taken from the archives of Pathology. Patient characteristics were: median age: 55 (range: 36-73); invasive ductal carcinoma: 24 (86%), invasive lobular: 3 (11%); mixed (ductal and lobular) type: 1 (3%). RESULTS Seventeen patients showed HER-2 amplification with HER-2/CEP17 ratio ranging from 2.1-8.5, whereas 11 FISH negative patients represented the control group. Patients positive by FISH were divided into two groups according to the HER-2/CEP17 ratio: low-level HER-2 amplification (HER-2/CEP17 ratio 2.1-3.9) and high-level HER2 amplification (ratio 4-8). Relevant histopathologic features of tumors in the three groups, no amplification/low-amplification/high-amplification, respectively, were as follows: high histologic grade (G3): 36/33/63% (p 0.07 Mantel-Haentzel test); vascular invasion present: 45/44/75%, high proliferative MIB-1 index (MIB-1 protein 20%): 27/44/63%. No significant difference was observed for ER and/or progesterone-receptor status. On follow-up ranging from 6 to 40 months the worst clinical outcome was among the group with amplification and chromosome 17 polisomy. CONCLUSIONS This is the first observation of a possible correlation between the level of HER-2 amplification and some relevant histopathological features of breast cancer.

Defining the importance of mitochondrial gene defects in Maternally Inherited Diabetes and Deafness and in neuromuscular presentations suggesting respiratory chain dysfunction: Screening of the entire mitochondrial genome in one hundred patients with Surveyor nuclease strategy. *S. Bannwarth[1,6], V. Procaccio[2,6], C. Rouzier[1], B. Vialettes[3], D. Raccah[3], B. Chabrol[3], C. Desnuelle[4], J. Pouget[3], J.F. Pellissier[3], D. Wallace[2], J.C. Lambert[1], V. Paquis-Flucklinger[1,5]* 1) Department of Medical Genetics, CHU Nice,Nice,France; 2) Center for Molecular and Mitochondrial Medicine and Genetics,University of California,Irvine,USA; 3) CHU Marseille,France; 4) CHU Nice,France; 5) UMR CNRS/UNSA6543,Medicine School,University of Nice-Sophia Antipolis,France; 6) These authors contributed equally to the study.

Mutations of mitochondrial genome(mtDNA)are responsible for respiratory chain defects in numerous patients. Recently,we have developed a new strategy for the rapid identification of heteroplsmic mtDNA mutations. This method,which is based on the use of a new mismatch-specific DNA endonuclease,named "SurveyorTM Nuclease",enables the systematic screening of the entire mitochondrial genome rapidly and can detect different mutants present at as low as 3% heteroplasmy. We have used this new strategy for screening the entire mtDNA in a large population including patients with diabetes,hearing deficit and history of diabetes in maternal relatives on the one hand,and patients with neuromuscular features suggesting respiratory chain dysfunction,on the other hand. Here,we show that,in clinical practice,the search for mtDNA mutations is not highly relevant in maternally inherited diabetes with deafness when 3243 mutation has been ruled out. On the contrary,we identified mtDNA deleterious mutations in 18% of patients (9/50) presenting with neuromuscular symptoms. Among the 9 identified mutations,3 were novel. This result validates the interest of Surveyor TM method in such patients when both 3243 mutation and mtDNA deletions have been ruled out. In one family, we identified the 8344 mutation in association with a second 4295 mutation in the tRNAIle gene.This result suggests that a combination of different mutations can be responsible for variable phenotypes. Last,we show that polymorphisms are frequently found in a heteroplasmy state.

Dosage analysis of the proteolipid protein 1 (PLP1) gene in Pelizaeus-Merzbacher disease. *B. Bilir[1], Z. Yapici[2], C. Yalcinkaya[3], E. Battaloglu[1]* 1) Bogazici University, Department of Molecular Biology and Genetics, Istanbul, Turkey; 2) Istanbul University, Istanbul Medical Faculty, Department of Neurology, Istanbul, Turkey; 3) Istanbul University, Cerrahpasa Medical Faculty, Department of Neurology, Istanbul, Turkey.

Pelizaeus-Merzbacher disease (PMD) is a rare hypomyelinating disorder of the central nervous system with X-linked recessive inheritance, mostly affecting males. The clinical severity and age of onset vary widely among the PMD patients, but common characteristics include nystagmus, ataxia, stridor, spasticity, and mental retardation. The prevalence in the US is estimated to be ~ 1/500,000. About 80 per cent of the patients, clinically diagnosed as PMD, have been shown to carry duplications, point mutations or deletions in the proteolipid protein 1 (PLP1) gene, which is located on chromosome Xq21.3-Xq22. Rest of the PMD cases (about 20 per cent) do not have mutations in the PLP1 gene, suggesting involvement of additional loci or mutations in noncoding regions of the PLP1 gene.

In the framework of this study, a total of 23 patients with PMD phenotype (18 males and five females) from 19 unrelated families were investigated in order to unravel the genetic basis of PMD in Turkey. Since PLP1 gene duplication is the most common (60-70 per cent) type of mutation observed in PMD, testing for the duplication is reasonably the first step for genetic analysis. Various techniques were used in this study in order to detect duplications and deletions of the PLP1 gene, including interphase FISH analysis, quantitative fluorescent multiplex PCR, and restriction fragment length polymorphism (RFLP) analysis. Interphase FISH analysis revealed that PLP1 duplication was present in seven male cases. No deletions were identified in the patients. These results were confirmed by quantitative fluorescent multiplex PCR analysis. Since restriction analysis for the exonic IV/AhaII and intronic DXS 17/TaqI polymorphisms revealed no heterozygosity in males, this method was noninformative for testing of the PLP1 duplication in this cohort of patients.

Intracontinental Distribution of Haplotype Variation: Implications for Human Demographic History. *M.C. Campbell[1], S.A. Tishkoff[2], C. D. Bustamante[3], J.H. Lee[4], A. Carracedo[5], E.J. Parra[6], R. DeSalle[7], R.L. Holloway[1]* 1) Department of Anthropology, Columbia University, New York, NY; 2) Department of Biology,University of Maryland, College Park, MD; 3) Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 4) Sergievsky Center, College of Physicians and Surgeons, Columbia University, New York, NY; 5) Institute of Legal Medicine, University of Santiago de Compostela, Galicia, Spain; 6) Department of Anthropology, University of Toronto, Mississauga, Canada; 7) Division of Invertebrate Zoology, American Museum of Natural History, New York, NY.

In human evolutionary studies, a continued challenge has been to characterize ancestral genetic structure among ethnically diverse human populations within continental regions, particularly in Africa. To approach this challenge, we examined the distribution of haplotype variation at Sortilin1 (SORT1) on chromosome 1 within major geographic regions (~1400 individuals from 59 human populations). SORT1 is a receptor protein that binds neuropeptides and has been associated with neurological disorders. We selected 18 HapMap SNPs located in the non-coding and coding regions of SORT1 for genotyping by mass spectrometry. SNP haplotypes were reconstructed using PHASE and PL-EM algorithms, and population divergence was measured using Wrights fixation index (F_{ST}) and Raymond and Roussets exact test of sample differentiation in ARLEQUIN. Our results show that the among-population F_{ST} value is significantly higher in sub-Saharan Africa than in Europe, the Middle East, Central/South Asia and East Asia. In addition, exact tests also indicate that sub-Saharan African populations are more differentiated (exact P-value = 0.00368 0.00035) than populations within Europe, the Middle East, Central/South Asia and East Asia. These results suggest that diverse African populations were more subdivided with lower levels of gene flow during human history. This study provides further information regarding intracontinental haplotype variability using a large sample of healthy individuals from diverse human groups, including 11 distinct African populations which are mostly underrepresented in genetic studies.

DMP1 mutations in autosomal recessive hypophosphatemia implicate a bone matrix protein in the regulation of phosphate homeostasis. *A. Benet-Pages[1], M. Bastepe[2], B. Lorenz-Depiereux[1], M. Amyere[3], J. Wagenstaller[1], U. Müller-Barth[4], K. Badenhoop[5], R.S. Rittmaster[6], A.H. Shlossberg[6], J.L. Olivares[7], C. Loris[8], F.J. Ramos[7], F. Glorieux[9], M. Vikkula[3], H. Jüppner[2], T.M. Strom[1]* 1) Institute of Human Genetics, GSF National Research Center and Technical University, Munich, Germany; 2) Endocrine and Pediatric Nephrology Unit, Massachusetts General Hospital and Harvard Medical School, Boston, USA; 3) Human Molecular Genetics, Universite catholique de Louvain, Brussels, Belgium; 4) Medical Genetics, Hanau, Germany; 5) Division of Endocrinology, University Hospital, Frankfurt/M, Germany; 6) QEII Health Sciences Centre, Halifax, Canada; 7) Department of Pediatrics, University Hospital of Zaragoza, Spain; 8) University Children's Hospital Miguel Servet, Zaragoza, Spain; 9) Shriners Hospital for Children, Montreal, Canada.

Monogenic phosphate-wasting disorders leading to rickets typically follow an X-linked (XLH) or autosomal dominant mode of inheritance (ADHR). We have now identified a novel autosomal recessive form of hypophosphatemia (ARHP) in three unrelated families. The affected individuals showed clinical and biochemical parameters that were similar to those observed in XLH and ADHR. We performed a genome-wide linkage analysis using SNP array genotyping. Assuming that the disease alleles could be identical by descent in each family because of their rare occurence, we analysed the data by homozygosity mapping and identified a 4.6 Mb candidate region on chrosomsome 4q21 between the SNPs rs340204 and rs722937 (max. LOD score of 3.1, 2.38 and 4.15, respectively, in families 1, 2, and 3). Sequence analysis of candidate genes identified homozygous loss of function mutations in DMP1 (dentin matrix protein 1), which codes for a non-collagenous bone matrix protein expressed in osteoblasts/osteocytes along with FGF23 (fibroblast growth factor 23) and PHEX (phosphate regulating endopeptidase). FGF23 plasma levels were elevated in two of three individuals indicating that DMP1 is involved in regulating FGF23 expression. Our results add DMP1 to the growing list of genes involved in phosphate regulation.

Family based association study of the 9p22 chromosomal region in Italian subjects with allergic asthma. *A. Begnini, E. Trabetti, G. Malerba, C. Bombieri, L. Xumerle, M. Biscuola, R. Galavotti, P.F. Pignatti* Department of Mother and Child, University of Verona, Verona, Italy.

A genome scan for allergic asthma in 123 Italian families revealed linkage of skin prick test positivity to common aeroallergens (SPT) or elevated total serum IgE (IgE) with chromosome 9p22 markers (Malerba G. et al., Am J Hum Genet. 2002, Vol. 71 n. 4 Abs 1662). An association study was now performed by Transmission Disequilibrium Test (TDT) on a subset of the 19 families with non-negative linkage for SPT or IgE, using 11 SNPs located in the linked region spanning ADAMTSL1 and SH3GL2 genes, showed significant associations with some of the studied SNPs (rs1888067: p = 0.005 for SPT; rs2811807: p = 0.009 for clinical asthma). Also, multilocus analysis revealed preferential trasmission of particular haplotypes with some phenotypes (e.g. rs1928580-rs960232-rs1888067 T-C-T: p = 0.0000087 for SPT and rs2811807-rs1928580-rs960232 C-T-C: p = 0.000056 for atopy). In order to confirm the association, we are extending the analysis of the 4 polymorphisms showing significant association individually or as haplotypes on a sample of 87 asthmatic families (391 subjects) from the same population. Preliminary results on 232 subjects show no significant association with any of the phenotypes (asthma, IgE, SPT, atopy), suggesting that the previous evidence of association might be due to different locations in the 9p22 region.

Somatic instability of CTGn expansion in Myotonic Dystrophy type 1 (DM1) patients and genotype-phenotype correlation. *E. Bonifazi[1], A. Botta[1], R. Iraci[1], L. Vallo[1], V. Romeo[2], M. Gennarelli[3], C. Angelini[2], G. Novelli[1]* 1) Dept. of Biopathology, Tor Vergata University, Rome, Italy; 2) Dept. of Neurosciences, University of Padua, Italy; 3) IRCCS S. Giovanni di Dio;,Brescia, Italy.

Myotonic Dystrophy type 1 (DM1; OMIM #160900), is an autosomal-dominant genetic disorder with multisystemic clinical features associated with a CTG expansion in 3'UTR of the DMPK gene (OMIM # 605377) on chromosome 19q13.3. The number of CTG repeats at DM1 locus is extremely variable (5-35 CTG) but stable in healthy individuals. When the repeats number is between 36 to 49, they became potentially unstable (premutation) and with a repeats length above 50, the pathology arises. The DM1 mutation shows somatic instability and the CTGn expansion size correlates with the severity of the pathology and the age of onset. In this study we analyzed the intra-individual dynamics of CTGn expansion and its possible relationship with the DM1 disease progression in a ten years-period (initial time=T0; final time =T10). For this purpose, 19 unrelated DM1 patients have been phenotypically and genetically re-evaluated, ten years after their first clinical and molecular diagnosis of DM1. Data colleted at time T10 have been compared to the phenotypic classification and to the CTGn expansion established on from peripheral blood at time T0, using a Long-PCR based protocol. Our data show that CTGn expansion containing up to 300 repeats (n=8 patients) remains relatively stable in time, whereas there is a variable increase of CTGn expansion in patients (n=11) with a repeats number 300. Percent variation of CTGn expansion size ranged from 7,2% to 55,1% and the calculated mean value of this variation is of 25,7%. Genotype-phenotype correlation showed that clinical parameters which are indicative of DM1 disease progression, correlate with the CTGn repeat length only for expansions up to 300 units. No obvious genotype-phenotype correlation has been observed in DM1 patients with CTGn expansion 300, possibly because of an higher degree of somatic instability. Our experience has confirmed that direct molecular analysis for the DM1 mutation is of considerable value in pre- and postnatal diagnosis and in phenotype prediction.

Association analysis of RAGE and BTNL2 genes with sarcoidosis in the Italian population. *C. Bombieri[1], I. Campo[2], M. Zorzetto[2], I. Ferrarotti[2], P.F. Pignatti[1], M. Luisetti[2]* 1) Section Biology & Genetics, DMIBG, Univ Verona; 2) Biochemistry and Genetics lab, Resp Dis Clinic, IRCCS, Univ of Pavia; Italy.

Sarcoidosis is a polygenic multisystemic immune disorder with predominant manifestations in the lung, characterised by infiltration of CD4+ activated T-cells leading to the formation of specific non-caseating granulomas. We performed a case-control association analysis with RAGE and BTNL2 genes, which could be implicated in the inflammatory process surrounding granuloma, and are located in a region (6p21) in linkage with sarcoidosis. RAGE -374T/A (rs1800624) and BTNL2 16071G/A (rs2076530) polymorphisms were analyzed in 2 series of DNA samples from sarcoidosis patients (99 from biopsies obtained for confirmation, and 101 from blood of a second replication set) and in 262 geographically matched controls (staff members and blood donors). RAGE -374 TT/AT genotype frequency was significantly higher in sarcoidosis biopsies than in controls (90% vs 76%, p=0.004). This findings was confirmed in the second group of patients (94% vs 76%, p=0.000105). Genotype and allele frequencies of BTNL2 16071G/A polymorphism showed no statistical difference between patients (A 60%) and controls (A 67%). BTNL2 16071G/A was associated with sarcoidosis in German and African-American populations (Valentonyte et al., Nat Genet 2005, 37:357-64; Rybicki et al., Am J Hum Genet 2005, 77:491-9). Data obtained in this study from the Italian population do not confirm the possible involvement of BTNL2 16071G/A in sarcoidosis susceptibility, as suggested by previous findings on other populations. In conclusion, this work provides evidence for a possible role of the RAGE gene as a risk factor for sarcoidosis.

Megamitochondria formation in a murine model of Mut class methylmalonic acidemia. *R.J. Chandler[1], M.S. Tsai[1], J. Sloan[1], P.M. Zerfas[2], V. Hoffmann[2], C.P. Venditti[1]* 1) Genetic Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland, United States of America; 2) Division of Veterinary Resources, Office of Research Services, National Institutes of Health, Bethesda, Maryland, United States of America.

Mut class methylmalonic acidemia (mut-MMA) is an autosomal recessive inborn error of metabolism caused by a defect in the adenosylcobalamin dependent enzyme, methylmalonyl-CoA mutase. Affected patients suffer from life-threatening intermittent metabolic decompensation, metabolic strokes, and renal failure; the etiology of these complications remains unknown. Current treatments include dietary restriction of precursors, vitamin B12 supplementation in responsive patients as well as liver and/or kidney transplantation in the most severely affected patients. Paradoxically, liver transplantation does not appear to substantially reduce the plasma levels of methylmalonic acid in comparison to non-transplanted patients with intact renal function, but does confer greatly increased metabolic stability. Murine models of mut-MMA were created to recapitulate the phenotype observed in human mut-MMA and mitochondrial morphology was studied. The use of a mixed genetic background afforded increased survival for some animals that were homozygous for the knock-out allele. Megamitochondria and increased lipid droplet formation in the hepatocytes in the mut-MMA mice were documented by ultrastructural studies utilizing electron microscopy. The proximal tubules of the affected animals were also found to have abnormal mitochondria, which were enlarged with distorted cristae and contained inclusions and unusual lamellar structures. Mitochondria in the skeletal muscle were normal. These findings indicate a tissue specific response inherent to mut-MMA and for the first time, provide evidence to link mitochondrial function as the etiology of organ system dysfunction seen in this disorder. Furthermore, these observations explain the protective effects of liver transplantation in methylmalonic acidemia and should guide the development and testing of new therapies for affected patients.

A de novo case of Alpha-Thalassemia Mental Retardation Syndrome detected by genome-wide analysis using BAC arrays. *W. Gibson[1], C. Harvard[1,2], Y. Qiao[1,2], M. Somerville[3], S. Lewis[1], E. Rajcan-Separovic[2]* 1) Dept Medical Genetics, UBC, Vancouver, Canada; 2) Dept Pathology, UBC; 3) Molecular Diagnostic Laboratory, Edmonton, AB.

We report an 8 year-old girl who presented with developmental delays and mild dysmorphic features. She spoke her first words at 2 years, and walked independently at 3 years. She had myringotomy tubes for conductive hearing loss. She exhibited delays in motor, social, academic and personal/self-care skills. She also had low truncal muscle tone. Assessment with the Stanford-Binet Intelligence Scales found her intellectual abilities ranged from below the 0.1st centile (Working Memory) to the 10th centile (Quantitative Reasoning). Growth was normal. Facial features included a broad forehead with up-slanting palpebral fissures, a prominent nasal root and bridge, and flattened maxilla. She had a high, arched palate and a tongue frenulum. Hb electrophoresis at 13 months showed H bodies with normal Hb A2. CT scan showed reduced volume of the periventricular white matter posteriorly. MRI showed a thin corpus callosum. Whole-genome BAC array analysis revealed a sub-microscopic loss of 16p material involving clones RP11-344L6 at 0.1Mb, RP1-121I14 at 0.2Mb and RP11-334D3 at 1Mb. FISH confirmed the deletion of RP1-121I14 was de novo, and revealed a slight difference in signal intensity for RP11-334D3, suggesting that a break occurred within this, the most proximal clone. Her deletion may thus be as large as ~1Mb. Deletions of the distal end of 16p are associated with Alpha-Thalassemia Mental Retardation Syndrome, (ATR-16; MIM No. 141750), characterized by mental retardation with mild, nonspecific dysmorphic features. Hb electrophoresis can provide a critical clue to diagnosis by showing mild hypochromic anemia and occasional Hb H inclusion bodies. The disorder is caused by a contiguous deletion on chromosome 16p that removes both alpha-globin genes, in addition to others such as SOX8, which are believed to be involved in brain development. Testing for SOX8 is pending in our patient. To facilitate future diagnoses, we review the main clinical features established so far and compare them with our patient.

Expanded newborn screening using tandem mass spectroscopy in Mississippi in 2005. *C.A. Friedrich[1], T. Carey[2], P. Hoggatt[2], B. Polk[2], D. Freer[3], H-G.O. Bock[1]* 1) Dept Prev Med, Medical Gen, Univ Mississippi Medical Ctr, Jackson, MS; 2) Mississippi State Dept of Health, Jackson; 3) Pediatrix, Pittsburgh, PA.

In June 2003 Mississippi became the first state to screen all newborns with an expanded test panel that included tandem mass spectroscopy (MS/MS) and selected DNA tests. Tests were performed under contract by Pediatrix (Pittsburgh, PA). In 2005, the most recent year for which complete results are available, 42,877 samples from 41,199 newborns were tested. 3.95% required repeat samples because the first sample was unacceptable, inconclusive, or positive. 95.65% showed no abnormalities. 1.73% were unacceptable, 1.25% were inconclusive, 0.93% were obtained < 24 hours after birth, and 0.44% were positive. 1140 (2.66%) were unacceptable including those drawn at < 24 hours. Of these 87% were partially acceptable. The most common technical reason for an unacceptable sample was insufficient quantity (60%). Of the presumptive positive samples 75 (0.17%) had a hemoglobinopathy, 33 (0.08%) had congenital hypothyroidism (one confirmed), 4 (0.01%) had congenital adrenal hypoplasia (one confirmed), 10 (0.02%) had galactosemia (4 confirmed by genotyping), 11 (0.03%) had biotinidase deficiency (5 confirmed), 7 (0.02%) had cystic fibrosis (6 confirmed clinically, 7 confirmed by genotyping), 2 (0.005%) had phenylketonuria), 4 (0.01%) had elevated methionine (one confirmed homocystinuria), 2 (0.005%) had elevated tyrosine, 5 (0.012%) had elevated propionylcarnitine (1 confirmed propionic acidemia), 3 (0.007%) had elevated butyrylcarnitine), 2 (0.005%) had MCAD (both confirmed by genotyping), and 1 each (0.002% each) had elevations of isovalerylcarnitine, 3-OH-isovalerylcarnitine, MADD deficiency, or tetradecenoylcarnitine. Additionally, many heterozygotes for sickle cell trait or cystic fibrosis were also detected but the program was not designed to provide long-term follow-up for those babies. Hurricane Katrina had a minor and transient impact on the receipt of samples for testing. The expansion of the traditional newborn screening program posed no insurmountable obstacles to the states public health and medical communities.

The Role of RUNX1 Gene Expression Variation in Down Syndrome-Related Leukemia. *K.J. Duffy, M. Olivier*
Physiology, Medical College of Wisconsin, Milwaukee, WI.

Trisomy 21, the cause of Down syndrome, affects 1 in every 800 to 1000 live births today. The phenotypes associated with this chromosomal abnormality range in severity and include an increased risk for several types of leukemia. Because children with trisomy 21 have a 20 times greater chance of developing acute myeloid leukemia and a 500 times greater chance of developing acute megakaryoblastic leukemia (AMKL), it is reasonable to postulate that the over-expression of genes on chromosome 21 may play a critical role in this process. RUNX1, a gene located on chromosome 21, plays a crucial role in the development of other acute myeloid leukemia (AML) subtypes. Here, we examined the linkage disequilibrium structure of the RUNX1 gene region and analyzed whether individual common haplotypes lead to over-expression of RUNX1, an effect that would be further potentiated in trisomy 21. Using the HapMap CEPH genotype data, we identified 95 blocks of high linkage disequilibrium (LD) across a 2Mb region of interest. We determined the common haplotypes (frequency >5%) in each of the eight largest LD blocks, the average size being 30kb. We subsequently identified CEPH individuals homozygous for common haplotypes within each block. Using lymphoblastoid cell lines (Coriell Cell Repository) for these homozygous individuals, we measured the relative mRNA expression levels of RUNX1 by real-time PCR. One of the eight blocks of LD showed a significant difference in RUNX1 mRNA expression between haplotypes. The block is 35kb in size and located in the middle of the RUNX1 gene. Six tag SNPs define seven common haplotypes in this block. Of these, cell lines homozygous for haplotype 2 (frequency 30%) showed significantly increased RUNX1 mRNA expression versus all other haplotypes tested. Expression was elevated approximately 1.7 fold ($p<.0002$). This haplotype-specific difference in RUNX1 gene expression in chromosomally normal cell lines suggests that sequence variants within RUNX1 combined with an over-expression of RUNX1 in trisomy 21 may play a functional role in the development of trisomy 21-related AMKL.

Haplotype analysis of the angiotensinogen (AGT) gene in 62 worldwide populations. *R.R. Ferrucci[1], A. Pace[2], S.W. Watkins[1], T. Nakajima[3], L.B. Jorde[1]* 1) Dept Human Genetics, Univ Utah, Salt Lake City, UT; 2) University of Utah School of Medicine, Salt Lake City, UT; 3) Department of Molecular Pathogenesis, Medical Research Institute and Laboratory of Genome Research, School of Biomedical Science, Tokyo Medical and Dental University.

We have constructed four-SNP haplotypes for the AGT gene in 62 worldwide populations using the Foundation Dausset-Centre dEtude du Polymorphisme Humain (CEPH) Human Genome Diversity Project (HGDP) panel and additional population samples from our laboratory (N = 1572 individuals). Our previous studies demonstrated high frequencies of ancestral AGT alleles in tropical African populations. Ancestral AGT alleles are associated with high levels of sodium retention, which, while predisposing adults to hypertension, may have been selectively advantageous in the sodium-poor tropical environment. We, therefore, would expect other tropical populations to have high frequencies of these alleles. Our results in South American and Oceanian populations are consistent with the salt retention hypothesis. Further analysis was performed on the South Asian Indian population sample, composed of Brahmins, two lower caste populations, and two tribal populations. Though some of these populations show consistency with the salt retention hypothesis, others do not. This likely reflects the effect of genetic drift. In addition, low heterozygosities and fixation or near-fixation for ancestral AGT alleles are given as evidence for founder effects in the peopling of South America and Oceania. Finally, a mutational model was developed for AGT evolution.

Niemann-Pick type C disease: molecular genetic study in a cohort of eleven patients with highly variable clinical manifestations. *L. Dvorakova, M. Hrebicek, M. Bouckova, H. Vlaskova, L. Stolnaja, M. Elleder* Inst Inherit Metabol Disorders, Charles University, 1st Sch Medicine, Prague, Czech Republic.

Niemann-Pick type C disease (NPC, OMIM #257220) is a severe autosomal recessive neuro-visceral disorder characterized by progressive neurological deterioration and hepatosplenomegaly. The most prominent biochemical feature is complex lipid storage of free cholesterol and glycolipids due to dysregulation of the cellular lipid trafficking. Molecular defects in two late endosomal/lysosomal proteins (NPC1 and NPC2) are involved in manifestation of NPC.

During the last 35 years about 40 NPC patients from Czech and Slovak populations (15 mil.) were diagnosed by histochemical and biochemical methods. Only one of these patients was proved to belong to NPC2 complementation group. To characterize the molecular basis of the disease, we established the methods for mutation analysis in *NPC1* and *NPC2* genes. Up to now we analyzed 11 patients coming from Czech Republic, Slovakia, Brazil and Germany. The patients had highly variable clinical manifestations - from infantile neurological form to adult solely visceral form. Although both genes (*NPC1* and *NPC2*) were examined in the patients, the molecular defects were detected only in *NPC1* gene. We have identified 17 different mutations on 21 NPC1 alleles, 7 of them being novel. Besides missense and nonsense mutations we found a 1bp deletion, a 2bp insertion and a small insertion/deletion leading to a frameshift. Out of 12 missense mutations two were located in sterol sensing domain and five resided in cysteine rich domain. Correlation with clinical phenotype suggests classification of several mutations. Mutation A927V was found in homozygosity in the patient with late onset of neurological symptoms. The adult solely visceral form was associated with S666N and N961S. On the contrary, R958X was present in homozygosity in the patient with infantile form of NPC. By this way mutation analysis may contribute to studies of the protein structure-function relationship.

The work was supported by IGA MZ CR NR/8351-3, VZ MSM CR 0021620806 and VZ MZ CR 64165.

Visual Interpretation of Epistasis Models using the Open-Source Multifactor Dimensionality Reduction (MDR) Software Package. *N. Barney, W. Holden, B.C. White, J.H. Moore* Computational Genetics Laboratory, Dartmouth Medical School, Lebanon, NH.

Epistasis is a central feature of the genetic architecture of complex traits. However, detecting epistasis in population-based studies is challenging due to the dimensionality associated with modeling combinations of genotypes from multiple loci. We have previously developed a multifactor dimensionality reduction (MDR) approach for detecting epistasis. MDR uses constructive induction for changing the representation space of the data to make it easier to detect interactions using methods such as logistic regression. Although MDR has good power for detecting interactions, the multilocus models it generates can sometimes be difficult to interpret. We have previously evaluated an approach for the statistical interpretation of epistasis models that makes use of graphical models and information theory (Moore et al., *J Theor Biol* 2006). We showed that estimation of interaction information makes it possible to decompose an MDR model into redundant, independent, and synergistic effects. We have implemented these entropy-based measures into the freely available and open-source MDR software package. We provide two different graphical models to facilitate interpretation of epistasis models. First, we organize the entropy results as a gene network that is color-coded according to the nature of the interaction (redundant vs. synergistic). The advantage of this is that both main effects and interactions are displayed. Second, we provide the same entropy results in the form of interaction dendrograms derived from a hierarchical cluster analysis that builds a distance matrix based on the strength of the interactions. The advantage of this is that variables with stronger interactions are grouped together. The dendrograms are also color-coded to allow quick visual interpretation of the nature of the interactions in addition to their strength. These new entropy-based tools and graphs make it possible for the first time to combine statistical and visual interpretation with the MDR algorithm for mining epistatic relationships. (Supported by NIH R01s AI59694 and LM009012, PI-Moore).

Validation of the Infinium Whole Genome Genotyping assay for segmental aneuploidy profiling. *S. Colella[1], C. Yau[2], J. Taylor[1], G. Mirza[1], H. Butler[1], P. Clouston[3], A.S. Bassett[4], A. Seller[3], C. Holmes[2], I. Ragoussis[1]* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 2) Department of Statistics, University of Oxford, UK; 3) Oxford Medical Genetics Laboratories, Churchill Hospital, Oxford, UK; 4) Centre for Addiction & Mental Health, University of Toronto, Canada.

Inherited copy number changes in the genome are linked to human disease and somatic chromosomal alterations are a key event in carcinogenesis. Several microarray platforms have been used to detect copy number variation, including BAC and oligo arrays. Among them, SNP arrays offer the opportunity to analyse segmental aneuploidy events while providing additional information from the genotyping data. The recently developed two Illumina Infinium whole genome genotyping assays on universal bead arrays (Infinium I and II) are promising SNP based platforms for copy number analysis in samples of clinical interest. We validated the performance of both Human-1 and Humanhap300 Genotyping arrays in detecting copy number changes using a set of well characterised patient samples. Twelve samples were tested, including: six 6p deletions, the parents of one 6p deletion patient, two 6p duplications, one *DMD* deletion and one Charcot-Marie-Tooth duplication. We used BeadStudio Genotyping module software tools for loss-of-heterozygosity(LOH)/copy number(CN) detection and also developed a new analysis strategy based on Hidden-Markov Models (HMM). With our method we were able to use all SNP genotyping calls, in contrast to the BeadStudio scores that use only the heterozygous calls (reducing the data to ~1/3). The higher data content, together with the HMM approach, allowed us to obtain a better mapping of the specific breakpoints. The combination of both datasets (total SNPs ~400,000) brought the mapping resolution to a few kilobases (down to 4kb), depending on the SNPs density on the arrays in the region of interest. The results obtained were in agreement with FISH and molecular mapping data available. We conclude that both Infinium assays are suitable for high-throughput analysis of copy number alterations and mapping of deletion/duplication breakpoints.

Hermansky-Pudlak Syndrome in Non-Puerto Rican Hispanic Children. *G.A. Golas, R. Hess, A. Helip-Wooley, M. Huizing, W.A. Gahl* MGB, NHGRI, NIH, Bethesda, MD.

Hermansky-Pudlak Syndrome (HPS) is a recessive disorder of organelle biogenesis characterized by oculocutaneous albinism, with abnormal melanosomes, and prolonged bleeding, with absent platelet dense bodies. Some patients have pulmonary fibrosis or granulomatous colitis. There are 8 known genetic subtypes, with different prognoses and management. Only HPS-1 and HPS-4 patients are at risk for pulmonary fibrosis. HPS-1 is common in northwest Puerto Rico (PR). We describe 3 non-Puerto Rican Hispanic children. Patient #125-5 is an 8 mo-old male of Mexican, German and Native American ancestry. He had nystagmus as an infant, with brown hair and irides, light skin, and decreased retinal pigment. Bruising and epistaxis led to the discovery of absent platelet dense bodies. There is no colitis. Sequencing of HPS5 revealed compound heterozygosity for c.1423dupC (exon 12) and c.835C>A (ex7); p.Q279K. Patient #150-4 is a 2 y-old male from Uruguay with blond hair, eyebrows and lashes and gray irides. Nystagmus and iris transillumination are present. Bloody stools began at 18 mo, along with nosebleeds and prolonged gingival bleeding after trauma. Dense bodies are absent. Molecular analysis revealed a heterozygous c.45delG mutation in exon 3 of HPS4. No second mutation was identified. Patient #163 is a 16-year old male of Honduran and Salvadoran ancestry. He has pale skin and his blond hair has darkened considerably. His irides are brown, and nystagmus is present. Mild bruising occurred during childhood; his platelets have no dense bodies. Episodes of abdominal pain, bloody diarrhea, and anal fissures prompted treatment for Crohns disease at age 13. Weight loss and persistent symptoms led to a colectomy with end ileostomy at age 16. A perforated bowel was found and he received 18u of platelets. There are no pulmonary symptoms. Molecular subtyping is pending. These cases provide examples of the varied clinical manifestations and molecular bases of HPS among non-PR Hispanic children. Such patients should not be assumed to have the HPS-1 subtype typical of northwest PR patients. Accurate molecular subtyping has significant prognostic and therapeutic implications.

Association tests in combined samples of nuclear families and unrelated subjects, allowing for uncertain haplotypes and missing genotypes. *F. Dudbridge* MRC Biostatistics Unit, Cambridge, United Kingdom.

In recent years many methods have been proposed to allow for haplotype uncertainty and missing genotypes in samples of case-parent trios and unrelated individuals. Rather less attention has been given to larger nuclear families and combined samples of families and unrelated subjects. Here I propose a general model for association, based on the multinomial logistic regression, which accommodates nuclear families of any size together with unrelated subjects in a single analysis. Missing genotype data is accommodated by summing over a distribution that is estimated by maximum likelihood. In special cases the model is equivalent to well-known methods for the transmission/disequilibrium test, haplotype relative risk, and logistic regression for unrelated subjects. Quantitative traits and genetic and environmental covariates are accommodated. A novel conditioning strategy is developed that allows valid tests of association in the presence of linkage for nuclear families of any size. The methods are implemented in a computer program, COCAPHASE, that is available from the author.

Haplotype analysis of Hailey-Hailey disease in Tunisian families. *M. BCHETNIA[1], S. DEGHAIS[2], R. BENMOUSLY[2], C. CHARFEDDINE[1], S. KASSAR[3], M. MOKNI[4], S. BOUBAKER[3], A. DHAHRI BEN OSMAN[4], I. MOKHTAR[2], S. ABDELHAK[1]* 1) Human genetics, Pasteur Institute of Tunis, Tunis Belvédère, Tunisia; 2) Department of Dermatology, Habib Thameur Hospital - Tunis; 3) Department of Pathology, Institut Pasteur Tunis; 4) Department of Dermatology, La Rabta Hospital - Tunis.

Hailey-Hailey disease (HHD), also known as familial benign chronic pemphigus, is a rare autosomal dominant genodermatosis characterized by persistent blisters, crusted erosions of the skin and warty papules. It typically presents in the third or fourth decade of life and is due to mutations in the ATP2C1 gene coding for a calcium ATPase localized to the Golgi in keratinocytes. In this study, we performed haplotype analysis of three unrelated consanguineous Tunisian families including 16 patients and a sporadic case using three microsatellite markers flanking the ATP2C1 gene which are D3S3606, D3S1587 and D3S3514. Results showed that there was four haplotypes cosegregating with the HHD in the tested Tunisian families. This haplotype heterogeneity provides evidence of mutation heterogeneity.

Analyzing the effects of mitochondrial tRNA gene of leu/lys and ATPase6, mutations as a possible cause of Friedreichs Ataxia in Iranian FA patients. *S. EtemadAhari[1,2], S. Kasraie[1,2], M. Houshmand[2], M. Moin[3], M. Bahar[1]*
1) Azad University of Science and Research, Tehran, Iran; 2) Molucular Medical Genetic Department, National Institute for Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran; 3) Immunology, Asthma & Allergy Research Institute, Tehran, Iran.

Friedreich's Ataxia (FA) is a severe inherited spinocerebellar ataxia that primarily affects the nervous system and heart leading to death. The gene defective in FA, FRDA, encodes a mitochondrial protein known as frataxin. A triplet repeat expansion within intron 1 of the FRDA gene results in a marked decrease in frataxin expression. Over the last years it has become clear that this results in mitochondrial iron accumulation that generates oxidative stress and results in mitochondrial iron accumulation that generates oxidative stress and results in damage to critical biological molecules. Due to the important role of the mitochondria we are analyzing mitochondrial tRNA gene of leu/lys and ATPase6 (because they have a lot of hot spots)to find point mutations,in about 20 Iranian patients. Some point mutations have been identified by PCR method and automated DNA sequence and we are going to confirm more point mutation by same methods to evaluate any possible specified point mutation related to the mitochondrial tRNA that can show the pathogenesis of the mitochondria in FA.

Mutation analysis in a cohort of 115 cases of Oral-facial-digital type 1 syndrome: an international collaborative effort. *B. Franco, C. Prattichizzo, V. Novelli, G. Giorgio, The International OFD collaborative research group* TIGEM, Fondazione Telethon, Naples, Italy.

Oral-facial-digital type 1 (OFD1; MIM 311200) syndrome belongs to the heterogeneous group of developmental disorders known as Oral-facial-digital syndromes (OFDs) of which at least nine different forms have been described. OFD type 1 is transmitted as an X-linked dominant condition with embryonic male lethality and, similar to all other forms of OFDs, is characterized by malformations of the face, oral cavity and digits, and by cystic kidney which is specific to type 1. The identification of the gene responsible for OFD1 has provided an important tool for genetic counseling and a molecular test is now available to patients and clinicians for OFD1 diagnosis and prenatal testing. To better define the clinical spectrum of Oral-facial-digital type 1 syndrome we collected though an international collaborative effort a cohort of 115 patients which includes typical OFD1 and cases with more general signs of oral-facial-digital syndromes. Mutation analysis for the OFD1 gene was performed in this collection on the 23 coding exons and the alternative spliced exons by DHPLC followed by direct sequencing. The analysis has been so far completed for 90 out of 115. Mutations were identified in 72 patients (80%). A total of 58 different mutations have been identified in exons 1 though 16, with most of the mutations occurring in exons 3, 13, and 9, respectively 15.5%, 13.8% and 10.3%. The mutations identified include frameshifts (58%), missense (13%), non sense (13%) and splicing mutations (13%). Interestingly, no mutations have been identified, so far, in the coding region spanning exons 17-23. According to our results, the incidence of polycystic kidney is underestimated in this pathology. In fact, 20 out of the 72 patients in which a mutation in the OFD1 gene has been identified and for which clinical information are available have cystic kidneys, thus indicating an incidence of polycystic kidney in this condition of at least 27.8%. Finally, an X inactivation study showed non-random X-inactivation in a third of the samples.

A Study of Mixed Mullerian Tumor with Thirteen Oncogene Probes. *S. Faruqi[1], C. Harsch[1], H. Spector[2], J. Noumoff[1]* 1) OB/GYN, Div Gynecologic Oncol, Crozer-Chester Medical Ctr, Upland, PA; 2) Department of Histology Crozer-Chester Medical Ctr, Upland, PA.

Mixed Mullerian tumors often present with multiple elements, principally including carcinoma and sarcoma. Little is known genetically about the induction of the oncogenic process or the differentiation/evolution of the tumor elements. We present here a study of a mixed Mullerian tumor (MMT) with a panel of 13 oncogenic DNA probes, selected on their potential for abnormality in general gynecologic cancers (and in MMTs). Sections of this tumor were hybridized with DNA probes for fluorescence in-situ hybridization (FISH). Probes used were single probes her-2/neu, p53, RB-1 (13q14), ZNF217 (20q13.2), c-myc, n-myc, Inversion 16 (inv16), and Cyclin D1, Multiple oncogene probes used were PML/RARA, LAvysion, Igh/myc, 15q22/6q21, 19q13/17p13, and FIP/CHIC/PDGFRA. Probes that showed significant deviation from the expected response of a healthy cell included that of ZNF217, a zinc finger protein gene recently implicated in several tumors with a relation to the female steroid hormones, and her-2/neu, also found to be amplified in breast and ovarian cancers. The multi-target probes of 15q22/6q21 and FIP/CHIC/PDGFRA showed significant amplification as well. Several other probes showed low-level amplification, defined as having an average probe count per cell of more than 2.3, but fewer than 3. The single probe for tumor suppressor gene p53 showed a low level deletion. Additionally, the dual probe 19q13/17p13 (p53) suggested deletion of at least one copy of p53 in all cells, and a low level deletion in 19q13. In general, these results have indicated areas that may be involved in the various stages of evolution and differentiation that are seen in a mixed Mullerian tumor.

Human *TRIM5* Polymorphisms and Haplotypes are Associated with Susceptibility to Human Immunodeficiency Virus Infection. *P. An[1], G.W. Nelson[1], G.D. Kirk[2], R. Detels[3], S. Buchbinder[4], S. Donfield[5], J.J. Goedert[6], J. Sodroski[7], S.J. O'Brien[8], C.A. Winkler[1]* 1) Laboratory of Genomic Diversity, SAIC-Frederick, Inc., Frederick, MD; 2) Johns Hopkins University, Baltimore, MD; 3) UCLA School of Public Health, Los Angeles, CA; 4) University of California, San Francisco, CA; 5) Rho, Inc., Chapel Hill, NC; 6) National Cancer Institute, Bethesda, MD; 7) Harvard Medical School, Boston, MA; 8) Laboratory of Genomic Diversity, National Cancer Institute, Frederick, MD.

Introduction TRIM5 protein in mammals is a major barrier to cross-species transmission of retroviruses. TRIM5 in rhesus monkey blocks infection of human immunodeficiency virus (HIV-1). Human TRIM5 is less potent at suppressing infection of HIV-1 *in vitro*. It is unclear whether human TRIM5 protects human from HIV-1 infection *in vivo*. We examined the effect of SNPs and haplotypes of human *TRIM5* on restricting HIV-1 infection in HIV-1 natural cohorts.

Methods Allelic frequencies were compared between high-risk exposed HIV-1-uninfected individuals (HREU) versus HIV-1 seroconverters (SC), and HIV-1 seronegatives (SN) versus seroconverters (SC),by the chi-square test. The Mantel-Haenszel test was used to assess the trend among SC, SN, and HREU groups with increasing resistance to HIV-1. The overall significance of the association was evaluated by the permutation test.

Results Four of 12 *TRIM5* SNPs tested were associated with modified risk of HIV-1 infection in African Americans. Two non-coding SNP variant alleles were elevated in HIV-1-infected groups and the variant alleles for H43Y and R136Q were elevated in HIV-1-uninfected groups. The ancestral haplotype specifying wild-type alleles was protective against HIV-1 infection. Permutation results indicated an overall significant association of variants with HIV-1 infection.

Conclusion These results suggest that genetic variation of human *TRIM5* influences susceptibility to HIV-1 infection. (Funded by NCI Contract N01-CO-12400).

Common coding variants in CASP8 and TGFB1 increase breast cancer risk. *A. Cox[1], A. Dunning[2], P. Pharoah[2], M. Garcia-Closas[3], D. Easton[4], The Breast Cancer Association Consortium* 1) Institute for Cancer Studies, University of Sheffield, Sheffield, United Kingdom; 2) Department of Oncology, University of Cambridge, Cambridge, United Kingdom; 3) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD; 4) Department of Public Health and Primary Care, University of Cambridge, Cambridge, United Kingdom.

Association studies are a useful tool to search for common low-penetrance breast cancer susceptibility alleles, but can often be under-powered. The Breast Cancer Association Consortium (BCAC) has been established to conduct combined analyses to confirm or refute putative genetic associations with breast cancer. In the present study we genotyped 9 single nucleotide polymorphisms (SNPs) for which there was prior evidence (published or from within the consortium) of an association with breast cancer: CASP8 D302H (rs1045485), IGFBP3 -202 c>g (rs2854744), SOD2 V16A (rs1799725), TGFB1 L10P (rs1982073), ATM S49C (rs1800054), ADH1B 3UTR a>g (rs1042026), CDKN1A S31R (rs1801270), ICAM5 V301I (rs1056538) and NUMA1 A794G (rs3750913). Data from 9-15 groups, comprising 11,323-17,229 cases and 13,733-21,643 controls, were included. Genotype-specific odds ratios (ORs) and 95% confidence intervals (95% CIs) were estimated by logistic regression, adjusting for study. A case-only analysis was carried out to look for age-specific effects.

We found strong evidence of an association with breast cancer risk for TGFB1 L10P (OR (95% CI) 1.07 (1.01, 1.13) and 1.16 (1.07, 1.25) for heterozygote and rare homozygote genotypes respectively, P-trend = 0.000094) and CASP8 D302H (0.89 (0.84, 0.94) and 0.77 (0.65, 0.92), P-trend = 0.000002). Both of these associations remained significant after excluding the original study (P= 0.0029 and P= 0.000018 respectively). There was no evidence of effect modification by age. There was weak evidence of a recessive effect of IGFBP3 -202 c>g (0.93 (0.87, 0.99), but no consistent evidence of association with the other six SNPs. TGFB1 L10P and CASP8 D302H are the first common alleles with convincing evidence of an association with breast cancer risk.

X-inactivation patterns in Aicardi syndrome. *T.N. Eble[1], P. Fang[1], W. Jin[1], V.R. Sutton[1], R.A. Lewis[1], I.B. Van den Veyver[1,2]* 1) Molecular and Human Genetics; 2) Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX.

Aicardi syndrome (AIC) is a severe sporadic neurodevelopmental disorder, characterized by a classic triad of agenesis of the corpus callosum, chorioretinal lacunae, and infantile spasms. Because nearly all affected individuals are female and the few known males with AIC have a 47,XXY karyotype, it is thought that the condition is caused by mutations in a gene subjected to X inactivation. Previous limited X-inactivation (XI) studies in AIC have had conflicting results. Therefore we studied XI in AIC, determined the parental origin of the inactive allele when skewed and investigated correlation between the severity of the phenotypes and the ratio of XI skewing, which has not been documented previously. The human androgen receptor assay was performed on DNA extracted from peripheral blood leukocytes (PBL) of 18 affected girls and their parents. Samples for this initial study came from girls with AIC who had all features of the classic triad. Phenotypic features of the study participants were confirmed with neurological and ophthalmologic examinations, parental interviews and review of medical records and were recorded in a database. With a cut-off of >70%:30%, the assay determined that 6 of 18 samples (30%) showed skewed patterns of XI. A tendency for skewing (66%:34%) was seen in 1 sample, and 1 sample was uninformative. Of the 4 samples with non-random XI where both parents could be studied, 3 preferentially inactivated the paternally inherited X chromosome. This is consistent with the hypothesis that AIC is caused by de novo X-linked mutations, which primarily arise on the paternal X chromosome. As subjects were selected by their more typical presentation, it was not surprising that we found no correlation between XI patterns and overall phenotypic features. However our data suggest a correlation with non-neurological features. DNA from additional individuals, including those with less severe phenotypes and from two brain samples, will be studied to confirm this and determine the extent of the XI-phenotype correlation. In conclusion, these initial findings support the hypothesis that the mutated gene for AIC is X-linked.

Increased power to detect disease genes in genetic linkage and whole genome wide association studies by employing a functional human gene network. *L. Franke[1], B.P.C. Koeleman[1], F. Dudbridge[2,3], M. Egmont-Petersen[4], C. Wijmenga[1]* 1) DBG-Department of Medical Genetics, University Medical Centre Utrecht, Utrecht, The Netherlands; 2) MRC Rosalind Franklin Centre for Genomics Research, Cambridge, United Kingdom; 3) MRC Biostatistics Unit, Cambridge, United Kingdom; 4) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

Identifying the disease genes in complex diseases is proving difficult, since hundreds of genes may reside in the susceptibility loci identified by linkage analysis. To help discriminate between the causative gene(s) and the non-disease genes contained in multiple loci, we have reconstructed a functional human gene network, (Franke *et al*, 2006, AJHG), available at www.genenetwork.nl, and used it to prioritize the individual genes in each locus by assuming that disease genes will usually be functionally closer together than the other non-disease genes. We have now applied this method to genome-wide SNP association studies, which permit the analysis of hundreds of thousands of SNPs. Usually, researchers only follow-up the top set of most significantly associated SNPs (Dudbridge *et al*, 2004, AJHG). By assuming that the real causative SNPs map within genes that are closely related in the gene network, we should be able to distinguish between these SNPs and the non-disease SNPs in this set. To assess the power of this method, we simulated genotypes for 300,000 SNPs in 750 cases and 750 controls for 96 different diseases, for which at least three disease genes were known for each disease. The SNPs that resided within the disease genes were assigned an odds ratio of 1.25. Initially, in each disease, we assessed how many of the true causative SNPs were contained in the top set for a fixed number of the most significantly associated SNPs. We then analyzed a SNP set of equal size that was generated by applying our method: the probability that the true causative genes lay within this adjusted set improved substantially, thus indicating that a functional gene network can help to identify causative genes in complex diseases.

Molecular analysis of the CYP1B1 gene from FTA cards in primary congenital glaucoma in European patients.
F. Gerson, O. Herbert, J.P. Moisan Dept Molecular Biol, IGNA, Nantes, France.

Primary congenital glaucoma (PCG) is a rare ocular disorder characterized by marked elevation of intraocular pressure (IOP) at birth or in early childhood, leading to ocular enlargement (buphtalmos) and corneal oedema, and then to irreversible damages on the optic nerves if it is not treated urgently. The frequency of this defect is 1 in 12,000 to 18,000 and represents 1% to 5% of all glaucomas. An autosomal recessive pattern of inheritance is common. A major gene, CYP1B1, a member of the cytochrome P450 gene family, mapping on chr.2p22.2, has been identified. This gene contains 3 exons and codes for the 544 amino acids cytochrome P4501B1 protein. In this study, we analysed the CYP1B1 gene from saliva on FTA cards of 15 cases with PCG. The male: female ratio was 8:7. Consanguinity was observed in 3 cases. The analysis, i.e. DNA extraction and PCR, was performed in our laboratory which is automated and fully computerised. By DNA sequencing analysis of the CYP1B1 gene, we found mutations in 8 patients and 3 of them were novel mutations. These data show that our process from saliva on FTA cards in an automated laboratory is reliable and rapid. This is particularly interesting for patients because of a non-invasive and painless sampling. In this study, more than 50% of the patients have at least one mutation in the CYP1B1 gene and we can conclude that PCG is not the consequence of mutations in this gene for about one of 2 patients.

Quality of life in families: children with birth defects. *B. Ballesteros[1], M. Novoa[1], I. Zarante[2], F. Suárez[2]* 1) Facultad de Psicología, Pontificia Universidad Javeriana, Bogota D.C., Colombia; 2) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogotá.

AIM: To investigate the psychological impact on family members, with a child less than 2 years old, affected with major birth defects. METHODS: A 62-item questionnaire divided in four blocks was designed to elicit from parents, and any relative living with the affected patient, the potential change in quality of life after the birth of a child with major birth defects. The first block considered the functional status of each individual in the family, the second block, evaluated the perception of the relatives, about the symptoms and the gravity of birth defects in the affected child. The third block evaluated the psychological impact in the family after the birth of the affected child. The last block measured the social behavior of the family members. 36 families (72 members) completed psychological interviews and questionnaires. No of the families had a prenatal diagnostic. The 36 affected children was less than 2 years old. The birth defects included neural tube defects, abdominal wall defects, limb defects and facial clefts. RESULTS: Stress, incomprehension, complaints about the health care system, medical appointments and prenatal procedures, lack of information about the children disease, and anxiety were often noted. But the overall score of the scales did not show any decrease in the quality of life of the family members. In fact a better cohesion between the family members was noted in almost every case. DISCUSSION: all of the familys members show behaviors associated to the unexpected birth defect but without a demonstrable decrease in quality of life. We believe that the potential change in quality of life, between the family members, are expected to appear during the future development of the affected, which is expected to be not easy, due to the complications and difficult for the required treatments and recuperation.

The Role of Protein Tyrosine Phosphatase 1 Beta (PTP1B) Sequence Variants in Obesity and the Metabolic Syndrome. *J. Eckert, T. Wang, J. Kim, A. Kissebah, M. Olivier* Physiology, Medical College of Wisconsin, Milwaukee, WI.

PTP1B negatively regulates insulin and leptin signaling. Individual single nucleotide polymorphisms (SNPs) in the gene for PTP1B have been shown to be associated with type 2 diabetes, insulin resistance, Body Mass Index (BMI) and alterations in plasma lipid levels. Recently, PTP1B haplotypes have been associated with hypertension, type 2 diabetes, and insulin sensitivity. In our study, we analyzed the linkage disequilibrium (LD) and haplotypes structure of the PTP1B genomic region on chromosome 20, and explored the association to obesity and metabolic syndrome related phenotypes. We genotyped 22 SNP in the gene region on 499 unrelated females of Northern European decent from the Midwestern U.S. A high LD region containing 16 intronic and synonymous SNPs and covering the entire gene region defined 8 haplotypes with a frequency greater then 1% and accounted for 92% of the total diversity. A common haplotype (28.6%) showed association with waist and hip circumference, BMI, fasting plasma insulin and leptin, and insulin glucose ratio (p=0.0006-0.0079) in a weighted regression model. In an effort to elucidate the potential function of this risk haplotype, we investigated its effect on mRNA expression levels by examining lymphoblast cell lines homozygous for the risk and other common haplotypes. The CEPH and Coriell Variation Panel were genotyped and homozygous females were identified. mRNA levels were quantified relative to the expression of stably expressed genes using TaqMan real-time PCR. The initial study examined six independent cell lines from female individuals, and we observed a 1.5 fold over-expression of PTP1B mRNA in cell lines homozygous for the risk haplotype compared to the most common haplotype (p=0.0001). A second confirmatory analysis in an additional set of twelve female cell lines confirmed this over-expression (p=2.2x10-6). Our analysis provides the first functional evidence for a cellular effect mediated by the associated PTP-1B risk haplotype, and the observed over-expression of the negative regulator may explain the association with insulin and leptin resistance in our cohort.

Sporadic Congenital Lymphedema Can Be Caused By A *De Novo VEGFR3* Mutation. *A. Ghalamkarpour[1], S. Morlot[2], J.B. Mulliken[3], L.M. Boon[1,4], M. Vikkula[1]* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology, Université catholique de Louvain, Brussels, Belgium; 2) Praxis für Humangenetik, Aerztliche Partnerschaft WagnerStibbe, Hannover, Germany; 3) Vascular Anomalies Center, Division of Plastic Surgery, Children's Hospital, Harvard Medical School, Boston, USA; 4) Centre for Vascular Anomalies, Division of Plastic Surgery, Cliniques Universitaires Saint-Luc, Brussels, Belgium.

Mutations in the *vascular endothelial growth factor receptor 3* gene, *VEGFR3/FLT4*, have been identified in a subset of families with hereditary lymphedema type I or Milroy disease (MIM 153100). In this study, we report a *VEGFR3* mutation in a patient with sporadic congenital lymphedema. The phenotype included bilateral swelling of the lower limbs, prominently below the knees, accompanied by upturned toenails and mild hydrocele. The mutation was heterozygous and not present in the non-affected parents and thus constitutes a dominant *de novo VEGFR3* mutation. All earlier reports have described *inherited* mutations in familial congenital lymphedema. Our data indicate that *VEGFR3* can be the pathophysiological cause of *sporadic* congenital lymphedema and *VEGFR3* screening in such patients may lead to a specific diagnosis. This has implications for follow-up care, as such individuals have a nearly fifty percent risk for occurrence of lymphedema in their children, compared to the low incidence in general population. In addition, as *VEGFR3* mutations can cause generalized lymphatic dysfunction, we conclude that sporadic hydrops fetalis may be a result of a *de novo VEGFR3* mutation. (http://www.icp.ucl.ac.be/vikkula) (vikkula@bchm.ucl.ac.be).

Evidence for Association of the KIAA0319-Like (KIAA0319L) gene on Chromosome 1p to Reading Disabilities.

C.L. Barr[1, 2], J.M. Couto[1], L. Gomez[1], K. Wigg[1], T. Cate-Carter[2], J. Archibald[2], B. Anderson[2], R. Tannock[2], M. Lovett[2], T. Humphries[2] 1) Cell and Molecular Division, Toronto Western Hosp, UHN, Toronto, ON, Canada; 2) Brain and Behaviour Programme, The Hospital for Sick Children, Toronto, ON, Canada.

Developmental dyslexia or specific reading disabilities (RD) is a learning disability characterized by difficulties with fluent word recognition and by poor spelling and decoding abilities. These difficulties result from deficits in the phonological components of language, and can occur despite at least average intelligence and effective classroom instruction. Many studies have found linkage and/or association of RD to several chromosomal regions. A locus on chromosome 1p34-36 (DYX8) has been previously linked to RD in three independent samples. Within this region we have identified a gene KIAA0319-Like (KIAA0319L) as a potential candidate based on its position, as well as its homology to KIAA0319, a gene that has been named as a RD susceptibility candidate on chromosome 6p (DYX2) in a number of independent association studies. In this study, association of KIAA0319L was assessed using 5 tagging SNPs in a sample of 263 nuclear families ascertained through a proband with reading difficulties. Evidence of association was found for rs7523017 ($c2 = 6.737$, $p = 0.009$; corrected $p = 0.035$) to RD defined as a categorical trait. We also observed evidence for association to quantitative measures of spelling and word reading efficiency (a composite of word identification and decoding). We conclude that KIAA0319L is likely the RD susceptibility gene on chromosome 1p and contributes to multiple reading components. These results also strengthen the case for KIAA0319 as the susceptibility gene on 6p. Studies are currently underway to find functional DNA changes in KIAA0319L that contribute to RD.

Metabolic disturbances in mice heterozygous for mevalonate kinase deficiency. *K.M. Gibson[1], A.S. Pappu[2], R.D. Steiner[2], G.F. Hoffmann[3], E.J. Hager[1]* 1) Pediatrics, Pathology, Human Genetics, Children's Hospital, Pittsburgh, PA; 2) Pediatrics and Medicine, Oregon Health & Science University, Portland, OR; 3) Pediatrics, University of Heidelberg, Germany.

Mevalonate kinase (MK; OMIM 251170/260920) catalyzes the first committed step in cholesterol and isoprene synthesis. Human MK mutations associate with diverse disorders, from hyperIgD/periodic fever syndrome to severe mevalonic aciduria. We ablated the murine MK gene employing a gene-trap disrupted ES cell line. Chimeric mice were generated by ES cell injection into blastocysts from strain C57BL/6, followed by implantation of injected embryos into pseudopregnant females for development to term. Male chimeras showing extensive ES cell-derived agouti coat color were bred with C57BL/6 females for germline transmission and identification of heterozygous MK +/- mice. Sequential MK +/- matings yielded no MK -/- animals; small litter sizes were dominated by MK +/- animals. Genotyping of 12 embryos (gestational day (E)14) revealed only MK +/- mice. Successful targeting was verified by RT-PCR and liver gene-dosage [MK/control enzyme: MK +/+; (n=4), 5.04 (1.66, SD); MK +/- (n=18), 2.54 (1.02, SD); p=0.001]. MK+/- mice appeared phenotypically normal; nonentheless, we characterized these animals for evidence of biochemical pathology. Quantitation of mevalonate in tissue extracts (heart (H), kidney (K), brain (B) and liver (L); n=8 MK +/+, n=6 MK +/-; mean (SEM), pmol/g tissue; all animals 6 weeks old) were: (H) MK +/+, 1134 (111); MK +/-, 2360 (65) ($p<0.0001$, nonparametric t test): (K) MK +/+, 2782 (300); MK +/-, 4727 (343) ($p<0.002$): (B) MK +/+, 482 (55); MK +/- 574 (46) (p=ns): (L) MK +/+, 5921 (894); MK +/-, 6784 (966) (p=ns). Metabolic disturbances in MK +/- mice suggest that additional pathway stress (e.g., statin, isoprene intervention) may induce a more prominent phenotype, and yield a model in which to explore the association of altered MK activity with disease pathology. Murine models in which MK is depleted will be useful to examine the biological role of MK related to tumorigenesis, hormone regulation, inflammatory processes, and development.

Mechanism of Isodicentric (Xq) Chromosome Formation in Turner Syndrome Patients. *N. Cohen[1], N.B. Kardon[1], W. Edelmann[2], L. Edelmann[1]* 1) Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Albert Einstein College of Medicine Bronx, NY.

Turner syndrome (TS) results from monosomy of the X chromosome and is mediated by haplo-insufficiency of genes that normally escape X-inactivation. Although half of all TS cases have a 45,X karyotype, the remaining half have other X-chromosome variants, the most frequent of which is the isodicentric (Xq) chromosome (idic(Xq)). Idic(Xq) is a spontaneously occurring chromosomal aberration that is present in 18% of TS cases, and it is the most common constitutional isochromosome in humans. The incidence of idic(Xq) is estimated at 1 in 13,000 females making idic(Xq) formation a significant cause of TS in live born females. Nine cases of idic(Xq) were analyzed to define the breakpoint regions and determine the mechanism of formation. In addition, seven translocations involving Xp11.2 were ascertained and the breakpoint regions were examined. Fluorescence In Situ Hybridization (FISH) also was performed using BAC clones from the physical map of the X chromosome that span 11 Mb from Xp11.21 - Xp11.23. Our data from the idic(Xq) and translocation cell lines indicate that most of the breakpoints fall within a 6 Mb region from 52 to 58 Mb on the physical map of Xp11.2 with clustering into at least four distinct breakpoint regions. Two of the regions contain repetitive gene clusters, including the SSX and GAGED genes, and one region harbors the inverted duplication that includes the ZXDA and ZXDB genes. Although there is not one specific region of susceptibility for idic(Xq) rearrangements, the Xp11.2 region contains a number of repetitive gene clusters which may contribute to the overall instability of this region. We are currently using high resolution oligonucleotide array CGH analysis to elucidate the exact sequences at each of the breakpoints. These studies will aid in our understanding of the role of genomic architecture on Xp11.2 in the generation of chromosomal rearrangement disorders.

Medical Sequencing at the Extremes of Human Body Mass. *N. Ahituv[1,2], N. Kavaslar[3], J. Cohen[4], R. Dent[3], R. McPherson[3], L.A. Pennacchio[1,2]* 1) Genomics Division, Lawrence Berkeley National Laboratory, Berkeley, CA; 2) US DOE Joint Genome Institute, Walnut Creek, CA; 3) University of Ottawa Heart Institute, Ottawa, Canada; 4) University of Texas South Western, Dallas, TX.

Human body weight is a quantitative trait with significant and complex heritability. To explore genetic contributors to this phenotype, we undertook a large-scale medical sequencing approach. We resequenced the coding exons and splice junctions of 58 BMI-related genes in 379 obese (average BMI 49.0 kg/m2) and 378 lean (average BMI 19.5 kg/m2) Caucasian individuals. In total, we generated over 90 Mb of sequence and detected 1074 genetic variants, the majority of which were rare (n=822, minor allele frequency <1%) of which 271 result in amino acid substitutions. While familial segregation of several characterized monogenic obesity genes failed to show complete correlation with BMI, analysis of their rare non-synonymous variants showed a significant frequency skew between the obese and lean panels (23 limited to obese versus 10 in lean). We thus used this paradigm as a filter for the other 51 genes and found 6 novel genes that may be implicated with human BMI (DGAT1, DGAT2, NMUR1, PRKAG3, and SIM1 with obesity and NTS with leanness), all showing significantly large skews between the two panels. In addition, using familial segregation analysis on a portion of the rare non-synonymous variants within the remaining novel genes, enabled us to detect other promising BMI-influencing variants. Association analysis of the 252 common variants (>1% minor allele frequency) that we discovered, failed to show any significant correlations with BMI, including previously suggested ones. Combined, these results point out the importance of complete variation identification in human genetic investigations to complement existing strategies focused on common variant mechanisms of disease susceptibility.

Early Markers of Disease Severity in Female Patients in the Fabry Outcome Survey. *P.B. Deegan[1], D.A. Hughes[2], F.A. Baehner[3], M-A. Barba-Romero[4], M. Beck[3] on behalf of the European FOS Investigators* 1) Department of Medicine, Addenbrooke's Hospital, Cambridge, United Kingdom; 2) Royal Free Hospital, London, UK; 3) Childrens Hospital, Mainz, Germany; 4) Albacete University Hospital, Albacete, Spain.

BACKGROUND: Fabry disease is an X-linked lysosomal storage disorder with heterogeneous expressivity in heterozygotes. It causes, inter alia, hypertrophic cardiomyopathy, stroke and renal impairment. Hypohidrosis commonly leads to heat intolerance. Once established, major organ involvement is often irreversible. Enzyme Replacement Therapy (ERT), though expensive, is available in many countries and may prevent progression of organ damage. Criteria for initiation of ERT in heterozygotes are still debated. AIMS: A method to predict future disease severity would assist in making decisions about early treatment. METHODS: An anamnestic questionnaire for completion by female patients was made available to clinicians participating in the Fabry Outcome Survey (FOS). Patients were asked whether they recalled experiencing less sweating, less physical activity, more days off school through ill-health and more days in hospital in childhood than their peers. Results were compared with the patients current disease severity as assessed by a modification of the Mainz Severity Score Index, corrected for age. 81 patients over 30 years of age were analysed separately. Differences in age-corrected severity scores were compared by unpaired T-test. RESULTS: 106 completed questionnaires were received. The 81 patients over 30 yrs of age were representative of the female cohort in FOS. In the group of 106 patients of all ages, all four parameters were associated with severity of disease ($p<0.05$). In 81 patients >30yrs, two parameters were associated with disease severity: less sweating and more time in hospital (p0.001). CONCLUSION: Female patients with severe features of Fabry disease recall less sweating and more admissions to hospital in childhood than their peers. These features may prove useful in predicting future disease severity in girls with Fabry disease and may inform decisions about treatment.

Cerebrotendinous Xanthomatosis: early presentation and response to treatment with Chenodeoxycholic acid.

M.T. Geraghty[1], P. Chakraborty[1], C. Armour[1], L. Kratz[2] 1) Dept Genetics, Children's Hosp Eastern Ont, Ottawa, ON, Canada; 2) Kennedy Krieger Institute, Baltimore, MD.

Cerebrotendinous xanthomatosis (CTX) is an autosomal recessive disorder due to deficiency of the mitochondrial sterol 27-hydroxylase. It is characterized by deficiency of bile acids esp. chenodeoxycholic acid (CDCA) and accumulation of cholestanol. We report a 6 year old boy who was referred at 5 years of age after surgical removal of 2 xanthomas from his left anterior thigh. He had bilateral cataracts that were removed. He had failure to thrive and long standing diarrhea. Plasma cholestanol was elevated and he had typical abnormal urinary bile acid and plasma sterol profiles. Brain MRI and BAERS were normal but VEPs were reduced. Liver function tests and vitamins D, E and K levels were normal. Psychometrics were in the average range with decreased visual and fine motor skills. CTX was confirmed by finding homozygosity for a known pathogenic mutation, c.1183C>T; p.Arg395Cys. Both parents are heterozygous with no history of consanguinity. He was started on CDCA, 15mgs/kg/day in 3 divided doses. There was cessation of diarrhea and increase in growth parameters from the 5th to the 25th centiles. A foot xanthoma resolved on therapy. Plasma cholestanol declined and other plasma sterols normalized. CDCA appears to be an effective treatment for this condition.

CDCA mg/Kg	Chol mg/L	8-DHC	Cholestano	Cholesteno	Desmo	7-DHC	Latho
0	1563	21	17.5	22.2	1.3	10.4	9
13	1861	0	9.7	0.4	1.3	0.2	1.1

Detection of genomic deletions of the *TP53* gene in the Li-Fraumeni syndrome. *G. Bougeard[1,2], S. Vasseur[1], C. Martin[1], L. Brugières[3], A. Chompret[4], B. Bressac-De Paillerets[5], P. Jonveaux[6], H. Sobol[7], L. Gladieff[8], P. Gesta[9], S. Baert-Desurmont[1,2], T. Frebourg[1,2]* 1) Department of Genetics, Rouen University Hospital, F-76000 France; 2) Inserm U614, Faculty of Medicine, Rouen, F-76000 France; 3) Department of Pediatric Oncology; Gustave Roussy Institute, Villejuif, F-94800 France; 4) Department of Oncogenetics - Gustave Roussy Institute, Villejuif, F-94800 France; 5) Department of Genetics - Gustave Roussy Institute, Villejuif, F-94800 France; 6) Department of Medical Genetics - Nancy University Hospital, F-54000 France; 7) Marseille Cancer Institute, Molecular Oncology Department, UMR599 Inserm and Paoli-Calmettes Institute, Marseille, France; 8) Department of Oncogenetics - Claudius Regaud Institute, Toulouse, F-31000 France; 9) Department of Oncology - Niort Hospital, F-79000 France.

Absence of detectable germline mutation of the *TP53* gene in a fraction of families with Li-Fraumeni syndrome (LFS) led us to screen for *TP53* genomic rearrangements, using QMPSF (Quantitative Multiplex PCR of Short Fluorescent fragments), families without detectable point mutation. We recently reported the first case of a complete heterozygous germline deletion of *TP53*, removing all the exons, in a large French family. The screening for *TP53* rearrangements has now been integrated into the routine diagnosis of LFS, using a QMPSF assay which explores the 11 exons and the promoter of the *TP53* gene. Analysis, using both sequencing and QMPSF, of 259 families suspected to present a LFS according to the Chompret criteria allowed us to identify a *TP53* germline alteration in 52 families (20%). We identified 3 large genomic deletions, indicating that *TP53* rearrangements represent about 6% of the *TP53* alterations. In 2 distinct families, we identified 2 deletions removing exon 1 and the promoter but respecting the 10 coding exons. These results constitute a definitive argument demonstrating that the LFS results from a haploinsufficiency at the *TP53* locus and suggest that screening for *TP53* rearrangements should be integrated in the LFS molecular diagnosis.

Exploring Managed Care Decision-Maker Perspectives on the Utility and Economics of Genetic Cancer Risk Assessment: Focus groups and an educational intervention. *J. Culver[1], K. Blazer[1], H. Bichkoff[2], J. Weitzel[1]* 1) Clinical Cancer Genetics, City of Hope, Duarte, CA; 2) California Cancer Care, Inc, Greenbrae, CA.

Genetic cancer risk assessment (GCRA) is considered standard-of-care for hereditary cancer syndromes, but many patients report barriers to access, in part due to insurer denial of coverage for cancer risk consultation and genetic testing. Given that a growing proportion of care is delivered via managed care organizations (MCOs), efforts to increase access to appropriately-recommended GCRA services will need to include the dissemination of evidence-based information about the clinical utility and economics of GCRA to decision makers within MCOs. As part of an educational intervention we conducted a formal focus group to identify key themes and then conducted 4 roundtable sessions with managed care decision makers (n=20 participants), such as medical directors of independent practice associations. Each roundtable session included a continuing medical education (CME) lecture about the process, economics, and utility of GCRA, followed by an abbreviated focus group component to elicit current practices and information needs. Participants GCRA knowledge and practices were surveyed. While 32% of participants reported being very aware of the process and utility of genetic testing for cancer risk, only 11% rated their organization similarly. Thirty-seven percent stated their organizations have a written policy regarding genetic testing for cancer risk, and 47% were aware of cancer genetics resources in their service area. Content analysis of the focus groups indicated a need for more evidence-based information about the utility of GCRA, concise summaries of syndromes, and cost-effectiveness data. The focus group process also yielded valuable information regarding knowledge, opinions, perceived need for and current organizational policies regarding GCRA authorization. The educational intervention was tailored using feedback from participants and will be disseminated to top-tier decision and policy makers about the process, efficacy and economics of GCRA.

Proteomic analysis of the purkinje cell degeneration mouse yields evidence for a bioenergetics basis for the neurodegeneration. *L. Chakrabarti, S. Ryu, B. Gallis, S. Schaffer, D. Goodlett, A. La Spada* Laboratory Medicine, University of Washington, Seattle, WA.

The Purkinje cell degeneration (*pcd*) mouse is a unique recessive model of neurodegeneration, as *pcd* mice undergo a dramatic postnatal degeneration of Purkinje cell neurons and retinal photoreceptors, yielding a phenotype of ataxia and blindness. In 2002, the causal gene for *pcd* was found to be *Nna1*. The Nna1 protein contains an evolutionarily conserved zinc carboxypeptidase domain, suggesting that loss of this protease function somehow results in rapid neurodegeneration and neuron cell death. Using a proteomics approach, we compared the protein expression profiles of retinas from sets of presymptomatic *pcd* mice and their wild-type littermates (n = 4 / group). After trypsin digestion, peptide counts were obtained by LC-MS/MS analysis on an LTQ-FT. The resulting tandem mass spectrometry data (obtained in triplicate) was searched using SEQUEST, and identified proteins filtered using the Protein Prophet probability score. Protein relative abundance was measured using protein sequence coverage, peptide/spectrum count, and peptide intensity area/height, using the spectral count method. Finally, ratios were calculated for relative abundance between mutant *pcd* and wild type samples, yielding a list of the most significantly changed, highly abundant proteins ($p < 0.05$ and abundance >15). Most of the proteins showing altered expression in pcd retina are involved in energy metabolism, with 2/3 localizing to mitochondrial metabolic pathways. Especially noteworthy was a preponderance of enzymes from the glycolytic pathway, whose expression alterations in retina and cerebellum have been confirmed by Western blot analysis. Our findings thus suggest that loss of Nna1 function resulting in a bioenergetics defect underlies *pcd* pathogenesis.

The P2 Promoter of Hepatocyte Nuclear Factor-4 alpha Gene is Associated with Type 2 Diabetes, the AADM Study. *Y. Chen[1], G. Chen[1], J. Zhou[1], A. Doumatey[1], H. Huang[1], A. Adeyemo[1], G. Dunston[1], F. Collins[2], C. Rotimi[1]* 1) National Human Genome Ctr, Howard Univ, Washington, DC; 2) National Human Genome Research Institute, Bethesda, MD.

Hepatocyte Nuclear Factor-4 alpha (HNF4a), located at chromosome 20q12-q13.1, is a transcription factor important to the development and function of the beta-cell. A number of studies based on several different populations including the Finns, Ashkenazi Jews, Pima Indians and Japanese, have demonstrated association of genetic variations of HNF4a with type 2 diabetes. African American is one of the ethnic groups with the highest prevalence of type 2 diabetes, which is twice as high as that of Caucasians. Our previous genome wide scan showed evidence of linkage of type 2 diabetes to 20q11.2-q13.3 region in West Africans, the founder population of African Americans. In this study, a total of 756 individuals from four tribes of two West African countries, Nigeria and Ghana, were genotyped. We found that the G allele of SNP rs6031558, located at the P2 promoter of HNF4a gene, was associated with 1.43-fold increased risk of type 2 diabetes. Considering that the frequency of G allele in this population is 49.5%, it appeared that HNF4a played an important role in the development of type 2 diabetes in West Africans.

Determining relative values of interphase Panel FISH and conventional chromosome studies in hematological malignancies. *R.A. Conte, L.A. Cannizzaro, D.T. Walsh, M. Zohouri, K.H. Ramesh* Department of Pathology, Montefiore Medical Center, Bronx, NY.

Characterization of hematological malignancies (HM) with greater certainty is warranted for improved patient care. Flow cytometry and bone marrow (BM) histology/hematology are routinely used to type the HM, cytogenetic testing usually follows. Our goal was to determine if interphase Panel FISH (PF) analyses, (diagnosis-specific battery of DNA probes), improved this capability. Using BM or unstimulated peripheral blood samples of 119 patients we determined relative values of chromosome analyses (CA) and PF results. There were 29 patients with myelodysplastic syndrome (MDS), 23 with acute myeloid leukemia (AML), 27 with acute lymphocytic leukemia (ALL), 15 with chronic lymphocytic leukemia (CLL), 8 with non-Hodgkin lymphoma (NHL), 13 with multiple myeloma (MM) and 4 with myeloproliferative disease (MPD). In 8/119 patients (6.7%), CA and PF results were abnormal; in 5/119 patients (4.2%), PF results were normal and CA results were abnormal; in 58/119 patients (48.7%), PF and CA results were normal, and in 48/119 patients (40.3%), the PF results were abnormal and the CA results were normal, had failed or inconclusive. Abnormal PF results (when CA were normal, had failed or inconclusive) were consistent with the suspected clinical diagnoses in 6/29 (20.7%) patients with MDS; 7/23 (30.4%) with AML; 16/27 (59.3%) with ALL; 10/15 (66.7%) with CLL; 2/8 (25.0%) with NHL; 6/13 (46.2%) with MM and 1/4 (25%) with MPD. Results revealed that in 40.3% of the patients with normal, failed or inconclusive CA, abnormalities were detected by PF analyses alone. PF analysis was most promising in detecting abnormalities in ALL (59.3%), CLL (66.7%) and MM (46.2%) where the detection of abnormalities by CA was normal, had failed or was inconclusive. If an abnormality has been established by PF, then the determined specific probes can be used to continually monitor the HM. This study showed that PF, when used alone or in conjunction with CA, is a vital and essential diagnostic tool that provides improved diagnostic capabilities to physicians in planning treatment modalities and monitoring prognoses.

Heritability of physical performance measures in older Amish. *P. Gallins[1], J.L. McCauley[1], L. Jiang[1], P.C. Gaskell[1], A.E. Crunk[2], M. Creason[1], L. Caywood[1], D. Fuzzell[2], C. Knebusch[2], M.C. Morey[1], E.R. Hauser[1], C.E. Jackson[3], J.R. Gilbert[1], M.A. Pericak-Vance[1], J.L. Haines[2], W.K. Scott[1]* 1) Duke University, Durham, NC; 2) Vanderbilt University, Nashville, TN; 3) Scott & White, Temple, TX.

Cognitive and physical decline are common, but not universal, features of aging. Variation in the degree of physical function has been observed, and several measures of physical function (such as grip strength and total score in the EPESE physical performance battery) are heritable in twin samples. We have measured several aspects of physical performance in our ongoing studies of successful aging (SA), or healthy longevity, in older Amish adults. The Amish communities of northeastern Indiana and central Ohio were founded in the mid-1800s by a small number of individuals and have remained socially and genetically isolated. Thus, they may have reduced numbers of genetic polymorphisms governing these traits and smaller variation in the traits due to environment, making identification of complex trait loci more feasible in this population. We have measured hand grip strength, lower extremity function (balance, gait speed, and standing from a chair), and cognition (3MS) in 246 Amish adults over age 65 clustered in 13 kindreds of closely related members. Heritability of these quantitative measures of function was determined using the polygenic model function of the SOLAR package. All measures were normally distributed or transformed to a normally distributed measure. Models contained sex, body mass index, age, and cognitive status (3MS) as covariates. Several performance measures were significantly heritable: log grip strength (h^2=0.43, p=0.03), total lower extremity function [sum of balance, gait speed, and chair stands from EPESE physical performance battery] (h^2=0.40, p=0.02), balance (h^2=0.45, p=0.006), and gait (h^2=0.36, p=0.04). These results suggest that several measures of physical performance are heritable in older Amish adults, confirming the prior twin studies. These traits might be useful intermediate traits for mapping genes involved in successful aging.

Multipoint PPL analysis of cleft lip with/out cleft palate (CL/P) provides compelling evidence in favor of linkage.

M. Govil[1], M.L. Marazita[1], J.C. Murray[2], L.L. Field[3], V.J. Vieland[4] 1) U of Pittsburgh,PA; 2) U of Iowa, IA; 3) U of British Columbia, Canada; 4) CCRI, Columbus, Ohio.

Non-syndromic CL/P, the most commonly occurring congenital craniofacial anomaly, presents a special challenge for testing and identifying candidate genes and regions due to its complex etiology, epidemiology, and ethnicity-specific prevalence. This necessitates analytical approaches, such as the posterior probability of linkage (PPL), capable of modeling expected heterogeneity and geographic variation in CL/P. The PPL integrates over the trait model parameters, explicitly allows for intra- and inter-sample heterogeneity, and accumulates evidence for/against linkage across heterogeneous data sets/subsets via sequential updating. Application of the PPL to a 2-point 10cM genome scan (Govil et al, ASHG, 2005) of ethnically diverse families indicated regions for multipoint analysis on chromosomes 1, 2, 6, 9 and 12. Since computing the PPL involves evaluation of a multi-dimensional likelihood integral with no analytical functional form, it is approximated using grid enumeration, which imposes a considerable computational burden. In the case of multipoint analyses, the complexity of a single likelihood calculation adds to the complexity of the method. For CL/P data from China, India, Philippines, Turkey and Pittsburgh, computation of the 3-point imputed PPL for select regions took 6 months on 36 processors. However, the statistic, computed for the pooled data and updated over 5 populations of origin (POP) and/or 4 cleft phenotypic groups (PG), provides striking results. First, based on POP, the PPL indicates a 90% probability of a gene linked to a 14cM region on 6q. Notably, association results were also observed on 6q (Marazita et al, this meeting). Second, updating over both PG and POP provides an 82% PPL for 2p, as compared to 10% for the pooled data. While effort is ongoing to improve the computational speed for the PPL, these results are exciting and clearly indicate very specific regions for further analysis. Molecular characterization of a pericentric inversion of chromosome 3 in a 3-generation family with short stature. *U. Dutta, F. Matthes, K. Peisker, I. Hansmann, D. Schlote* Institut für Humangenetik und Medizinische Biologie, Halle/Saale, Germany.

Structural chromosomal aberrations are often associated with a specific phenotype and they are a significant cause of human disorders.Characterization of the breakpoints may lead to the identification of the responsible gene.Here we report a case of short stature in a girl with a karyotype of 46,XX,inv(3)(p24.2q26.1). Cytogenetic analysis had revealed a familial inversion 3, being heterozygous in the proband, mother and her grandmother. In order to characterize the breakpoints FISH (Fluorescence- *in situ* -hybridization) experiments were performed. Initially YAC (Yeast Artificial Chromosome) clones were selected by *in silico* analysis using the respective human genome database. From the four p-specific YACs selected , YAC clone CEPHy904H0787 (1090 kb) gave a split signal on the metaphase chromosomes of the proband assigning the breakpoint to 3p24.2.The split signal indicates that the target sequence carries the inversion breakpoint. YAC insert end sequencing was also done which lead to the identification of BACs (Bacterial Artificial Chromosome) for further FISH analysis. Out of the 15 YACs selected on the q arm, YAC CEPHy904G07889 (1610 kb) showed a split signal assigning the breakpoint to chromosomal band 3q26.1. Further analysis using 10 BACs in this region narrowed down the breakpoint to 100 kb represented in BAC RP11-12N13 thus giving a split signal. Using subcloned fragments of this BAC as well as Long range PCR products as probes the breakpoint is now located with in a region of 13 kb. This should help us in identifying putative candidate genes in the region of interest correlating the inversion with the phenotype of the proband.

The MICA gene distinguishes the extended HLA Type 1 Diabetes (T1D) associated risk haplotypes: findings from an association study and a meta-analysis. *B.Z. Alizadeh[1,2], P. Eerligh[2], A. van der Slik[2], A. Shastry[3], A. Zhernakova[1], J.G. Bruining[4], C.B. Sanjeevi[3], C. Wijmenga[1], B.O. Roep[2], B.P.C. Koeleman[1,2]* 1) Complex Genetic Section, Dept. Medical Genetics, UMC Utrecht, The Netherlands; 2) Dept. Immunohematology & Blood Transfusion, LUMC, Leiden, the; 3) Dept. of Molecular Medicine Karolinska Hospital, Stockholm, Sweden; 4) Dept. of Pediatrics, EMC, Rotterdam, the Netherlands.

The association of HLA complex cannot explain the total linkage of HLA region on chromosome 6 to autoimmnue disorders, leading to the hypothesis that there are other causal genes in the HLA region for immune related diseases. The MICA gene on chromosome 6 is involved in immune signal transduction, and was associated to autoimmune diseases, including T1D. Its variations are informative genetic indicators of recent human migration. Thus, a co-analysis of MICA with the HLA DQ DR haplotype may reveal secondary genes involved in T1D. In our cases (n=350) and controls (n=540), we found that the MICA*A5 and MICA*A6 variants were significantly associated with an increased and decreased risk for T1D, respectively. In a meta-analysis of 14 published studies, we confirmed the significant association of MICA*A5 to T1D only in Caucasians, but the protective effect of MICA*A6 in T1D was found worldwide. We found a significant LD between MICA and HLA complex. Thus, we performed a conditional analysis on T1D-associated high risk HLA DQ-DR haplotypes. Overall, conditional analysis did not confirm a significant HLA-independent association of MICA with T1D. MICA*A6 showed the highest risk for T1D when it was coinherited with T1D-risk HLA DQ2-DR3 haplotypes. In carriers of the T1D-risk HLA DR4-DQ8 haplotype, MICA*A9 showed a significant association to increased risk for T1D. Despite the initial findings of our data and the meta-analysis that confirmed the association of MICA with T1D, we found no HLA-independent relationship between MICA and T1D. Our results showed the highest T1D-associated risk lies with the co-inheritance of MICA*A6-HLA DQ2-DR3 haplotype, indicating this is the most likely haplotype to harbor the additional T1D-associated genetic factors in the HLA region.

Variants in *TCF7L2* are Associated with Predictors of Type 2 Diabetes Mellitus in Pima Indians. *T. Guo, Y. Muller, M. Traurig, J. Mack, L. Ma, R. Hanson, S. Kobes, C. Bogardus, L. Baier* Diabetes Molecular Genetics Section, NIDDK, NIH, Phoenix, AZ.

The transcription factor 7-like 2 gene (TCF7L2 or TCF4) has been reported to be associated with type 2 diabetes mellitus (T2DM) in Iceland,Danish and US populations.In that report,the strongest association was observed with marker DG10S478,positioned within intron 3 of TCF7L2.To investigate whether *TCF7L2* also has a role in T2DM susceptibility in the Pima Indians,a population with the worlds highest prevalence of T2DM,the marker DG10S478 and 38 SNPs that span *TCF7L2* were genotyped in 1311 Pima Indians.DG10S478 was essentially monomorphic for the protective allele in Pima Indians (1290 of the 1311 subjects were homozygous for allele 0). Only one SNP (rs1225404) within intron 10 was associated with T2DM (p= 0.01).However,several other SNPs were associated with pre-diabetic traits among non-diabetic Pima Indians who had been metabolically phenotyped (N=356).Five SNPs,all in high linkage disequilibrium (LD:D>0.9),spanning the 5-flanking region and exon 1 were associated with BMI (p=0.02-0.0002).Three additional SNPs, in high LD among themselves, within intron 3 were also associated with BMI (p= 0.01-0.04).Six SNPs spanning intron 3-4,the region containing marker DG10S478,were associated with measures of insulin secretion (acute insulin response as determined following an intravenous bolus glucose injection,p=0.02-0.002, and 30 min. plasma insulin concentration after an oral glucose tolerance test,p=0.03-0.0075) among 188 normal glucose tolerant Pima Indians. Several SNPs spanning exon 5 through the 3UTR were modestly associated with measures of insulin action, with the strongest association coming from rs10787475 (p= 0.00001 for 60 minute glucose response to an OGTT, and p=0.03 for glucose uptake rate in response to physiologic insulin concentrations during a clamp).Expression profiling of *TCF7L2* identified the major transcripts in all tissues that were tested, including pancreas, islet, adipose, liver and skeletal muscle. These results indicate that *TCF7L2* may have multiple roles in T2DM susceptibility, by affecting BMI, insulin secretion and insulin resistance.

Prenatal screening by array comparative genomic hybridization: A proposal for clinical practice guidelines. *M. Cho, The CIRGE Genetics Policy Working Group* Pediatrics/Genetics, Stanford Center for Biomedical Ethics, Palo Alto, CA.

Array-based comparative genomic hybridization (aGCH) and other techniques for genome-wide analyses have begun to be used for genetic screening, including the prenatal screening context. These techniques may also be used soon on single cells for preimplantation genetic diagnosis (PGD). These technologies, relying primarily on measures of copy number variation compared to a normal reference standard, raise a number of clinical, social and ethical issues that should be addressed before widespread use. Uncertainty about the clinical meaning of the data generated by aCGH, the potential for widespread use in conjunction with amniocentesis or chorionic villus sampling, the vast number of conditions and loci that could be included in aCGH screening, the complexity of genetic counseling necessary for such screening, and access are just some of the issues that should be considered in the clinical application of aCGH. In the summer of 2006, the Center for Integration of Research on Genetics and Ethics (CIRGE) at Stanford University invited a group of nationally known clinicians (including clinical geneticists, genetic counselors, and obstetrician/gynecologists), genetic researchers and ethicists to attend a workshop to address these issues. The group also includes members representing professional societies such as ACMG and ACOG. The purpose of this workshop is to develop a framework for clinical practice guidelines, with input from a variety of disciplinary perspectives. The goal of this group effort is to create a proposal for guidelines for the translation of aCGH from the research to the clinical setting that will be useful for clinicians and researchers developing similar technologies at universities and biotechnology companies. The proposed guidelines will address the currently proposed applications (including prenatal screening) and those proposed for the near future (including PGD) and will serve as a resource for development of practice guidelines by professional societies.

Identification of a novel locus on chromosome 7 in familial cases of Premature Ovarian Failure. *S. Caburet[1], P. Laissue[1], S. Christin-Maitre[2], P. Bouchard[2], Z. BenNeriah[3], S. Shalev[4], S. Copelli[5], D. Bacq[6], S. Heath[6], M. Lathrop[6], R.A. Veitia[1], M. Fellous[1]* 1) Team 21, Cochin Institute, Paris, France; 2) Service of Endocrinology, St-Antoine Hospital, Paris, France; 3) Hadassah Hospital, Jerusalem, Israel; 4) Haemek Medical Center, Afula, Israel; 5) Caece University, Buenos Aires, Argentina; 6) National Center for Genotyping, Evry, France.

Premature ovarian failure (POF) is a disease affecting 1 to 3 % of women before the age of 40 years and 0.1 % of women below the age of 30 years. Patients present a primary or a secondary amenorrhea and an hypergonadotroph hypogonadism. Genetic alterations or mutations have been involved in POF. The most frequent anomalies are chromosome X alterations, such as monosomy associated with Turner syndrome, deletions or X:autosome translocations. Unfortunately, in more 90 % of POF patients, the aetiology of the disease is still unknown. For this reason, we set up an international network in order to perform a positional cloning approach in familial cases. We have collected a large panel of familial cases (9 families with 30 POF cases). A genome-wide genotyping was performed using 457 microsatellite markers for all the individuals (affected or not). Evidence for significant linkage was detected on the long arm of chromosome 7 with a peak lod-score of 3.85 in 7q21-22, defining a 62 Mb-long region between markers D7S502 and D7S530. This large region was refined using 35 microsatellites between D7S502-530. The region of interest is presently 10 Mb long and contains more than 130 genes. As some of the studied families present consanguinity, we also analyzed the results of the genome scan by homozygozity mapping. The identified region on 7q coincides with a minimal region of homozygosity by descent shared between the affected members of the consanguinous families. We are currently refining the region of interest by adding new individuals and new families in our study. In addition, two functionnal candidate genes present in the region will be sequenced soon. Finding new genes involved in POF will contribute to a better understanding of normal folliculogenesis and ovarian physiopathology.

Anti-inflammation treatment by Indomethacin extended the life span of the Krabbe disease variant saposin A deficient mice. *S. Barnes, Y. Sun, G. Grabowski* The Division and Program in Human Genetics, Children's Hospital Research Foundation, and University of Cincinnati College of Medicine, Department of Pediatrics, Cincinnati, OH.

Prosaposin is the precursor of four ~80 amino acid proteins known as saposins (termed A, B, C, or D) that are necessary for the activity of several lysosomal hydrolases in the glycosphingolipid metabolic pathway. Genetic deficiencies of individual saposins lead to lysosomal storage diseases that phenotypically mimic the deficiencies of the cognate enzymes e.g., saposin A is essential for galactosylceramidase (Krabbe enzyme) activity. We seek to characterize and elucidate the differential cellular characteristics and temporal events important to central nervous system deterioration in complete or partial prosaposin deficiencies, including the role of proinflammatory reactions. Here, 21 day-old saposin A (Sap A -/-) deficient mice were treated with low doses (0.8 mg/kg/day) of indomethacin, an inhibitor of the COX II (cyclooxygenase) proinflammatory pathway. Indomethacin treated mice lived longer (>7 days) than their untreated littermates. Immunohistochemical studies showed decreased levels of CD68 positive staining in the brains and spinal cords of indomethacin-treated mice that correlated with increased survival. In contrast, no effects on CD68 were observed in sciatic nerve. Western blot analyses revealed significantly decreased Il-1 and TNF- and glial fibrillary acid protein levels in Sap A -/- mice receiving indomethacin. However, at end stage (12 wks), treated mice showed similar levels of these inflammatory-related molecules as untreated mice. This study demonstrates that inflammation is a component of disease progression. Activation of the cyclooxygenase pathway may contribute, but is not the major inflammatory pathway involved in the pathogenesis of saposin A galactosylceramidosis.

Clinical and molecular study of 348 children with Marfan syndrome and related type I fibrillinopathies out of a series of 1057 probands with a pathogenic FBN1 mutation. *L. Faivre[1,2], C. Stheuner[3], G. Collod-Beroud[4], P. Chevallier[3], A. Child[5], B. Callewaert[6], C. Binquet[2], E. Gautier[2], E. Arbustini[7], K. Mayer[8], A. Kiotsekoglou[5], P. Comeglio[5], B. Loeys[6], J. De Backer[6], P. Coucke[6], U. Francke[9], L. Ades[10], A. De Paepe[6], C. Boileau[3], G. Jondeau[3]* 1) Dept Genetics, Dijon, France; 2) Inserm CIE1, Dijon, France; 3) Consultation pluridisciplinaire Marfan, Hôpital Ambroise Paré, France; 4) IURC, Montpellier, France; 5) St Georges Hospital, London, UK; 6) Medical Genetics, Ghent, Belgium; 7) Molecular Diagnostic, Pavia, Italy; 8) Human Genetics, Martinsried, Germany; 9) Stanford University Medical Center, USA; 10) Royal Alexandra Hospital, Sydney, Australia.

From a large series of 1057 probands with a FBN1 mutation, data from 348 patients aged less than 18 years were analyzed (33%). The population was classified as follows: 17% neonatal MFS, 18% severe MFS, 31% classical MFS and 34% probable MFS (defined by incomplete Ghent criteria in childhood). No differences were noted in the frequency of specific diagnostic manifestations when compared to adults, ie ectopia lentis (EL, 56%), ascending aortic dilatation (AAD, 70%) and major skeletal involvement (22%). In contrast, striae distensiae (18%) and family history (29%) were underrepresented. When excluding patients with neonatal MFS, the mean age at diagnosis was 8.2 years. The first diagnostic feature was EL in 18%, AAD in 28%, both EL and AAD dilatation in 29% and other presentations in 25% of cases. 32% of mutations were located in exons 24-32 vs 13% in adults ($p<0.0001$), 27% in the 5 region vs 30% in adults (p NS), 26% of mutations resulted in premature stop codons vs 36% in adults ($p=0.0006$) and 64% were missense mutations involving a cysteine vs 58% in adults (p NS). Only 55% of the children met the Ghent criteria, and this proportion rose to 81% when the presence of a FBN1 mutation was considered as a major feature. Because of the low sensibility of clinical Ghent criteria during childhood, we recommend mutation screening in children with one major and one minor criteria and aortic follow-up even in children with incomplete Ghent criteria.

Wnt Signaling in Craniofacial Patterning. *S. Brugmann[1], A. Gregorieff[2], P. Leucht[1], H. Clevers[2], J. Helms[1]* 1) Department of Plastic Surgery, Stanford University, Stanford, CA; 2) Hubrecht Lab, Netherlands Institute for Developmental Biology, The Netherlands.

Wnt signaling has been implicated in numerous aspects of craniofacial development, including the generation of neural crest cells and the patency of cranial sutures. Herein, we examined the role of Wnt signaling during development of the facial prominences using the TOPgal reporter mouse line as an indicator of cells that have responded to a canonical Wnt signal. We observed that Wnt responsive cells define distinct boundaries within the frontonasal prominence (FNP). By E9.5 the central region of the FNP is devoid of Wnt responsive cells. This marked absence of Wnt responsiveness in the FNP is maintained to E15.5 and beyond, and delineates the midline infranasal depression (also known as the philtrum) from the more lateral regions of the midface. To confirm a role for Wnt signaling in medial/lateral patterning we used two separate methods to attenuate Wnt signaling. First, we inhibited Wnt signaling by knocking out two intracellular enhancers of Wnt signaling, Lef1 and TCF4 (i.e., Lef1-/-/TCF4-/-). Second, we used in utero gene transfer to inhibit Wnt signaling by infecting murine embryos with an adenovirus expressing the soluble Wnt inhibitor, Dickkopf 1 (Dkk1). Attenuating Wnt signaling using both experimental conditions resulted in the expansion of facial midline. Midline expansion, defined by an increased distance between lateral populations of Wnt responsive cells in TOPgal reporter mice, was often accompanied by a flattened infranasal depression and/or a dysmorphic nasal septum. We examined the in situ hybridization patterns for Wnt target genes and performed histological analyses in embryos with expanded midlines to characterize the molecular and cellular nature of this phenotype. Collectively these data begin to elucidate a role for Wnt signaling, independent of neural crest generation, in the development and patterning of the craniofacial complex.

MAOA promoter polymorphism is associated with brain structure volumes in autism. *L. Davis[1], C. Hazlett[2], M. Mosconi[2], J. Piven[2], T. Wassink[1]* 1) Department of Psychiatry, University of Iowa Carver College of Medicine, Iowa City, IA; 2) Neurodevelopmental Disorders Research Center and Dempartment of Psychiatry, University of North Carolina, Chapel Hill, NC.

Monoamine oxidase A (MAOA) is an enzyme expressed in the brain that metabolizes dopamine, norepinephrine, epinephrine and serotonin (Lenders, 1996). Abnormalities of serotonin neurotransmission have long been implicated in the psychopathology of autism. A polymorphism exists within the promoter region of the MAOA gene that influences MAOA expression levels. This polymorphism has four common alleles that can be grouped into high activity and low activity based on in vitro and in vivo expression studies (Sabol et al., 1998). The low activity alleles are associated with increased neurotransmitter levels in the brain. Individuals with autism often exhibit elevated serotonin levels (Anderson et al., 1987). This suggests a deficit in serotonin metabolism that may be accounted for by low activity MAOA expression. Additional studies indicate that the low activity allele may be associated with lower IQ and more severe autistic symptoms (Yirmya, 2002). In this study we genotyped the MAOA promoter polymorphism in a group of 33 males (age 2-3 yrs) with autism for whom brain MRI data was available. Using ANCOVAs, we tested relationships between MAOA genotype and frontal lobe, temporal lobe, parietal-occipital lobe gray and white matter volumes and cerebellar gray and white matter volumes. Covariates included age at the time of scan and head circumference. We found a consistent association between the low activity allele and larger brain volumes for several regions of the brain, including total cerebral gray ($F_{1,25}=5.31$, $p=0.03$), total cerebral white ($F_{1,25}=4.81$, $p=0.04$), frontal white matter ($F_{1,25}=7.29$, $p=0.01$), and frontal gray matter ($F_{1,25}=4.10$, $p=0.05$). These results correlate well with the replicated finding that children with autism often have macrocephaly. Future studies will determine if there is a more severe clinical phenotype associated with both the low activity genotype and the larger brain volumes in our sample.

Surgical interventions in MPS I patients: a significant burden in all phenotypes. *P. Arn*[1], *E. Wraith*[2] 1) Div Genetics, Nemours Children's Clinic, Jacksonville, FL; 2) Willink Biochemical Genetics Unit, Royal Manchester Children's Hospital, Manchester, UK.

Mucopolysaccharidosis I (MPS I) is caused by a deficiency of -L-iduronidase, the lysosomal enzyme that hydrolyzes the terminal -L-iduronic acid residues of dermatan and heparan sulfate. Patients with MPS I have traditionally been classified as having Hurler, Hurler-Scheie, and Scheie syndromes, however there is substantial clinical overlap between the phenotypes. All patients with MPS I suffer from a number of progressively debilitating symptoms affecting multiple organ systems. BioMarin/Genzyme LLC established the MPS I registry to track the outcomes of patients with MPS I. The registry was queried to assess the surgical needs of patients with MPS I. Of the 425 patients enrolled in the registry at the time of the query, 919 surgical interventions were reported. Repetition of the same surgery (ex multiple PE tube placements) was considered a single procedure. Age at the time of the surgical intervention ranged from 2 months to 65 years. The most common interventions were PE tubes, hernia repair, and adenoidectomy. Median age at these procedures was 1.8 years for PE tubes and for hernia repair and 2.8 years for adenoidectomy. Of 141 patients reporting PE tube placement 29 procedures were done prior to diagnosis of MPS I; of 136 reporting hernia surgery, 58 were performed prior to diagnosis, and of 124 adenoidectomies 26 were done prior to diagnosis. In total, 177 surgical procedures were performed prior to the diagnosis of MPS I. These procedures included 8 VP shunts, 5 spinal cord decompressions, 3 cardiac valve replacements, and a corneal transplant. Surgery prior to diagnosis was reported in all classifications of MPS I, Hurler, Hurler-Schie, and Scheie. The type and ages at intervention for all procedures will be reported. We conclude that the surgical burden of all phenotypes of MPS I is high. A large number of MPS I patients undergo surgical procedures prior to diagnosis, potentially putting them at risk for complications. Education programs aimed at surgeons may assist in earlier diagnosis of these patients.

Ascertainment of multiplex families can decrease the power of association analysis. *M.A.R. Ferreira[1], P. Sham[2], M.J. Daly[1], S. Purcell[1]* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Institute of Psychiatry, King's College London, UK.

Many Mendelian diseases have been reported to have both sporadic and familial forms, i.e. present in either one or multiple relatives in a family. Familial cases are thought to arise from the inheritance of a genetic mutation and so are the natural choice for gene mapping of Mendelian traits. The same assumption is often made in the context of family-based designs for complex diseases. Indeed, many association studies use families with multiple affected relatives in the hope that this will increase power to detect a disease locus. However, our recent work and that of others has indicated that the converse is often true - for a range of scenarios that are likely to be encountered for common diseases, preferentially ascertaining multiplex families can actually reduce power, even for the same total sample size. Critically, the performance of different ascertainment strategies depends on residual sources of variation (i.e. other than the locus being studied), a fact that has often been ignored in previous work. Here, we describe a set of web-based tools that quantify the relative merits of different design strategies, tailored to the specifics of the disease under study. These tools implement a liability threshold model that allows researchers to estimate the power of the TDT for different effect sizes, residual heritability, shared environmental variance and family structures. Users can also specify more than one disease model in the population and so assess the impact of etiologic heterogeneity. For example, the power provided by 400 trios selected with disregard of the affection status of other relatives was 0.885 (= 0.05), assuming a disease prevalence of 5%, a locus that explains 1% of the variance in liability to disease (MAF = 5%), heritability of 40% and shared environmental variance of 10%. By contrast, the power provided by 400 trios selected conditional on having 2 additional affected sibs was 0.686. With these tools, researchers can determine whether the extra effort involved in selecting multiplex families will be helpful or counterproductive.

Gender-specific association of the UGT2B17 gene deletion with decreased glucuronidation of NNAL and increased risk for lung cancer. *C.J. Gallagher, J.E. Muscat, A.N. Hicks, A.M. Dyer, G.A. Chase, J.P. Richie Jr., P. Lazarus* Penn State Cancer Institute, Penn State College of Medicine, Hershey, PA.

UGT2B17 is a phase II metabolizing enzyme that mediates the detoxification of the tobacco smoke carcinogen, NNAL, by converting it to its glucuronide (NNAL-Gluc). A deletion allele encompassing the entire UGT2B17 gene was identified and found to reduce the rate of NNAL glucuronidation in human liver microsomes *in vitro*. The goal of the present study was to determine if the UGT2B17 deletion genotype is associated with reduced rates of glucuronidation *in vivo* and with increased risk for lung cancer. We developed a novel multiplex real-time PCR assay to genotype the UGT2B17 gene deletion. In a screening of 82 white smokers, the urinary concentrations of NNAL and NNAL-Gluc were measured. A significant decrease in urinary NNAL-Gluc to NNAL ratio was observed among smokers with the UGT2B17 deletion [(0/0)] genotype when compared to smokers with at least one intact UGT2B17 allele (p-value=0.049). This association was only observed in females (p-value=0.058); no association was observed in males (p-value=0.597). In an analysis of 398 white subjects with newly-diagnosed primary lung cancer and 697 white controls, a significant increase in risk for lung cancer was observed in women with the UGT2B17 (0/0) genotype when compared to women with at least one intact UGT2B17 allele (OR=2.0, 95% CI=1.04-3.75). No association was observed between the (0/0) genotype and lung cancer risk in men (OR=0.7, 95% CI=0.39-1.39). The association between the (0/0) genotype was stronger in women with adenocarcinoma (OR=3.2, 95% CI=1.48-6.90); this association was also not present in men (OR=1.3, 95% CI=0.58-3.09). The association of the UGT2B17 gene deletion was highest for adenocarcinoma, which is consistent with animal model studies demonstrating that NNAL is a selective inducer of lung adenocarcinoma. In summary, the UGT2B17 (0/0) genotype was shown to be associated with decreased glucuronidation of NNAL and increased risk for lung cancer (specifically for adenocarcinoma) in women. This is the first study to show a genetic basis for the observed excess risk of lung cancer in women versus men.

An association study of CD74 and Metallothioneins in multiple sclerosis. *K. Duvefelt[1,3], M. Swanberg[2], C.M. Lindgren[1], O. Lidman[2], T. Olsson[2], H. Harbo[4], J. Saarela[5], A. Oturai[6], J. Hillert[3]* 1) Mutation Analysis Facility, Clinical Research Center, Karolinska University hospital, Stockholm, Sweden; 2) Neuroimmunology Unit, Department of Clinical Neuroscience, Karolinska Institutet,Sweden; 3) Division of Neurology, Department of Clinical Neuroscience, Karolinska Institutet, Sweden; 4) Institute of Immunology, Rikshospitalet University Hospital, Oslo, Norway; 5) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 6) Department of Neurology, Copenhagen University Hospital, Rigshospitalet, Copenhagen, Denmark.

We studied two gene loci, CD74 (also known as invariant chain) on chromosome 5q33 and Metallothionein (MT) on chromosome 16q, for a possible importance in determining susceptibility to Multiple Sclerosis (MS), based on their upregulated transcription in the spinal cord in an experimental animal model of inflammation and neurodegeneration. Seven single nucleotide polymorphisms (SNP) in the CD74 gene and 9 SNPs in the MT cluster were analyzed in a Swedish cohort consisting of 890 MS patients and 775 controls. Three SNPs belonging to the same linkage disequilibrium (LD) block in the MT region were found to be associated with the risk of MS (P0.05, OR: 1.24-1.47) as well as one haplotype (P=0.018) consisting of the three associated SNPs and two additional SNPs. One SNP in CD74 showed borderline signs of association, while the other SNPs in the same LD block did not show any association. The associated SNPs in the MT gene region were subsequently studied in a Nordic case control material of 1277 MS samples and 1396 controls. In the Nordic material no association to the risk of MS were found for the studied SNPs.

A Direct Long SAGE Tag-to-Gene Mapping Scheme. *A.E. Dellinger, T. Wang, C.B. Rickman, M.A. Hauser* Center for Human Genetics, Duke University, Durham, NC.

Serial Analysis of Gene Expression (SAGE) is a commonly used, open source technique that evaluates the level of genes expression via total RNA. cDNA is synthesized from RNA and 14bp tags are cut by *NlaIII* and *MmeI*. One difficulty of SAGE is determining the most appropriate method of mapping this tag to a gene. With the advent of the 21bp Long SAGE tag, we can map the tag directly to its gene(s). A straightforward yet biologically thorough method of Long SAGE tag-to-gene mapping has not been defined until now. Our method provides a quick transition from raw data to the goal of SAGE- the analysis of gene expression.

A virtual Long SAGE library was generated by scanning Build 36 of the human genome for tags associated with *NlaIII* sites on both forward and reverse strands. In 56 Long SAGE libraries, 48% of tags mapped to exon regions are antisense. Thus, we always consider both strands. Each tag was mapped to its physical location(s) in the genome. Not all tags map by this method. Over 8% of all human genes contain at least one SNP associated tag (1). SNPs can alter tags or create them by creating *NlaIII* sites. A PERL script found the SNP generated tags in SNPdb (2). Another PERL script found the 5.3% of virtual Long SAGE tags that cross exon boundaries. These tags were reconstituted by concatenating the partial tags with a sufficient number of nucleotides from the next transcribed exon to complete the 17 bp tag. Alternative splicing resulted in multiple tags. Tags from these three techniques were mapped to exons by comparing the genomic locations of the tags and the exons in our exon database, which consolidates the Ensembl (3), UCSC known genes, and EST databases (4). The results of the initial genome scan can be downloaded and the SNP and exon programs run all in minutes. Once the full virtual tag library is created, a Long SAGE library can be quickly mapped to exons. Thus, any library can be ready to search for genes of interest in minutes.

The Language Acquisition Discrepancy (LAD) score: A new phenotyping strategy for genetic analyses in autism (AUT). *M. Cuccaro[1], J.S. Brinkley[1], J. Jaworski[1], R.K. Abramson[2], H.H. Wright[2], J.P. Hussman[3], J.R. Gilbert[1], E.R. Martin[1], M.A. Pericak-Vance[1]* 1) Ctr Human Genetics, Duke Univ Med Ctr, Durham, NC; 2) USC-SOM, Columbia, SC; 3) Hussman Foundation, Ellicott City, MD.

A variable feature in the AUT phenotype is age at language acquisition (age at first words, age at phrase speech). While genetic analyses of AUT have used language acquisition variables in stratified analyses, these variables have not been studied in a joint fashion. We developed the Language Acquisition Discrepancy (LAD) score, based on the difference in age at first words and age at phrase speech as measured by the ADI-R. Clustering algorithms using LAD score, age at first words and ADI-R composite scores (reciprocal social interaction, nonverbal communication, verbal communication, repetitive behaviors) yielded four clusters within our AUT dataset (N = 693 families; M:F = 4.5:1). Defined by a bivariate trait based on age at first words [normal 18 mos delayed] and LAD score [normal 15 mos delayed] the four clusters are: DD = delayed first words/delayed LAD score; DN = delayed first words/normal LAD score; ND = normal first words/delayed LAD score; NN = normal first words/normal LAD score. The clusters differed significantly with respect to ADI-R domains and developmental indicators with the exception of age at walking. The DD cluster was more impaired across variables. Using the pedigree disequilibrium test (PDT) we tested for association in 473 families stratified on the basis of the clusters. We tested 69 SNPS in 14 known autosomal GABA receptor subunit genes. Allelic association (p .05) was detected for SNPs on chr4 in GABRG1 (rs2350439, rs1826923), GABRA4 (rs2280073), and GABRB1 (rs1372496, hcv11353524, rs6289). These results confirm our earlier work suggesting that GABRA4 and GABRB1 interactions may be involved in risk for AUT. Two SNPs on chr15 showed evidence of association (hcv428306, rs1426217). None of the positively associated SNPs fell in the DD cluster suggesting that association is concentrated in the verbal clusters. These results highlight use of LAD in conjunction with age at first words as a potential language based phenotypic metric for genetic analyses of AUT.

Autozygosity mapping of a consanguineous family with an autosomal recessive fifth mandibular incisor phenotype using the 500K SNP Affymetrix microarray. *J.M. Gee[1], S. El-Toum[2], G.A. Mendoza[3], T.J. Pemberton[3], A. Cassia[2], A. Feki[4], A. Megarbane[5], P.I. Patel[1,3]* 1) School of Dentistry, University of Southern California, Los Angeles, CA; 2) Department of Oral Diagnostic Sciences, Lebanese University School of Dentistry, Beirut, Lebanon; 3) Institute for Genetic Medicine, University of Southern California, Los Angeles, CA; 4) Department of Oral Medicine and Oral Surgery, University Hospital of Strasbourg, France; 5) Medical Genetic Unit, Saint-Joseph University, Beirut, Lebanon.

Supernumerary teeth, or the presence of an extra tooth in the oral cavity, is a condition that is present within 0.5-3.8% of the general population. While they can be found in any region of the dental arch, they are usually located in the upper maxillary region between the two central incisors. We have ascertained a highly consanguineous extended family with a very rare autosomal recessive phenotype where four individuals display five incisors in the anterior mandible. We performed autozygosity mapping using the Affymetrix 500K SNP microarray on the four affected individuals, each from a distinct branch of the pedigree separated by seven generations. Analysis of the SNP data using an MS Excel EXLUDEAR-based method for homozygosity determination identified 48 regions of homozygosity within these four affected members that were between 0.2 to 1 MB in length. Microsatellite markers from within these regions were genotyped within 16 family members (affecteds and selected first-degree relatives of affecteds) to confirm or refute putative homozygosity. The five largest regions of homozygosity identified in the SNP scan were interrogated and have been ruled out as candidate regions. The remaining regions are being analyzed by similar microsatellite marker genotyping to identify the candidate region and to guide mutational analysis of candidate genes.

The absence of endothelin-2 partially rescues photoreceptor (PR) death in a model of inherited photoreceptor degeneration (IPD). *A. Bramall[1,2], M.J. Szego[1,2], L. Pacione[1,2], P. D'Orléans-Juste[3], M. Yanagisawa[4], R.R. McInnes[1,2]* 1) Progs in Genet & Dev Biol, Hosp for Sick Children, Toronto; 2) Dept Mol & Med Genet, Univ of Toronto; 3) Dept Pharm, Med School, Univ de Sherbrooke; 4) HHMI & Dept of Mol Genet, Univ of Texas Southwestern Med Center, Dallas.

IPDs are the most common monogenic cause of blindness in humans. The mutant PRs are at a constant risk of death (Clarke et al. Nature 2000) but function remarkably well for years to decades in humans. To identify genes that may influence the risk of death, we performed microarrays and real-time PCR on wild-type (wt) and mutant retinas. Endothelin-2 (*Edn2*) mRNA was 32-fold (p 0.0006) and 14-fold (p 0.009) in the $Rds^{+/-}$ and *Tg(RHO P347S)* mouse models of IPD, respectively. Edn2 is one of three Edn peptides with vasoconstrictive, prosurvival and proapoptotic effects. In $Rds^{+/-}$ retinas, *in situ* hybridization revealed increased *Edn2* mRNA solely in PRs; no *Edn2* mRNA was detectable in wt retinas. By HPLC and RIA, the Edn2 peptide was also increased: minimally 3-fold, but likely more, as Edn2 was undetectable in wt retinas. The mRNA levels of *Edn1*, *Edn3*, and of both endothelin receptors, were unchanged. To determine if Edn2 is pathogenic in IPDs, we generated $Edn2^{-/-}$; $Rds^{-/-}$ and $Edn2^{-/-}$; *Tg(RHO P347S)* mice. At age 40 days, $Edn2^{-/-}$; *Tg(RHO P347S)* retinas showed a 41% rescue of PR degeneration: PR nuclear layer thickness of 94.4 7.6 units vs. 564.7 units in wt mice (p0.003; n=5/genotype). At 40 days, no rescue effect was detectable in the slower degenerating $Edn2^{-/-}$; $Rds^{-/-}$ retinas. We conclude that the protective effect of the $Edn2^{-/-}$ genotype in *Tg(RHO P347S)* retinas is due to either to i) a pathogenic role of Edn2, ii) an *Edn2* tightly linked modifier, or iii) downstream effects of the $Edn2^{-/-}$ genotype, such as the capillary vasodilation we see in $Edn2^{-/-}$ retinas, or Muller cell activation (indicated by increased GFAP staining). Since the *Edn2* mRNA increase (~18 days of age) occurs well after the onset of PR death (~10 days in $Rds^{-/-}$ mice), Edn2 may contribute to the progression of PR death but not its initiation. These findings have therapeutic implications, since Edn receptor blockers might slow PR death in IPDs.

Genetic structure analysis of three Hispanic populations from Costa Rica, Mexico and the Southwest United States, using Y-STRs markers and mtDNA sequence. *R. Campos-Sánchez[1], R. Barrantes[2], S. Silva[1], M. Escamilla[3], A. Ontiveros[4], H. Nicolini[5], R. Mendoza[6], R. Muñoz[7], H. Raventós[1]* 1) CIBCM, Universidad de Costa Rica; 2) Universidad de Costa Rica, Escuela de Biología; 3) Department of Psychiatry, University of Texas Health Science Center at San Antonio; 4) INFOSAME, Monterrey México; 5) Grupo de Estudios Médicos y Familiares Carracci S.C, Ciudad de México; 6) David Geffen UCLA School of Medicine; 7) Family Health Centers of San Diego.

We studied the genetic structure of three Hispanic populations from Mexico, the Southwest USA and Costa Rica, in order to characterize their genetic relationships. The sample of 217 men utilized was drawn from two NIMH (National Institute of Mental Health) funded studies to map schizophrenia susceptibility genes. Our study reports the maternal and paternal relationships between these groups, based on the analysis of 12 Y-STRs and HVI mtDNA sequences. Similarities between these populations have not been previously reported. Our results demonstrate that these populations are genetically related to each other. They are very similar when we compare their internal genetic characteristics as revealed by analyses of diversity. The relationship is stronger through their maternal lineage than the paternal, as a higher number of shared haplotypes and polymorphisms are seen in the mtDNA (compared to Y-STRs). These results provide evidence of previous contact between these populations and shared histories, as explained by common migration movements from Europe, the slavery trade from West Africa, and similar native communities of Amerindians. An analysis of molecular variance (AMOVA) revealed no genetic differentiation for the mtDNA (Fst=0.006) for the three populations but does for the Y-STRs (Rst=0.04). Genetic distance analysis confirms that these populations are very closely related, probably due to migration between close neighbors, as indicated by shared haplotypes. These results suggest that Latin American and Hispanic populations can be studied together for specific purposes as genetic mapping and association studies, which are of most interest in these schizophrenia related samples.

Tubulopathy and pancytopenia with normal pancreatic function: A variant of Pearson syndrome. *A. Atale[1], A. Rotig[2], A. Fischer[3], S. Perez-Martin[1], C. Thauvin-Robinet[4], P. Bonneau-Amati[5], F. Huet[1], L. Faivre[4]* 1) Pediatrics, Hopital d'Enfants, Dijon, France; 2) Immuno-Hématologie Pédiatrique, Hôpital Necker-Enfants Malades, Paris, France; 3) Genetics, Hôpital Necker-Enfants Malades, Paris, France; 4) Génétique, Hôpital dEnfants, Dijon, France; 5) Biologie Moléculaire, CHU Angers, France.

We report on two patients with an atypical presentation of Pearson syndrome, including growth deficiency, pancytopenia and tubulopathy but an absence of malfunction of exocrine pancreas. Patient 1 was a 2 ½- year-old boy with a personal history of thrombopenia and spontaneous regression of a metabolic acidosis in a context of gastroenteritis at 1 year of age. A new episode of gastroenteritis revealed growth retardation, central pancytopenia, mild cytolysis, metabolic acidosis hyperlactacidemia leading to the diagnosis of proximal tubulopathy. A cystinosis and a tyrosinemia were ruled out. Despite normal exocrine pancreatic deficiency, study of mitochondrial DNA revealed a 3.5 kb deletion leading to the diagnosis of Pearson syndrome. Follow-up showed two episodes of acidosis and the finding of hyperinsulism at 3 ½ years of age. Patient 2 had a personal history of pancytopenia necessitating blood transfusions at 11 years of age. She was seen at the age of 2 years for the evaluation of growth retardation. Metabolic acidosis leaded to the diagnosis of proximal and distal tubulopathy but exocrine pancreatic deficiency could not be evidenced. She died at 30 months of age in a context of intractable metabolic acidosis. Postmortem studies revealed a 4.9 kb deletion of the mitochondrial DNA, in favour of Pearson syndrome. A review of the literature revealed that this type of presentation of Pearson syndrome with tubulopathy, pancytopenia without exocrine pancreatic deficiency was rare and often lead to multiple investigations and diagnostic delay. In conclusion, Pearson syndrome should be searched in a child presenting with the association of tubulopathy, pancytopenia and growth retardation even in the absence of exocrine pancreatic deficiency.

Gathering evidence for an adaptive evolution of skin pigmentation in humans. *S. Alonso-Alegre[1], I. Smith-Zubiaga[2], N.P. Smit[4], D. Boyano[3], J.L. Díaz-Pérez[5], I. Garcia[1], N. Izagirre[1], C. de la Rua[1]* 1) Genetics, Physical Anthropology and Animal Physiology. Fac. Science and Technology UPV/EHU, Barrio Sarriena s/n. Box 9600 2300 RC Leiden. the Netherlands; 5) Cruces Hospital. Dermatology Service. Plaza de Cruces s/n, 48903 Barakaldo, Bizkaia, Spain.

While the combination of pale skin and intense sun exposure results in an important health risk for the individual, it is less clear if at the population level this risk has possessed an evolutionary meaning. In this sense, a number of adaptive hypotheses have been put forward to explain the evolution of human skin pigmentation. It is expected that if skin pigmentation is adaptive we might be able to see the signature of positive selection on some of the genes involved. In order to detect this signature we have a) data-mined the available resources and analyzed a battery of 81 candidate loci by means of phylogenetic and population genetic tests; b) resequenced 4kb of the 5' region of the main melanogenic loci TYR, TYRP1 and TYRP2 (DCT) in a total of 116 chromosomes from worldwide populations, including Europeans, European melanoma patients, Senegalese, Pygmies, Chinese and Australians; and c) investigated the gene expression profile (Affymetrix U133Av2 chips) of 7 cultured human melanocytes from donors of light (n = 4) and dark (n = 3) pigmentation, and compared them to the expression profiles of the same cells after repeated irradiation with dayly doses of approximately 50mJ/cm2 of UVA and UVB (once a day for consecutive 6 days). Overall, we find evidence of positive selection, which indicates that skin pigmentation may be adaptive. This adaptation may be related to skin photoprotection against DNA damage.

In the year 2020: Representations of the Promise of Personalized Medicine. *A. Adair[1], T. Caulfield[1, 2, 3]* 1) Health Law Institute, University of Alberta, Edmonton, AB, Canada; 2) Faculty of Law, University of Alberta; 3) Faculty of Medicine and Dentistry, University of Alberta.

In the popular media and scientific publications alike the dream of personalized medicine has resulted in an ongoing narrative of medical revolution that broaches science fiction and biotechnological advances, raising public expectation and venture capital. Building on the recent concern about genohypethe overstatement of technological advance in the biotechnology spherethis paper reviews the pressures behind the creation of a cycle of hype in the context of personalized medicine. Concrete examples of genohype in science journals, the popular press and industry publications from 1989 to 2006 are examined to investigate the role that optimistic messaging strategies play in the representation of genetic and biotechnological developments in Canada and the United States. This paper considers not only a tautology of hype surrounding the representation of personalized medicine, but responses to this hypedepictions that are deliberately understated or complicated. Moreover, the articles reveal a number of strains of representation of personalized medicine: as a panacea, a re-personalization of medical care, a movement away from one-size-fits-all medicine, and a means of empowering the health care patient/consumer. The tenor and scope of these predictions reveal more about the relationship between the scientific community, the media and the public, than about medical and biotechnological advances. Almost twenty years since claims first appeared in public discourse, the personalized medicine narrative has evolved largely in the absence of concrete results or government policy. Its original representation has shifted to a encompass pharmaceuticals targeted to self-identified racial groups; it has been imbricated in the justification for the creation of broad-based biobanks; and it has become an international focus of investment. As ongoing claims about personalized medicine draw government and consumer attention, capital and consent, this paper cautions against the power of genohype in the public consumption of biotechnology.

Prevalence of vertigo in GJB2 deafness. *K.M. Dodson[1], K.A. Arnos[2], S.K. Burton[2], R.S. Marin[2], K.O. Welch[2], V. Norris[2], S. Ackley[2], W.E. Nance[3], A. Pandya[3]* 1) Department of Otolaryngology, Virginia Commonwealth University, Richmond, VA; 2) Department of Biology, Gallaudet University, Washington, DC; 3) Department of Human Genetics, Virginia Commonwealth University, Richmond, VA.

Mutations in GJB2 (connexin-26) are the most common cause of autosomal recessive nonsyndromic hearing impairment. Despite the widespread expression of connexin-26 throughout the vestibular system, vertigo has not previously been reported as a common finding in connexin deafness. Based upon our observations of vertigo accompanying connexin deafness in several large families, we hypothesize that vertigo may actually be a common, yet often overlooked component of GJB2 deafness. To define the prevalence of vertigo in connexin deafness, a vertigo survey was designed and distributed to deaf subjects previously identified with pathogenic mutations in GJB2 and/or GJB6 through our research protocols. The survey quantified duration, frequency, and length of episodes of vertigo, as well as past medical history and a prior history of other vertiginous disorders including Menieres disease, benign paroxysmal positional vertigo, and migraine. 105/214 surveys were completed and returned (49%). The mean age of respondents was 37.6 (range 13-76 years of age). 54/105 (51%) of the responders reported a history of vertigo, which was intermittent in nature in 98%. The majority of patients (57%) reported that vertigo lasted for minutes to hours and had a positional component in 70%. Most (81%) suffered with vertigo for greater than 1 year, with a mean of 9.9 years duration. Most (65%) patients had to lie down in order for vertigo to subside and 50% reported that vertigo interferes with activities of daily living. In conclusion, vertigo appears to be more common in GJB2 deafness than previously reported, and frequently affects activities of daily living in these patients. Further study, including association with objective vestibular testing, is underway.

Why does increasing sample size often dim rather than illuminate? A question of locus heterogeneity. *C.W. Bartlett, V.J. Vieland* Center for Quantitative and Computational Biology, Columbus Children's Research Institute, The Ohio State University, Columbus, OH.

Over the past few years, researchers have increasingly collaborated to create linkage samples with hundreds of families pooled together. With very few exceptions, the best-pooled results are generally similar in magnitude what any individual sample may have produced; furthermore, many if not all detected loci are novel. We set out to recreate these conditions in a simulation paradigm, examining the relative performance of various linkage detection statistics. We simulate a single marker in a sample of N=160 general nuclear families under locus heterogeneity with 0, 1, 2, 4, 6, 8 or 10 background genes. Replicates with observed HLODs > 3 were retained as an initial finding and four unselected samples of 160 families were simulated using the same heterogeneity model in order to simulate follow-up samples; analysis was performed for N=160, 320, 480, 640 & 800 families using the Kong and Cox LOD score (KCL), the HLOD, the MOD (an HLOD maximized over all model parameters), and a statistic that integrates rather than maximizes over the parameter space, the Posterior Probability of Linkage (PPL). Increasing sample size does increase linkage detection with 6 genes or less, though increases become more modest with more genes. When 8 genes are present the average KCL, HLOD and MOD all decrease from N=160 to N=320 (e.g., the KCL decreases from 2.5 to 2.0), then increases again as more samples are added (e.g., the KCL increases from 2.0 at N=320 to 2.4 at N=800); in contrast, the PPL continues to increase as sample size increases (e.g., going from 0.52 to 0.71 with no decreases). In the 10 gene condition, average KCL, HLOD and MOD all decrease from N=160 to N=320 and largely level off (e.g., the KCL drops from 2.5 to 1.8 and stays approximately constant thereafter); again, the PPL continues to increase with increasing sample size (from 0.51 to 0.61 with no decreases). As expected, all statistics will on average decrease under null simulations. We discuss the implications of this work for complex disease gene detection and provide extensions to multipoint localization.

Classical and Duarte galactosemia: Newborn screening, biochemical phenotype, and clinical outcome. *A. Cunningham[1,2], C. Techakittiroj[1,2], R. Sharma[1], C.T. Dvorak[1, 2], P. Hooper[3], D. Baye[3], H.C. Andersson[1,2]* 1) Hayward Genetics Center, Tulane University Health Sciences Center, New Orleans, LA; 2) Department of Pediatrics, Tulane Health Sciences Center, New Orleans, LA; 3) LA State Genetics Program, Office of Public Health, New Orleans, LA.

Newborn screening for galactosemia is routine in 50 US states, but detects many newborns with partial galactose-1-phosphate uridyltransferase (GALT) deficiency (less than 10% normal activity). Lactose restriction for the early months has been proposed for partial GALT deficiency, including Duarte variants, but no clinical outcomes of a prospective cohort of partial GALT deficiency patients has been reported. We report newborn screening data for LA and the clinical outcome of a prospective treatment protocol forpartial GALT deficiency patients. 151,468 infants in Louisiana from Dec 2002 -April 2005 were screened by detecting GALT; 112 presumptive positive cases of galactosemia were reported. After confirmatory testing of 106 cases, 5 cases were normal, 65 cases were galactosemia carriers (G/N) and 37 were affected with galactosemia (3G/G, 7D/D, 27D/G). The incidence of galactosemia in LA is 1: 4,094 live births (including Duarte variants). Duarte variant galactosemia patients (D/G, D/D) were lactose-restricted and challenged with galactose at age 1 year. 14/14 DG patients had normal Gal-1-P (less than 1.0 cM/L) when challenged with lactose-containing diets at age 1y and were placed on an unrestricted diet. At 2y, 6/6 DG and 2/2 D/D patients had normal eye exams, growth, liver function studies and normal Gal-1-P levels. While further follow-up is needed to determine whether Duarte variant patients develop late sequelae of galactosemia, no pathology was demonstrable at 2 years of age with galactose restriction discontinued at 1y.

Testing a genome-wide panel of non-synonymous SNPs for association to multiple common disease phenotypes.
P. Deloukas for the Wellcome Trust Case-Control Consortium Human Genetics, Wellcome Trust Sanger Inst, Cambridge, United Kingdom.

Systematic studies of sequence variation in humans have allowed the compilation of a comprehensive list of circa 10 million common variants, predominantly SNPs. Exonic SNPs that cause amino acid changes or alter STOP codons, non-synonymous (nsSNPs), are by definition very likely to have an impact on phenotype including disease. The Wellcome Trust Case-Control Consortium (WTCCC; http://www.wtccc.org.uk) which is a collaborative network of 24 laboratories across the UK, set up an experiment to test the impact of nsSNPs in four common diseases namely ankylosing spondylitis (AS), breast cancer (BC), multiple sclerosis (MS) and autoimmune thyroid disease (ATD). The study design includes 1000 cases for each disease (national UK Caucasian samples) and 1500 common controls from the 1958 British Birth Cohort (58 BBC). We selected a non redundant set of 15,897 nsSNPs with frequency above 1% in Caucasians and use them together with 1216 tag SNPs from the MHC region to generate a custom chip for use with the Infinium assay (Illumina). We also included 114 ancestry informative markers. Following synthesis, the chip harboured 15,436 loci of which 14,639 (94.8%) passed our quality metrics. We further flagged 385 loci deviating from Hardy-Weinberg Equilibrium ($p < 10^{-3}$). We have completed typing the controls and three of the disease cohorts so far, 5000 samples, and obtained a call rate of 99.4% for markers that passed QC. The 58 BBC controls have also been typed across the Affymetrix 500K arrays; comparison of a set of 980 markers common to both arrays showed concordance above 99%. Assocation analysis is ongoing and results will be discussed at the meeting.

Association Study of Neurotrophic Tyrosine Kinase Receptor 3 Gene in Childhood-Onset Mood Disorder. *Y. Feng[1], N. King[2], A. Vetro[3], E. Kiss[3], K. Kapornai[3], G. Daroczy[3], J.L. Kennedy[2], M. Kovacs[4], C.L. Barr[1,5], The International Consortium for Childhood-Onset Mood Disorders* 1) Dept Cell & Molecular Biol, Toronto Western Hosp, Toronto, ON, Canada; 2) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 3) Department for Child and Adolescent Psychiatry, Szeged University, Szeged, Hungary; 4) University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA; 5) The Hospital for Sick Children, Toronto, Ontario, Canada.

Major depressive disorder (MDD) is multifactorial disorder with moderate heritability. Family and twin studies show the highest relative risk for MDD in families of probands with early age at onset and/or recurrent episodes compared with the risk in the general population. Chronic antidepressant treatment up-regulates the neurotrophin signaling pathways which is involved in neural plasticity and survival. Deficits in neural plasticity have been suggested to underlie the development of depression. A genome scan of families multiply affected with recurrent, early onset MDD by Holmans et al. (2004) revealed significant linkage on chromosome 15q25.3-q26.2 (LOD = 3.73). One candidate gene located in this 15q region, NTRK3 (neurotrophic tyrosine kinase receptor 3) was particularly interesting because NTRK3 is a key gene involved in neural plasticity. The results of family based association studies of the NTRK3 gene show three markers have significant association with childhood-onset mood disorder (COMD) in our sample ($p<0.035$). The sample consists of 394 families with 459 affected children recruited from 21 mental health facilities across Hungary. Further investigation of the NTRK3 gene will be important to establish the contribution of this gene in the etiology of COMD.

Allelic association of the interleukin 7 receptor gene (IL7R) with multiple sclerosis (MS). *S.G. Gregory[1], S. Schmidt[1], J. Hart[1], A. Prokop[1], J. van der Walt[1], L.F. Barcellos[2], C. DeLoa[3], J.R. Oksenberg[3], S.L. Hauser[3], J.L. McCauley[4], M.A. Pericak-Vance[1], J.L. Haines[4]* 1) Dept Medicine, Ctr Human Genetics, Durham, NC; 2) School of Public Health, University of California, Berkeley; 3) Department of Neurology, University of California, San Francisco; 4) Center for Human Genetics Research, Vanderbilt University Medical Center.

Multiple sclerosis (MS) is the prototypic human demyelinating disease, with evidence for genetic influences arising from numerous sibling risk, adoption and twin studies. The disease is most common in young adults, with less than 10% of identified cases beginning after the age of 55 and less than 5% before the age of 14. Females are 2-3 times more frequently affected than males and disease course can vary from some patients suffering major disability several decades post-diagnosis, while others reach wheelchair dependency within a few months or years upon onset. We identified 8 genes, from eight published MS RNA expression analyses, that were differentially expressed within at least two of the studies. SNPs within one of these candidate genes, the interleukin 7 receptor gene (IL7R), are significantly associated with MS by PDT analysis within our combined dataset of almost 950 patients and their relatives. One SNP, localizing to alternatively spliced transmembrane domain of the protein, shows strongest association with risk (p=0.00006). Two independent studies have previously implicated IL7R with primary progressive MS, however, our analysis finds that this gene is also associated with the risk of developing the more common relapsing-remitting MS. Our result implicating the involvement of IL7R, therefore, not only represents a functionally relevant gene involved with the risk of MS development but also the replication of two previous studies. Molecular work to investigate the effect that the coding SNP has upon the functioning of the protein is currently underway.

Predicting BRCA1 and BRCA2 Mutations in Women with Carcinoma In Situ of the Breast. *T. Geva[1, 2], J.N. Weitzel[1], A. Dagis[1], J.A. Longmate[1], J.O. Culver[1], M.R. Palomares[1]* 1) City of Hope National Medical Center, Duarte, CA; 2) California State University, Northridge, CA.

BACKGROUND: The utility of existing BRCA mutation probability models for women with carcinoma in situ (CIS) of the breast has not been established. We evaluated existing BRCA mutation prediction models in women with a personal diagnosis of CIS who underwent genetic testing. METHODS: The Couch, Myriad, BRCAPRO, and Tyrer-Cuzick models were tested in 63 CIS patients who were enrolled in an IRB-approved registry and had BRCA analysis in the City of Hope Cancer Screening & Prevention Program Network between April 24, 1997 and March 31, 2005. Since all the models were based on invasive breast cancer history, they were adapted to accommodate the CIS history in three ways: (1) including CIS as invasive breast cancer at the age of CIS diagnosis; (2) including CIS as invasive breast cancer with 10 years added to the age at diagnosis; and (3) excluding CIS and utilizing only the remaining family history. Probability estimates were compared using Wilcoxon rank-sum tests and receiver operating characteristics (ROC) analyses. RESULTS: None of the models evaluated performed well in our sample of women with CIS, regardless of whether or how their CIS diagnoses were included in the probability calculation. Deleterious mutations were found in 6 of the 63 subjects (9.5%). The proportion of CIS patients with a detectable BRCA mutation was similar to that reported with invasive breast cancer, and BRCA carriers with CIS were younger at diagnosis than non-carriers (40.5 versus 46.0, respectively). Not all women with positive test results had a significant family history of breast and/or ovarian cancer. CONCLUSIONS: These findings suggest that BRCA testing is appropriate for women with a personal diagnosis of CIS at a young age and for those with otherwise compelling family cancer history, but that it is necessary to establish a more accurate method of estimating mutation probability for this population.

Frequency of Fragile X in multiplex autism: testing the AGRE families. *W.T. Brown[1], S.L. Nolin[1], C.S. Dobkin[1], G.S. Houck[1], A. Glicksman[1], X.D. Ding[1], S.J. Spence[2], D.H. Geschwind[2]* 1) Dept Human Genetics, NYS Inst Basic Research, Staten Island, NY; 2) Neurology Dept, UCLA School of Medicine, Los Angeles, CA.

Autism has high heritability. The Autism Genetic Resource Exchange (AGRE) is a publicly available resource of well-characterized multiplex families for genetic studies of autism. To better characterize this resource, we conducted fragile X DNA analysis (Brown 93) on one proband in each of 480 AGRE families, with follow-up family studies when indicated. Testing revealed 6 families to be positive for fragile X. These have been flagged in the AGRE database. Review of 326 available medical records showed 114 (35%) had prior negative genetic testing. Thus, the prevalence of fragile X among the approximately 312 previously untested AGRE families was ~ 1.9%. An estimate of the IQ score of the autistic subjects was 8035 with range 34-144, based on the Raven. Thus, the AGRE sample is likely to have a higher IQ distribution than typical for fragile X subjects (mean ~4025). Previous prevalence studies of fragile X in autistic samples range from 0 to 16% with mean ~4% (Feinstein 98). Our 1.9% is similar to a report of 1.6% among 123 unrelated autistic individuals (Bailey 93), but lower than the 13% we found on an earlier multicenter study of 183 individuals (Brown 86). An additional 166 families added to AGRE subsequent to this study, who had received a more rigorous prescreen for genetic conditions, have also been tested and found negative for fragile X. Conclusions: A growing awareness of fragile X syndrome may increase the probability of prior fragile X screening in multiplex autism families and their exclusion from AGRE. The observed frequency of 1.9% is lower than the expected 4%. This appears due to higher mean IQs in AGRE subjects than typical for fragile X syndrome. It confirms an association of fragile X and autism.

Expression pattern of WHSC3 (Wolf-Hirschhorn syndrome candidate gene 3) during neocortex and cerebellum development suggests a role in neuronal migration. *A. Boerdlein, S. Schlickum, A. Winterpacht, S.U. Endele* Institute of Human Genetics,University of Erlangen-Nuremberg, Erlangen, Germany.

Wolf-Hirschhorn syndrome (WHS) is a complex and variable malformation syndrome which is caused by partial deletion of the short arm of one chromosome 4. WHS is thought to be a contiguous gene syndrome with a yet unknown number of genes contributing to the phenotype. We focused on the neurological features of the syndrome (mental retardation, seizures) and further investigated a recently cloned gene (*WHSC3*) from the Wolf-Hirschhorn syndrome critical region (WHSCR1) which is strongly expressed in brain and testis. Human *WHSC3* encodes a protein of 90 amino acids, which probably encodes a preprohormone or neuropeptide precursor. Here, we present a detailed expression study of *Whsc3* during murine neocortex and cerebellum development by RNA-in situ-hybridization of mouse embryos. Expression in the cerebral cortex starts after the preplate stage (> E12). At E14.5 to E17.5 *Whsc3* is expressed in the intermediate zone and in the marginal zone (most probably in the Cajal Retzius cells) of the developing cortex. In newborn mice, we could detect signals in neurons of the cortical plate and in Cajal Retzius cells (marginal zone) whereas in adult brain signals were present in all cortical and subcortical regions of the brain. In the developing cerebellum, expression could be detected in the intermediate zone at stages E.13 to 17.5, in the molecular layer in newborn mice and in the granular and molecular layer in adult mice (most probably in the interneurons). In conclusion, the expression pattern suggests a potential role of this gene in neuronal migration processes, and thus in the pattern formation of human cerebral and cerebellar structures.

Genome-wide association study combining incomplete high resolution SNP data with sparse markers from a linkage scan. *W-M. Chen, G.R. Abecasis* Center for statistical Genetics, Dept. of Biostatistics, Univ. of Michigan, Ann Arbor, MI.

With millions of single nucleotide polymorphisms (SNPs) identified and characterized, genome-wide association studies are underway to identify susceptibility genes for complex traits and diseases. Given limited genotyping resources, we propose an approach that can produce large increases in power for genome wide association scans. We show that, by combining high-resolution SNP genotypes for just a few individuals with sparse marker data from a typical linkage scan, genotypes for many related individuals can be inferred with high accuracy, and power for the genome-wide association analysis can be substantially increased.

First, our algorithm involves calculation of a probability distribution for each missing genotype in pedigree. We implemented this step using the Elston-Stewart algorithm, for larger pedigrees, and the Lander-Green algorithm, for smaller pedigrees. Next, observed genotypes and probability distributions for unobserved genotypes are combined in a rapid association test that characterizes association between genetic variants and quantitative phenotypes in families.

We investigate the properties of the method in different family structures by simulation. We identify optimal family genotyping strategies for many different pedigree structures and show that in many cases it is sufficient to genotype <50% of the individuals in family to infer >90% of genotypes with near certainty. To illustrate our method, we carried out genome-wide association analysis for 27 gene expression phenotypes in 20 CEPH families, in which ~0.8 million SNPs are only genotyped in grandparents and parents, and a subset of 6,564 SNPs are genotyped in all 168 CEPH individuals. In addition to increasing evidence for association of 15 previously identified cis-acting associated alleles, our genotype inference algorithm allowed us to identify 4 novel cis-acting associated alleles that were missed when analysis was restricted to individuals genotyped by the HapMap project. Our genotype inference algorithm and the proposed association test are implemented in computer programs GHOST and Merlin.

dup(15)(q15q25) as a sole anomaly in a case of polycythemia vera: Trisomy 15 in hematological disorders revisited. *A. Adeyinka, S. Wei, J. Sanchez* Dept Medical Genetics, Henry Ford Health System, Detroit, MI.

Trisomy 15 as a sole clonal autosomal anomaly in hematological malignancies reportedly is uncommon. Nonetheless, trisomy 15 as a sole abnormality has been documented in a wide range of hematological disorders, especially myelodysplastic disorders. However, complicating an understanding of the possible role of this anomaly in tumorigenesis and/or tumor progression are its frequent association with loss of the Y chromosome in males, the fact that it is commonly seen in older patients and its presence in individuals without hematological malignancy. We report a cytogenetic and fluorescent in situ hybridization (FISH) analysis in a case of polycythemia vera with dup(15)(q15q25). G-banded metaphase cells obtained from short-term culture of a bone marrow sample from an 87-year-old female patient were 46,XX,dup(15)(q15q25)[5]/46,XX[15]. The dup(15q) was further delineated by FISH studies using whole chromosome 15 painting probe (WCP15), *SNRPN*, *PML*, and D15Z1 probes. FISH analysis confirmed duplication of 15 q-arm distal to *SNRPN* and encompassing the *PML* locus. Furthermore, we identified through a search of our database of cytogenetically characterized hematologic disorders, 22 cases with trisomy 15 as the sole autosomal anomaly. Including the case of dup(15q), all 23 samples with gain of 15q were from older patients, age range 65-92 years with a median age of 81 years, who were mostly males (70%). In nine (1 female and 8 males) (39%) of the 23 individuals, trisomy 15 was associated with loss of a sex chromosome. Among all 23 individuals, a wide range of hematological conditions was associated with trisomy 15/gain of 15q, including hematological malignancies and non-neoplastic marrow. Our data show that trisomy 15 is associated with hematological malignancies as well as non-neoplastic hematological conditions, making it a poor marker of malignancy. Nonetheless, our present finding of dup(15)(q15q25) as a sole abnormality in polycythemia vera and a previously published case of acute promyelocytic leukemia with dup(15)(q15q26) as a sole abnormality suggest that duplication of genes on 15q may be of pathogenic importance in some hematological malignancies.

Families with nonsyndromic cleft lip with or without cleft palate (CL/P) have an increased frequency of lip print whorl patterns, which may be associated with IRF6. *K.W. Chirigos, K. Neiswanger, K.M. Bardi, C.A. Brandon, M.E. Cooper, M.L. Marazita* Ctr Craniof Dent Genet, U Pittsburgh, Pittsburgh, PA.

CL/P is a common birth defect with genetic and environmental components. Van der Woude syndrome (VWS) is an autosomal dominant form of CL/P, in which cleft palate only and/or lower lip pits also affect some family members. VWS is due to mutations in IRF6; different IRF6 variants increase susceptibility to CL/P (see Marazita et al, this meeting). Lip prints are permanent and unique to each individual, with several basic pattern types. Lip whorls consist of one medial whorl on the upper lip and/or two paramedial whorls on the lower lip. As part of the Pittsburgh Oral-Facial Cleft study, we analyzed lip prints from 232 subjects: 167 from cleft families (43 individuals with CL/P, 124 unaffected relatives) and 65 controls with no family history of clefting. Lip prints were taken using the Faurot inkless method, electronically scanned, and contrast-enhanced. Patterns were scored by two independent raters blind to the cleft status of the subjects. 30.5% (51/167) of the subjects from cleft families had whorls, compared to 10.8% (7/65) of the controls ($p = 0.001$). The frequency of whorls did not differ significantly between family members with CL/P (16/43, 37%) and their unaffected relatives (35/124, 28%; $p = 0.34$). 117 cleft and non-cleft family members also were genotyped for three IRF6 SNPs. One of the three SNPs (rs2013162, highly associated with CL/P) showed an association with whorls, both by genotype ($p = 0.03$) and with the common allele ($p = 0.02$). When subjects with CL/P and unaffected relatives were analyzed separately, the trend continued for both genotypes and alleles, with somewhat more significance in the unaffected relatives. If these results are confirmed with additional IRF6 SNPs and larger samples of unrelated individuals, they suggest that individuals with whorl patterns may carry IRF6 variants that increase their risk of having children with CL/P. These results are particularly interesting since the VWS phenotype includes lip pits. Supported by NIH grants R01-DE016148, P50-DE016215, CIDR NIH contract N01-HG-65403.

Replication Stress Induced Tumor-like Deletions of FRA3B in Human/Mouse Cell Hybrids. *S.G. Durkin, R.L. Ragland, T.W. Glover* Dept Human Genetics, Univ Michigan, Ann Arbor, MI.

Common fragile sites (CFS) are regions of the genome that form gaps and breaks on metaphase chromosomes when DNA synthesis is partially inhibited. While normally stable in somatic cells, CFS and associated genes are frequently rearranged in cancer cells and may be indicators of DNA replication stress early in tumorigenesis. We and others have previously reported the induction of large scale chromosome rearrangements, including translocations and terminal deletions with breakpoints at CFS in normal cells in vitro. However, the great majority of rearrangements observed at CFS in cancer cells are not these types of rearrangements, but are intra-locus deletions spanning tens to hundreds of kb. Although it has been assumed that these tumor deletions are due to replication stress-induced CFS destabilization, it has been unclear if replication stress and CFS breaks in vitro can also result in tumor-like deletions. To this end, we have utilized human/mouse cell hybrids harboring a single human chromosome 3 that contains the most frequently broken human CFS, FRA3B. To induce replication stress, these cells were exposed to a low-dose of aphidicolin, which induces CFS breaks, for five days followed by one day of recovery. Seventy-four resulting clonal cell populations were analyzed by PCR spanning FRA3B at approximately 10-30 kb marker intervals to detect deletions. Thirty clones (40%) were detected to have deletions within the CFS critical region, previously defined to lie between intron 3 to intron 7 of FHIT. Ten of the 30 deletion clones were shown to have contiguous deletions within this region ranging from approximately 300 to 800 kb, similar in size and location to those deletions observed in esophageal adenocarcinomas, renal carcinomas and other cancers while other clones exhibited smaller deletions. We are currently cloning the specific breakpoints of these deletions to gain insight on the sequences involved in these rearrangements and how they are repaired, and are analyzing deletion clones for CFS breakage. These findings support a direct mechanistic relationship between replication stress and CFS breaks in vitro, and genome rearrangements in cancer.

Fine mapping of chromosome 19 candidate region shows association in autism. *A.L. Collins[1], D.Q. Ma[1], R. Rabionet[1], I. Konidari[1], E.R. Martin[1], H.H. Wright[2], R.K. Abramson[2], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) School of Medicine, University of South Carolina, Columbia, SC.

Autism is a neurodevelopmental disorder of complex genetics characterized by impairment in social interaction and communication as well as repetitive behavior. Evidence from several genome-wide screens suggests the involvement of Chromosome 19 in autism. Results of our linkage study on 210 multiplex families ascertained through Duke and AGRE gave significant evidence for heterogeneity showing that a subset of AGRE families (AGRE1) was significantly different with respect to these data (p=0.001) resulting in a maximum heterogeneity linkage score (HLOD) of 3.56 at marker D19S593 (17.2Mb), Thus, we used the AGRE1 subset (N=99) to fine map the region surrounding this marker (13.7Mb-19.9Mb) by genotyping 424 SNPs with MAF>0.01 across this region, resulting in an average spacing of one SNP every 15kb. We identified two clusters of associated markers, one near 16.3Mb (rs875622; p=0.00008) and a second at 18.1Mb (rs273506; 0.0004). Analysis in the subset of families (N=38) showing positive linkage throughout the region targeted the region at 16.3Mb as the most likely location of an autism risk gene (rs4808047; p=0.0003) in the *EPS15L1* gene (epidermal growth factor receptor pathway substrate 15-like 1). The protein encoded by *EPS15L1* is thought to be a component of clathrin-coated pits that is required for receptor-mediated endocytosis. In summary, we have found evidence for significant association in a linkage region for autism risk and have targeted several genes including *EPS15L1* for follow-up and additional analysis.

Autism Genome Project: Linkage Analyses. *B. Devlin* Dept Psychiatry, Univ Pittsburgh, Pittsburgh, PA. for the Autism Genome Project (AGP).

The genetic architecture of autism spectrum disorders (ASD) is undoubtedly complex, and identification of risk loci requires large samples. For this reason the Autism Genome Project (AGP) Consortium was formed from 4 consortia in North America and Europe: Autism Genetics Cooperative, Autism Genetics Resource Exchange, Collaborative Programs of Excellence in Autism and International Molecular Genetic Study of Autism Consortium. For linkage analysis, DNA from MPX families was genotyped using the 10K Affymetrix SNP microarray. After quality control analyses, 1168 MPX families had genotypic and diagnostic data useable for linkage analysis. These families were partitioned by diagnosis into narrow, broad and hASD, depending on the distribution and severity of ASD in the MPX families. Narrow is a subset of broad, but hASD for this analysis is considered an independent set of families, which are more heterogeneous for diagnosis and possibly etiology. Thus we focus on the narrow and broad analyses. Families were further subdivided into whether they contained affected females (FC) or only affected males (MO), because the male:female ratio for those diagnosed with autism is 4:1, and on the basis of inferred parental ancestry into all families or European. Multipoint linkage analyses were performed using the exponential S-all statistic and MERLIN. Linkage information, as reported by ALLEGRO, averaged 95% over the genome. Its minimum occurred at telomeres (> 71%). The information for linkage is large because of good coverage of markers and because parental genotypes were typically available. There were 522 MPX families meeting narrow diagnostic criteria (329 MO and 193 FC) and 731 meeting broad criteria (458 MO and 273 FC). The most compelling linkage statistics emanate from the FC families, consistent with standard quantitative genetics theory of threshold models. Results from FC families nominate regions of Chromosome 11p, 9p and 5p for targeted follow-up analysis: 11p is genome-wide significant, whereas 9p and 5p meet suggestive linkage. Two other regions that drew support from previous linkage studies, namely 7q and 2q, continue to draw support from the enlarged sample.

Chronic subdural hematomas in a male with ornithine transcarbamylase deficiency. *M. Gucsavas-Calikoglu[1], J. Koepke[1], M. Tennison[2], R. Greenwood[2], J. Muenzer[1]* 1) Dept Pediatrics, Univ of North Carolina, Chapel Hill, NC; 2) Dept Neurology, Univ of North Carolina, Chapel Hill, NC.

Ornithine transcarbamylase (OTC) deficiency is a rare X-linked urea cycle disorder with hyperammonemia and devastating neurological outcomes in affected males. Neuroradiological findings consist of diffuse cortical edema with compression of third and lateral ventricles during hyperammonemic episodes and bilateral low-density white matter lesions and diffuse cortical atrophy with ventriculomegaly in survivors. Subdural hematomas, however, have not been reported in OTC. Here we present a 22 month-old male who developed multiple and recurrent subdural hematomas. He was diagnosed at less than 24 hours of age because of a positive family history and had an initial ammonia of 75 mol/L. He was adequately treated with ammonia scavenger drugs and low protein diet. Mutation analysis revealed a donor splice site error in intron 5 at IVS5 + 2(T>C), previously reported in severe neonatal disease. He remained neurologically intact until 5 months of age when his ammonia rose to 448 mol/L with a viral illness. A CT scan within 48 hours of treatment showed diffuse cerebral edema with effacement of the sulci, Sylvian fissures and lateral ventricles. He became spastic and regressed in development after this episode. At age 7 months, he presented with partial-complex seizures and MRI showed large bilateral subdural hematomas and marked frontotemporal cortical atrophy. Investigation for child abuse was negative. He continues to experience multiple hyperammonemic episodes with further neurological deterioration and recurrent acute, subacute and chronic subdural hematomas. He has spastic quadriplegia and cortical blindness. It is likely that stretching of bridging veins secondary to severe cortical atrophy resulted in susceptibility to recurrent bleeding in our patient. In conclusion, subdural hematomas should be considered among the neurological complications of OTC. In addition, OTC should now be included among the inborn errors of metabolism associated with the development of subdural hematomas such as glutaric academia type I, Menkes disease, and D-2-hydroxyglutaric aciduria.

A Genome-Wide Study for Determinants of Type 2 Diabetes Mellitus in the Pima Indians. *L. Baier, R. Hanson, W. Knowler, C. Bogardus* PECRB, NIDDK/NIH, Phoenix, AZ.

The Pima Indians of Arizona have the highest reported prevalence of type 2 diabetes mellitus (T2DM). To identify genes that contribute to this disease, we have recently completed a genome-wide association (GWA) study using the Affymetrix Mapping 100k SNP chip. This study was done in two phases. Phase 1 was designed to detect potential associations with young-onset T2DM, by genotyping 300 early-onset T2DM subjects (onset age<25 yrs) and 329 non-diabetic controls (age >45 yrs), and 271 additional subjects who were diabetic and non-diabetic siblings of the selected subjects. Associations for T2DM were calculated using both a case/control analysis (N= 629) and a within-family analysis (482 siblings from 169 sibships), and SNPs that had the strongest association for the combined associations were prioritized. Phase 2 of the GWA was designed to detect associations with pre-diabetic traits (% body fat, insulin action as measured by the hyperinsulinemic euglycemic clamp technique, and the acute insulin response to an intravenous bolus of glucose). Six hundred non-diabetic subjects who had been metabolically phenotyped for these predictors of T2DM were genotyped using the 100k chip. SNPs were prioritized that were associated with a pre-diabetic trait and had also been associated with early-onset T2DM in GWA Phase 1. Prioritized SNPs from the GWA analyses are being further genotyped, by the method of SNPplex, in a large population-based sample of full-heritage Pima Indians (N= 3600) to identify variants that also have an effect on a population level. To date, 124 SNPs have been genotyped in the population sample and 12 of the 124 SNPs are associated with early-onset T2DM, a pre-diabetic trait, and T2DM at the population level. All of these 12 SNPs map to distinct chromosomal regions. Follow-up studies within these regions are ongoing.

Infant with Vascular Malformations most closely resembling Klippel-Trenaunay Syndrome with Hypoplastic Thumbs and Extensive Mongolian Spots. *C.A. Bay, S. Morrill-Cornelius, R.G. Cadle, B.D. Hall* Division of Genetics, Department of Pediatrics University of Kentucky, 740 S. Limestone Dr. Lexington, KY 40536.

We have observed a female Hispanic/Caucasian infant at age 8 days and at FU at 3 1/2 months with striking cutaneous findings and dysmorphic features including extensive capillary malformations and mongolian spots of the full face, thorax, and extremities; subtle extremity hemihypertrophy, and bilateral hypoplastic thumbs. We feel she is most consistent with the diagnosis of Klippel-Trenaunay(KT) syndrome, and broadens the clinical spectrum to include thumb anomalies. We wonder if her extensive mongolian spots may be due to differences in parental pigmentation. She was the 44.5 cm (<10 centile), 3.09 kg (25-50 centile) product of a 39 week gestation to a 28 year old G1P1 pale caucasian female. Father was 48 years old; of Hispanic ancestry with reported dark skin pigmentation. Pregnancy was unremarkable. Teratogens: Insulin; good control for DM; 1 PPD cigarettes; antibiotic for UTI. Family history: negative for vascular malformations, hemihypertrophy; positive for mongolian spots. At age 8 days: length: just below 5th centile, weight: 25-50 centile, and OFC 25 centile. She had striking flat capillary malformations and blue-gray color of the full face, thorax, abdomen, and all extremities; subtle hemihypertrophy of the right leg; bilateral hypoplastic thumbs. Brain MRI unremarkable, echocardiography: mild LVH, mild hypoplasia transverse aorta, flow acceleration across MV. Ophthalmic exam: mild increase in ocular pressures. At age 3 1/2 months skin showed less blue-gray discoloration and red areas, but they were still clearly visible. Same degree of leg hemihypertrophy, but fullness of right face was seen for first time. Development is age appropriate. We feel that the diagnosis is most consistent with Klippel-Trenaunay syndrome. Malformations of the hands including polydactyly and oligodactyly have been reported in KT syndrome, but to our knowledge thumb anomalies have not been reported previously. One of us (BDH) has seen a case of KT with triphalangeal thumbs. This extends the spectrum of anomalies in KT syndrome to include thumb anomlies.

Mis-expression of Zic2 and dominant-negative Zic2 in mouse ES cells results in abnormal proliferation and axon growth. *S. Brown, L. Brown* Dept. Ob/Gyn, University of Vermont, Burlington, VT.

Our previous work has shown that that the holoprosencephaly-associated transcription factor, Zic2 is highly expressed in the inner cell mass of the blastocyst as well as in ES cells. As ES cells differentiate, expression of Zic2 diminishes, suggesting that Zic2 is a marker of pluripotentiality. This observation has led us to attempt probe the role of Zic2 in ES cell biology by manipulating the expression in ES cells. To this end, we have developed several systems for mis-expression of wtZic2 and dominant-negative Zic2 (dnZic2)in ES cells. These include cell lines with a Zic2 transgene that is regulated by tamoxifen inducible Cre recombinase as well as cell lines in which Zic2 alleles are regulated by tetracycline.

Studies with these cell lines show that, in the undifferentiated state, mis-expression of wtZic2 or dnZic2 is tolerated and that the cells continue to grow apparently normally, although transgene expression is down-regulated over time. During in-vitro differentiation, mis-expression of either wtZic2 or dnZic2 has profound effects on ES cell growth. In one neural differentiation paradigm, in which cells are allowed to form embryoid bodies and are then physically disrupted to form single cell suspensions and are plated on glass, mis-expression of Zic2 results in a near complete failure of the cells to proliferate. Lower levels of Zic2 misexpression results in cells that proliferate and differentiate into neurons but exhibit very abnormal axon growth. In another differentiation paradigm, in which cells are allowed grow as embryoid bodies that are then fixed and sectioned, Zic2 mis-expression results in abnormal apoptosis as well as abnormal embryoid body morphology. *Based on the fact that Zic2 is normally expressed in ES cells and that perturbations in its expression result in abnormal growth and differentiation of ES cells, we conclude that Zic2 is likely to have an important role in regulating early neural differentiation events. Current work is aimed at understanding the molecular mechanisms underlying Zic2 action.

Amyotrophic lateral sclerosis (ALS) and superoxide dismutase (SOD1) mutations: an intronic perspective. *R.M. Game, J. Lynes, N.J. Schisler* Biology, Furman University, Greenville, SC.

ALS, a fatal neurodegenerative disease, currently affects 30,000 people in the United States with 5,000 new cases annually. About 10 percent of cases of ALS are familial; of these 15 to 20 percent are associated with mutations in the SOD1 gene on chromosome 21q22.1. Sporadic cases of ALS may also be due to novel mutations in the SOD1 gene.

Lindberg et al. (2002) assessed folding-related defects by comparing the unfolding behavior of 5 mutants: A4V at the interface between the N and C termini, C6F in the hydrophobic core, D90A at the protein surface, and G93A and G93C, which decrease backbone flexibility. With the exception of A4V and C6F, these mutations only marginally affected the stability of the native protein, but showed pronounced destabilization of the metal-free apo state of the enzyme which was correlated with lower mean survival time for ALS patients. Hough et al. (2004) also suggested a subset of mutations located close to the dimeric interface can lead to a major destabilization of the mutant enzymes.

The primary medical literature inventories 418 mutations in SOD1-associated ALS patient that are non-randomly distributed: 404 missense, 5 deletions, 6 insertions and 3 nonsense. The vast majority of missense mutations were found in exon 1 (111) and 4 (222), which include the folding-related defects described above. Exons 2, 3, and 5 had the fewest missense mutations (29, 8, and 34 respectively).

The present study seeks to determine if intronic elements play a role in the origin of ALS-associated mutations. The mutation free/reduced regions that included exon 2 and 3 were found to be associated with repeated elements located in introns 1 and 2. The relative importance of these intronic sequences is assessed using phylogenetic comparisons with other species including mice.

Exploration of 100 cardiovascular candidate genes across different ethnic groups in the INTERHEART study.

J.C. Engert[1], S. Yusuf[2], B. Keavney[3], G. Paré[4], D. Serre[4], A. Montpetit[4], M. McQueen[2], H. Cordell[3], T.J. Hudson[1,4], S. Anand[2] 1) Depts Med and Human Genetics, Royal Victoria Hospital, McGill Univ, Montreal, Quebec, Canada; 2) Population Health Research Institute and McMaster Univ, Hamilton, Ontario, Canada; 3) University of Newcastle upon Tyne, Institute of Human Genetics, United Kingdom; 4) McGill University and Genome Québec Innovation Centre, Montreal, Quebec, Canada.

With the advent of high throughput genotyping technologies, it has become increasingly practical to do association studies on large numbers of genes and SNPs in well-powered study samples. The ability of tagging SNPs developed from the HapMap data set, to capture unassayed SNPs has been well characterized within specific ethnic groups, but their performance in a truly global study remains to be determined. The INTERHEART myocardial infarction (MI) case/control sample consists of >27,000 individuals recruited from 52 countries around the world. In a sample of three ethnicities (~10,000 European, South Asian and Arab individuals) from this study population, we have genotyped 1536 SNPs from ~100 candidate loci to determine their association with myocardial infarction and multiple associated measured risk factors. All three HapMap ethnic groups were used to select tSNPs from the gene regions to capture common variation (minor allele frequency > 5%). Hardy-Weinberg Equilibrium was tested for all SNPs, but only SNPs that failed a visual quality control inspection were eliminated from further analysis. In addition, we have used the program STRUCTURE to identify ethnic outliers and miscategorized individuals. We performed separate analyses within each ethnic group, but also analyzed all samples together (cases and controls were matched by ethnicity and geographical region). Significant differences in the allele frequencies of some SNPs in candidate genes were observed between ethnic groups, which may affect their role in the pathogenesis of MI.

Evaluation of the aryl hydrocarbon receptor nuclear translocator (ARNT) gene on 1q21 as a type 2 diabetes (T2DM) susceptibility gene in the Old Order Amish. *M. Fu[1], C. Damcott[1], M. Sabra[1], S. Ott[1], X. Shi[1], A.C. Naj[1,2], L. Reinhart[1], J. Gunton[3], T. Pollin[1], J. O'Connell[1], B.D. Mitchell[1], C.R. Kahn[3], A.R. Shuldiner[1,4]* 1) Dept Med, Div Endocrinology, Univ Maryland, Baltimore, MD; 2) Dept Epid, Johns Hopkins Univ, Baltimore, MD; 3) Joslin Diab. Cent., Harvard Med School, Boston, MA; 4) GRECC, VAMC, Baltimore, MD.

ARNT is a member of the basic helix-loop-helix Per/AhR/ARNT/Sim (bHLH-PAS) family of transcription factors. Its expression is markedly decreased in pancreatic islets of humans with T2DM. Decreases in expression of ARNT in cultured cells using siRNA and in mice with a cell-specific deletion of ARNT causes significant abnormalities in insulin secretion and glucose metabolism. ARNT is located within a region on chromosome 1q21-q24 linked to T2DM in the Old Order Amish and six other populations. We hypothesized that variation in ARNT may affect glucose-stimulated insulin secretion, thus increasing susceptibility to type 2 diabetes. We sequenced the 22 exons, the surrounding intronic sequences, and the proximal regulatory region of ARNT in 24 Amish samples. We identified 16 polymorphisms, including a missense mutation (D511N) and a silent mutation (V174V). Sixteen haplotype-tagging SNPs and the cSNPs were genotyped in more than 1,300 subjects of the Amish Family Diabetes Study for association analysis. None of the SNPs showed evidence of association with T2DM in the Amish. However two SNPs (rs10847 and rs11204737) significantly associated with insulin levels at 30 and 60 min following a 75 gram oral glucose tolerance test in nondiabetic individuals (P = 0.004-0.039). Individual homozygous for the rare alleles of D511N were found in one diabetic patient and in two subjects with impaired glucose tolerance but not in any normoglycemic subjects. Our data do not suggest that ARNT can explain the linkage of T2DM to this region, but polymorphisms in ARNT may play a modest role reducing early insulin secretion in response to glucose. Whether homozygosity for the D511N missense mutation affects T2DM susceptibility in a small number of subjects merits further investigation.

Regulation of endogenous L1 expression by splicing and polyadenylation. *V.P. Belancio, P.L. Deininger*
Epidemiology, Tulane University, New Orleans, LA.

LINE-1 is the only active autonomous non-LTR human retroelement. The expression and activity of these elements contribute to human genomic instability. LINE-1 elements comprise 17% of the human genome, which translates into about 5x105 L1 copies, the majority of which are defective due to truncations at their 5 end. We have demonstrated that LINE-1 mobility is significantly attenuated by the presence of functional polyadenylation signals throughout the coding region of L1 genomes. Additionally, we reported a number of functional splice donor and acceptor sites present throughout the L1 sequence. These splice and polyadenylation signals are utilized by both transiently transfected and endogenously expressed L1 elements. Typical polyadenylation and splice sites are composed of highly conserved as well as variable cis-elements that are recognized by the cellular proteins for processing. The strength and usage of any given signal may vary between tissues as demonstrated by the presence of tissue-specific alternatively spliced and/or polyadenylated transcripts of numerous mammalian genes. We have analyzed the expression profiles of endogenous L1 elements from different human cell lines. We find that some of the splice and polyadenylation signals are used constitutively, while others seem to be utilized differentially, resulting in significant variation in the amount of specific spliced and polyadenylated L1-related RNA species among these cell lines. This apparent regulation of the post-transcriptional processing events brings up the possibility that L1 elements have differential impacts in different tissues based on both the level and nature of the specific transcripts expressed.

Psoriasis-associated alleles from the haplotype block harboring PSORS1 within the HLA class I interval have differential enhancer activity compared to wild type alleles. *L. Cao[1], Y. Liu[1], C. Helms[1], M. Fernandez[2], A. Bowcock[1]* 1) Dept Genetics, Washington Univ, St Louis, MO; 2) Dept. Laboratory Medicine, University of Texas M.D. Anderson Cancer Ctr, Houston, TX.

Psoriasis is a complex inflammatory disease of the skin affecting 1-2% of the Caucasian population. Associations with alleles from the histocompatibility locus antigen cluster (HLA) class I region (now known as PSORS1), particularly HLA-Cw*0602, were described over 20 years ago. However, extensive linkage disequilibrium (LD) within this region has made it difficult to identify the true susceptibility allele from this region. We recently performed a comprehensive case/control and family-based association study on 242 Northern European psoriasis families and two separate European control populations. With all tests, association was strongest with single markers and haplotypes from a block of LD harboring HLA-C and SNP n.9, a locus lying 4kb upstream from HLA-C. HLA-Cw*0602 is commonly over-transmitted to affected members, but rare over-transmitted haplotypes also harbor HLA-Cw*12 alleles. HLA-Cw*12 family members are closely related to HLA Cw*0602, sharing identical sequences in their alpha-2 domains, peptide binding pockets A, D and E and all 3 introns. The introduction of a potential binding site for the RUNX/AML family of transcription factors in intron 7 (CINT), is also specific to these HLA-C alleles. Genotyping of CINT in patients revealed that it is in complete LD with SNP n.9 and SNP n.7 that lies 10kb from the start of HLA-C. Transient transfections with luciferase reporter constructs of alleles from these loci revealed that they harbor enhancer activity that differentiates psoriasis-associated and wt alleles. This suggests that several HLA-C alleles may be responsible for psoriasis susceptibility, or that PSORS1 is an enhancer affecting expression of genes within the class I region such as HLA-C itself, or skin-specific genes such as corneodesmosin (CDSN) that lies ~150kb downstream from HLA-C. This is consistent with our observation that CDSN is up-regulated in patients with predisposing HLA class I alleles.

Genomewide association with eleven intermediate phenotypes for CVD in women. *D.I. Chasman[1,5,8], D.T. Miller[3,5,6,8], P. Kozlowski[3,5,8], J. Suk Danik[1,5,8], R. Lazarus[4,5,8], R.Y.L. Zee[1,5,8], N.R. Cook[1,5,7,8], D.J. Kwiatkowski[3,5,8], P. M. Ridker[1,2,5,8]* 1) Preventive Medicine; 2) Cardiovascular Medicine; 3) Hematology; 4) Channing Laboratory; 5) Brigham and Women's Hospital; 6) Children's Hospital; 7) Harvard School of Public Health; 8) Harvard Medical School, Boston, MA.

The biological processes underlying cardiovascular disease (CVD) may be understood through analysis of intermediate phenotypes corresponding to disease etiologies based in lipid metabolism, inflammation, and thrombosis/hemostasis. Among 28,000 participants from the Womens Health Study (WHS), a prospective cohort of initially healthy women with over 10 years of follow-up observation and over 600 accrued CVD events, we had previously measured 11 plasma-based intermediate phenotypes thought to be associated with disease risk including: LDL, HDL, triglycerides, total cholesterol, apoA1, apoB, and Lp(a) for lipid-based etiologies, C-reactive protein (CRP), soluble ICAM-1, and fibrinogen for inflammation-based etiologies, and homocysteine and fibrinogen for thrombosis/hemostasis-based etiologies. We have now collected Affymetrix GeneChip 100K single nucleotide polymorphism (SNP) data on a subset of about 1000 Caucasian, non-smoking WHS participants who were also not using hormone replacement therapy at enrollment. In preliminary analysis, we have identified significant candidates for association with the 11 plasma biomarkers. The initial candidates include previously known associations with the biomarkers, e.g. CRP gene SNPs with CRP and an MTHFR gene SNP with homocysteine, as well as potentially novel genes and SNPs that may contribute to the risk and progression of CVD. To validate the initial candidates, we are re-examining the associations through replication in additional subsets of 1000 subjects from the WHS. Once validated, candidate associations with the intermediate phenotypes will be tested for association with incident CVD in the WHS and in other prospective cohorts.

Identification of Down syndrome heart defect candidate genes. *L.J.H. Bean[1], K.J. Dooley[2], S.B. Freeman[1], T.C. Rosser[1], C. Oxforc-Wright[1], C. Kohler[3], G. Capone[3], S.L. Sherman[1]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Sibley Heart Center, Dept Pediatrics, Emory Univ, Atlanta, GA; 3) Div Neuro and Dev Med, Kennedy Kreiger Institute, Baltimore, MD.

Individuals trisomic for chromosome 21 exhibit a wide range of phenotypes known as Down syndrome (DS). DS is mainly characterized by mental retardation and clinical features that include hypotonia, abnormalities of the face, hands, and feet. Other variable phenotypes associated with DS may include congenital heart disease (CHD), digestive tract abnormalities, congenital cataracts, or leukemia. The prevalence of DS, approximately 1 in 600 to 1 in 1000 live births, makes this syndrome the most commonly identified form of mental retardation. Compared to the general population, individuals with DS are at a 2000-fold increased risk for complete atrioventricular septal defects (AVSDs), a severe form of CHD. The purpose of this study is to identify genetic variants on chromosome 21 that contribute to CHD susceptibility using a candidate gene approach in a DS population with complete AVSDs. We have ascertained the largest reported collection of DNA on complete AVSD DS cases and their parents. Studies done in the mouse indicate that several genes within the candidate region are differentially expressed during heart development. We hypothesize that genes expressed in fetal, but not adult, heart may play a role in the etiology of congenital heart defects. The human heart expression pattern of several interesting candidate genes in a 10Mb DS CHD critical region on chromosome 21 has been determined. Interestingly, the PDE9A gene has specific splice variants whose expression is developmentally regulated. Combining this expression data with the vast array of genomic resources available for chromosome 21, we will use molecular approaches to identify candidate genes for DS CHDs within a 10 Mb heart defect critical region. We are in the process of genotyping 384 SNPs within this region in our population of approximately 125 Caucasian cases(DS with AVSD) and controls (DS with no heart defect) and 40 African-American cases and controls. Parent samples will also be genotyped.

Patterns of gene flow between human populations. *D. Garrigan[1], Z. Mobasher[2], S.B. Kingan[1], M.M. Pilkington[2], M.F. Hammer[2]* 1) Organismic & Evolutionary Biol, Harvard University, Cambridge, MA; 2) Genomic Analysis & Technology Core, University of Arizona, Tucson, AZ.

It is widely recognized that human populations exhibit low levels of genetic differentiation, as evidenced by low observed values of summary statistics such as FST. However, summary statistics do not take full advantage of all the information in DNA sequence data and it is difficult to know whether low FST values are due to recent population divergence, high rates of gene flow, or both. To overcome this limitation, we estimate parameters of a general isolation-with-migration (IM) model of population structure with re-sequenced data in large samples from 10 human populations. A Markov chain Monte Carlo (MCMC) technique is used to infer simultaneously divergence times, rates of directional gene flow, and changes in population size. The results indicate that sub-Saharan African populations diverged at least 100 thousand years ago (kya), while most non-African populations diverged as recently as 7-25 kya. The divergence time between African and non-African populations is estimated at 40 kya, suggesting that non-African populations descend from a genetically structured ancestral African population. There is no support for radical historical changes in African population sizes, while non-African populations appear to have experienced a strong, recent bottleneck(s). Rates of gene flow, both within and between continents, are estimated to be highly asymmetrical and implicate Asia as the primary source for most recent human gene flow. Lastly, the estimated locus-specific rates of gene flow, including mitochondrial DNA and Y chromosome data, reveal complex patterns of sex-specific gene flow.

Association analyses of common SNPs in *TCF7L2* with type 2 diabetes covariates, gender, age of onset and BMI, and the interaction with other diabetes risk alleles. *L. Gianniny[1], R. Saxena[1,2], N. Burtt[1], V. Lyssenko[3], C. Giuducci[1], M. Sjögren[3], J.C. Florez[1,2,4], P. Almgren[3], B. Isomaa[5], M. Orho-Melander[3], U. Lindblad[3,6], M.J. Daly[1,2,4], T. Tuomi[5], J.N. Hirschhorn[1,4,7], K. Ardlie[1,8], L. Groop[3], D. Altshuler[1,2,4]* 1) Medical & Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, M; 3) Department of Clinical Sciences- Diabetes & Endocrinology, University Hospital MAS, Lund University, Malmö, Sweden; 4) Department of Medicine, Harvard Medical School, Boston, MA; 5) University of Helsinki, Helsinki, Finland; 6) Skaraborg Institute, Skövde, Sweden; 7) Divisions of Genetics and Endocrinology, Childrens Hospital, Boston, MA; 8) Genomics Collaborative Inc., Cambridge, MA.

Common non-coding variants in the *TCF7L2* gene are reproducibly associated with increased risk of type 2 diabetes. We genotyped 13 SNPs across *TCF7L2* in 8,310 individuals from Scandinavia, Poland and the US. We examined the correlation of *TCF7L2* genotypes with gender, body mass index (BMI) and age of onset, to test if *TCF7L2* variants contribute to risk of type 2 diabetes through an effect of these covariates. It was observed that *TCF7L2* risk associated with type 2 diabetes was stronger in men than in women (men n=3389, OR 1.50 (95%CI 1.35-1.67), $P = 5.9 \times 10^{-14}$ vs. women N= 3529, OR 1.33 (1.19-1.47), $P = 8.8 \times 10^{-8}$). We found that diabetic individuals with the risk allele(s) are leaner than diabetic individuals who do not carry the risk allele ($P = 0.01$). Additionally, no significant association of *TCF7L2* variants with BMI were observed in controls or with age of onset ($P = 0.64$) in cases. Finally, we tested for epistatic interactions between *TCF7L2* rs7903146, *PPAR* P12A, and *Kir6.2* E23K and found no significant evidence of epistasis. Our results indicate that *TCF7L2* variants may exert sex-specific effects, and may interact with BMI to influence the risk of type 2 diabetes.

Genomic Approaches for Pathway Identification in Regenerating Sensory Epithelia of the Inner Ear. *D. Alvarado, K. Powder, D. Hawkins, S. Bashiardes, V. Bhonagiri, R. Veile, J. Speck, M. Warchol, M. Lovett* Washington Univ, St Louis, MO.

The cochlea and the utricle of the vertebrate inner ear utilize sensory hair cells as mechano-electric transducers of sound and balance respectively. In mammals if these sensory hair cells are damaged they cannot regenerate. In contrast, avian sensory hair cells of the utricle and cochlea maintain their regenerative ability. To identify genes involved in hair cell regeneration, avian sensory epithelia (SE) from the cochlea and utricle were separately damaged by laser or chemical ablation and changes in gene expression were measured at recovery time points on a custom transcription factor (TF) gene microarray. Approximately 90 of the ~500 differentially expressed genes are involved in known genetic signaling pathways such as *Pax, Tgf*, Hedgehog, Notch, *Ap1, Igf* and NfkappaB pathways. To identify TFs that are required for early events in SE regeneration, 20 were knocked down by targeted siRNA in a high throughput proliferation assay. Knockdowns of components of the *Pax* pathway, of *JunD* and *Cebpg*, as well as chemical inhibition of the Jun kinase (*JunK*) pathway, significantly inhibited SE proliferation. Many of these TFs specifically affect inner ear SE proliferation, as evidenced by failure of RNAi treatments to inhibit proliferation in retinal epithelia. We identified novel epistatic relationships by conducting gene expression profiles on the SE of targeted siRNA knockdowns. For example, the TF *Cebpg* was placed in this way as being downstream of the *Ap1* (*JunK, JunD*) pathway. Five more genes were positioned downstream of *Cebpg*: *IRX4, LRP5, TAF-172, RARA,* and *ZNF44*. Three of these are specifically required for proliferation in the utricle SE. Interestingly, one of these, *LRP5*, is a co-receptor for *Wnt* signaling. Six known components of *Wnt* signaling are also differentially expressed during the SE regenerative process. Taken together our observations indicate that the *Ap1* pathway may directly intersect with *Wnt* signaling during the early stages of hair cell regeneration and that this pathway is necessary and important for early events in the regenerative process.

SNP correlates with LDLR splicing efficiency in pre-menopausal women. *K.E. Grear[1], H.M. Tucker[2], H. Zhu[1], S. Estus[1]* 1) Department of Physiology, Sanders-Brown Center, University of Kentucky, Lexington, KY; 2) Department of Pediatrics, University of Kentucky, Lexington, KY.

The liver is an important organ in cholesterol homeostasis. Seventy percent of low-density lipoprotein (LDL) is removed from circulation by the liver via low-density lipoprotein receptors (LDLRs). Excess LDL in the circulation can lead to a myriad of health problems, including myocardial infarctions, strokes and peripheral vascular disease. Our laboratory has found a single-nucleotide polymorphism (SNP) that modulates splicing efficiency differences in LDLR in vitro. This SNP also associates with higher LDL levels in pre-menopausal women. To test our findings in vivo, I obtained 30 pre-menopausal female liver samples from the Brain and Tissue Bank for Developmental Disorders at the University of Maryland and extracted RNA via the phenol-chloroform method. Primers were designed that flanked the exon containing the SNP and resided in exon 10 and exon 14 of LDLR. I performed RT-PCR, separated the products on an 8% polyacrylamide gel and quantified the ratio of full-length LDLR to total LDLR. Each of the samples were then genotyped for the SNP using a TaqMan Custom SNP Genotyping Assay. LDLR splicing efficiency was found to correlate in vivo with SNP genotype ($p=0.02$). These results support the hypothesis that the SNP correlates with splicing efficiency differences in pre-menopausal female liver. Future experiments will include evaluating LDLR splicing efficiencies in male and post-menopausal female liver tissue.

Genetic basis of Hirschsprung disease in Down syndrome. *S. Arnold, A. Chakravarti* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Hirschsprung disease (HSCR), a condition characterized by aganglionosis along varying lengths of the colon, manifests as an intestinal obstruction in neonates and children. The risk of HSCR among individuals with Down Syndrome (DS) is fifty fold greater than in the general population. Mice heterozygous for loss of function mutations in both the receptor tyrosine kinase RET and a second HSCR susceptibility gene, EDNRB, phenotypically recapitulate most of the characteristics of HSCR and display disregulation of nine genes in the DS critical region. Interestingly, there is evidence to suggest that one of the upregulated genes, superoxide dismutase (SOD1), interferes with RET dimerization when overexpressed in cultured cells. Taken together, these results suggest that an additional copy of a gene (or genes) on Chromosome 21, likely in an over-represented, mutant form, combines with a mutation in RET to elevate the incidence of HSCR in the DS population.
In accord with this hypothesis, a recently described enhancer mutation in Intron 1 of RET is overtransmitted in individuals with HSCR and DS to the same extent as in individuals with HSCR alone. However, the involvement of Chromosome 21 in increased HSCR risk for DS individuals is less clear. Microsatellite genotyping of individuals with HSCR and DS and comparison to results obtained from DS controls shows no relationship between reduction to homozygosity and increased incidence of HSCR. This weakens support for the contribution of an over-represented Chromosome 21 mutation to disease. In addition, no Hirschsprung phenotype was detected in mice overexpressing SOD1 and heterozygous for the RET null mutation, though the possibility remains that the combined overexpression of multiple Chromosome 21 genes is essential for the development of HSCR in this context. To this end, the introduction of the RET null mutation into mice overexpressing genes orthologous to one-third of the genes on human Chromosome 21 (the Ts65Dn mouse) is underway.

The National Coordinating Center (NCC) for the Genetics and Newborn Screening Regional Collaborative (RC) Groups: A national resource for enhancing services in local communities. *J. Benkendorf[1], M. Lloyd-Puryear[2], M. Mann[2], J. Shuger[2], M. Watson[1]* 1) American College of Medical Genetics, Bethesda, MD; 2) MCHB/HRSA, Rockville, MD.

In 2004, the ACMG entered into a cooperative agreement with MCHB/HRSA to serve as the NCC for the 7 RCs. Because genetic services are multifaceted, multidisciplinary, but best delivered locally the NCC enhances abilities of the RCs to strengthen and support genetics and newborn screening (NBS) capacities of States and address maldistribution of genetics providers. The NCC provides infrastructure, coordination and technical assistance, and it generates materials to address issues of common interest, avoiding duplication of efforts and allowing the RCs to focus on their unique needs. The NCC also facilitates collaborations between the RCs and national projects, using local communities to pilot materials and programs for policymakers, health professionals and families. 16 national organizational partners contribute additional resources. NCC initiatives include building national capacity in the use of telegenetics; establishing a searchable national network of genetic service and subspecialty providers experienced in diagnosis and management of infants detected in NBS programs; collecting and disseminating data that establish the value of genetic services to payers and policymakers; developing disaster preparedness measures to assure that NBS programs and treatment of patients with metabolic conditions are not interrupted; bridging NBS and genetic testing laboratories with the medical home through development and distribution of management guidelines, including the transition of patients from pediatric to adult care; and developing resources for State policymakers. National data collection efforts include tracking pilot NBS programs, and establishing and maintaining a patient follow-up database useful in rare disease research. Maximizing collaboration between the genetic services, primary care, NBS and public health communities is critical to the success of each effort and the collective impact of the NCC and the RCs. Mechanisms for local, national, and organizational involvement will be emphasized.

Follow up genome-wide SNP assay reveals additional structural variation and confirms extended homozygosity and cell-line induced alterations in normal individuals. *A.F. Britton[1], J. Simon-Sanchez[1, 2], S. Scholz[1], H.-C. Fung[1], M. del Mar Matarin[1], D. Hernandez[1], J.R. Gibbs[1], F. Wavrant de Vrieze[1], E. Peckham[3], K. Gwinn-Hardy[4], A. Crawley[4], J.C. Keen[5], J. Nash[5], D. Borgaonkar[1], J. Hardy[1], A. Singleton[1]* 1) Laboratory of Neurogenetics, NIA, Bethesda; 2) Unidad de Genética Molecular, Departamento de Genómica y Proteómica, Instituto de Biomedicina de Valencia-CSIC, Valencia, Spain; 3) Human Motor Control Section, NINDS, Bethesda; 4) Neurogenetics Branch, NINDS, Bethesda; 5) Coriell Institute for Medical Research, Camden.

Previous genome-wide SNP assay of 109, 365 SNPs in 276 neurologically normal North American Caucasian individuals revealed extended homozygosity (contiguous tracts > 5 Mb) in 6.9 % (19/273) and gross chromosomal abnormalities in 8.8 % (24/276) of DNA samples assessed. These data suggest that structural genomic variation is a common occurrence in the general population. It is also believed that individuals with a least one large region of homozygosity are likely to harbor other large regions of homozygosity, indicating parental consanguinity. Given this, a follow-up assay of 317, 511 SNPs was conducted in the same subjects. There are 18, 072 SNPs in common between the two arrays, providing data on 408, 803 unique SNPs. DNA for both assays was extracted from the Epstein-Barr virus (EBV) immortalized lymphocyte cell lines (LCLs) and directly from the blood sample used for each immortalization. Data was visualized by two metrics; B allele frequency (which determines the ratio of alleles at each genotype) and log R ratio (which provides the copy number of each SNP), derived from Genome Viewer within Beadstudio v2.2.22 (Illumina Inc. San Diego, CA). The raw genotype data from these efforts are available on the Coriell website (http://ccr.coriell.org/ninds/catalog). Based on the greater accuracy of assaying 317, 511 SNPs, we identified additional structural variation and confirmed extended homozygosity and chromosomal abnormalities in individuals from the previous assay. These data confirm the strength of identifying chromosomal abnormalities in the general population using genome-wide SNP assays.

Genome-wide copy-number analysis of parathyroid carcinomas by single nucleotide polymorphism arrays. *J. Costa-Guda[1], N. Kawamata[2], H.P. Koeffler[2], A. Arnold[1]* 1) Molecular Medicine, University of Connecticut Health Center, Farmington, CT; 2) Hematology/Oncology, Cedars-Sinai Medical Center, Los Angeles, CA.

Parathyroid cancer is a rare, clinically aggressive cause of primary hyperparathyroidism. Inactivation of the *CDC73* (*HRPT2*) tumor suppressor gene, encoding parafibromin, is a central contributor to the molecular pathogenesis of parathyroid cancer, but other genes essential to parathyroid carcinogenesis remain unknown. To identify regions of allelic imbalance potentially harboring oncogenes or tumor suppressor genes central to the development of parathyroid carcinoma, we performed genome-wide copy-number and loss of heterozygosity (LOH) analysis using Affymetrix 50K SNP Mapping Arrays on 13 parathyroid carcinomas, local recurrences or distant metastases and matched normal control DNA from 9 individuals. Copy number analysis was performed using Copy Number Analyzer for GeneChip software and LOH was determined by direct comparison of genotype calls from each patient's normal and tumor DNA. Recurrent regions of allelic loss were observed on chromosomes 1p, 3, 13q, and 14, including instances of copy-number neutral LOH, strongly suggesting that tumor suppressor genes important to parathyroid carcinogenesis are located in these chromosomal locations. Recurrent allelic gain was seen on chromosome 16, suggesting the likely presence of a key parathyroid oncogene(s) on this chromosome. While recurrent changes on 1p, 3, 13q and 16 have been described in prior studies using comparative genomic hybridization and molecular allelotyping (Agarwal, *Cancer Genet Cytogenet*, 1998 and Imanishi, *J Bone Miner Res -Suppl. 1*, 1999), our results narrow the target regions on 1p and 13q and recurrent allelic loss on chromosome 14 in parathyroid cancer is a novel finding. Further studies are needed to determine which of the candidate genes in these chromosomal locations are important to the molecular pathogenesis of parathyroid cancer.

Interactions Between Candidate Genes, Nutritional and Lifestyle Factors in Osteoporosis. *S.L. Ferrari* Geneva University Hospital, Geneva, Switzerland.

Osteoporosis is a bone fragility disorder caused by low bone mass and deterioration of skeletal microarchitecture. The major nutritional and lifestyle factors implicated are poor dietary calcium intake, vit.D insufficiency and low physical activity. However genetic effects account for 60 to 80% of the population variance in bone mass. Numerous quantitative trait loci for bone density have been identified as well as dozens of candidate genes that are more or less strongly associated with bone mass and/or fracture risk. Among them, vit.D receptor gene 3'-UTR (Bsm1) alleles have been associated with small differences in bone density and an independent risk of osteoporotic fractures. Some reported interactions between calcium intake and VDR alleles, both in children and the elderly, seemingly with a modulation of intestinal calcium absorption and mineral homeostasis by VDR genotypes. Consistent with the known role of IL-6 on mediating the effects of estrogen-deficiency on bone resorption and bone loss, allelic variants in the IL-6 gene promoter have been associated with bone turnover, bone density and wrist fracture risk. In 1574 unrelated men and women from the Offspring Cohort of the FHS, the relationship between IL-6-174 genotypes and bone mineral density in women was influenced by significant interactions with years since menopause, oestrogen status, dietary calcium and vit.D intake. Recently described non-synonymous SNPs in the LDL-receptor related protein 5 gene (LRP5), implicated in the regulation of bone formation, have been related to bone density, vertebral bone size and spinal fracture risk with a net predominance in males. Some data suggest this gender-related association is mediated by LRP5 interaction with physical activity which effects on the skeleton could therefore be partially transduced by the Wnt-LRP5 canonical signaling pathway. Eventually Ppar gamma polymorphisms, a member of the nuclear receptor superfamily of transcription factors that plays an essential role in the selective differentiation of mesenchymal stem cells towards the adipogenic vs osteogenic lineage, have been associated with bone density. Work in progress suggests interactions with the lipid content of the diet.

Translocation breakpoint mapping in four 1p36 subjects with der(1)t(1;22)(p36;q11 or q13). *M. Gajecka[1], C.D. Glotzbach[1], K.L. Peterson[1], R. Saadeh[2], K. Spodar[3], M. Iliszko[4], D. Chitayat[5], B.C. Ballif[6], L.G. Shaffer[1,6]* 1) Hlth Res and Educ Ctr, Washington State Univ, Spokane, WA; 2) McKusick-Nathans Inst of Genet Med, Johns Hopkins Hospital, Baltimore, MD; 3) Dept of Med Genet, Children's Hospital Memorial Health Inst, Warsaw, PL; 4) Dept of Biol and Genet, Medical Univ, Gdansk, PL; 5) Dept of Pediatr, The SickKids, Univ of Toronto, Toronto, ON; 6) Signature Genomic Laboratories, LLC, Spokane, WA.

Although terminal deletions of 1p36 are relatively common, occurring in about 1 in 5,000 individuals, unbalanced translocations of 1p are rare, and little is known about their mechanism of formation. Of the 132 1p36 deletion cases ascertained by our laboratory to date, 22 (16.7%) are derivative chromosomes. Here we present the mapping and cloning of the breakpoints in four subjects with der(1). Two der(1)t(1;22)(p36;q13.3) are paternally inherited and one is maternally inherited, whereas the der(1)t(1;22)(p36;q11.2) is maternally inherited. To determine the sizes of the 1p36 deletions and 22q partial trisomies, we performed array CGH using the SignatureChip (Version 4.0) with cell lines derived from each of the four subjects. This microarray contains 55 BACs representing the most distal 11 Mb of 1p36 and 52 BACs from chromosome 22 targeted mainly to the cat eye syndrome region, DiGeorge syndrome region, breakpoint cluster region, and the subtelomere. Array CGH and metaphase FISH analyses showed that the 1p36 deletions and 22q duplications vary in size. To identify the breakpoints, we generated somatic cell hybrids from the subjects and/or their carrier parents containing the derivative chromosomes 1 or 22 segregated from the normal chromosomes 1 or 22 and performed PCR and STS marker walking. After narrowing the regions containing the junctions, we used the TOPO Walker protocol to amplify across the derivative chromosome junctions. Junctions were identified and analyses of the DNA sequence surrounding the breakpoints were performed. Alignment of the derivative chromosome junctions revealed a lack of sequence similarity between the breakpoints implicating nonhomologous end joining in stabilizing these broken chromosomes.

Novel intraoral phenotypes in hyper-immunoglobulin E syndrome. *D.L. Domingo[1], S.M. Holland[2], A.F. Freeman[2], J. Davis[3], T.C. Hart[1]* 1) NIDCR, National Institutes of Health, Bethesda, MD; 2) NIAID, National Institutes of Health, Bethesda, MD; 3) NHGRI, National Institutes of Health, Bethesda, MD.

OBJECTIVE: Hyperimmunoglobulin E syndrome (HIES) is a multi-systemic primary immunodeficiency characterized by eczema, recurrent skin and lung infections with pneumatocele formation, and extremely elevated serum immunoglobulin E. The genetic etiology is unknown, but most cases are sporadic or inherited in an autosomal dominant manner. Due to variable clinical expressivity, the familial nature may be overlooked in some cases . Non-immunologic findings include characteristic facial features (prominent forehead, broad nasal bridge, fleshy nasal tip and increased interalar distance) and skeletal involvement (pathological fractures, scoliosis and craniosynostosis). Retention of primary teeth and delayed eruption of permanent teeth have been described. This study aims to characterize the intraoral soft tissue features in HIES patients. METHODS: 56 HIES patients (4-54 years; 25 males; 31 females) received comprehensive intraoral examinations and craniofacial radiographic evaluations. Soft tissue anomalies of the hard palate, tongue, buccal mucosa and lip mucosa were characterized. Chronological dental development was also assessed. The association of intraoral lesions and two previously noted HIES features - (1) characteristic facies and (2) retention of primary teeth - were evaluated. RESULTS: 55% manifested asymptomatic irregularities of the hard palate and/or dorsal tongue. Palatal lesions ranged from a generalized surface keratosis to a midline sagittal fibrotic bridge in varying degrees of severity. Dorsal tongue lesions consisted of multiple fissures and pyramidal midline clefts. Lip and buccal mucosal lesions, consisting of keratotic plaques and/or surface fissures, were found in 21% and 7% of patients, respectively. 75% of patients manifested at least one intraoral soft tissue finding, of which 92% also exhibited characteristic facial features and 79% had delayed primary tooth eruption. CONCLUSIONS: Alterations of oral mucosa and gingiva were present in the majority of HIES patients. These novel intraoral findings may facilitate the diagnosis of HIES.

Experts' ethical concerns about a genetic screen for nicotine addiction. *M.J. Dingel, B.A. Koenig* Biomedical Ethics Research, Mayo College of Medicine, Rochester, MN.

Studies in behavioral and addiction genetics can give insight into the ethical issues of behavioral genetic research more broadly. For example, genetic studies of smoking can serve as a test case for analyzing the practicality of public health genetics in the realm of behaviors. If there is a genetic susceptibility to nicotine addiction, might this information be used for prophylactic interventions such as a nicotine vaccine (a product currently under development)? In our study, we interviewed 54 expert stakeholders (17 research scientists, 17 clinicians, and 20 prevention workers) to discover their ethical and practical concerns with a hypothetical genetic screen for smoking behaviors. These experts do not wholeheartedly support genetic screening for susceptibility to nicotine addiction. In general, while these experts did not believe screening would be a silver bullet to keep people from smoking, they also did not think it would promote fatalism in individuals. They were split between thinking that genetic knowledge would help people make better choices, and thinking that it would make no difference in peoples actions. Scientists were the only group to express concern about how the genetic information was communicated to the public. Clinicians and prevention workers, but not scientists, argued that it was important to have a course of action suggested by a genetic test. Though a course of action, the nicotine vaccine, is under development, significant resistance exists among experts for using the vaccine in concert with public health genetics to prevent smoking behaviors. Though some would advocate widespread vaccination of susceptible individuals, in general our experts have reservations about the safety and ethics of giving this vaccine to people who have not yet started smoking, and see its best use instead to be as a cessation device. The experts concerns highlight barriers to incorporating genetic screening for behaviors into clinical settings. Specifically, for testing to be adopted, it appears that there must be a safe therapy, and there must be a clear way of accurately communicating risk.

Characterization of the ubiquitin hydrolase activity of mouse ataxin-3 and of its subcellular localization in skeletal muscle. *M.C. Costa, A.-J. Rodrigues, P. Maciel* ICVS, School of Health Sciences, Univ. Minho, Portugal.

Machado-Joseph disease (MJD) is a neurodegenerative disorder, caused by the expansion of the $(CAG)_n$ tract in the *ATXN3* gene, encoding ataxin-3 (ATX3)- a protein with deubiquitinase (DUB) activity. The *ATXN3* mouse homologue gene (*Mjd*) is very similar to its human counterpart, and is highly regulated by MyoD (a muscle-specific transcription factor). Mouse ataxin-3 (mATX3) is ubiquitously distributed, and particularly abundant in the neurons of the affected regions of the MJD patients, in all types of muscle, testis and in ciliated cells, suggesting a role in cell structure and/or motility. Although the ubiquitin proteasome system plays an important role in mediating skeletal muscle protein wasting, the function of mATX3 in this tissue is unknown. We have expressed the recombinant His:mATX3 that, similarly to human ATX3, had a DUB activity, towards both K48 and K63 polyubiquitin chains *in vitro*. His:mATX3 was used for the production of a polyclonal antibody, anti-mATX3, which revealed to be specific for this protein. In mouse skeletal muscle protein extracts, both the anti-mATX3 and the anti-humanATX3 antibodies recognized mainly a band of 33 KDa; however the first detected another band at 55 KDa and the second at 42 KDa, suggesting that these antibodies may recognize different protein species. To gain insight into the subcellular localization of mATX3 within mouse skeletal muscle, we have performed immunoelectron microscopy, using anti-mATX3 and anti-ATX3. Interestingly, both antibodies revealed similar labeling patterns. Mouse ATX3 was present both in the nucleus (with a higher concentration in the heterochromatin), and in the cytoplasm, where it was mostly localized inside vesicles, in the endoplasmic reticulum, and in the mitochondrial matrix. In the sarcomeres, mATX3 was mostly present in the A band, and to a minor extent in the I band, being also present in a vestigial content in both M and Z bands; it was present inside the sarcoplasmic reticulum and in the mitochondrial matrix. In conclusion, mATX3 is not exclusively associated with a specific cellular structure of skeletal muscle; its enzymatic activity may regulate different cellular pathways.

A multimarker method to localize signals of differential selection by analyzing SNP frequency differences between two populations. *M.J. Barber[1,2], H.J. Cordell[3], J.A. Todd[2]* 1) Department of Statistics, University of Washington, Seattle, WA; 2) Diabetes & Inflammation Lab, Department of Medical Genetics, Cambridge, UK; 3) Institute of Human Genetics, University of Newcastle upon Tyne, International Centre for Life, Newcastle upon Tyne, UK.

Three problems exist if signals of differential selection are localized by the F_{ST} metric of genetic differentiation for each SNP individually. Firstly, the distribution of the F_{ST} metric is unknown. Secondly, any localization is biased towards regions of high SNP density. Thirdly, any localization is insensitive to the neighboring per SNP F_{ST} metrics. The method applied here overcomes all three problems by defining a multi-SNP localizing statistic that relies on the property of exchangeability of locations under the null hypothesis of no differential selection. Specifically, the multi-SNP localizing statistic is calculated from using linear regression on the quantiles of the per SNP F_{ST} metrics observed within a sliding window of genetic distance from a test location given an expected correlation matrix between the quantiles, which is estimated as the average correlation between all pairs of quantiles across the genome that are separated by a similar genetic distance. The multi-SNP localizing statistic is ignorant of the phase information between the SNPs but has three beneficial properties. Firstly, it can be assumed to follow a standard normal distribution under the null hypothesis of no differential selection, irrelevant of how differentiated the two populations are. Secondly, from use of genetic distance within the sliding window the multi-SNP localizing statistic is a property of the test location and not just of the test region. Thirdly, inference can rapidly be made on a genome-wide level with a dense genotyped set of SNPs (e.g. phase II of the HapMap project) without the need for any simulations. Application to the different SNP frequencies observed for the four HapMap populations has shown two things, firstly, that the multi-SNP localizing statistic follows a standard normal distribution for almost all test locations, and secondly, that there are six regions of interest with a *P*-value of less than 10^{-8}.

Renal phenotype of heterozygous Lmx1b knockout mice (Lmx1b+/-) after uninephrectomy. *S.U. Endele[1], S. Klein[1], T. Molter[1], S. Richter[1], B. Klanke[2], A. Winterpacht[1]* 1) Institute of Human Genetics, University of Erlangen-Nuremberg,Erlangen, Germany; 2) Department of Medicine IV, University of Erlangen-Nuremberg, Erlangen, Germany.

The Nail-Patella Syndrome (NPS) is a rare autosomal-dominant disorder characterized by dysplastic nails, absent or hypoplastic patellae, dysplasia of the elbows and, in some cases (~50%), nephropathy. Nephropathy is the most serious aspect of NPS and often results in complete renal failure. NPS is caused by heterozygous loss-of-function mutations in the transcription factor gene *LMX1B*. Despite of identical or very similar mutations only 50-60% of the NPS patients develop a renal phenotype, which suggests genetic modifiers in the outbred human genetic background. $Lmx1b^{-/-}$ knockout mice (Chen et al., 1998) show an NPS-like phenotype including renal dysplasia but die within a few days after birth, while $Lmx1b^{+/-}$ mice seem to be phenotypically normal. We started to evaluate the Lmx1b knockout mouse as a possible model for the mapping of genetic modifiers of LMX1b activity in the kidney. This requires the identification of a renal phenotype in the heterozygous $Lmx1b^{+/-}$ knockout animals. Since we were not able to identify a renal phenotype in C57BL6 or different mixed genetic backgrounds by conventional histological examination, we tried to induce renal damage and thus provoke a renal phenotype in $Lmx1b^{+/-}$ mice. In total, 30 $Lmx1b^{+/+}$ and $Lmx1b^{+/-}$ mice (23 in C57BL6 and 7 in JF1 genetic background) underwent unilateral nephrectomy and received a salt diet for 6 weeks. Renal damage was evaluated following measurements of organ weights, urine albumin and total protein excretion as well as glomerular volume, mesangiolysis and glomerulosclerosis indices. Although we identified a slight, strain specific difference in kidney weight gain, no significant differences between the $Lmx1b^{+/-}$ and $Lmx1b^{+/+}$ mice could be detected. We therefore assume a compensatory mechanism in $Lmx1b^{+/-}$ mice explaining the missing phenotype in heterozygous Lmx1b knockout mice.

Genetic Heterogeneity of Meckel Gruber Syndrome. *L. Deda[1], S. Herd[1], D. Chitayat[3,4], E. Héon[1,2]* 1) Genetics and Genomic Biology, Sick Kids Hospital, Toronto, Ontario, Canada; 2) Dept of Ophthalmology and Vision Sciences, Sick Kids Hospital, Toronto, ON, Canada; 3) Prenatal Diagnosis and Medical Genetics Program, Mt. Sinai, Toronto, ON, Canada; 4) Dept of Clinical and Metabolic Genetics, Sick Kids Hospital, Toronto, Ontario, Canada.

Meckel Gruber Syndrome (MKS) is a severe autosomal recessive disorder characterized by bilateral renal cystic dysplasia, developmental abnormalities of the central nervous system, hepatic ductal dysplasia and polydactyly. Although incidence rates range from 1:3,400 to 1:140,000 amongst different populations, MKS represents the most common form of syndromic neuronal tube defects (NTDs) and shares phenotypic similarities with Bardet-Biedl syndrome (BBS). MKS is genetically heterogeneous with three documented loci MKS1 (17q21-24), MKS2 (11q13), MKS3 (8q21.13-q22.1) and two genes identified: *MKS1* and *MKS3* (*TMEM67*). Genotype analysis with highly heterozygous STRP markers was performed for all three loci on a non-consanguineous Portuguese family of 5 affected and 3 unaffected individuals. Suggestion of linkage was identified with the *MKS3* (*TMEM67*) locus on chromosome 8, between markers D8S167 to D8S1774 (~30Mbp interval). No pathogenic sequence changes in *TMEM67* were identified through mutational analysis of genomic and cDNA samples. This work further supports the genetic heterogeneity of MKS.

Mitochondrial Haplogroup U and Prostate Carcinogenesis: Possible Roles in Both Prostate Cancer and High-Grade Prostatic Intra-epithelial Neoplasia (HGPIN). *J.A. Canter, A.R. Kallianpur, J.L. Haines, J.H. Fowke* Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Mitochondria, with their maternally inherited DNA, are critically important in free radical generation, apoptosis and cellular energy production. Accumulating evidence suggests that variation in the mitochondrial genome plays a role in carcinogenesis. We recently reported an association between the mitochondrial DNA G10398A polymorphism and invasive breast cancer in two separate populations of African-American women, and the same polymorphism was subsequently reported to be associated with prostate cancer in African-American men. (Mims et al, Cancer Res 2005;65: 8028-33) Recently, Booker et al (J Urol. 2006;175: 468-72) reported an association between Haplogroup U and prostate cancer risk in Caucasian men (OR=1.95, p=0.02). Haplogroup U is defined in part by a polymorphism (A12308G) that alters the structure of one of the tRNAs for leucine encoded by the mitochondrial genome. In this study, we determined the Haplogroup U status of 268 Caucasian participants in the Nashville Mens Health Study: 71 with prostate cancer, 69 with high-grade intra-epithelial neoplasm (HGPIN), a prostate cancer precursor, and 128 controls without cancer or HGPIN on biopsy. We first found that Haplogroup U was over twice as common in prostate cancer cases compared to controls (26.7% vs. 11.7%). The crude and age-adjusted odds ratios for the association of haplogroup U with prostate cancer in this study population were 2.75 (95% CI 1.2-6.3, p=0.007) and 2.79 (95% CI 1.3-6.0, p=0.008), respectively. Next, we extended the investigation to include HGPIN and found a suggestive positive association between Haplogroup U and this previously unstudied phenotype (age-adjusted OR =1.56, 95% CI 0.70-3.58). This finding is consistent with an etiologic role for this mitochondrial DNA variant in the progression to prostate cancer. A larger study is currently underway to accurately determine the magnitude of this risk. Prostate cancer remains a leading cause of cancer-related mortality. Further research focusing on the mitochondrial genome may uncover new factors important in prostate carcinogenesis.

Rapid prenatal detection of partial chromosome imbalance by Quantitative Fluorescent PCR (QF-PCR). *V. Cirigliano[1,2], G. Voglino[3], E. Ordoñez[1], M.P. Cañadas[1], A. Marongiu[3], E. Lloveras[4], A. Plaja[4], C. Fuster[2]* 1) Dept Molecular Genetics, General Lab, Barcelona, Spain; 2) Unitat de Biologia. Departament de Biologia Cellular, Fisiologia i Immunologia. Universitat Autònoma de Barcelona. E-08193 Bellaterra. Barcelona, Spain; 3) Molecular Genetics and Cytogenetics Lab. Promea-Day Surgery, 1026 Turin. Italy; 4) Departament de Citogenètica. General Lab. 08021 Barcelona, Spain.

The Quantitative Fluorescent PCR (QF-PCR) assay allows performing prenatal diagnoses of common chromosome aneuploidies in a few hours after sampling. Highly polymorphic STR markers are needed on chromosomes X, Y, 21, 18 and 13 to minimise uninformative samples; STRs selection along the examined chromosomes may also allow detecting partial trisomies. We developed a QF-PCR assay including 4 markers on each of the examined chromosomes and two sequences for sexing that has been applied to screen over 30.000 clinical cases. Samples found homozygous for all markers on one chromosome as well as all aneuploid cases were than retested using chromosome specific assays developed to amplify 10 markers on the X and Y, 7 on both chromosomes 21, 18 and 6 markers on chromosome 13. All 1106 aneuploidies were readily detected with 100% sensitivity and specificity. In the course of this study it was also possible to detect 12 fetuses with partial trisomies resulted from unbalanced translocations, duplications, insertions and other structural rearrangements. Chromosome 18 was involved in 4 cases, 6 fetuses had either X or Y derived extra sequences and in two more samples partial trisomies 21 or 13 were also readily detected as trisomic patterns for two or more markers. In 6 cases QF-PCR was crucial to achieve the correct diagnosis. In this study we demonstrate that an appropriate marker selection for QF-PCR assays also allows the identification of partial chromosome imbalance. The main advantages of the assay are its low cost, speed and automation enabling a single operator to analyse up to 60 samples per day. QF-PCR reaches the purposes of relieving anxiety of most parents within 24 hours from sampling or to accelerate therapeutical interventions in case of abnormal result.

Hyperprolinemia is a risk factor for cognitive and psychotic symptoms in VCFS patients. *D. Campion[1], E. Bumsel[1], B. Hecketsweiler[1], T. Van Amelsvoort[2], A. Swillen[3], A. Vogels[3], V. Drouin-Garraud[1], S. Le Gallic[1], S. Manouvrier-Hanu[4], C. Fantini[4], D. Heron[5], N. Philip[6], M. Carlier[6], A. Gerard[6], P. Sarda[7], A. Philippe[8], D. Lacombe[9], O. Boespflug-Tanguy[10], T. Frebourg[1]* 1) Inserm U614, Faculty of Medicine and Departments of Genetics and Biochemistry, University Hospital, Rouen, France; 2) Dpt of Psychiatry, University of Amsterdam, The Netherlands; 3) Center for Human Genetics, University Hospital, Leuven, Belgium; 4) Dpt of Genetics, University Hospital, Lille, France; 5) Dpt of Genetics, La Pitié-Salpétrière, Paris, France; 6) Dpt of Genetics, University Hospital, Marseille, France; 7) Dpt of Genetics, University Hospital, Montpellier, France; 8) Dpt of Genetics, Necker, Paris, France; 9) Dpt of Genetics, University Hospital, Bordeaux, France; 10) Dpt of Genetics, University Hospital, Clermont-Ferrand, France.

The Velo Cardio Facial Syndrome (VCFS) results from heterozygous deletions of the 22q11 region. About one third of VCFS patients present mild mental retardation, a small subset severe mental retardation, and a high rate of psychotic illness has been reported in VCFS. We had previously shown that heterozygous alterations of *PRODH*, causing moderate hyperprolinemia, were a weak risk factor for schizoaffective disorders whereas homozygous alterations, causing hyperprolinemia type I (HPI), were associated with mental retardation, seizures and behavioural disorders. Since 50% of VCFS patients have hyperprolinemia, we determined if hyperprolinemia is a risk factor for cognitive and/or psychotic symptoms in VCFS patients. Ninety two VCFS patients aged 15 years or older were evaluated for psychiatric and cognitive symptoms, plasma proline levels were measured and the *PRODH* and *COMT* genes were analyzed, since an epistatic effect between both genes has recently been reported. We found that (i) a subset of VCFS patients with severe hyperprolinemia has a phenotype distinguishable from that of other VCFS patients and reminiscent of HPI, and (ii) hyperprolinemia associated with the low activity *met-COMT* allele is a joint risk factor for psychosis in VCFS patients, as predicted by the *Pro/Re* mice model.

Normal telomere length in 5p- with a telomerase reverse transcriptase *TERT* deletion. *HY. Du[1], R. Idol[1], S. Robledo[1], J. Ivanovich[2], D.B. Wilson[3], A. Londono-Vallejo[4], P.J. Mason[1], M. Bessler[1]* 1) Internal Medicine; 2) Surgery; 3) Pediatrics, Washington University School of Medicine, St. Louis, MO63110; 4) Institut Curie, 75248 Paris, France.

Telomerase, which maintains the ends of chromosomes, consists of two core components, the catalytic subunit (TERT) and the telomerase RNA component (*TERC*). We have recently shown that haploinsufficiency for *TERC* leads to progressive telomere shortening and disease of autosomal dominant dyskeratosis congenita. Here, we investigated the consequences of *TERT* deletion in patients with 5p- syndrome. The 5p- or Cri du chat syndrome is caused by a partial deletion of the short arm of chromosome 5. 33 individuals with 5p- were investigated during the Annual Meeting of the 5p- Society in St. Louis, 2005. The median age was 7 (1-39). 57 family members aged from 12 to 68 years old with median of 39 served as controls. All individuals with 5p- had or have clinical features characteristic of the syndrome. Individual probands had ridged fingernails, atrophic skin on palms and early graying, indicative of premature aging. Peripheral blood cell analysis showed normal values for hemoglobin (12.891.10g/dl) white blood cell (8.542.83×K/mm3) platelets (277.3880.66×K/mm3) and mean corpuscle volume (86.264.89fl). 4 individuals with 5p- had slightly decreased hemoglobin levels (11.2, 11.2, 12.7, 13g/dl respectively). All participants with 5p- had a deletion of the *TERT* as confirmed by Q-PCR and FISH analysis. Telomere length was measured in peripheral blood cells using flow-FISH. In 29 individuals with 5p- (88%) telomere length was between the 10th and 90th percentile of the healthy controls. In 4 individuals telomeres were below the 10th percentile. While telomere length in 54 family members (95%) were within the 10th to 90th percentile, 3 were below the 10th percentile. There was no correlation between telomere length, blood cell counts or signs of premature aging. Our results demonstrate that the majority of individuals with 5p- including a *TERT* deletion have telomere lengths similar to healthy controls, indicating that premature shortening of telomeres does not contribute to the clinical manifestations in 5p-.

New Insights into Mechanisms and Consequences of Small Marker (Ring) Chromosomes. *E.L. Baldwin, L.F. May, C.L. Martin, D.H. Ledbetter* Dept. Human Genetics, Emory University, Atlanta, GA.

Supernumerary marker chromosomes occur in 1/1000 prenatal diagnostic studies and in 4/1000 individuals with mental retardation. The mechanisms of formation and clinical consequences of marker chromosomes are poorly understood. We developed a panel of 871 unique BAC clones in the pericentromeric regions of each human chromosome in order to evaluate the euchromatic makeup of marker chromosomes and to investigate their mechanism of origin. Seven small non-satellited markers derived from acrocentrics were studied, and 5 were found to be negative for the most proximal unique BAC clones, consistent with a normal phenotype. Two cases contained 1.6 and 5.9 Mb of euchromatin, including 11 and 20 predicted genes. Of 8 cases of non-acrocentric small ring marker chromosomes, 6 contain euchromatic material from either the p- or q-arm, but not both arms. This is consistent with a breakpoint within the centromeric alpha-satellite which can produce two functional chromosomes (ring and deletion), as a major mechanism of marker chromosome formation. Normal individuals may be balanced carriers of complimentary ring and deletion chromosomes, and therefore at high risk for genetically unbalanced offspring. Only 2 markers (both derived from chromosome 8) contain euchromatic material from both the p- and q-arms. Chromosome 8-derived markers are the most frequently occurring non-acrocentric ring marker chromosomes. Since breakage in both the p- and q-arms would produce only one centric chromosome product (small ring) and two acentric arms, it is possible that this mechanism is associated with a trisomy 8 conception followed by trisomy rescue by marker formation. For the above cases, marker sizes range from less than 1 Mb (containing only 3 known genes) to 15 Mb (containing over 170 known genes). Large markers can be readily detected and sized using array CGH, but small marker chromosomes containing only segmental duplications can be problematic. Although these small markers do not contain euchromatic DNA, the individual may be at risk for UPD of the normal homologs. In addition, array CGH cannot detect balanced carriers containing complimentary ring and deletion chromosomes.

PhenCode: Connecting Genome and Phenotype. *B. Giardine[1], W.J. Kent[2], R.C. Hardison[1], PhenCode Consortium* 1) Center for Comparative Genomics and Bioinformatics, Huck Institutes of the Life Sciences, Penn State University, University Park, PA; 2) Center for Biomolecular Science and Engineering, University of California, Santa Cruz, CA.

PhenCode (Phenotypes for ENCODE) is a collaborative project to better understand the relationship between genotype and phenotype in humans. The initial project connects human phenotype and clinical data in various locus-specific databases (LSDBs) with data on genome sequences, evolutionary history, and function in the UCSC Genome Browser. Detailed data on naturally-occurring human mutations and the phenotypes they cause tend to be scattered among literature articles and/or individual databases dedicated to a specific gene or disease. PhenCode aims to connect these databases and make it easy to compare their data with the kinds of genotypic and functional data available at the browsers. With PhenCode, Genome Browser users can find interesting mutations and follow links back to the LSDBs for more detailed information. Alternatively, LSDB users can start with queries on mutations or phenotypes and then display the results at the Genome Browser to view complementary information, such as chromatin modifications and protein binding from the ENCODE consortium. Furthermore, users can query on phenotype across loci (e.g. all mutations that cause anemia, regardless of gene). PhenCode is not a new database, but a new conduit among existing resources. It is implemented as a Human Mutations track at the Genome Browser, and is updated regularly from the source LSDBs, who continue to curate their data.

Universal Detector for Single Sample SNP Genotyping. *A. Broomer, D. Merrill, R. Koehler, C. Chen* Applied Biosystems, Foster City, CA.

A conventional TaqMan SNP Genotyping Assay interrogates one SNP from one gDNA sample with a specific forward primer, a specific reverse primer, and two allele-specific TaqMan probes. However, multiple gDNA samples must be assayed in order to provide definitive allelic clustering and accurate allelic calls. Here, we present a new method termed Universal Detector, which overcomes the issues of specific PCR oligos and the required use of multiple gDNA samples. The two-step method first encodes 48 SNPs from one gDNA sample in one 48-plex OLA reaction. The resulting OLA products are then decoded in 48 singleplex PCR reactions with one pair of universal TaqMan detectors and 48 pairs of universal ZipCode PCR primers. These universal oligos are used for all SNPs ever to be tested. Statistics of design rate, call rate, conversion rate, and accuracy (concordance with conventional TaqMan SNP genotypes) will be presented. Universal Detector should prove valuable in cases of human identification and clinical diagnostics where SNP profiling of one individual is desirable and obtainable without positive assay controls. Also, the method may be expanded to include studies of gene expression, gene copy number, and DNA methylation.

Turbo Genomic Control. *W.J. Astle, D.J. Balding* Centre for Biostatistics, Department of Epidemiology and Public Health, Imperial College London.

In the analysis of association studies, Genomic Control[1] (GC) adjusts the Armitage trend statistic to correct the type I error for the effect of population substructure, but it does not maximise power. We generalise GC to incorporate co-variation of relatedness and phenotype, retaining control over type I error while improving power. For example, a closely-related pair of subjects with concordant phenotypes should carry less weight in the test statistic than either (a) a distantly-related pair with concordant phenotypes or (b) a closely-related pair with discordant phenotypes. We derive appropriate weights from an approximation to the score statistic of a mixed-model likelihood. Our approach is similar to that of Yu *et al*.[2], but we extend to binary (case-control) in addition to quantitative phenotypes, we implement improved estimation of relatedness coefficients, and we derive an explicit statistic that is simple and fast to compute.

The problems of population structure and cryptic relatedness are essentially the same: if patterns of shared ancestry differ between cases and controls, whether distant (coancestry) or recent (cryptic relatedness), false positives can arise and power can be diminished. With large numbers of widely-spaced genetic markers, coancestry can now be measured accurately for each pair of individuals via patterns of allele-sharing. Our method dispenses with the notion of subpopulation, working instead with a coancestry coefficient for each pair of individuals in the study.

We present simulation studies and real data analyses to illustrate the performance of our method in a range of scenarios incorporating both substructure and cryptic relatedness.

Alternative Complement Pathway Genes Strongly Associate with Age Related Macular Degeneration (AMD). *B. Gold[1], LS. Hancox[3], JE. Merriam[2], J. Bergeron[5], AJ. Taiber[3], J. Zernant[2], AK. Olsh[1], GR. Barile[2], LI. Hardisty[3], K. Cramer[4], J. Neel[4], RT. Smith[2], JD. Borchardt[3], GS. Hageman[3], R. Allikmets[2], M. Dean[1]* 1) Lab Genomic Diversity, National Cancer Inst, Frederick, MD; 2) Dept of Ophthalmology, Pathology & Cell Biology, Columbia University, New York, NY; 3) Dept of Ophthalmology, University of Iowa, Iowa City, IA; 4) Sapio Sciences, LLC, York, PA; 5) SAIC-Frederick, Frederick, MD.

Age related macular degeneration (AMD) is a complex genetic disorder and is the most frequent cause of vision loss in the elderly. Genetic and biological studies implicated the complement factor H (CFH) gene in AMD. A haplotype containing the Y402H variant in CFH confers a 3-5 fold risk for AMD and in addition, we found haplotypes (H2 and H4) that are protective. As CFH is the major inhibitor of the alternative complement pathway, we examined the role of the major activator, complement factor B (BF). BF is adjacent to the complement 2 (C2) gene in the Class III region of the MHC locus, and SNPs in both BF and C2 confer significant protection from AMD. When we analyzed CFH and C2/BF SNPs in a joint analysis, 74% of affected individuals and 56% of control clinical phenotype can be explained on the basis of their CFH and C2/BF haplotype. Both the CFH and BF loci contain common variants differing significantly among separate racial and ethnic groups suggesting balancing selection, similar to other immune function genes. The variants modifying risk for AMD are common in both African and European populations and are less common in Asian and Native Americans. Recently a third locus on chromosome 10q26 containing the PLEKHA1 and hypothetical LOC387715 genes has been implicated in AMD. We have confirmed a strong association between the S69A SNP in LOC387715 in cohort of 643 cases and 368 controls from Columbia University. The effect of the LOC387715 locus is much more prominent in late stage AMD than in early AMD. Combined analyses of these three loci will enhance pharmacogenetic studies of AMD. Our data are consistent with a major role of the alternative complement pathway in the etiology of AMD.

Integrating personalized medicine into the U.S. health care system: A comprehensive study of key stakeholder groups. *P. Deverka[1], T. Doksum[2], S. Shoemaker[2], R. Carlson[3]* 1) Inst Genome Sciences & Policy, Duke University, Durham, NC; 2) Abt Associates Inc., Cambridge, MA; 3) University of Washington, Seattle, WA.

Scientific advances in personalized medicine (PM), including pharmacogenetics, have potential to positively impact health, yet reveal many hurdles in the translational pathway to clinical integration. The objectives of this study were to characterize the current and future landscape for PM, describe perceived risks/benefits of PM and barriers/enablers to the integration of PM, and elicit recommendations to ensure that the potential benefits of PM are realized. METHODS: During Spring 2006, 60 in-depth telephone interviews were conducted with leaders from government agencies, payers, health care delivery organizations, professional societies, consumer groups, academic institutions, venture capital firms, and industry. Interviewees were selected based on their reputations as experts in their field and because they were involved or could become involved in PM. Interviews were recorded, transcribed, and analyzed using a qualitative data analysis package. RESULTS: Most stakeholders agreed that PM is likely to improve health outcomes, but felt that there are few examples where this is occurring in clinical practice today. The reasons identified for the limited integration of PM were varied and complex, and included typical issues facing many medical innovations (e.g., scientific, financial, regulatory), but also encompassed challenges specific to genetics and the goal of personalization. Stakeholders called for further evidence of clinical utility of PM, as they expressed concerns about the system cost impacts of adding complex new tests to predict risk. In addition, enabling technologies such as linked electronic health records were identified as rate-limiting to the integration of PM. A number of pilot PM projects provided insights into potential solutions. CONCLUSION: PM has broad support but will require changes in how personalized technologies are evaluated, how health care is financed and delivered, and how clinicians and consumers are prepared. The recommendations from the stakeholders in this study will be instrumental in devising strategies to appropriately integrate PM.

Gene Repair in SMA Using Single-stranded Oligonucleotides. *D.M. DiMatteo, L. Ferrara, E.B. Kmiec* Biology, University off Delaware, Newark, DE.

Spinal muscular atrophy (SMA) is a recessive, neuromuscular disease characterized by symmetrical muscle wasting, caused by the death of motor neurons, leading to muscle weakness. It is the leading genetic cause of death in children under 5 years. The causal gene is the survival motor neuron (SMN) gene. It is located on chromosome 5q13 in two nearly identical copies- SMN1 and SMN2. The SMN1 gene produces full-length, functional protein and it is this copy that is deleted or mutated in SMA patients. The SMN2 gene produces approximately only 10% of full-length protein due to a single base pair change in exon 7. This base change from a C in SMN1 to a T in SMN2 causes exon 7 to be skipped, leading to a non-functional protein that is quickly degraded. Current clinical trials include drugs that increase transcription or activate splicing and, subsequently, increase the amount of functional protein. Our lab has pioneered a method for introducing single, base changes into dysfunctional and/or mutant genes. With this method, short, single-stranded DNA oligonucleotides (ODNs) are introduced into a cell where they utilize both DNA repair and replication mechanisms to catalyze the base exchange. The resulting product of this activity is a corrected gene that can make the normal protein. In effect, the cell uses the ODN as a template and endogenous repair activities to correct the mutant gene. This approach avoids the problems of long-term drug treatment. ODNs are well known to exhibit low toxicity in humans and have been used extensively in clinical setting for other purposes. We chose to study the disease SMA since making a single base pair change would create a functional gene. This is possible because SMA patients have only the SMN2 gene. We have used ODNs to change a C in exon 7 to create an SMN1-like gene able to make the full-length functional protein. In patients, more protein would lead to milder symptoms. Currently, the drugs used to treat SMA are highly toxic and have many side-effects. Many patients discontinue use of these medications and fail to realize the potential benefits of the drug. Our method would eliminate the need for life-long for drug treatment.

The clinical utility of enhanced subtelomere coverage in array CGH. *B.C. Ballif, S.G. Sulpizio, R.M. Lloyd, S. Gaskin, S.L. Minier, K. Sundin, M. Lincicum, E.A. Rorem, C.D. Kashork, B.A. Bejjani, L.G. Shaffer* Signature Genomic Laboratories, Spokane, WA.

Telomeric chromosome abnormalities are a substantial cause of mental retardation and birth defects. Although subtelomeric FISH probes have been widely used to identify submicroscopic telomeric rearrangements, array-based comparative genomic hybridization (array CGH) has emerged as a more efficient and comprehensive approach to the identification of chromosomal aberrations. Due to the clinical relevance of telomeric abnormalities, it has been proposed that array CGH using panels of BAC clones which map to regularly spaced intervals along the length of each telomere could be used to more precisely characterize subtelomeric aberrations in a single experiment. We have constructed a CGH microarray that includes expanded coverage for 41 subtelomeric regions using 1120 FISH-mapped BAC clones. Contigs of clones were selected in increments of ~0.5 Mb, beginning with the most distal unique sequence for each telomere and extending on average 5.7 Mb. We have used this microarray to analyze 62 cases with known subtelomeric aberrations previously characterized using an array with only a single contig of 3-6 clones at each telomere. The expanded telomere coverage was sufficient to define the breakpoint regions of over half (55%) of the chromosome abnormalities. However, 45% of the subtelomeric aberrations extended beyond the size of our expanded coverage suggesting that many subtelomeric abnormalities are 5 Mb in size and that representation extending to 10 Mb may be of even greater value. The enhanced coverage not only clarified the size of the telomeric rearrangements, it also identified at least one case with a more complex subtelomeric rearrangement which may shed light on its mechanism of formation. In addition, we have identified 6 cases of interstitial deletions that would have been missed by both subtelomere FISH and limited array CGH using clones only to the most distal unique sequences. These data suggest that increased coverage at the subtelomeres improves the diagnostic usefulness of array CGH and detects unsuspected complexity of these clinically significant regions.

Congenital Erythropoietic Porphyria: High Affinity Purification, NMR Resonance Assignments, and Localization of the Active Site of Human Uroporphyrinogen III Synthase. *L. Cunha[1], M. Kuti[2], D.F. Bishop[1], M. Mezei[2], L. Zeng[2], M.-M. Zhou[2], R.J. Desnick[1]* 1) Department of Human Genetics; 2) Department of Molecular Physiology and Biophysics, Mount Sinai School of Medicine, New York, NY.

Congenital erythropoietic porphyria (CEP) results from the deficient activity of uroporphyrinogen III synthase (URO-synthase), the fourth enzyme in the heme biosynthetic pathway. This 29.5 kDa monomeric enzyme catalyzes the cyclization and D-ring isomerization of hydroxymethylbilane to form uroporphyrinogen (URO'gen) III. Previously, the X-ray crystal structure of the enzyme was determined, but the active site was only inferred, due to the inability to co-crystallize the enzyme with substrate analogues. To determine the URO-synthase three-dimensional solution structure, its possible interaction in a cytosolic complex with the third and fifth enzymes in the pathway, hydroxymethylbilane synthase (HMB-synthase) and uroporphyrinogen decarboxylase, and to characterize its active site, milligram quantities of stable-isotope-labeled active human recombinant enzyme were expressed and purified for NMR studies using an 800 MHz instrument with a cryoprobe. NMR analyses permitted 100% assignment of the URO-synthase backbone ^{1}H and ^{13}C resonances, 94% of the ^{1}HN, and non-proline ^{15}N resonances, and 85% of the side chain ^{1}H and ^{13}C resonances. The absence of chemical shift changes in the ^{15}N spectrum of URO-synthase when it was mixed with the human recombinant HMB-synthase apoenzyme and/or URO-decarboxylase precludes the occurrence of a stable two or three enzyme cytosolic complex. *In silico* docking experiments using the reaction product URO'gen III as a flexible ligand, localized the putative enzymatic active site to a refined cleft region between the enzymes two major domains. Localization of the active site region was confirmed by NMR analyses of URO-synthase titrated with the competitive inhibitors UROgen III and N_D-methyl-1-formylbilane revealing resonance perturbations of residues lining the cleft. These studies will facilitate prediction of genotype/phenotype correlations and decisions for early bone marrow transplantation in this porphyria.

Study of disease-relevant polymorphisms in the TLR4 and TLR9 genes: a novel method applied to the analysis of the Portuguese population. *A. Carvalho, P. Maciel, F. Rodrigues* Life and Health Sciences Research Institute (ICVS), School Of Health Sciences, University of Minho, Braga, Portugal.

Toll-like receptors (TLRs) are cellular receptors that mediate recognition of microbial challenges and the subsequent inflammatory response. Mutations within the TLR4 gene at the 299 and 399 residues have been shown to be associated with blunted physiological responses to inhaled lipopolysaccharide. Furthermore, the Asp299Gly TLR4 mutation was proposed to underlie an increased risk of gram-negative septic shock, whereas the variation within the promoter region of TLR9 at position -1237 has also been associated with an increased risk for asthma. We developed a simple and rapid method based in the bi-directional PCR amplification of specific alleles (Bi-PASA) for genotyping known sequence variants in TLR4 (Asp299Gly and Thr399Ile) and TLR9 (T-1237C) genes. This method allows the genotype determination in a single reaction and is amenable to high throughput analysis. We used this methodology to characterize the distribution of these polymorphisms in the Portuguese population. Two hundred randomly selected blood donors of Portuguese origin (107 females and 93 males) were genotyped and allele and genotype frequencies were determined. Among the tested individuals, 11.5% were heterozygous for both the Asp299Gly and Thr399Ile polymorphisms. None of the individuals was a homozygote for the TLR4 polymorphisms. In what concerns the T-1237C variation in TLR9, 25.7% were heterozygous and 3.2% were homozygous for this polymorphism (none of the polymorphisms deviated from the Hardy-Weinberg equilibrium; D=1.000). These data provide valuable information on the distribution of TLR polymorphisms in the Portuguese population that can be used to stratify risk patients with increased susceptibility to infection. * Carvalho, A. was the recipient of a fellowship from Fundação para a Ciência e Tecnologia (FCT), Lisbon, Portugal (SFRH/BD/11837/2003) This study was partially supported by Fundação para a Ciência e Tecnologia, Portugal (POCI/SAU-ESP/61080/2004) and by Fundação Calouste Gulbenkian, Serviço de Saúde e Desenvolvimento Humano, Portugal (Proc/60666-MM/734).

The ciliary proteome database: An integrated community resource for the genetic and functional dissection of cilia. *E.E. Davis, A. Gherman, N. Katsanis* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

In vertebrates, cilia have been recruited in a virtually ubiquitous fashion to carry out a menagerie of diverse tasks. Not surprisingly, dysfunction of the cilium and its anchoring structure, the basal body, have been associated with a number of phenotypes that include defects in neural tube development, retinal dystrophy, renal cystic disease and situs inversus. These observations have highlighted the existence of the ciliopathies, an expanding group of diverse but overlapping clinical entities, and have suggested that an improved understanding of ciliary structure and function has the potential to inform the genetic and cellular basis of such phenotypes. To facilitate these efforts, we assembled and manually curated the recent results of ten unique, yet overlapping proteomics investigations to decipher the repertoire of proteins required for ciliary biogenesis and function in eukaryotes. Our database (available online at http://www.ciliaproteome.org) consists of some ~1200 non-redundant human ciliary, basal body, and centrosomal proteins and provides the means to probe the ciliary proteome with user-defined stringency criteria through basic search, study-based search, or BLAST query options. In addition, we are populating this dataset with useful technical reagent information (ORF and shRNA vectors) and corresponding cell localization data for each putative ciliary protein as well as other phenotypes, (through overexpression or suppression). Preliminary analyses of the human ciliary proteome suggest that our integrated effort markedly improved the saturation of the ciliary proteome, revealing the importance of data amalgamation from diverse sources to compensate for the strengths and weaknesses of each individual proteomics method. Currently, the greatest challenges are to confirm experimentally and characterize further the proteins in the database. As our comprehension of ciliary biology evolves, we are committed to appending new information and encourage community-wide participation in the continued curation of this resource.

Infertility and reproduction failure in autosomal translocations carriers. *N.B. Abdelmoula[1], A. Amouri[2], M. Meddeb[3], A. Sallemi[1], T. Rebai[1]* 1) Laboratory of Histology, University of Medicine, Sfax, Tunisia; 2) Laboratory of Cytogenetics, Pasteur Institute, Tunis, Tunisia; 3) Laboratory of Genetics, Tunis, Tunisia.

Cytogenetic investigations were performed in 242 infertile men because of severe male infertility with low sperm count and in 47 couples because of recurrent miscarriages. Out of the 131 oligospermic and 111 azoospermic men, 32 had an abnormal karyotypes (13.2% : 20,7% in azoospermic and 6,87% in oligospermic men). Chromosome aberrations observed were 22 sex chromosomal aberrations [comprising 46,XX (n=1), 47,XXY(n=18), 47,XYY(n=1) and 46,X,del(Yq) (n=2)] and 10 autosomal aberrations including 4 reciprocal translocations in oligospermic men [t(4;9)(p15.3;p21), t(11;22)(q24;q11),t(2;3)(p24;q26) and t(16;22)(q13;q12)] and 6 robertsonian translocations [t(13;14) in 2 oligospermic and 2 azoospermic men and t(14;21) in an oligospermic and an azoospermic brothers]. The incidence of autosomal balanced structural abnormalities in oligospermic men was higher than in azoospermic men especially for reciprocal translocations (44,4 % v/s 0%). For robertsonian translocations carriers, a maternal meiosis transmission is recorded in two cases while for reciprocal translocations, a familial history is noted for 2 cases. In the other hand, chromosomal abnormalities were recorded twice out the 47 couples, in a female partner and in a normozoospermic male partner, who carried reciprocal translocations [46,XX,t(1;4)(q31;q26) and 46,XY,t(4;17)(p16;p12)]. None of theses translocations carriers come to conceive naturally or with assisted conception. In fact, fertilization failures in previous ICSI attempts (one to 5 attempts) were recorded for 6 couples. So, there is interest in preimplantation genetic diagnosis with assisted conception in carriers of autosomal translocations to improve the implantation rate and protect the couple from termination of pregnancy. Unfortunately, this practice is not yet available in our country.

Development of upQMPSF and mutation-specific multiplex PCR for detecting large germline genomic rearrangements. *S. Azrak[1], L. Li[2], W.D. Foulkes[2], P. Liang[1]* 1) Department of Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada.

Large germline genomic rearrangements, mostly heterogyzous deletions or duplication of genomic regions ranging from several hundreds of base pairs to several hundreds of kb in size, constitute a significant portion of the mutation spectrum associating with genetic diseases, such as hereditary non-polyposis colorectal cancer (HNPCC). The detection of these types of mutations has been technically difficult as they tend to escape from the classical mutation screen methods. Recently, a number of new methods, including Multiplex Amplifiable Probe Hybridization (MAPH), Multiplex Ligation-dependent Probe Amplification (MLPA), Quantitative Multiplex PCR of Short fluorescent Fragments (QMPSF), quantitative multiplex polymerase chain reaction (QMPCR), have been developed for the detection of such types of genomic rearrangements. We report here the development of two additional methods. The first method is a modified version of the QMPSF, in which the fluorescent labeling of individual primers are replaced with a universal fluorescent primer (upQMPSF). In comparison with QMPSF, upQMPSF achieves significant cost saving without sacrificing the sensitivity. The second method is the use of Mutation-specific Multiplex PCR (MM-PCR) primer sets designed via a bioinformatics approach for the detection of all known genomic rearrangements in a given gene. MM-PCR is performed as a regular PCR and is analyzed on agarose gels with the samples carrying targeted genomic rearrangements yielding an extra product smaller than the positive control and the normal samples generating only the control product. Therefore, MM-PCR can be used as a very cost-effective and easy-to-use method for genetic screening of known genomic rearrangements. We used a set of HNPCC samples carrying previously characterized rearrangements in MLH1 and MSH2 to demonstrate the efficiency of our methods and compared the results with those obtained using QMPSF and MLPA. (This research is in part supported by NCI grants (CA16056 and CA101515) and grants from Roswell Alliance Foundation and Gynecological Cancer Foundation.).

Generation of a novel mouse model by targeted insertion of a PGK-NEO cassette into murine *Zic3* locus: a mouse model of Goldenhar Syndrome/Oculo-Auriculo-Vertebral (OAV) spectrum? *J.W. Belmont, L. Zhu, J.L. Peng, K.G. Harutyunyan, M.D. Garcia, M.J. Justice* Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Goldenhar Syndrome (OMIM164210), also called oculo-auriculo-vertebral (OAV) spectrum, is a rare birth defect characterized by unilateral deformity of the external ear, hemifacial microsomia, epibulbar dermoid, and defects of the vertebral column. Although candidate regions in the human genome are under investigation, no human gene mutations or mouse models for Goldenhar Syndrome are known. In this study we generated a novel allele by insertion of a PGK-neo cassette into the 5 of the murine *Zic3* locus. *Zic3*^{neo} mutant mice exhibited hemifacial microsomia, asymmetric low set ears, unilateral deformity of the external auricle, microphthalmia, mandible underdevelopment, kyphosis and scoliosis; a combination of defects which mimics Goldenhar Syndrome. *Zic3* is a zinc finger transcription factor located in the X chromosome and is the first gene unequivocally associated with human heterotaxy. Mice bearing a null mutation in *Zic3* correctly model the laterality defects found in human patients, but have no apparent abnormalities in tissues derived from neural crest. However, overexpression of *Xenopus Zic3* induces neural crest marker expression, the formation of enlarged and coarse head, and poorly developed eyes. Interestingly, *Zic3* transcript in this novel *Zic3*^{neo} allele was up-regulated in ES cells and in E9.0 embryos, but no ectopic expression was detected. Unlike the *Zic3*^{null} mutation in which only 20% of mutant animals survive to adulthood, there was no evidence of excess fetal death caused by the *Zic3*^{neo} allele. Penetrance of the individual defects observed in the *Zic3*^{neo} allele was relatively low, with the exception of kyphoscoliosis. This study indicates that the dosage of Zic3 is critical for embryonic development. Given the X-linked inheritance and low penetrance observed in Goldenhar Syndrome, we hypothesize that *ZIC3* may be one of the genes contributing to this rare disease and future study will focus on screening both the coding and noncoding sequence of *ZIC3* in Goldenhar Syndrome patients.

A detailed study of the serotonin pathway in autism. *B. Anderson[1], N. Schnetz-Boutaud[1], J. Bartlett[1], H.H. Wright[3], R.K. Abramson[3], M.L. Cuccaro[2], J.R. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetics Research and Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Human Genetics and Department of Medicine, Duke University Medical Center, Durham, NC; 3) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC.

Classic autism is characterized as one of the Pervasive Developmental Disorders (PDDs) of childhood, a spectrum of often severe behavioral and cognitive disturbances of childhood development. The high heritability in autism has driven multiple efforts to identify susceptibility genes, but to no avail. Numerous studies have suggested that deficits in the peripheral and central metabolism of serotonin (5-HT) may play a role in the pathophysiology of autism. We hypothesize that multiple variations in the serotonergic pathway genes are involved in autism. We assembled a dataset collected through the collaborative efforts of Vanderbilt and Duke Universities. Our sample includes 284 total autism families consisting of 155 parent-child trios and 129 multiplex families, a screening subset of our overall dataset of 333 trios and 158 multiplex families. We prioritized our work to include 15 prominent serotonin pathway candidate genes for detailed study within our autism families. Ninety-three SNPs were genotyped within candidate genes involved in serotonergic function: *HTR1A*, *HTR2A*, *DDC*, *TPH1*, *TPH2*, *SLC6A4*, *SLC7A5*, *AANAT*, *MAOA* and *MAOB*. Parametric two-point analyses identified a peak LOD score of 1.38 for marker rs1522307 within the *TPH2* gene when the complete dataset was considered. Stratification of the dataset to include male-affected-only demonstrated a highly significant p-value of 0.006. Another candidate *SLC6A4*, the serotonin transporter, has been associated with autism in other datasets, but no significant signal was observed in our overall dataset. These results suggest that individual polymorphisms within the serotonin pathway may not be important in autism. However, significant effects may arise through tests for gene x gene interactions, which are underway.

LINE-1 expression and retrotransposition in Human Embryonic Stem Cells. *J.L. Garcia-Perez[1], K.S. O'Shea[2], J.V. Moran[1]* 1) Human Genetics, Univ Michigan Med Sch, Ann Arbor, MI; 2) Cell and Developmental Biology, Univ Michigan Med Sch, Ann Arbor, MI.

Long Interspersed Element-1 (LINE-1 or L1) is an abundant retrotransposon that comprises ~17% of human DNA. The average human genome contains approximately 100 retrotransposition-competent L1s (RC-L1s) and their mobility in both germ and somatic cells has resulted in a variety of genetic disorders, including hemophilia A, muscular dystrophy, and colon cancer. The proteins encoded by RC-L1s also are responsible for the mobilization of Alu elements and the formation of processed pseudogenes, which together comprise at least 10% of human DNA. Thus, either directly or by the promiscuous mobilization of cellular RNAs, L1 retrotransposition has had a tremendous impact on human genome evolution. Despite these findings, questions remain about how frequently, in what cell types, and when during development L1 retrotransposes in vivo. Here we show that undifferentiated human embryonic stem cells (hES) express endogenous L1 transcripts and the L1 ORF1-encoded protein. We demonstrate further that these cells also can accommodate retrotransposition of engineered L1 elements in vitro. Analysis of six retrotransposition events revealed hallmarks of L1 integration and indicate that L1 can retrotranspose into genes in hES cells at frequencies cells similar to those reported in both cultured human HeLa cells and mouse models. Although L1 retrotransposition in hES cells appears relatively inefficient when compared to retrotransposition in HeLa cells, the data also demonstrate that small genomic deletions can accompany L1 retrotransposition events. Together, these findings suggest that L1 mobility can lead to genetic variability in hES cells. In addition, we report that cultured embryonic carcinoma cell lines can support L1 retrotransposition in vitro, and that the resultant integration events often undergo epigenetic silencing either during or soon after retrotransposition. We hypothesize that epigenetic silencing may represent a host mechanism to restrict the number of retrotransposition-competent L1 sequences in mammalian cells. Supported by a NIH P20 GM-069985 grant.

AUTISM GENETICS COOPERATIVE: Preliminary results of a combined linkage genome scan. *R. Goedken* On behalf of the Autism Genetics Cooperative.

A genome screen for autism was completed on data collected as part of the Autism Genetics Cooperative (AGC), a consortium established to facilitate the discovery of genes that contribute to autism. The cooperative currently consists of 6 groups that have worked toward a goal of effectively sharing data and continues to assemble a comprehensive database of genotypic and phenotypic genome screen data.

Data originating from independent genome screens carried out by participating groups, each using a different marker set, were gathered for common analyses. Thus far, an ~10 cM genome screen (2593 microsatellite markers total) has been performed on 338 families, primarily affected sib-pairs, incorporating language and IQ phenotypes. The analyses included the Posterior Probability of Linkage (PPL) and the Kong and Cox LOD. For the PPL, the families were grouped by i) contributing site, ii) phrase speech delay (at least two affected children with onset of phrase speech greater than 36 months), and iii) IQ (at least two affected children with IQ less than 50). The PPL uses Bayesian sequential updating to accumulate evidence across the subgroups. Results indicate 2 distinct regions showing non-negligible evidence in favor of linkage, with peak PPLs of 49% and 60%, on Chromosomes 2 (159 cM) and 16 (62 cM), respectively. The Kong and Cox LOD analysis was based on all families as one group and yielded LODs < 3.0 across the entire genome. We will be updating these results with additional follow-up markers in the peak regions. In addition, we are in the process of gathering full ADI information on all families for inclusion into a common database for further analyses.

A systematic HAPMAP-based survey of schizophrenia candidate genes in the German population. *S. Cichon[1], T. Mühleisen[1], A.M. Hillmer[1], R. Fürst[1], R. Abou Jamra[2], J. Schumacher[2], P. Hoffmann[1], M. Alblas[1], S. Kopmann[1], A. Georgi[3], T.G. Schulze[3], P. Propping[2], M. Rietschel[3], M.M. Nöthen[1]* 1) Dept. of Genomics, Life & Brain Center, Bonn, Germany; 2) Institute of Human Genetics, University of Bonn, Bonn, Germany; 3) Dept. of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health, Mannheim, Germany.

Recent association studies have identified a number of potential schizophrenia susceptibility genes that currently await replication in independent, large samples of schizophrenia. In our present study, we systematically covered 6 promising genes with haplotype tagging SNPs capturing all haplotypes with a frequency >1% using HAPMAP phase I and II data and tested these SNPs for association in a total of 2,230 individuals, comprising a family-based sample of 210 parent-offspring trios with schizophrenia and in an independent sample of 800 schizophrenia patients and 800 controls, all of German origin (all four grandparents and parents German). All diagnoses were made based on DSMIV criteria. Using Illuminas GoldenGate assays, we genotyped a total of 628 SNPs in these samples, covering the genes RGS4 in chromosomal region 1q23.3 (15 SNPs), the DISC1/DISC2/TSNAX locus on 1q42.1 (138 SNPs), ENTH on 5q33 (30 SNPs), DTNBP1 on 6p22.3 (45 SNPs), NRG1 on 8p21 (384 SNPs), and COMT on 22q11.2 (16 SNPs). We have completed genotyping of all individuals. Genotypes are currently under statistical analysis using TDT and FAMHAP. For associated variants/haplotypes detailed genotype/phenotype correlations will be performed.

Glycerol Kinase Expression Increases Metabolic Flux Through The Pentose Phosphate Pathway: Implications for Glycerol Kinase Deficiency. *K. Dipple[1,2,3], L. Rahib[1,3], J. He[1], A.E. Campos[1], J.C. Liao[3,4], G. Sriram[1,4]* 1) Dept. Human Genetics; 2) Dept. Pediatrics; 3) Biomedical Engineering; 4) Dept. Chemical and Biomolecular Engineering, UCLA Los Angeles CA.

Glycerol kinase deficiency (GKD) is an inborn error of metabolism (IEM) that is caused by mutations in the glycerol kinase (GK) gene on Xp21. GK is an important lipogenic enzyme in liver and patients present with metabolic crisis. GKD exhibits complexities that are not explained by lack of the biochemical activity; therefore, there is no correlation between genotype and phenotype in patients with this disorder. We hypothesize that systems dynamics, including flux through metabolic pathways, can play a significant role in explaining the lack of genotype-phenotype correlation. Therefore, we investigated comparative flux analysis of wild type and GK-overexpressing (GK transgenic) H4IIE rat hepatoma cell lines. H4IIE cells were cultured on a mathematically designed mixture of U-^{13}C, 1-^{13}C, and naturally abundant glucose. Gas chromatography-mass spectrometry was used to measure mass isotopomer abundances in protein hydrolysates from the cells. Fluxes were evaluated from the isotopomer data using a comprehensive isotopomer balancing. The GK transgenic cell lines exhibited significantly reduced cell growth and lactate production rates compared to the wild type, while consuming carbon sources at nearly the same rates as the wild type, thus suggesting a futile cycle. Principal component analysis revealed that carbohydrate metabolism in the GK transgenic cell lines was significantly different from that in the wild type. Metabolic flux analysis revealed that in the presence of transgenic GK, there was significantly increased flux through the pentose phosphate pathway (2.04 0.10 times that of wild type, $p <$ 0.01). We hypothesize that this is due to the increased requirement of cytosolic NADPH needed for increased triglyceride synthesis. This shows that cellular metabolism is sensitive to dosage of metabolic genes and that the metabolic pathways with altered flux are not always predicable. These findings will be important to understanding the complex nature of GKD and other IEM.

Association between iNOS and Age-related Macular Degeneration: Potential effect modification by cigarette smoking. *G.E. Byfield[1], S. Schmidt[1], P. Gallins[1], E.A. Postel[2], W.K. Scott[1], A. Agarwal[2], K. Spencer[3], J.L. Haines[3], M.A. Pericak-Vance[1], M.A. Hauser[1, 2]* 1) Duke Center for Human Genetics, Durham, NC; 2) Ophthalmology, Duke University Medical Center, Durham, NC; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Age-related macular degeneration (AMD) is one of the most common causes of blindness in older adults in the United States. Genetic and environmental factors have been strongly implicated in this retinal degenerative disease which causes impairment of central vision. Cigarette smoking is the most consistently identified non-genetic risk factor for AMD. Inducible nitric oxide synthase (iNOS) is the primary source of nitric oxide (NO) and smoking has been associated with decreased production of NO. Polymorphisms in the iNOS gene have been previously linked to neurodegenerative diseases such as Parkinson disease and multiple sclerosis but not AMD. It is against this background that we tested associations between polymorphisms in the iNOS gene and AMD while controlling for smoking. We genotyped 13 single nucleotide polymorphisms (SNPs) across a 60kb region on chromosome 17 in a data set of 610 cases and 259 controls. Genotyping used TaqMan Allelic Discrimination Assays (ABI) and association analysis of each SNP utilized logistic regression. A comparison between the grades 3, 4, & 5 AMD vs controls revealed very significant association of the intronic SNP rs8072199 in the dominant model (p=0.0007). Subtype analysis of individuals with grade 5 vs 1 AMD (International Classification Criteria, Bird et al. 1995), revealed significant association with AMD risk in 367 grade 5 cases (p=0.0024). This association was even more significant (p=0.0013) when the same SNP was analyzed in smokers with grade 5 AMD compared with grade 1 controls. Analysis of this SNP in non-smoking individuals in the equivalent groups was not significant (p=0.39). Other markers exhibiting significant association with AMD risk and smoking included rs2255929 and rs3794766. The data support our previously noted association of the iNOS SNP rs8072199 with AMD and further implicate smoking is as an integral environmental component in AMD susceptibility.

Localisation of a gene for Human Premature Hair Greying on chromosome 9q34. *J.-L. Blouin[1], O. de Lacharrière[2], E.T. Dermitzakis[3], C. Deloche[2], P. Galan[4], P. Bastien[2], G. Duriaux Sail[3], M. Gagnebin[3], C. Gehrig[3], A. Christen[3], B. Bernard[2], S. Hercberg[4], S.E. Antonarakis[1,3]* 1) Medical Genetics, Univ Hosps Geneva, Switzerland; 2) LOREAL Recherche, Clichy, France; 3) Genetic Medicine and Development, University of Geneva School of Medicine, Switzerland; 4) UMR INSERM-INRA-CNAM-ParisXIII, CRNH Ile de France, France.

Hair greying is one of the most common traits linked to aging process in humans. To identify the genomic basis of this trait, we investigated premature hair greying (PHG) which is known to have a familial clustering and is linked with some autoimmune diseases. We first carried out a genome-wide linkage analysis in 12 multigeneration families and found 2 intervals with significant LOD scores (3.52, 3.37) on chr. 6p12-p21 and 9q31-qter respectively. We then performed a case-control association study (187 cases/186 controls) matched for sex, hair color at 18 yrs, geographical origin, ethnicity, with a dense set of SNPs within the 2 candidate intervals. The association analysis with SNPs under the linkage peaks confirmed the previous results. On 6p, the association was quite diffuse on the entire HLA region. However on 9q, the association was localized to a 100 Kb region at 9q34. A further study with additional SNPs (5-Kb ave. interval) revealed a highly significantly associated haplotype (defined by SNPs rs3739902, rs2583805, rs377090) with PHG, centered around genes *GTF3C4* and *DDX31*. The highest $p=6x10^{-5}$ was obtained with SNP rs3739902 in intron 3 of *DDX31*. Mutation search in coding regions, splicing sites of *DDX31* and *GTF3C4*, and intronic CNCs, showed a few variants with unclear functional significance, not present or present under significant different frequency in controls. Interestingly, yeast two-hybrid experiments revealed a functional link between DDX31 and PAX3 (involved in the pigmentation pathway since pathogenic mutations cause Waardenburg syndrome). DDX31 which belongs to helicase family and its genomic region appears to be a strong candidate for harbouring variability that predisposes to PHG. *Authors JLB, OL had equal contribution Acknowledgements to the SUVIMAX team and volunteers for their high involvement in the study*.

Predominant Ashkenazi BRCA1/2 mutations in families with pancreatic cancer. *E. Dagan[1,2], M. Haimi[1], R. Gershoni-Baruch[1,3]* 1) Departement of Human Genetics, Rambam Medical Center, Haifa, Israel; 2) Departement of Nursing, the faculty of health and social studies, University of Haifa, Israel; 3) The Ruth and Bruce Rappaport faculty of medicine, Technion, Haifa.

To study the frequency of the three predominant BRCA1 and 2 Ashkenazi mutations in patients with pancreatic cancer, we evaluated 1014 families recruited at our high risk breast-ovarian cancer onco-genetic clinic. Twenty three families with either personal or family history of pancreatic cancer were identified. In nine families the probands themselves presented with pancreatic cancer and two of them (22%) were found to carry a BRCA mutation (185delAG in one case and 6174delT mutations in BRCA1 and BRCA2, respectively). In the other 14 families, only a family history of pancreatic cancer was reported. Of these, seven families segregated either the 185delAG (3 families) or the 6174delT (4 families) mutation. Pedigree analysis shows that four of the seven pancreatic cancer cases were obligatory carriers. In the other seven families, without mutations in BRCA1 and 2, according to the family pedigrees, it seems that the patients with pancreatic cancer were non-carriers. In summary, in the 23 families with either a personal or family history of pancreatic cancer, reported in this study, six (26%) BRCA1 /2 mutation carriers were identified. In Ashkenazi Jews, mutations in BRCA1 and 2, may constitute a major cause for pancreatic cancer as is the case with ovarian cancer.

Large-scale genomewide association analysis of multiple disease phenotypes: The Wellcome Trust Case-Control Consortium Study. *P. Donnelly for the Wellcome Trust Case Control Consortium* Dept Statistics, Univ Oxford, Oxford, United Kingdom.

Efforts to identify genome sequence variants underlying common complex diseases have met with limited success thus far. All too often, poorly-designed, underpowered studies have generated false positive findings that cannot be replicated. Completion of the International HapMap project and advances in genotyping technologies now allow implementation of systematic, well-powered genomewide studies of complex trait susceptibility. The Wellcome Trust Case Control Consortium (www.wtccc.org.uk) represents a collaborative network of 24 UK laboratories established to examine questions relevant to the design, execution and analysis of disease association studies, as well as to deliver etiological insights through susceptibility gene discovery. The study is principally based around a series of UK-wide case samples (2000 each of type 1 and 2 diabetes, coronary heart disease, bipolar disorder, rheumatoid arthritis, hypertension, Crohn's disease) each compared to 3000 common UK controls (equal numbers from the 1958 Birth Cohort and a national blood donor collection). All are being typed with the Affymetrix 500k chip. A parallel analysis of tuberculosis susceptibility is underway in Gambian case-control samples. In addition, we are typing 1000 cases each of ankylosing spondylitis, breast cancer, multiple sclerosis and autoimmune thyroid disease and the 1500 birth cohort controls using a custom-made chip (Illumina) based around 15000 non-synonymous SNPs. First stage genotyping for the main study (1000 from each case set and all 3000 controls) will be completed during June 2006 and second stage genotyping (the balance of each case sample) during August. Data release of genotypes for the 1500 birth cohort controls is imminent. The WTCCC represents one of the largest studies of complex trait susceptibility yet undertaken (in terms of disease range, sample size and marker density): it is expected to generate important clues to the etiopathology of complex traits, and to inform on a range of issues pertinent to the implementation of large-scale association studies.

Prenatal detection of absent nasal bone predicts malformation syndromes. *N. Blagowidow[1], M. Ferguson[1], A. Kimball[1], M. Cunningham[2], A.D. Kline[1]* 1) Harvey InstituteFor Human Genetics, Greater Baltimore Medical Center, Baltimore, MD; 2) Seattle Children's Hospital, University of Washington, Seattle, WA.

Detection of absent or hypoplastic nasal bone by ultrasound is known to be associated with possible fetal aneuploidy, particularly Down syndrome, more often in a high risk population. Its utility in the general population has been questioned, and there is ethnic variation. Few other chromosomal abnormalities and malformation syndromes have been described in association with absent nasal bone. We report our series of 11 patients with absent or hypoplastic nasal bone detected in pregnancy. Case 1 is a Hispanic female with bilateral cleft lip and palate and normal chromosomes, who was postnatally found to have lobar holoprosencephaly. Case 2 is a mixed White and Asian female with prenatal choroid plexus cysts, echogenic focus and normal chromosomes. After birth marked dolichocephaly, a huge posterior fontanel, and a duplicated 5th toe were noted. She, her mother and maternal grandmother appear to have the parietal foramina syndrome. Case 3 presented with polyhydramnios and pyelectasis in the 3rd trimester. The newborn was noted to have dysmorphic features, natal teeth, pectus and hypotonia. Chromosomal analysis revealed 46,XX,der(22)t(14;22)(q24;q13)[95]/46,XX[5]. Three of the other 8 cases had trisomy 21, including one in which the absent nasal bone was the only ultrasound abnormality. Of the remaining 5 cases, three patients have delivered normal newborns, and 2 are pending delivery, including one fetus with post-axial polydactyly. The nasal bone, detectable by prenatal ultrasound between 11 and 13 weeks gestation, is formed from the frontonasal prominence. An interruption of normal neural crest migration, as is seen in a number of malformation syndromes, could lead to absence of the nasal bone. Because the nose continues to grow throughout life, the postnatal consequences may be less dramatic. Although it is challenging to acquire expertise in recognition of this finding, it could prove to be useful in early detection of multiple malformation syndromes.

Curry-Jones syndrome: A new case associated with trichoblastoma of the skin and a review of the literature.

D.K. Grange[1], D. Berk[2], A. Lind[3], S.B. Mallory[1,2], B. Tapia[3] 1) Departments of Pediatrics; 2) Internal Medicine (Dermatology) and; 3) Pathology, Washington University School of Medicine, St. Louis, MO.

We report a case of Curry-Jones syndrome in a 6 month-old male. At birth, he had abnormal skin, iris colobomas and polydactyly. At 3 months, MRI of the brain showed hydrocephalus, agenesis of the corpus callosum (ACC) and Chiari I malformation. A VP shunt was required. He has mild plagiocephaly without craniosynostosis, bilateral iris colobomas, bilateral pre-axial polydactyly and syndactyly of the hands and left foot. Pale white to yellowish, slightly raised, streaky and swirling skin plaques partially follow lines of Blaschko on the trunk and extremities. There are brownish, atrophic lesions on the soles, linear scar-like lesions around the nails and raised pearly lesions on the left eyelid. Skin biopsy showed trichoblastoma, not previously reported in Curry-Jones syndrome. Karyotype and chromosome microarray analysis were normal. Temple (1995) reported five cases of Curry-Jones syndrome, 2 of which were originally described by Curry and Jones. Two additional cases were described by Mingarelli (1999) and Thomas (2006). Features include craniosynostosis, coloboma or microphthalmia, and pre-axial polydactyly and syndactyly of hands and/or feet. Intestinal abnormalities include malrotation, dysmotility and myofibromata. ACC, dilated ventricles and developmental delays may occur. Streaky skin lesions following lines of Blaschko are often hypopigmented or atrophic. Skin biopsies in previous patients were normal, or showed findings of sebaceous or epidermal nevi. Patches of abnormal hair growth, including the periocular region, may be present. Trichoblastoma is a benign skin tumor of the hair germ cell, composed of primordial epithelium associated with collagenous stroma, with occasional sebaceous or primitive follicular differentiation, and is the most common tumor arising in sebaceous nevi. The unusual skin lesions in Curry-Jones syndrome have shown characteristics of sebaceous and epidermal nevi, and now in our patient, trichoblastoma. Further investigation of the molecular pathogenesis of these skin lesions may provide clues to the genetic basis for Curry-Jones syndrome.

Primary Care Physicians Knowledge of Race, Ethnicity, Human Genetic Variation and Health. *V. L. Bonham[1], L. Cooper[2], D. Frank[3], T. Gallagher[3], A. Odunlami[1], E. Phillips[1], E. Price[4], S. Sellers[5]* 1) NHGRI, NIH, Bethesda, MD; 2) Johns Hopkins Univ., Baltimore, MD; 3) Univ. of Washington, Seattle, WA; 4) Tulane Univ., New Orleans, LA; 5) Univ. of Wisconsin-Madison, Madison, WI.

While physicians are assuming a key role in translating genomic knowledge to the public, few studies have explored physicians attitudes and knowledge regarding human genetic variation, race and ethnicity. A mixed-method study was conducted to assess primary care physicians knowledge of race, ethnicity and genetics. Ninety self identified Black and White general internists participated in 10 race-concordant focus groups in 5 geographic areas in the country. The physicians discussed their knowledge of human genetic variation, their beliefs regarding the genetic basis of racial and ethnic differences in disease morbidity and mortality, and the clinical applicability of race-based therapeutics. Focus group discussions were audio taped, transcribed and coded using grounded theory. Two investigators independently reviewed each transcript and identified distinct themes. Participants: 43% of the physicians self-identified as Black, 53% as White; 73% of the physicians were males; 88% had been practicing internal medicine for at least 10 years; 48% are academic physicians; 73% of the physicians rated their exposure level to genetics as low, 22% as medium and 3% as high. Considerable confusion was present among physicians regarding basic concepts of human genetic variation. Limited consensus existed regarding key topics, such as the relationship between race, human genetic variation and health disparities or the role of race and ethnicity in clinical decision-making. The physicians opinions varied widely about the medical relevance of racial, ethnic and ancestral information. White physicians expressed more concern about talking directly with patients about their racial, ethnic and ancestral background. Developing a deeper understanding of physicians knowledge of and attitudes about human genetic variation, and use of medical application of race, ethnicity and ancestry will be instrumental for successfully translating genomics into clinical practice.

A Novel Form of Autosomal Recessive Lethal Congenital Arthrogryposis Mapped to Chromosome 19p13 Using SNP microarrays. *G. Narkis[1,2], D. Landau[2], E. Manor[2], R. Ofir[1], K. Elbedour[2], O.S. Birk[1,2]* 1) MK Lab. of Human Molecular; 2) Genetics Institute, Soroka Medical Center, Ben-Gurion University, Beer-Sheva, Israel.

We have recently described a novel autosomal recessive syndrome, lethal congenital contractural syndrome type 2 (LCCS2), in a large Israeli Bedouin kindred. Genome-wide linkage analysis demonstrated a region of homozygosity on chromosome 12q13. In the present study we set out to determine the disease-associated locus in another non-related Bedouin family with a similar phenotype of LCCS. We excluded linkage to the LCCS2 locus on chromosome 12q13 and to two other known candidate regions associated with autosomal recessive arthrogryposis (5q35 related to arthrogryposis multiplex congenita in a large Israeli-Arab inbred family, and 9q34 associated with the Finnish type of lethal arthrogryposis). We performed genome-wide linkage analysis using the Affymetrix 10K SNP arrays. A region of homozygosity containing 5 SNPs (5.3 Mb interval) was identified on chromosome 19q13. Using microsatellite markers, the interval harboring the disease-associated locus was confirmed and narrowed down to a chromosomal region spanning 4.5 Mb (based on recombination events). Two point linkage analysis using SUPERLINK program demonstrated maximum LOD score of [Zmax] = 4.0 at recombination fraction [] = 0.0. The linkage established allows for molecular prenatal diagnosis of the disease in the affected families. Identification of the disease-associated mutated gene is underway. It should be noted that in nine other non-related Israeli Bedouin families affected with LCCS we have now ruled out linkage to the new locus or to any of the previously known loci associated with the disease. Thus, we suggest that there are at least 3 genes related to LCCS in the Israeli Bedouin population.

Association of a common interferon regulatory factor 5 (*IRF5*) variant with increased risk of systemic lupus erythematosus (SLE). *F.Y. Demirci[1], S. Manzi[2], R.L. Minster[1], F. Bontempo[3], P.S. Shaw[2], A.H. Kao[2], M.I. Kamboh[1]*
1) Dept. of Human Genetics, GSPH, Univ. of Pittsburgh, Pittsburgh, PA; 2) Division of Rheumatology and Clinical Immunology, Lupus Center of Excellence, Univ. of Pittsburgh, Pittsburgh, PA; 3) Dept. of Medicine, School of Medicine, Univ. of Pittsburgh, Pittsburgh, PA.

Systemic lupus erythematosus (SLE) is a systemic inflammatory autoimmune disease caused by a complex interaction of genetic and environmental factors. The serum interferon (IFN)- levels and the expression of the type I IFN-inducible genes have been shown to be correlated with SLE activity and severity, suggesting the involvement of the type I IFN system in the pathogenesis of SLE. *IRF5* belongs to a family of transcription factors that controls the trans-activation of the type I IFN system-related genes, as well as the expression of several other genes involved in immune response, cell signaling, cell cycle control and apoptosis. Two recent studies reported significant association between the *IRF5*/rs2004640 T allele and SLE in cohorts from Sweden, Finland, Argentina, Spain and the US. The T allele creates a consensus GT donor splice site for an alternative exon (exon 1B) of *IRF5*, allowing the expression of transcripts containing this alternate exon. The purpose of this study was to replicate the reported rs2004640 SNP association in our independent Caucasian American SLE case-control cohort. DNA samples from 308 women with SLE and 407 healthy control women were genotyped using the TaqMan Assay-on-Demand (ABI) for the rs2004640 SNP. The genotype frequencies were in Hardy-Weinberg equilibrium in both case and control groups. The frequency of the T allele was significantly higher in cases than controls (55.8% vs. 50.0%; p=0.028). The age-adjusted odds ratio (OR) for T allele carriers was 1.68 (95% CI: 1.16 - 2.43; p=0.0057), which is within the range of the reported ORs (1.31 - 1.84). Our results in an independent case-control sample confirm the robust association of the *IRF5*/rs2004640 T allele with SLE risk and support the important role of the type I IFN system in the pathogenesis of SLE and autoimmunity.

Chemokine Levels and Their Receptors are Increased in Hermansky Pudlak Syndrome Type I. *H. Dorward*[1], *T. Markello*[2], *W.A. Gahl*[1] 1) MGB, NIH/NHGRI, Bethesda, MD; 2) Children's National Medical Center, Washington, DC.

All patients with Hermansky Pudlak syndrome (HPS) have oculocutaneous albinsim and a platelet storage pool deficiency due to absent platelet dense bodies. There are 8 different genetic subtypes of HPS, each representing a putative defect in intracellular trafficking of lysosome-related organelles; these organelles include the dense bodies of platelets, the melanosomes of melanocytes, and the lamellar bodies of type II pneumocytes. For unknown reasons, up to 70% of patients with type I HPS have a fatal pulmonary fibrosis. This process appears homologous to that of idiopathic pulmonary fibrosis (IPF), i.e., Usual Interstitial Pneumonitis, or UIP. A current hypothesis regarding the etiology of IPF/UIP involves dysregulation of the chemokines that are involved in wound healing. We measured the levels of the chemokines MCP-1 and TGF-beta in bronchioalveolar lavage fluid (BALF) from patients with HPS. Compared to normal BALF, the HPS fluid exhibited increased levels of MCP-1 and TGF-beta on Western Blotting. Preliminary estimates suggest 3 to 5 fold increases. We also assayed CCR2, the receptor of MCP-1, in paraffin fixed autopsy lung sections of: 1 IPF, 3 HPS and 1 normal control patient(s) using immuno-histochemical staining. The level of CCR2 in HPS lung was dramatically upregulated compared to that in normal lung, and was indistinguishable from control IPF lung sections. Staining for CCR2 colocalized with fibrotic sections of the autopsy lung tissue HPS lung pathology appears to represent a pathologic process equivalent to that of IPF. This allows studies of lung fluid and lavage cells in presymptomatic HPS patients who are at high risk for pulmonary fibrosis, and to test current models of the role of specific cytokines and chemokines to initiate some of the pathologic changes seen in pulmonary fibrosis.

Recurrent Interstitial Deletions of Proximal 18q: Description of a New Syndrome Involving Expressive Speech Delay. *J.D. Cody, A. Malik, C. Sebold, P. Heard, A. Duran, E. Carter, D.E. Hale* Dept Pediatrics, Univ Texas Health Sci Ctr, San Antonio, TX.

The majority of individuals with deletions of chromosome 18q have deletions involving the distal 30 Mb of the chromosome. We have identified 5 individuals with cytogenetically diagnosed interstitial deletions that are all proximal to the most commonly deleted region. The extent of the deletions was characterized using molecular and molecular cytogenetic techniques. In addition, each patient was assessed under the comprehensive clinical evaluation protocol for the Chromosome 18 Clinical Research Center. Three of the five individuals were found to have identical interstitial deletions between 37 Mb and 42 Mb. One individuals deletion was much larger and extended from a more proximal breakpoint of 23 Mb to a more distal breakpoint at 43 Mb. The fifth individual had an identical proximal breakpoint, but a distal breakpoint at 43.5 Mb. The medical and developmental histories of these individuals suggest a clinical phenotype that is distinct from that of the terminal 18q deletions. In general, proximal interstitial deletions appear to be associated with relatively minor dysmorphic features. Two of the five patients had congenital defects requiring intervention (bilateral Hutch diverticuli, cryptorchidism). Hypotonia and seizures as well as vision problems and recurrent ear infections were present in two of the five patients. Two of the patients also had agenesis/hypoplasia of the corpus callosum. Of note, some of the features common in individuals with terminal deletions were absent in this patient population. None of the patients with proximal interstitial deletions had growth hormone deficiency, stenotic ear canals, or cleft lip/palate, although one had delayed myelination. All individuals exhibited developmental delays and mental retardation. However, not all aspects of development were affected to the same degree. Receptive language skills were universally better preserved than expressive language. This leads us to hypothesize that there are genes in this region of chromosome 18 that are specific to the neural and motor planning domains necessary for speech.

Method for analyzing markers in linkage disequilibrium using polychoric correlation. *S. Bacanu, M. Nelson, L. Li, M. Ehm* GlaxoSmithKline, RTP, NC.

Datasets pertaining to association scans with dense sets of markers are coming online at a rapid pace. However, there are a lot of theoretical questions that remain at least partially unanswered. Do we analyze markers in high linkage disequilibrium (LD) singly or jointly? What analysis methods do we employ? What measure of LD should we use to cluster markers to be analyzed jointly? How to identify which combinations of markers to analyze jointly? What is the influence of missing genotype rates on the power of different methods? For validation purposes, how to efficiently simulate a large number of markers in high LD? To answer these questions we estimated power via simulation for a host of univariate and multivariate tests. Genotypes for markers in high LD were obtained by first simulating a latent multivariate normal observation. Gnotypes at each locus in the cluster are obtained from latent variables using thresholds based on allele frequencies and assuming Hardy-Weinberg equilibrium. In our simulations, the (polychoric) correlation structure of latent variables associated with disease marker and observed markers was assumed to be either exchangeable or autoregressive. Cases were obtained via rejection sampling. Simulations, requiring hundreds of years of CPU time, were carried on the GSK parallel computing GRID. Simulation results showed a poor performance of traditional multivariate methods, especially with realistic missing data rates. A near optimal test was a Bonferroni-adjusted minimum p-value of two different types of tests. The first test employs a minimum p-value of univariate tests for additive, dominant and recessive models at each marker in the cluster. The second test is a multivariate chi-square test obtained from the first two principal components of the Pearson correlation matrix of univariate tests above. For complete genotype data, optimal LD threshold for obtaining marker clusters were estimated to be 0.4-0.5 on a square polychoric correlation scale; it is even lower than 0.2 for realistic missing genotype rates. Theoretical results are compared with simulation results using LD structure derived from an Affymetrix 500K genome scan containing 500 subjects.

Development and validation of a Real Time PCR assay for detection of *MECP2* gene rearrangements. *D. del Gaudio, B.B. Roa, C.M. Eng, P. Fang* Department of Molecular and Human Genetics , Baylor College of Medicine, Houston, TX.

Mutations in the *MECP2* gene cause Rett syndrome, a progressive neurodevelopmental disorder that affects ~ 1 in 10,000 females. In addition, *MECP2* mutations are found in females and males with a wider spectrum of neurodevelopmental phenotypes. Diagnostic sequencing of the *MECP2* coding region detects ~86% of mutations in classic Rett syndrome. Our laboratory previously implemented a dosage-sensitive Southern analysis for deletions and duplications in *MECP2*, which detects an additional ~10% of mutations in classic Rett syndrome. However, heterozygous duplications in females are difficult to assess by Southern analysis. We recently developed and validated a quantitative real-time PCR assay (qRT-PCR) for *MECP2* gene dosage analysis. This assay uses multiple Taqman probes covering the entire *MECP2* gene coding region (exons 1-4), with each target amplicon co-amplified with an internal control (RNaseP). Amplicon copy number in patients versus sex-matched controls is determined by the comparative cycle threshold method (ddCt). The assay was validated using 12 blinded control samples (10 females and 2 males) that were previously tested by Southern analysis and multiplex ligation-dependent probe amplification (MLPA). Our qRT-PCR assay correctly identified *MECP2* heterozygous partial gene deletions in 7 females, and whole gene duplication in 1 male and in his heterozygous carrier mother. In comparing several methods, a female patient with a heterozygous deletion in *MECP2* exon 3 was identified by Southern analysis and by qRT-PCR using Taqman probes located at the 5 and 3 ends of exon 3, but not by MLPA. Confirmation of the deletion was provided by long-range PCR, followed by sequencing of the junction amplification product (205_IVS3+287del460). Our data demonstrate the utility of quantitative real time PCR analysis to detect *MECP2* gene rearrangements with high sensitivity and highlight the value of incorporating multiple probes in a gene dosage assay used in a clinical diagnostic setting.

Analysis of the expression of *mRib72-1/Efhc1* gene during mouse brain development. *F.F. Conte, P.A.O. Ribeiro, L. Sbragia Neto, R. Gilioli, F. Cendes, I. Lopes Cendes* Medical Genetics, UNICAMP, Campinas, Brazil.

Missense mutations in the *mRib72-1/Efhc1* gene have been identified to co-segregate with juvenile myoclonic epilepsy (JME) patients. In addition, functional studies have demonstrated that expression of *mRib72-1/Efhc1* gene induces apoptosis in neurons in culture. However, the exact relationship between *mRib72-1/Efhc1* function and epileptogenesis is still unclear. The objective of this study was to determine the expression pattern of Missense mutations in the *mRib72-1/Efhc1* have been identified to co-segregate with juvenile myoclonic epilepsy (JME) patients. In addition, functional studies have demonstrated that expression of *mRib72-1/Efhc1* gene induces apoptosis in neurons in culture. However, the exact relationship between *mRib72-1/Efhc1* function and epileptogenesis is still unclear. The objective of this study was to determine the expression pattern of *mRib72-1/Efhc1* gene in mouse brain in order to investigate its possible role in programmed cell death during development. Balb/c mice were submitted to programmed mating to obtain animals in different developmental stages. The brains of embryos aged 15, 17 and 18 days old and of neonates aged 1, 7, 14 and 28 days old were subsequently removed. We used brains of three animals for each age studied. After RNA extraction, the relative gene expression of *mRib72-1/Efhc1* was determined by the real-time PCR technique using TaqMan assay. *GAPDH* gene expression was used as an endogenous control. Preliminary results demonstrate that the expression of *mRib72-1/Efhc1* is higher in embryos than in neonates (p=0.001), with a progressive decrease from embryos aged 18 days to neonates. The highest expression of the *mRib72-1/Efhc1* gene in embryo brains in comparison to neonates suggests that the putative pro-apoptotic role of this gene may be necessary for the correct organization of the central nervous system during its initial phases of development. Supported by CAPES.

Congenital myotonic dystrophy presenting as unexplained neonatal death. *T. Friedberg[1], M. Thomas[1], D. Chitayat[1,2]* 1) The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada.

Myotonic dystrophy type I (MDI) is an autosomal dominant disorder with intrafamilial and interfamilial variability in the clinical findings ranging from mild and late onset to severe and congenital depending on the size of the CTG repeat in the DMPK gene. Congenital myotonic dystrophy is characterized by infantile hypotonia, mental retardation, and respiratory deficits, which may lead to early death. Here, we report on two families whose babies died shortly after birth, presumably of an unknown cause, and were subsequently found to be affected with congenital myotonic dystrophy based on maternal examination. Case 1: Fetal ultrasound done at 20 and 28 weeks gestation showed mild bilateral ventriculomegaly and mild polyhydramnios and at 30 weeks gestation a distended abdomen and polyhydramnios were noted. Delivery was at 33 weeks gestation and the baby died 10 minutes after birth. On autopsy, no significant abnormalities were identified apart from megalencephaly (OFC of 38 GA). The mother had features of DMI not noted before and on Analysis had 14 and 100 CTG repeats. The baby had 11 and 3800 CTG repeats. Case 2: The parents were first cousins and had five pregnancies in the 1980s and 1990s in Iran which resulted in children who died in the first two weeks of life. They had two daughters diagnosed as having hydrocephalus, one daughter with IUGR, and two sons with macrocephaly. The cause of death in any of the children was not known and was suspected to be an AR condition. Investigations were initiated on the mother due to this history and identified a DMPK gene expansion of 13 and 700 CTG repeats, thus she is affected with DMI and the early death of her children is most likely due congenital myotonic dystrophy. Unexplained neonatal death can be the result of congenial DM and this should taken into consideration in the forensic investigation.

Differential effects of DRB1*0301 and DQA1*0501-DQB1*0201 on the activation and progression of islet cell autoimmunity. *E. Eller[1], P. Vardi[2], K.K. McFann[1], S.R. Babu[1], L. Yu[1], G.S. Eisenbarth[1], P.R. Fain[1]* 1) Barbara Davis Center for Childhood Diabetes, University of Colorado Health Sciences Center, Aurora, Colorado, USA; 2) Felsenstein Medical Research Center (Beilinsen Campus), Tel Aviv University, Petah Tikva, Israel.

We have found an unusual DR3 haplotype, DRB1*0301-DQA1*0102-DQB1*0502, in a Bedouin Arab kindred that is characterized by a high prevalence of autoimmune diseases including type 1 diabetes (T1D) and celiac disease. While the usual DR3 haplotype DRB1*0301-DQA1*0501-DQB1*0201 is frequent in this family and occurs in 23 of the 24 relatives with T1D, the novel 0301-0102-0502 haplotype occurs disproportionately in individuals who are positive for islet cell autoantibodies but do not have T1D. This kindred provides a unique opportunity to investigate the effects of the two DQ loci conditioned on DRB1*0301. We show that the 0301-0102-0502 haplotype is overtransmitted to autoantibody-positive relatives without T1D, suggesting that the DQA1*0102-DQB1*0502 haplotype creates conditions for autoantibody positivity but decreases the probability of progression to type 1 diabetes.

Estimating the split time of Human and Neanderthal populations. *G. Coop[1], S. Kudaravalli[1], J.P. Noonan[2,3], D. Smith[2], J. Krause[4], J. Alessi[2], D. Chen[2], D. Platt[2], S. Pääbo[4], J.K. Pritchard[1], E.M. Rubin[2,3]* 1) Human Genetics, University of Chicago, Chicago, IL; 2) US DOE Joint Genome Institute, Walnut Creek, CA; 3) Genomics Division, Lawrence Berkeley National Laboratory, Berkeley, CA; 4) Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany.

Previous genetic studies of Neanderthal ancestry have used mtDNA and thus have been limited in their conclusions on the relationship of humans and Neanderthals. We present here the first use of Neanderthal genomic DNA to assess the joint history of human and Neanderthal populations. Our data consist of 37kb of short fragments of genomic DNA sequenced in Neanderthal. By studying the degree to which modern human diversity is shared with Neanderthal we can assess the time at which the human and Neanderthal populations split. We use a flexible simulation based approach that demonstrates the power of using human variation data in such analyses. We find that the two populations split ~400,000 years, predating the emergence of modern humans. Our best fitting model predicts that the Neanderthal lineage will be outgroup to the human population ~52% of the time.

A High Density Linkage Screen for POAG: Evidence for Different Loci by Race. *R.R. Allingham[1], J.L. Wiggs[2], F.L. Graham[1], K.R. LaRocque-Abramson[1], C. Santiago-Turla[1], A. Ventura-Viray[1], J.L. Haines[3], M.A. Pericak-Vance[1], M.A. Hauser[1]* 1) Duke Univ Medical Ctr, Durham,NC; 2) Harvard Medical School, Boston,MA; 3) Center for Human Genetics Research, Nashville,TN.

Primary open-angle glaucoma(POAG) is a common complex inherited disorder. Here we report a major SNP-based genome-wide screen on a large POAG family dataset, consisting of 142 multiplex POAG families (including 87 Caucasian and 37 African-American families), each containing 2 or more affected family members. The marker panel consisted of 5067 single nucleotide polymorphisms (SNPs)and was performed utilizing the Illumina Bead Station platform. Two-point and multipoint heterogeneity lod scores were calculated using Allegro. For multipoint analyses a single SNP was selected from each bin of SNPs in linkage disequilibrium (r2 0.16). Genotype data were analyzed *in toto* and after stratification by Caucasian and African-American race. The two-point analyses was performed on the total dataset. For multipoint analyses the Caucasian and African-American family subsets were also analyzed. Peak two-point MLOD scores for chromosomes 3, 6, 14, and 15 were 4.4, 2.6, 4.4, and 3.5, respectively. Peak multipoint(parametric or non-parametric)lod scores for chromosomes 3, 6, 14, and 15 were 2.6, 1.7, 2.1, and 2.6, respectively. Additional multipoint lod scores 2.0 were found on chromosomes 12 (2.2) and 17 (2.0). Multipoint lod scores for the loci on chromosomes 3,14, and 15 were primarily obtained from the African-American subset. The lod score for the locus on chromosome 12 was derived from the Caucasian subset. Contributions from both racial subsets contributed to the lod scores on chromosomes 6 and 17. We have performed the most definitive genome-wide linkage screen for POAG described to date, using over 5000 markers in one of the largest reported multiplex family datasets. For the first time we report known and novel chromosomal loci for POAG that appear to be derived primarily from either Caucasian or African-American family subsets. These findings suggest that different genetic loci may in part explain variations in the prevalence and phenotype of POAG among races described in population-based studies.

The impact of folic acid fortification on the prevalence of congenital anomalies other than neural tube defects. *K. Godwin[1], B. Sibbald[2], T. Bedard[2], B. Lowry[2], B. Kuzeljevic[3], L. Arbour[1]* 1) Medical Genetics, Children's and Women's Health Centre of BC, Vancouver, BC, Canada; 2) Alberta Congenital Anomalies Surveillance System, Department of Medical Genetics, Alberta Childrens Hospital, Calgary AB; 3) BC Research Institute for Childrens and Womens Health, Vancouver BC.

INTRO: There is evidence for a reduction in NTDs in Canada where mandatory grain fortification with folic acid was initiated in 1998. However, there has been little exploration as to whether the fortification program is also impacting the rates of other congenital anomalies (CAs). METHODS: Using the ACASS, we examined changes in birth prevalence of select CAs between 1992-1996 (pre-fortification) and 1999-2003 (post-fortification). Changes in birth prevalence between the two time periods were assessed by calculating odds ratios and 95% confidence intervals for each CA. RESULTS: We found a statistically significant decrease in the prevalence of spina bifida (OR 0.51, 95%; CI 0.36-0.73) and ASDs (OR 0.80, 95%; CI 0.69-0.93). However, between those time periods there were also significant increases in the prevalence of obstructive urinary tract defects (OR 1.45, 95%; CI 1.24-1.70), abdominal wall defects (OR 1.40, 95%; CI 1.04-1.88), particularly gastroschisis (OR 1.91, 95%; CI 1.29 - 2.84) and pyloric stenosis (OR 1.49, 95%; CI 1.18-1.89). CONCLUSION: The results of this study are consistent with the reductions in birth prevalence reported elsewhere for NTDs after fortification of the Canadian grain supply. As previously suggested with multivitamin studies, folic acid fortification may also modestly decrease the risk of ASDs; while increasing the risk of obstructive urinary tract defects. The increase in abdominal wall defects, most notably gastroschisis, is likely related to a pre-existing trend, documented in several regions around the world. The increase in prevalence of pyloric stenosis has not been seen in other studies related to folic acid/multivitamin consumption and perhaps represents a general increasing trend in this CA. Similar studies by other CA surveillance systems are needed to provide further confirmation of these trends.

The GATOR program for association analysis on quantitative traits with and without censoring. *J.C. Curry*[1], *Y.W. Li*[1], *E.R. Martin*[1], *A.S. Allen*[2], *Y.J. Li*[1] 1) Ctr for Human Genetics, Duke Univ Med Ctr; 2) Dept Biostatistics and Bioinformatics, Duke Univ.

Mapping loci contributing to quantitative traits is recognized as an important component in dissecting the etiology of complex diseases. Although many statistical methods for linkage and association studies have been proposed for quantitative traits, most of them require assumption of the distribution of the trait(e.g. normal distribution). Furthermore, censored data can be found in some quantitative phenotypes. For instance, age-at-onset data is censored in the unaffected individuals. Therefore, there is a need to develop a method that utilizes the additional information from censored individuals (e.g. unaffected individuals for studying age-at-onset). We recently proposed a novel family-based association method, genetic association tests based on ranks (GATOR), for analysis of quantitative traits both with and without censoring (Allen et al. 2006). We have examined the power and efficacy of the GATOR method through a serious of simulation studies. We are currently developing a computer program for GATOR method in order to analyze real data. The input files include a file with pedigree and marker information and a phenotype file that contains information on quantitative phenotypes and censoring status for up to 20 traits. This new program is able to perform the GATOR test for four different genetic models: general, dominant, recessive, and additive models. Our current program development plan focuses on biallelic markers. However, it is possible to extend to multi-allelic markers in the future. As described in our previous study, this method can handle parent-offspring (triads), sibships with and without parents, and extended multi-generation pedigree data. In order to accommodate future whole genome association studoes, this program will have the capacity to read in up to 500K markers. We will test the program by both simulated and real data. We will use this program to analyze SNP data generated from an ongoing project to detect genes associated with age-at-onset of Alzheimer and Parkinson diseases. The final GATOR program will be freely distributed from our website.

Initial Un-biased Identification of Genes for Exceptional Longevity in Humans. *G. Atzmon[1], K. Ye[2], N. Barzilai[1]* 1) Institute for Aging Research, Department of Medicine; 2) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY 10461.

We reasoned that the rare selected survivors who became centenarians are enriched with benefactor alleles compared to elderly persons in their 70s. We have previously identified several genotypes that are over presented in this population based on a candidate approach. In order to have an un-biased approach, we reasoned that genome association studies to identify loci that underlie complex traits are feasible and cost-effective as a result of development in technologies. Here we pooled DNA from 250 Ashkenazi Jews centenarians (Age 98.2 +/- 0.5, Mean +/- SE) and 250 unrelated individuals (Age 69.1 +/- 1.4), and subjected these pools to Affymetrix GeneChip Mapping array. We established 5 DNA pools (50 samples each) of centenarians and 5 DNA pools (50 samples each) of control groups. These ten DNA pools were subjected to high throughput genomic genotyping using the STY set of the Affymetrix GeneChip Mapping 500K. There were no significant differences within the 5 pools of centenarians and controls. Comprehensive statistical analysis was performed to detect differences of allele frequency estimates from the pooled DNA. As a reference for significant, the flanking SNPs of the previously shown longevity associated genes (CETP and APOC3) were use. Out of ~240k possible SNPs, 8435 (3.5%) passed the significant threshold. Detected SNPs were distributed evenly on the chromosomes with average of 390 SNPs per chromosome (0.2%) and average distance of 344Kbp. One and a half percent (3686 SNPs) were either different genes or unassigned SNP with average distance of 600Kbp. This broad based approach provide us with loci that can be further validated with individual genotyping, establishing effects of heterozygosis and homozygosis, and use for association studies for prevalence of age-related disease, and with longevity according to genotype. Whether longevity is a polymorphic trait modulated by numerous genes or few genes will become apparent only after such individual assessment.

Whole Genome Scans for HDL-C in French Canadian Families Confirms a QTL on Chromosome 16q. *Z. Dastani[1, 3], M. Lemire[2], J. Faith[2], T. Hudson[1, 2, 5], D. Gaudet[4], M. Marcil[3], J. Genest[3, 4], J. Engert[1, 3]* 1) Human Genetics, Mc Gill University, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Canada; 3) Cardiovascular Genetics Laboratory, McGill University Health Centre, Royal Victoria Hospital, Montréal, Canada,; 4) Dyslipidemia, Diabetes and Atherosclerosis Group and Community Genomics Research Center, Université de Montréal and Complexe hospitalier de la Sagamie, Chicoutimi, Canada; 5) Department of Medicine, McGill University, Montreal, Canada.

HDL cholesterol (HDL-C) is a well-known independent risk factor for atherosclerotic vascular disease. To identify genes that contribute to HDL-C levels, we performed a genome-wide scan with 485 microsatellites (an average spacing of ~6 cM) on 362 individuals from 12 large multiplex French Canadian families (QUE) with an average size of 39 individuals. The estimated heritability of HDL-C in these families was 62%. Variance components methods implemented in SOLAR identified several regions of linkage with HDL-C, including a locus on chromosome 16q with a LOD score of 2.30 (P=0.00057) at 95 cM. This linkage was replicated in a cohort of large sibships from the Saguenay-Lac-Saint-Jean (SLSJ) region of Quebec (410 individuals from 61 families). The heritability of HDL-C in this cohort was also high (56%). A LOD score of 2.55 (P=0.00030) was observed at 85 cM (10 cM from the QUE peak). Previous studies on Mexican Americans and Finnish and Dutch cohorts resulted in linkage peaks that are less than 20 cM from the two peaks presented here. 183 SNPs were genotyped in a sub sample of the SLSJ cohort in candidate genes from the region under the linkage peak (29.7 cM; 23 Mb). While several SNPs demonstrated significance ($p<0.05$), none of these survived a correction for multiple testing. Affected members in four families of the QUE cohort share a 2 microsatellite haplotype. In a subset of families with positive LOD scores and visible segregation, 38 genes were selected for sequencing. One gene contained an amino acid change that appeared to segregate in four families, but this variant was also found in unaffected individuals.

Gaucher Disease: Novel Null and Hypomorphic Alleles in Chitotriosidase, a Diagnostic and Therapeutic Marker.
M. E. Grace, M. Balwani, R. J. Desnick Department of Human Genetics, Mount Sinai School of Medicine, New York, NY.

Chitotriosidase (CHITO), a chitinase secreted at high levels by activated macrophages of patients with Gaucher disease (GD), is a useful diagnostic and therapeutic biomarker for this lysosomal disorder. Of the >340 Type 1 GD patients [86% Ashkenazi Jewish (AJ)] screened for CHITO genotype and plasma enzyme levels at the Mount Sinai Comprehensive Gaucher Disease Treatment Center, 36% were found to be carriers of the common CHITO null allele (dup24), with 4% being homozygous. Of note, 5 patients with no plasma CHITO activity were dup24 negative. Sequencing identified three novel CHITO alleles: two missense, G102S and E74K, and one complex (G354R+K385K+c.1168+4delGATT). Expression of the mutant cDNAs in COS-7 cells demonstrated that, relative to the wild type allele, G102S and E74K had ~ 23% and 51% reduced catalytic activity, respectively. Constructs containing the G354R mutation alone or with K385K did not express detectable CHITO activity or protein in cell lysates. In addition, RNA studies indicated that the complex G354R null allele caused significant missplicing. Screening 250 unrelated GD patients for these novel CHITO alleles demonstrated that the E74K allele was rare (1.2%), and found only in AJ patients. The complex G354R allele was found in two patients, both of Dominican descent. Surprisingly, the G102S allele was present in ~31% of our AJ GD patients, including 7 who were homozygous. Recognition of these lesions, particularly G102S, will facilitate the interpretation of disease severity and permit more informed monitoring of disease therapy.

Compound heterozygous mutations in the diastrophic dysplasia sulfate transporter gene (DTDST) in a family with intermediate SEMD phenotype between MED and diastrophic dysplasia. *M. Czarny-Ratajczak[1, 2], K. Kozlowski[3], A. Latos-Bielenska[2], D.J. Prockop[1]* 1) Center for Gene Therapy, Tulane University, New Orleans; 2) Department of Medical Genetics, Poznan University of Medical Sciences, Poznan, Poland; 3) Department of Medical Imaging, New Childrens Hospital, Sydney, Australia.

DTDST mutations cause a spectrum of diastrophic dysplasia disorders characterized by a defect of the proteoglycans sulfation. Reduction of a sulfate transporter activity is manifested by lower sulfate uptake and depends on a combination of mutations in the DTDST gene. DTDST mutations can result in four autosomal recessively inherited chondrodysplasias: two lethal forms, achondrogenesis type 1B and atelosteogenesis type 2, a severe form, diastrophic dysplasia and a mild form, multiple epiphyseal dysplasia.We analyzed a family from the Polish population with an autosomal recessive form of spondyloepimetaphyseal dysplasia (SEMD). Three affected and six unaffected family members were included in the studies. A detailed clinical and radiological examination was performed on all affected family members and most of the unaffected family members. Molecular analysis of the DTDST gene revealed that three affected brothers from this family are compound heterozygotes for C653S/A715V mutations. We classified the phenotype of the patients as a new form of SEMD, characterized by short stature, club foot, brachydactyly and clinodactyly of the fifth fingers. Radiographs showed platyspondyly most marked in the lower thoracic and upper lumbar spine, epiphyseal dysplasia affecting predominantly the femoral heads and widening of the metaphyses. Other distinctive features were prominent trochanters minor and ischial spines, grossly normal carpal/tarsal bones and early onset, severe osteoarthritis. Clinical and radiological analysis revealed that the patients have a new border phenotype between diastrophic dysplasia and multiple epiphyseal dysplasia. Supported by grants from: The Louisiana Gene Therapy Research Consortium and The Polish State Committee for Scientific Research (grant 3P05E00722 to M.C-R.).

Patient and Provider Readiness for Pharmacogenomics: A User Survey. *A. Ginsberg[1], T. Brown[2], P. Billings[1], M. Lai-Goldman[2]* 1) Strategic Planning, Laboratory Corporation of America, Burlington, NC; 2) National Office of Science and Technology, Laboratory Corporation of America, Research Triangle Park, NC.

Adverse drug reactions were the 5th leading cause of death in 2004 in this country, and account for 4% of hospitalizations, and approximately $200B in healthcare expenses each year. Pharmacogenomic tests have been developed to reduce morbidity and mortality related to adverse drug events and improve adherence and compliance with proven therapies. We surveyed physician providers and patients on their readiness to adopt these tests in to current use. We utilized mixed quantitative and qualitative survey strategy using both telephonic and web input. 250 physicians, part of the ePocrates registry, randomly selected, responded to a structured questionnaire on the internet with opportunities for open ended response. They came from a range of specialties and parts of the country. 2,000 patients, representative of the U.S. population, were also contacted as part of GfK NOPs OmniTel phone survey and queried with a similarly constructed interview vehicle. Key questions addressed providers and patients level of interest in predictive laboratory testing to determine drug therapy efficacy, safety, and dosing guidance. The data were analyzed for statistically significant differences as well as qualitative themes. Significant findings from the physician survey include widespread acceptance of pharmacogenetic testing, with reduced interest depending on the use of the test or type of physician: for example, primary care physicians interest in a predictive test used for dosing guidance. Overall, although physicians were interested in the concept, relatively few were familiar with examples of predictive tests. Approximately 88 percent of patients would allow their physician to order a pharmacogenetic test, regardless of its application to efficacy, safety, or dosing. While significant barriers exist to the adoption of pharmacogenomic testing in routine clinical use, our survey suggests that a significant number of patients and providers are now ready to use pharmacogenomic tests if offered in routine clinical settings.

A founder mutation of *MYH* associated to adenomatous polyposis and colorectal cancer in North Africa. *S. Baert-Desurmont[1,2], A. Rouquette[1,2], J. Mauillon[1], E. Bessenay[1], N. Soufir[3], I. Ratbi[4], A. Sefiani[4], H. Chaabouni[5], T. Frebourg[1,2]* 1) Department of Genetics, University Hospital, Rouen, France; 2) Inserm U614, Faculty of Medicine, Rouen, France; 3) Department of Genetics, Bichat-Claude Bernard Hospital, Paris, France; 4) Laboratory of Genetics, Faculty of Medicine, Rabat, Morocco; 5) Department of Congenital and Hereditary diseases, Charles Nicolle Hospital, Tunis, Tunisia.

MYH-associated polyposis (MAP) has been initially characterized as an autosomal recessive disease predisposing to variable number of colorectal adenomas with high risk of degenerescence. Numerous studies have indicated that 2 missense mutations (p.Tyr165Cys in exon 7 and p.Gly382Asp in exon 13) account for about 80 % of *MYH* allelic variants in Caucasians. During the systematic screening of *MYH* in patients with colorectal adenomas and / or cancer, we detected in 3 unrelated patients a homozygous germline mutation c.1186_1187insGG, p.Glu396fsX42, within exon 13. The first patient was a woman presenting at 36 years a colorectal adenocarcinoma associated with 6 adenomas. The second subject presented, at the age of 42 years, 2 synchronous colorectal adenocarcinomas and about 20 adenomas. The third patient, a man of 49 years of age, had approximately 30 colorectal and 2 duodenal adenomas. All these individuals originated from North Africa. Analysis of intragenic SNPs and 6 microsatellite markers revealed a common 1.65 cM haplotype between *D1S451* and *D1S322*, suggesting a founder effect. Screening for the c.1186_1187insGG *MYH* mutation in 150 unrelated healthy individuals from Morocco and Tunisia allowed us to estimate the allelic frequency of this *MYH* mutation to 0.33%. Considering the high level of consanguinity in North Africa, it is likely that *MYH* biallelic mutations may contribute to the remarkable frequency of colorectal cancer observed in young patients. In particular, the presence of the c.1186_1187insGG founder mutation should be considered in young patients originated from North Africa presenting sporadic colorectal cancer even with a limited number of adenomas.

Use of HapMap Data and TagZilla to Design Large Scale Multiplex Assays for Candidiate Gene And Gene Pathway Analyses. *L. Burdett[1], K. Jacobs[1,2], R. Welch[1], M. Beerman[1], B. Staats[1], L. Qi[1], T. Li[1], Z. Wang[1], S. Chanock[3], M. Yeager[1]* 1) SAIC-Frederick, NCI, DCEG, CGF, Gaithersburg, MD; 2) Bioinformed Consulting Services, Gaithersburg, MD; 3) Pediatric Oncology Branch, CCR, NCI, Bethesda, MD.

The National Cancer Institutes (NCI) Core Genotyping Facility (CGF) is using information derived from the HapMap Project with the goal of designing custom Illumina GoldenGate multiplex genotyping panels to maximize the number of candidate genes covered without sacrificing quality of coverage. Illumina GoldenGate design scores are incorporated in a tag SNP selection process using HapMap genotype data in gene regions (20kb upstream and 10kb downstream) of interest. Tag SNPs are selected with the TagZilla software using data on HapMap Caucasians, an r2 = 0.8, and MAF>5%. SNPs that have unacceptable design scores are given the designation obligate-exclude, though they are still used as information in the binning process. Design scores obtained from the submission of dbSNP IDs are compared to locally generated annotated sequences in order to identify and eliminate potential genotyping errors. Selection of alternative tags or re-binning is done as necessary when tag SNPs with low design scores must be removed. Two panels have been designed, one for genes involved in innate immunity and another for genes in pathways associated with Non-Hodgkin Lymphoma. Both are intended to be used on several thousand samples from large cohort or case/control studies. An initial comparison of genotyping results from these two panels indicates that a design score cutoff of 0.6 results in lower genotyping replication error rate (0.3%) and a higher cluster separation (0.82) compared to the panel that used a 0.4 design score cutoff (143 snps with design scores < 0.6). While the Illumina GenTrain scores and call frequency are not significantly different, the recommended data cleaning steps will significantly lower the overall number of usable genotypes. We plan to further validate the effectiveness of our design process examining genotype concordance with HapMap samples. Funded by NCI Contract N01-CO-12400.

Functional centromere in a stable ring 5q13q34 in a child with mental retardation. *M. Artigas-Lopez, S. Moreno, A. Pérez-Juana, A. Alonso, T. Durá, M.A. Ramos Arroyo* Dept Genetics, Hospital Virgen del Camino, Pamplona, Spain.

We report a 14-year-old male with severe mental retardation, spastic tetraparesis, failure to thrive and dysmorphic features. He is the product of the second and uneventful pregnancy of an unrelated couple from Ucrania. Previous history is remarkable because, allegedly, he had had a normal development until 2 years of age. He started to walk at 9 months and started to talk at 11 months. By 18 months of age a decrease in his head growth was observed. By 2 years he presented frequent falls and regression of acquired skills. At 2 and a half years of age he developed seizures and started stereotypic movements of the hands that have presently disappeared. He has never been toilet trained, and he has lost completely his language and communications skills. He is microcephalic, with weight and height below the 3rd centile, he has spastic quadriplegia and he is wheelchair-bound.

Chromosome analysis showed a mitotically stable supernumerary marker chromosome. The karyotype showed a deleted small chromosome 5, in which a segment between bands q13-q34, was missing in all cells studied. In addition, a supernumerary ring chromosome 5 was also evident in all analysed metaphases: 47,XY,-5,+der(5)(pterq12::q35qter),+r(5)(q13.q34).ish der(5)(5p15.2)(D5S23+, D5S721+)(ptel+,qtel+).ish r(5)(5q31)(EGR 1+). In a few proportion of cells the ring chromosome was duplicated, carrying two centromeres. The neocentromere formation has probably been the mechanism for the mitotic stabilisation of the initially acentric ring chromosome. Parental chromosomes were normal

In 1981 Cote et al proposed the term ring syndrome and it has been suggested that the ring syndrome is caused by a continuous generation of secondary aneuploid cells with increased cell mortality, responsible of the clinical picture.

Genome-wide linkage analysis for aggressive prostate cancer in Utah high risk pedigrees. *G.B. Christensen, N.J. Camp, J.M. Farnham, L.A. Cannon-Albright* Biomedical Informatics, University of Utah, Salt Lake City, UT.

It has been proposed that studying alternative phenotypes, such as tumor aggressiveness, may be a solution for overcoming the apparent heterogeneity that has hindered the identification of prostate cancer genes. We present the results of a genome scan for predisposition to aggressive prostate cancer using the Utah high-risk pedigree resource. We identified 259 subjects with aggressive prostate cancer in 57 extended and nuclear families. Subjects were classified as having aggressive disease if any of the following criteria were met: regional or distant stage, poorly differentiated or undifferentiated grade, or death due to metastatic prostate cancer confirmed by death certificate. Parametric and non-parametric multipoint linkage statistics were calculated for a genome-wide set of 401 microsatellite markers using the MCLINK software package. No significant results were observed at the genome-wide level, but suggestive evidence for linkage was observed on chromosomes 9q (HLOD=2.04), 14q (HLOD=2.08), 6p (HLOD=1.75); several pedigrees showed individual evidence for linkage at each locus (LOD > 0.58). Stratification analyses by the number of affected subjects (less than five, five or more) and the average age at diagnosis of affected subjects (less than 70 years, 70 or more years) were also performed. The subset of pedigrees with earlier age at onset demonstrated suggestive linkage evidence on chromosomes 3q (HLOD=1.79), 8q (HLOD=1.67) and 20q (HLOD=1.82). The late onset subset showed suggestive linkage on chromosome 6p (HLOD=2.37) and the subset of pedigrees with fewer than 5 affected subjects showed suggestive linkage on chromosome 10p (HLOD=1.99). The evidence for chromosomes 6p and 20q support previously reported prostate cancer aggressiveness loci.

Mitochondrial Genetic Regulation of Nuclear Transcription. *J.E. Curran[1], M.P. Johnson[1], H.H.H. Göring[1], T.D. Dyer[1], J.B.M. Jowett[2,3], J.W. MacCluer[1], G.R. Collier[3], E.K. Moses[1], J. Blangero[1,3]* 1) SW Fndn Biomedical Research, San Antonio, TX; 2) International Diabetes Institute, Melbourne, AU; 3) ChemGenex Pharmaceuticals, Geelong, AU.

Mitochondrial biogenesis is responsible for up to 20% of total cellular protein production. Therefore, mitochondria likely play a role in regulation of transcription. Both mitochondrial biogenesis and dysfunction are influenced by sequence variation within the mitochondrial genome. In this study, we test whether mitochondrial genetic variation influences the basal transcriptional machinery of the nuclear genome. As part of the San Antonio Family Heart Study, we obtained genome-wide quantitative transcriptional profiles from 1,240 individuals. Using lymphocytes, we quantitated 20,413 transcripts. For each transcript, we tested for linkage to the mitochondrial genome using the variance components method. Given large extended pedigrees, this test is powerful even in the absence of mitochondrial genetic markers. Seven of ten mitochondrial encoded transcripts showed strong evidence ($p<0.0001$) for mitochondrial linkage including *MTC01*, *MTND1* and *MTATP6*, suggesting that mitochondrial variants are involved in mitochondrial biogenesis/function. Examination of nuclear gene transcription revealed that 1,525 transcripts showed nominally significant ($p<0.05$) evidence for regulation by a mitochondrial genetic component. When we utilized a false discovery rate of 0.33 across the whole experiment, we identified 349 transcripts exhibiting evidence for linkage to the mitochondrial genome ($p<0.005$). Of these several exhibited overwhelming evidence that mitochondrial genetic variation influences their expression levels. These genes included *CBX1* ($p=7\times10^{-29}$), *AP2B1* ($p=9\times10^{-22}$), *C16orf20* ($p=4\times10^{-18}$), *PRPH* ($p=2.8\times10^{-12}$) and *OAZ2* ($p=4.5\times10^{-10}$). Given the small size of the mitochondrial genome, direct resequencing of the available mitochondrial lineages should lead to rapid identification of the functional variants responsible for the observed effects on nuclear gene transcription. Our results show the utility of large-scale transcriptional profiling for the identification of major genetic determinants of gene expression.

Genetic analysis of transcriptional profiles for the identification of genes influencing obesity. *J.C. Charlesworth[1], J.E. Curran[1], M.P. Johnson[1], H.H.H. Göring[1], T.D. Dyer[1], A.G. Comuzzie[1], S.A. Cole[1], M.C. Mahaney[1], J.B.M. Jowett[2,3], J.W. MacCluer[1], G.R. Collier[3], E.K. Moses[1], J. Blangero[1,3]* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) International Diabetes Institute, Melbourne, AUS; 3) ChemGenex Pharmaceuticals, Geelong, AUS.

The identification of candidate genes for human quantitative traits is typically based upon subjective knowledge of a biological pathway that is extrapolated to a particular phenotype. In this study, we propose an objective approach to candidate gene discovery that utilizes large-scale transcriptional profiling to identify novel *cis*-acting genes that correlate with a given quantitative trait. Using RNA extracted from lymphocytes, we obtained genome-wide quantitative transcriptional profiles from 1,240 individuals in the San Antonio Family Heart Study. In this data set, we were able to significantly detect ~20,000 transcripts. Using quantitative trait linkage analysis, we identified over 3,000 autosomal *cis*-acting QTLs for which we have significant evidence for variation at the transcripts genomic location that influences expression levels. To identify potential novel candidate genes involved in obesity, we examined correlations between expression levels of these *cis*-acting genes and two obesity-related indicators, the body mass index and fat mass (as measured by bioimpedance). Using high-dimensional endophenotypic search procedures, we identified 383 autosomal genes (many novel) that correlate with these obesity-related phenotypes. Several known candidate genes for obesity, including *IGBP3* and *CDF* (which encodes adipsin) were confirmed. The novel genes identified vary in their general biological actions, from mitochondrial functions to inflammation and growth factors. Because these genes were chosen to have large *cis*-acting effects on transcription levels, it is likely that some of our findings reflect causal relationships with risk of obesity. Our results point to the utility of large scale family-based transcriptional data bases for identifying human quantitative trait loci.

An exonic point mutation in SBCAD is very frequent in the Hmong ethnic group and causes exon 10 skipping by simultaneous ESE disruption and ESS strengthening. *B.S. Andresen[1], P. Madsen[1], V.C. Dung[2], N.T. Liem[2], N.T. Hoan[2], D. Hougaard[3], T.J. Corydon[1], R.J.A. Wanders[4], J.P.N. Ruiter[4], A. Kar[5], J.Y. Wu[5], L. Schroeder[1], N. Gregersen[1]*
1) Aarhus Univ, DK; 2) Nat Hosp Pediat, Hanoi, Vietnam; 3) SSI, Copenhagen, DK; 4) AMC, Amsterdam, The Netherlands; 5) NW Univ, Chicago, USA.

SBCAD deficiency is a defect in isoleucine metabolism. Recently, numerous newborns with SBCADD have been detected by MS/MS-screening in the US. The vast majority belong to the Hmong ethnic group, who originates from South-East Asia. We have previously identified a missense mutation, c.1165A>G, in SBCAD exon 10 in these children. We have now genotyped 2053 blood spots from Vietnam. The c.1165A>G mutation was not prevalent in the general population, but very prevalent in Ha Giang, where the Hmong in Vietnam live (Carrier freq. of 1:9). Thus, in the Hmong ethnic group >1:300 are homozygous, which explains the high number of Hmong newborns identified with SBCADD in the US. However, only very few individuals homozygous for c.1165A>G have presented clinically. To explore this enigma we investigated the molecular pathology of c.1165A>G. Analysis of patient cells showed that despite its location far from the splice sites, c.1165A>G is associated with complete exon 10 skipping (no activity). However, over-expression showed that the encoded M389V protein has high residual enzyme activity. Therefore, even a low level of correctly spliced c.1165A>G SBCAD mRNA may result in sufficient enzyme activity to avoid disease manifestation. Consequently, we used minigenes and in vitro RNA techniques to study c.1165A>Gs effect on splicing in detail. This showed that it simultaneously destroys an exonic splicing enhancer (ESE) and strengthens an exonic splicing silencer (ESS). Combined mutagenesis of the ESE/ESS motifs showed that splicing efficiency is determined by a fine balance between their relative strengths. We speculate if variations in the abundance of the splicing regulatory proteins that bind to the ESE/ESS may influence SBCAD exon 10 splicing efficiency and if this may contribute to an explanation for the clinical phenotype of c.1165A>G homozygotes.

Role of ATM during L1 retrotransposition. *S.L. Gasior, P.L. Deininger* Department of Epidemiology, Tulane Cancer Center, New Orleans, LA.

Mobile elements represent a source of insertional mutagenesis in all genomes studied to date. The human L1 belongs to the non-Long Terminal Repeat class of retrotransposons and is the only known active autonomous element in the human genome. L1 encodes an APE-like endonuclease and a reverse transcriptase that enable the L1 RNA to initiate its integration into the genome, a process termed Target Primed Reverse Transcription (TPRT). TPRT suggests that a double-strand break (DSB) would be a potential intermediate, and we have demonstrated previously that overexpression of L1.3 induces -H2AX foci and COMET tails under neutral conditions. Both are hallmarks of DSBs.

To further understand the role of cellular DNA repair proteins in response to L1 DSB formation and integration, we are characterizing whether ATM is activated and/or required during L1 TPRT. ATM is an important kinase for the repair of DSBs. After expression of L1.3, ATM autophosphorylates and ATM-P localizes on chromatin as foci similar to how ATM responds to ionizing radiation. We have also tested the requirement for ATM in a colony plating assay in which colonies represent a cell with an L1 integration. Treatment of cells with wortmannin or caffeine, two molecules that inhibit ATM kinase, lowers the frequency of colonies. Further analyses with an ATM dominant negative allele and AT-deficient cells suggest L1 integration specifically requires ATM.

These results impart an important new understanding for sources of DNA damage that leads to genetic instability in humans. Because L1 expression is elevated in many cancer cells, it may be a major contributor of DSBs, which in turn promote chromosomal rearrangements. In cells deficient in DSB repair, there may be additional consequences for genetic instability due to L1 activity.

Evidence for a susceptibility gene for type 2 diabetes on chromosome 11. *M.R. Erdos[1], H.M. Stringham[2], P.S. Chines[1], N. Narisu[1], A.U. Jackson[2], W.L. Duren[2], L.L. Bonnycastle[1], C.J. Willer[2], L.J. Scott[2], K.F. Doheny[3], E.W. Pugh[3], N.L. Riebow[1], T.T. Valle[4], R.M. Watanabe[5], T.A. Buchanan[5], R.N. Bergman[5], J. Tuomilehto[4], K.L. Mohlke[6], M. Boehnke[2], F.S. Collins[1]* 1) NHGRI, NIH, Bethesda, MD; 2) U. Michigan, Ann Arbor, MI; 3) CIDR, Johns Hopkins U., Baltimore, MD; 4) National Public Health Institute, Helsinki, Finland; 5) U. Southern California, Los Angeles, CA; 6) U. North Carolina, Chapel Hill, NC.

The FUSION study of the genetics of type 2 diabetes mellitus (T2D) previously performed microsatellite linkage scans of two samples of Finnish affected sib pair families in an attempt to identify the genetic variants conferring susceptibility to T2D. The strongest genome-wide evidence for linkage was found on chromosome 11 at 82.0 cM (LOD = 2.98). Subsequent SNP genotyping on pools of 748 probands, 228 older controls, and 182 unaffected spouses in the 12.4 Mb linkage region (achieving an average SNP density of 33.6 kb) identified a closely spaced cluster of associated SNPs with an estimated maximum allele frequency difference > .10 ($p = 4.6 \times 10^{-5}$). Follow up genotyping of individual cases, spouses, and controls confirmed three SNPs with allele frequency differences between cases and controls > .054 ($p < .001$). An additional 28 SNPs were typed in the same region; 18 of these identified a block of linkage disequilibrium (LD) of approximately 210 kb showing association with T2D. Located within this block is the GRB-2 associated binding protein 2 (*GAB2*) gene, a plausible candidate for T2D. We are now performing genome-wide association (GWA) analysis using the Illumina HumanHap300 panel, which includes 1,459 SNPs genotyped in this chromosome 11 linkage region on 1171 cases and 1186 controls from the FUSION study and the Finrisk 2002 population-based study. Initial analysis of the GWA data on 885 cases and 885 controls has identified 61 SNPs with T2D association p-value < .05 adjusted for testing three genetic models per SNP in the linkage region. Although no SNPs in the *GAB2* gene show $p < .05$, the best T2D association result ($p = 0.0011$) is located 1.9Mb proximal to *GAB2* and four additional SNPs show association ($p < .003$) within 1.0Mb distal to the gene.

Emergence of new primate genes by retrotransposon-mediated sequence transduction. *M.A. Batzer[1], J. Xing[1], H. Wang[1], V.P. Belancio[2], R. Cordaux[1], P.L. Deininger[2]* 1) Department of Biological Sciences, Biological Computation and Visualization Center, Center for BioModular Multi-Scale Systems, Louisiana State University, 202 Life Sciences Building, Baton Rouge, LA; 2) Tulane Cancer Center SL-66, Department of Environmental Health Sciences, Tulane University Health Sciences Center, New Orleans, LA.

Gene duplication is one of the most important mechanisms for creating new genes and generating genomic novelty. Retrotransposon-mediated sequence transduction (i.e. the process by which a retrotransposon carries flanking sequence during its mobilization) has been proposed as a gene duplication mechanism. L1 exon shuffling potential has been reported in cell culture assays and two potential L1-mediated exon shuffling events have been previously identified in the genome. SVA is the youngest retrotransposon family in primates and is capable of 3 flanking sequence transduction during retrotransposition. In this study, we examined all the full-length SVA elements in the human genome to assess the frequency and impact of SVA-mediated 3 sequence transduction. Our results showed that ~53 kb of genomic sequences have been duplicated by 143 different SVA-mediated transduction events. In particular, we identified one group of SVA elements that duplicated the entire AMAC gene three times in the human genome via SVA-mediated transduction events which happened before the divergence of humans and African great apes. In addition to the original AMAC gene, the three transduced AMAC copies contain intact open reading frames in the human genome and at least two are actively transcribed in different human tissues. The duplication of entire genes and the creation of new gene families via retrotransposon-mediated sequence transduction represent an important mechanism by which mobile elements impact their host genomes.

Comprehensive Genomic Analysis of Unilateral Retinoblastoma Tumors: Old Disease, New Clues. *A. Ganguly[1], C. MacMullen[1], L. Swanson[1], S. Diskin[2], G. Grant[2], E. Rappaport[3], G. Bunin[4], C. Shields[5], A. Meadows[4], K. Nichols[4]*
1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Department of Bioinformatics university of Pennsylvania; 3) Department of Pediatric Oncology Childrens Hospital of Philadelphia; 4) NAPCORE, CHOP; 5) Wills Eye Hospital, Philadelphia.

Background Retinoblastoma (RB) is a childhood onset ocular tumor associated with compromised vision and death in many cases. Inactivation of both copies of the RB1 gene in a retinal cell is followed by additional genetic changes leading to tumor formation. It is known that inactivations of p53, p107/p130 in addition to pRb proteins are required to initiate RB formation in mice. However, in human RB tumors, TP53 mutations have not been observed. **Methods** Whole genome SNP based assays were performed on DNA isolated from a set of 25 sporadic, unilateral RB tumors and matched blood samples using Affymetrix 10K SNP-Chips. Gene expression analysis was performed using Affymetrix U133 V2.0 chips on a subset of 18 RB tumors to detect correlations with genomic amplification/loss. **Results and Discussion** The results confirmed previous observations and identified 2q33-37, 3p21, 3q25, 11q14, 11q23, 14q22-23, 15q26.3 and 20q13.12, as novel regions of amplification. In addition,1q21.1, 1q32.2 and 1q44, were identified as minimal regions of gain. RB tumor clusters were defined by presence/absence of loss of heterozygosity (LOH) of chromosome 13. The LOH in most cases was due to copy neutral events caused by mitotic recombination or non-disjunction. No correlation to age, gender or mutation at RB1 was observed. However, the gene expression profiles of tumors were variable. In particular, expression of genes present on 1q32 resulted in two clusters of RB tumors defined by ages of onset. Higher expression of MDM4(1q32) was observed among other genes. This observation is significant as MDM4 in conjunction with MDM2 have unique roles in modulating the level of p53. We will discuss the implications of this finding for novel therapeutic options targeting the MDM4/MDM2 molecules.

Genetic Variants in the Farnesyl-Diphosphate Farnesyltransferase Gene (FDFT1) Region is Associated with Susceptibility to Coronary Heart Disease. *R. Do[1], S.D. Bailey[1], A. Montpetit[3], G. Pare[1,3], K. Desbiens[2], J. Faith[3], T.J. Hudson[1,2,3], D. Gaudet[4], J.C. Engert[1,2]* 1) Department of Human Genetics, McGill University, Montréal, PQ; 2) Department of Medicine, McGill University, Montréal, PQ; 3) McGill University Genome Québec Innovation Centre, McGill University, Montréal, PQ; 4) Université de Montréal, Chicoutimi, PQ.

Research has shown that genetic variants may predispose to various cardiovascular diseases. Founder effect populations are useful tools in linkage disequilibrium mapping due to reduced genetic heterogeneity. The Saguenay-Lac St. Jean region of Quebec is a known founder population that is currently being used to map complex traits of genetic disease. Recently, we have performed a genome-wide linkage scan on a Saguenay-Lac St. Jean cohort and have identified a susceptibility loci for coronary heart disease on Chromosome 8 (non-parametric linkage score = 3.53). Within this region, the squalene synthase (farnesyl-diphosphate farnesyltransferase (FDFT1)) gene is a strong candidate. Squalene synthase catalyzes the first committed step leading to cholesterol biosynthesis in the isoprene biosynthetic pathway. It is believed that levels of squalene synthase may correspond to the intracellular production of cholesterol and therefore, plasma cholesterol levels. We have identified SNPs in the exons and intron-exon boundaries of the FDFT1 gene through sequencing of a small subset of our study population and these SNPs were then genotyped in all individuals. Additional genotype data has been generated for 14 SNPs in the FDFT1 region. In a family-based association test, a silent SNP in exon 1 and a SNP in intron 1 of the FDFT1 gene were significantly associated with CHD ($p<0.02$)) in 24 families. In a sliding window haplotype analysis approach, the strongest associations between haplotypes and CHD were observed between exons 1 and 3 in the FDFT1 region ($p<0.004$). These results suggest that genetic variation in the FDFT1 region may be associated with increased susceptibility to CHD and one of the identified SNPs may either be the causative variant or may be in linkage disequilibrium with the causative variant.

Noninvasive screening for aneuploidy also identifies infants at risk for common malformations:Results from the FASTER Trial. *D.W. Bianchi[1], L.M. Sullivan[2], B. MacKinnon[1], J.D. Hoffman[1], J. Collins[1], F.D. Malone[3], M.E. D'Alton[3], FASTER Trial Research Consortium* 1) Tufts-New England Medical Ctr, Boston, MA; 2) DM-Stat, Inc., Malden, MA; 3) Dept Ob-Gyn, Columbia Univ Sch of Med, NY, NY.

The FASTER trial compared 1st and 2nd trimester screening methods for aneuploidy (NEJM 353:2001-11). Research coordinators also recorded pediatric outcome information (36,837 cases, 97% ascertainment). Here we examined relationships between serum and ultrasound (US) markers (AFP, estriol [uE3], human chorionic gonadotropin [hCG], inhibin A, nuchal translucency [NT]) and pediatric anomalies. All cases with a positive serum or NT screening result as well as a 10% random subject sample underwent medical record review. Unaffected controls were selected for each anomaly, matched by enrollment site, maternal age, race, gestational age, and infant gender. Serum and US markers were dichotomized to either or 2 multiples of the median (MoM), or 0.5 or 0.5 MoM. Conditional logistic regression analysis assessed the relationship between each marker and outcome. Only odds ratios (OR)2 are reported here. The most common anomalies (incidence per 10,000 live births)were hydrocele (34.1),undescended testis(12.4), 2-vessel cord (11.8), pyloric stenosis (5.4), and multicystic dysplastic kidney(3.7). Women with inhibin A 2 MoM had significantly increased risk of multicystic dysplastic kidney (OR=27.5) and 2-vessel cord (OR=4.22). Inhibin A 0.5 MoM carried an increased risk of pyloric stenosis (OR=7.88). Women with free hCG 2 MoM had increased risk of pyloric stenosis (OR=2.31) and multicystic dysplastic kidney (OR=2.73). hCG level 2 MoM had increased risk of multicystic dysplastic kidney (OR=19.56) and hydrocoele (OR=2.48). uE3 2 MoM had increased risk of undescended testis (OR=3.64); uE3 0.5 MoM had increased risk of 2-vessel cord (OR=7.78). In this large prospective study statistically significant associations were found between routine maternal screening markers and pediatric anomalies. This suggests that there may be previously unrealized benefits to screening programs that are primarily designed to detect aneuploidy.

Identifying the major genetic contribution of complex diseases using pooling-based genome-wide SNP association studies. *D. Craig, J. Pearson, M. Huentelman, R. Halperin, W. Tembe, V. Zisman, K. Coon, J. Webster, E. Reiman, D. Stephan* Dept Neurogenomics, TGen, Phoenix, AZ.

Genome-wide association (GWA) studies using hundreds of thousands of single nucleotide polymorphism (SNPs) have the potential to revolutionize our ability to identify the genetic cause to complex traits. Unfortunately, these studies are inaccessible to most researchers, and indeed, for many complex disorders, due to the exorbitant costs of genotyping hundreds to thousands of cases and controls. We have developed an analysis software program called GenePool to conduct analysis of pooling-based GWA studies. We report the development of experimental methods, study designs, and analysis tools for completing pooling-based GWA studies on various high-throughput SNP genotyping platforms. We describe the implementation of single marker and multi-marker statistics, and demonstrate their ability to resolve association signals. We apply these methods to case-control population populations and demonstrate successful identification of the correct genetic susceptibly locus for a monogenic disease, a rare complex disease, and a common complex disease.

BDNF Val66Met polymorphism in Bipolar Disorder: Genomic Imprinting or Neuronal Miswiring? *V. De Luca, J. Strauss, D.J. Müller, M. Semeralul, A. Wong, J.L. Kennedy* Dept Neurogenetics, Univ Toronto, Toronto, ON, Canada.

Background We reported the Val66Met and the GT(n) repeat polymorphisms of the BDNF gene to be associated with bipolar disorder (BD). However, nobody has investigated the possibility of genomic imprinting in BDNF gene in conferring risk for BD. Aims To investigate genomic imprinting in the BDNF gene for association with BD we investigate the Parent of Origin Effect (POE) and differential allele expression in BD. Method We performed a family-based association study and ETDT analyses with 312 nuclear families including the Val66Met polymorphism. Results Maternal and paternal transmission analysis were both significant (p=0.003 and p=0.006 respectively). The effect size for the Val66 allele was higher in the maternal transmissions (RR=2.1) suggesting the presence of the genomic imprinting. Conclusions This data suggests the possibility of genomic imprinting in BDNF gene, on the other hand the differential allelic expression in post-mortem brains and lymphoblast cells can be conclusive to confirm the genomic imprinting or support the hypothesis that different BDNF messenger RNA transcripts can be localized at different subcellular locations in cortical neurons of bipolar patients.

Identification and characterization of a dynactin associated protein (Dynapsin) involved in late-onset Alzheimer disease (AD). *J.R. Gilbert[1], S. Zuchner[1], C.A. Browning[1], G.F. Wang[1], C.R. Lu[1], P.G. Bronson[1], C.F. Potocky[1], S.M. Garvey[1], C.C. Kroner[1], J.R. Gibson[1], J.M. van der Walt[1], Y.J. Li[1], P.T. Xu[1], D.E. Schmechel[1], W.K. Scott[1], J.M. Vance[1], J.L. Haines[2], E.R. Martin[1], M.A. Pericak-Vance[1]* 1) Duke University, Durham, NC; 2) Vanderbilty University, Nashville, TN.

To date four genes, PS1, PS2, APP and APOE have been shown to be involved in the etiology of AD. Using ordered subset analysis (OSA) we established linkage (MAXLOD=3.8) on chromosome 2q33.3 in 31 multiplex AD families with >1 individual with age at onset of AD between 50-60 years. To prioritize candidate genes in the linkage region, we used genomic convergence integrating our linkage data with SAGE expression analysis derived from AD hippocampus. One novel gene, dynapsin was identified. Genotyping a dense array of SNPs across the linkage region further supported the involvement of dynapsin in AD with significant evidence for association in multiple SNPs (minimum p=0.008) in the gene. The association was strengthened when the sample size was increased to a total of 73 AD pedigrees meeting the OSA criteria for chromosome 2 (minimum p=0.003). Little is known about dynapsin or its functional role in the CNS. We identified up to 8 different cDNA isoforms and analyzed their relative expression levels in AD and control brains. Isoform 7 was more highly expressed and variable in AD brains versus controls. In AD brain sections, dynapsin is found in neurons and importantly, in AD neuritic plaques. We also demonstrated that dynapsin immunoprecipitates with components of the dynein-dynactin motor complex and was localized to cytoplasmic vesicles in a cell culture of Neuro2A cells. We hypothesize that dynapsin is a newly identified linker protein between vesicles and the dynein-dynactin complex and is involved in endosomal trafficking. Axonal transport and synaptic integrity are key elements of the proposed pathways for AD. Our combined genetic, molecular and functional results strongly suggest a role for dynapsin in the etiology of AD and that variation in dynapsin is responsible for at least some of the risk of developing AD in these families.

The African genetic contribution to the Brazilian genetic pool. *C.M.B. Carvalho[1, 2], V.F. Gonçalves[1], H.J. Bandelt[3], S.P. Bydlowski[4], M.C. Bortolini[5], S.D.J. Pena[1]* 1) Dept Biochemistry, UFMG, Brazil; 2) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 3) University of Hamburg, German; 4) Dept. of Hematology, FMUSP; 5) Dept. of Genetics, UFRGS, Brazil.

From 1550 to 1870 approximately four million Africans were brought to Brazil as slaves. Through intense and prolonged interbreeding with Amerindians and Europeans they were an important component in the formation of Brazilian people. We have been studying the details of this process with lineage markers. We have previously shown that while White Brazilians displaying about equal proportions of African, Amerindian and European mtDNA lineages, the vast majority of them carry Y-chromosomes of European origin. This suggested the occurrence of a sexually asymmetric genetic admixture. We have now studied in detail the maternal and paternal lineages from 120 Black males from the city of Sao Paulo, Brazil. Y-chromosome typing was performed hierarchically using biallelic markers. Only 48% of the individuals presented Y-chromosome haplogroups characteristic of sub-Sahara Africans (E1, E2, E3a*, E3a4, E3a7 and B). Sub-lineages E3a* and E3a7 represented 88.3% of the African patrilineages, suggesting a primary Central African origin. Matrilineages were assessed by sequencing of the control region of mtDNA and RFLP typing of the coding region. Eighty five different haplotypes were seen (99.1% diversity). Sub-Saharan African haplotypes were seen in 85% of cases and their careful mapping in Africa again suggested that, consistently with the historical record, Brazilian slaves were predominantly Bantu-speakers from Central-Africa, with a secondary West-African component. The fact that most of the matrilineages, but only 48% of the patrilineages of Brazilian Blacks were from Africa confirms our previous observation of a sexual bias in the formation of the Brazilian people, with a predominant European paternal component and with a majority of matrilineages originating from Amerindian and African women.

Epigenetic factors influence segregation of human artificial chromosomes in cultured mouse cells. *A. Breman, R. Slee, C. Steiner, B. Grimes* Med & Molecular Genetics, IUSM, Indianapolis, IN.

Human artificial chromosomes (ACs) form following transfection of alpha-satellite DNA into human cultured cells. In order to evaluate the potential of human ACs in gene therapy, it will be necessary to incorporate genes into ACs and to test their function in animal models. Towards this goal, we have constructed a human AC (FIXAC) that has assembled a 33kb factor IX (FIX) gene. Factor IX mutations cause Hemophilia B, an inherited bleeding disorder. FIXAC was generated by co-transfection of a 165 kb PAC with an insert spanning the FIX gene and a 99 kb BAC harboring alpha-satellite DNA into human HT1080 cells. FIXAC was detected in most chromosome spreads in 9/21 cell lines and segregated efficiently under non-selective conditions. As a measure of the potential of FIXAC to segregate in mouse cells, FIXAC was transferred into immortal mouse L-A9 cells. In recipient line L1, FIXAC was maintained as an extra chromosome and assembled the mouse centromere protein, cenp-c. However, FIXAC exhibited reduced mitotic stability in L1 cells when cultured without selection (loss rate 2.58%/division). It was hypothesized that only a subset of FIXACs had acquired all necessary epigenetic modifications for mitotic stability, resulting in a high aggregate FIXAC loss rate in L1 cells. To test this possibility, L1 cells were plated at low density to form single colonies. By Southern analysis, the alpha-satellite segments on FIXAC were similar in structure in L1 and in 5 sub-clonal lines, indicating that FIXAC is structurally stable. FIXAC mitotic stability was variable in sub-clonal lines, ranging from 0.67%/division (corresponding to FIXAC retention in 72% of cells after 30 days off selection) up to 2.27%/division. This suggests that epigenetic factors influence FIXAC segregation efficiencies in mouse L-A9 cells. We anticipate that FIXAC will segregate efficiently in primary cells and animals which, unlike L-A9 cells, do not exhibit genomic instability. In future studies we will test the capacity of FIXAC to rescue factor IX deficiency in the mouse.

Complex management of a patient with a contiguous Xp11.4 gene deletion involving the ornithine transcarbamylase gene. *M. Deardorff[1], P. Kaplan[1], J. Ganesh[1], C. Ficicioglu[1], R. Deberardinis[1], M. Yudkoff[1], T. Markello[2], B. Loechelt[3], U. Lichter-Konecki[2]* 1) Section of Metabolic Diseases, The Childrens Hospital of Philadelphia, Philadelphia, PA; 2) Division of Genetics and Metabolism and; 3) Division of Immunology, The Children's National Medical Center, Washington, DC.

A male infant was diagnosed prenatally with a partial Ornithine Transcarbamylase (OTC) deletion secondary to family history. Following an uncomplicated pregnancy, labor and Cesarean section delivery, treatment with protein restriction, appropriate calories and ammonia scavenger drugs was begun within 10 minutes of birth. Postnatal OTC gene analysis confirmed deletion of exons 1-8. He displayed neurological abnormalities despite effective management of serum ammonia (average 34 umol/L, range 1.5-125; lab normals 9-33). He also had hypoalbuminemia (2.1 g/dL) from birth and developed pleural effusions, ascites, and anasarca. Due to features not solely explained by OTC deficiency, further deletion analysis was pursued. PCR analysis of seven genes from Xp11.4-p21.1 (cen-OTC, RPGR, SYTL5, CYBB, PRRG1 and TMEM47, dystrophin-tel) showed OTC exons 9 and 10, and dystrophin exon 3, were present. PCR confirmed the absence of OTC exons 1-8, and the other five genes. RPGR mutations cause retinitis pigmentosa with recurrent respiratory infections (RP3), features reported in the mother. Defects in CYBB cause an X-linked chronic granulomatous disease (CGD), which was clinically proven. SYTL5, PRRG1 and TMEM47 have not been linked to human diseases. Between CYBB and PRRG1 lies the XK (Kell antigen) gene. Defects in XK are the cause of McLeod syndrome, an X-linked disorder with late onset neuromuscular, hematopoietic abnormalities and transfusion complications. CGH array analysis confirmed presence of the dystrophin gene and absence of three anonymous probes in this region. This case illustrates the complex challenges in a contiguous gene syndrome including treatment of a urea cycle disorder (UCD) plus CGD, and potentially RP3 and McLeod syndrome. It also shows the value of detailed evaluations in seemingly isolated gene deletions.

Yeast NDI1 gene improve oxidative phosphorylation capacity and increases protection against oxidative stress in cells carrying a Lebers Hereditary Optic Neuropathy mutation. *Y. Bai, J. Park, Y. Li* Cellular & Structural Biol, Univ Texas Health & Sci Ctr, San Antonio, TX.

Lebers hereditary optic neuropathy (LHON) is a maternally transmitted disease characterized by bilateral loss of central vision with degeneration of retinal ganglion cells. A transition mutation, G to A, at mitochondrial nucleotide 11778 in the ND4 gene of NADH-ubiquinone oxidoreductase is the most common primary mutation found in LHON patients, accounting for more than 50% of LHON cases. The NDI1 gene, which encodes the rotenone-insensitive internal NADH -quinone oxidoreductase in Saccharomyces cerevisiae, was introduced into the nuclear genome of a human cell line, Le1.3.1, carrying the 11778 mutation. Two transformants. LeNDI1-1 and 2 cells were chosen for detail analysis. In these cells, total and complex I-dependent respiration, were largely resistant to complex I inhibitor, rotenone, indicating a dominant role of NDI1 in transfer of electrons from NADH to ubiquinone in the host cells. Whereas the original mutant Le1.3.1 cell grows poorly in medium containing galactose instead of glucose, the LeNDI1-1 and 2 cells have a full restored growth capacity in galactose medium, although the ATP production was not totally recovered. Furthermore, the increased oxidative stress in the cells carrying the 11778 mutation was alleviated in LeNDI1-1 and 2 cells, demonstrated by a decreased reactive oxygen species (ROS) level. Finally, LeNDI1-1 and 2 were also shown to be desensitized to induction to apoptosis, and also exhibited greater resistance to paraquat-induced cell death. It is concluded that the yeast ND11 enzyme can improve the oxidative phosphorylation capacity in cells carrying the 11778 mutation, and it can also protect the mutant cells from oxidative stress and cell death.

Real Time PCR Analysis of Parkin Exon Copy Number Variation in Large a PD and Aged Control Population. *J. Deng, J. Bunch, J. Grimsley, GM. Mayhew, YJ. Li, J. Connelly, SG. Gregory, MA. Hauser, WK. Scott, JM. Vance* Ctr Human Genetics, Duke Univ, Durham, NC.

Parkin is one of the most significant genes identified in which mutations lead to both early- and late-onset forms of Parkinsons Disease (PD). The genomic region in chromosome 6 where Parkin is located is rich in long and short repetitive sequences, which indicates a high level of genomic instability, and is known to have minimal linkage disequilibrium. Various forms of Parkin mutations have been identified in PD patients including point mutations and chromosome aberrations. But few large scale screening studies for PD patients has been made including copy-number evaluations of the Parkin gene, and even less in the control population. Thus, to evaluate exon copy number variation and its potential contribution to the risk and susceptibility to PD, we developed a screening method based on ABI real-time PCR technique. We validated the real-time PCR results using known Parkin exon heterozygous deletions, and XY chromosome mismatches , and utilized other assistant techniques such as denature high performance liquid chromatography (dHPLC) and comparative genomic hybridization (CGH) to evaluate the patients. We screened Parkin exons in over 900 PD patients and 200 unaffected, neurologically-examined older controls, providing a large database to evaluate the occurrence of these changes. We found that real-time PCR correlates well with those of other methods, and is suitable for detection of large genomic deletions in a large sample set. Our preliminary results indicate that there is a higher frequency of exon duplication or deletion in the Parkin gene than that of other regions of the genome in both PD patients and non-PD controls. Further analysis of possible association of the Parkin exon copy number variation with PD and interaction with other susceptibility genes is currently underway.

Clinical and Genetic Phenotype of a Cohort of 34 patients with Micro-Anophthalmia. *P. Bitoun[1], C. Edelson[2], B. Benzacken[3], E. Semina[4], L. Benzacken[5], J.C. Murray[6], J. Gaudelus[7]* 1) Gen Medicine, CHU Paris-Nord, Hopital Jean Verdier, Bondy, France; 2) Fondation Ophtalmologique Rothschild, Ophtalmopédiatrie, Paris; 3) Embryo-Cytogénétique et Biologie de la Reproduction,Hosp Jean Verdier, Bondy; 4) Molecular Genetics, Medical College of Wisconsin, Milwaukee; 5) Hopital Robert Ballanger, Ophtalmologie ,Aulnay s/b 93; 6) Pediatrics & Biological Sciences , University of Iowa, Iowa City; 7) Pédiatrie, Hopital Jean Verdier, Bondy.

Purpose : to study the clinical phenotype and genetic causes of a cohort of 34 consecutive patients with congenital micro/anophthalmia (MA) Material and Methods: Patients where assessed by a pediatric ophthalmologist and an ophthalmic geneticist to define the ocular and extra ocular dysmorphogy phenotype. Brain MRI , karyotype, telomeric screen and CGH array were performed in some patients. Gene mutation analysis were performed by PCR and sequencing and are still ongoing for several genes including PITX2, PITX3, OTX2, SOX2, BCOR, ND, NHS, LRP5, SIX6 and PAX6. Results: The cohort was divided into primary and secondary MA (post infectious, post-surgical, post retinal detachment or post-phthisis) The cohort is comprised of 34 patients 2 months to 38 years (average 7.9 y), 10 (29%) females and 24 (61%) males. 25 patients (74%) had primary MA and 9 (26%) had secondary MA. Primary MA had 36% female while the Secondary had 11% females . Blindness affected 15/25 (60%) patients with primary MA versus 3/9 (33%) with secondary MA. Patients were classified as ocular alone in 10/25 (40%) of primary MA versus 7/9 (78%) with secondary MA or syndromic in 60% of primary MA versus 22% of the secondary MA patients. MA was unilateral in 3/25 (12%) of primary MA and in 5/9 (55%) of secondary MA patients. 2/25 patients with primary MA died and none of the 9 patients with secondary MA. Genetic evaluation showed 11 patients had a familial case (66%) of secondary MA and 20% of Primary MA. Discussion: The excess of males and the paucity of X linked genes involved with primary MA seems to imply that most of the X linked genes involved with MA are still to be uncovered.

X chromosome investigations in X-linked infantile spinal muscular atrophy (*XL-SMA*): New observations and new strategies. *L. Baumbach[1], J. Ramser[2], M.E. Ahearn[1], K.O. Yariz[1], C. Lenski[2], M.M. Barmada[3], A. Meindl[2]* 1) Miller Sch Med, Univ. Miami, Miami, FL; 2) Gynaekologische Tumorgenetik Ismaningerstr, Munchen, Germany; 3) Univ. Pittsburg Grad Sch Public Health, Pittsburg, PA.

We previously reported an X-linked form of infantile lethal motor neuron disease (MIM 30021), which clinically mimics Werdnig-Hoffman disease, with additional features of early onset or congenital contractures/fractures, in a single family that mapped to Xp11.3-q11.2. We have identified 14 unrelated families. Major and minor clinical features have been defined. Seven families have been tested for X-chromosome linkage; each maps to the same region as the first family. Multipoint linkage has narrowed the disease gene interval to between DXS8080-DXS7132. These results strongly support the existence of a major disease locus in this region. Our studies in the past two years have focused in four areas: 1)further narrowing the candidate gene interval using microsatellites and SNPs; 2)mutation screening of all known cDNAs in the region, 3)searching for small chromosomal duplications or deletions using comparative genomic hybridization arrays; and 4)X-inactivation analysis. CGH studies have not detected a chromosome alteration; however, one *XL-SMA* family evidences strongly skewed X-inactivation of the X chromosome containing the presumed disease gene. We are now focusing on new avenues of investigation for gene discovery. SNP analysis using the Affymetrix SNP chip in selected *XL-SMA* families; Fiber FISH to rule out a large pericentromeric inversion; and further investigation of the skewed X-inactivation family. We are also screening for mutations or alterations in expression of microRNA sequences encoded within the region. Lastly, we are beginning to examine SMN and gemin protein/mRNA levels in cell lines from *XL-SMA*, SMA and control subjects, to determine if the SMN/gemin pathway is implicated in *XL-SMA*. We have demonstrated strong evidence for an X-linked form of infantile SMA with a single disease locus. Our data suggest that *XL-SMA* may not be as rare as previously assumed, and patients negative for SMN mutations might be affected by *XL-SMA*.

Broad Institute Genetic Analysis Platform Utilizing Illumina BeadLab Technology. *S. Gupta, J. Moore, A. Camargo, M. Hagar, N. Beattie, Y. Hoshida, M. Nizzari, T.R. Golub, S.B. Gabriel* Genetic Analysis Platform, Broad Institute , Cambridge, MA.

High throughput, high quality, flexible and affordable genotyping platforms are needed to accomplish wide-ranging goals of todays genetic studies. As a national center for genotyping the Broad Institute has integrated three different platforms for SNP genotyping, each suited to different study designs. Genome-wide analysis is carried out on the Affymetrix and Illumina platforms; targeted SNP genotyping for large numbers of selected SNPs is conducted on the Illumina platform (hundreds-thousands of SNPs) or Sequenom platform (fewer than hundreds of SNPs). Here we present our experience specifically with the Illumina platform for a diverse set of genotyping projects. In total we have designed in excess of 100,000 custom assays for SNP genotyping, as part of the Hap Map and a range of disease mapping projects. Assay conversion rates on average exceed 90%. We have implemented rigorous DNA sample quality control measures from sample intake and observe a sample failure rate less than 0.5%. In addition, the oligo-ligation based genotyping assay has been extended to analyze gene expression, specifically targeting formalin-fixed paraffin-embedded (FFPE) tissue samples that have not yielded to standard microarray analysis. Because the assay targets short segments of DNA degraded samples, degradation in FFPE samples can be surmounted. We have developed a panel for 6,000 cancer related genes and demonstrated that it can be used for sample clustering and marker gene analysis on samples over 20 years old. Finally, early experience with the new genome-wide genotyping products shows excellent data quality with high accuracy (>99.5%) and call rates exceeding 99%.

Fetal acrania associated with cardiac defects. *D. Albu, E. Severin, C. Albu* Dept Human Genetics, Carol Davila Univ Med & Pharm, Bucharest, Romania.

Background: Acrania is a lethal cranial abnormality characterized by complete absence of the skull, with complete but abnormal development of the cerebral hemispheres. It can occur isolated or associated with other fetal abnormalities.**Objectives:**To specify the role of 3D ultrasonography as a screening tool for the early prenatal detection of acrania; to describe and analyze the severity of congenital malformations associated with acrania. **Patient:**A 24-year-old pregnant Caucasian female was referred at 37 weeks gestation for prenatal ultrasound diagnosis. The patient was send to our department for evaluation of fetal abnormalities.The patient and her husband were not genetically related and had a normal general health. The family had a low socioeconomic status.**Methods:**: The patient was examined with Color Doppler and 3D system. Fetal evaluation was made by ultrasound scans for fetal growth, congenital malformations, and amniotic fluid volume. Triple test (AFP,uE3, hCG) was used too. We also collected information about family medical history. Amniotic fluid samples were taken to perform prenatal cytogenetic diagnosis.**Results:**The patients obstetrics history revealed one previous miscarriage in the second trimester (unknown causes).Her second pregnancy was evaluated late, at the 37th gestation week. Ultrasonography revealed a singleton pregnancy with growth deficiency, absence of the skull bones, development abnormalities of cerebral hemispheres, dilatation of ventricles, absent cerebellum, cardiac defects, truncus arteriosus communis, anomalies of the aortic arch, abnormal abdominal wall and skeletal defects.Lymphocytes from both parents blood were analyzed for chromosomal abnormalities and showed normal karyotype for the father (46, XY) and chromosome instability for the mother. The maternal serum tests were positive. Fetal chromosomal analysis showed a deletion of 11q and chromosome instability.**Conclusions:**acrania was correctly identified at the first scan; prenatal diagnosis was confirmed postnatally;genetic counseling and early evaluation based on both 3D ultrasonography and cytogenetic analysis should be considered for the next pregnancy.

A set of putative functional IDE and PLAU variants shows significant, replicable association with Alzheimers Disease. *M. Carrasquillo[1], S. Younkin[1], M. Kashino[1], S. Wilcox[1], T. Dincman[1], L. Younkin[1], L. Ma[1], F. Zou[1], N. Taner[1,2], M. Allen[1], R. Petersen[2], N. Graff-Radford[1], S. Younkin[1]* 1) Mayo Clinic, Jacksonville, FL; 2) Mayo Clinic, Rochester, MN.

In IDE and PLAU, which are excellent positional and functional candidate genes for late onset Alzheimers Disease (LOAD), conserved regions (>70% human vs. mouse) were screened for variants likely to be functional. Using logistic regression, conserved IDE variants were tested for association with AD in three large case/control series. Six conserved variants in non-coding regions formed 4 haplotypes with frequencies over 1%: three were protective, one was risky. In the young age group where association was strongest, these 4 haplotypes showed the same significant association with AD in the exploratory (nominal global p = 0.010) and two follow-up series (global p = 0.013 and 0.007). The three protective haplotypes (H2, H3, H4) pair to form 6 genotypes likely to be protective. These were used as a referent group and compared to the four remaining common genotypes (H1/H1, H1/H2, H1/H3, H1/H4). Three genotypes were equivalently risky, one (H1/H4) was indistinguishable from the referent group, and they showed the same significant association with AD in the exploratory (nominal global p = 0.005) and two follow up series (global p = 0.002 and 0.004). Compared to the set of 7 protective genotypes (16%), the combined set of 3 risky IDE genotypes (84%) had ORs of 4.1, 4.3, and 2.6 in the three series (p = 0.0004, 0.0005, and 0.0015). In the combined series, the OR was 3.2 (2.1-5.0) for the set of risky genotypes compared to the set of 7 protective genotypes with a p-value of 6.5x10-8 and a PAR of 65% (48% - 77%). Importantly, we observed a significant 1.5-fold elevation of IDE mRNA in the cerebella of 140 subjects with protective genotypes as compared to 22 subjects with risky genotypes (p=0.005). These results indicate that IDE is likely to be an important LOAD gene with variants that influence risk of AD by altering IDE expression. Similar analysis of variants in conserved regions of PLAU showed that multivariate PLAU haplotypes and genotypes also show significant association with LOAD.

Isolated renal transplantation in an adult with cobalamin-responsive methylmalonic acidemia. *A. Gropman[1], K. O'Brien[2], J. Sloan[3], C.P. Venditti[3]* 1) Dept Pediatrics, Georgetown Univ Medical Ctr, Washington, DC; 2) MGB, NHGRI, NIH, Bethesda, MD; 3) GDRB, NHGRI, NIH, Bethesda, MD.

Solid organ transplantation has been used as a therapeutic modality in methymalonic acidemia but the nature and indication for transplantation as well as the number of transplant recipients is unknown. We describe a 33 yr old female with vitamin B12-responsive methylmalonic acidemia who underwent kidney transplantation for renal failure. The patient presented in the first year of life with a poorly defined renal tubular acidosis syndrome and had intermittent decompensations during the first few years of life before the diagnosis of was established at age 8. Her renal function declined over the next decade and she progressed to needing hemodialysis at the age of 24. At age 31, she received a cadaveric renal allograft and has been stable from a renal perspective since that time. She had intermittent compliance with her medical regimen - which consisted of IM OH-cobalamin and carnitine - after transplantation but has maintained a low protein diet of ~0.6 g/kd/d of whole protein. She had not received cobalamin for more than one-year prior to her visit. Evaluation at our center demonstrated plasma MMA levels in the 135-223 uM range (normal= <0.4 uM) with a urinary MMA concentration of the 223 mg/g/Cr (normal=<3 mg/g/Cr). The amino acid profiles showed elevated glycine, alanine, glutamine, and proline suggestive of inadequate metabolic control. The plasma B12 level was in the normal range at 288 pg/ml ([normal range: 220-960 pg/ml]). Cobalamin-responsiveness was determined by injecting 2 mg OH-cobalamin IM twice over a two-day period, waiting one day and reassessing metabolic parameters. After injection, plasma B12 levels rose to >200,000 pg/ml. Metabolic studies revealed a 10-fold drop in the plasma (19 uM) and urinary MMA concentrations (18 mg/g/Cr). We conclude that cobalamin therapy and dietary management are still required after solid organ transplantation, even in patients who have milder MMA syndromes, and that renal transplantation by itself does not normalize metabolism in B-12 responsive patients.

Development of A Coordinated Approach to Experimental Design and Analysis. *K.P. Clancy[1], M. Duan[2], J. Yen[2], F. Liang[2]* 1) Bioinformatic Sciences, Invitrogen Corp, Frederick, MD; 2) Bioinformatic Sciences, Invitrogen Corp, Carlsbad CA.

With modern genomics, scientists now examine groups or families of genes rather single genes, and need a more coordinated approach to experimental design. Software and databases that manage the relationships between biological data, reagent applications and resultant data, and protocols facilitates experimental planning and helps scientists coordinate performancing and reporting more complex experimental methodologies. We developed a Matched Reagents database, by linking NCBI RefSeq genes and gene products to associated designed reagents. Methods to detect ongoing changes to RefSeq records that affect pre-designed reagents were incorporated to manage the transient nature of this data. Genes were associated with GeneGO data to incorporate pathway data and other public data, including dbSNP, OMIM and others were included. A web tool, iPath, was developed to browse and evaluate the pathways and genes in this database for biological context and applicable technologies. Genes and experimental reagents were then coordinated with experimental technologies using more than a quarter of the protocols from the Wiley Current Protocols series and the entire Invitrogen product protocol collection. Protocols were parsed as a series of XML documents and entities that corresponded to experimental reagents were identified, marked up, and updated in the Matched Reagents database in a vendor neutral fashion. Bioinformatic tools needed for design of reagents were identified and incorporated. iProtocol, a second web based tool, was developed to permit the browsing and identification of protocols and associated reagents. This is a generalizable approach to coordinating the activities and reagents of groups of laboratories. The database has increased our efficiency for targeting genes with appropriate ranges of technologies. This database currently coordinates 65,000 genes with > 430,000 individual Invitrogen products and > 1,500,000 competitor products. Such a database approach can form the basis of a more complex system for automated or semi automated experimental design softwares.

Chromosome Rings/Markers as a Model to Determine Rearrangement Mechanisms. *C. Fitzpatrick[1], L. Christ[2], C. Crowe[3], M. Graf[4], S. Schwartz[1]* 1) University of Chicago; 2) Case Western Reserve University; 3) Metro Heath Medical Ctr, Cleveland OH; 4) TGen, Pheonix AZ.

The underlying mechanisms of chromosome rearrangements and how they translate to disease phenotypes have recently begun to be discovered. Genomic architecture can predispose a chromosomal region to rearrangement and can be an important tool in understanding how such rearrangements occur. From a collaborative study of marker chromosomes, we have ascertained 172 marker/ring chromosomes as well as 17 constitutional ring chromosomes (i.e. the abnormal complement of one normal chromosome). The pattern of chromosomal involvement of accessory rings shows no specific chromosomal predominance. However, the pattern identified among constitutional rings shows a clear over-representation of chromosomes 9, 18, and all acrocentric chromosomes. Because few studies have been reported that examine the structure of either type of ring chromosome, we have expanded our initial analysis on a subgroup of the marker/rings to include breakpoint analysis using BACs, fosmids and real time PCR in an attempt to better understand the mechanism of formation. Analysis of three constitutional rings derived from chromosome 9 has revealed that all breakpoints involved are unique with the exception of two out of three rings having an intact subtelomeric region. Likewise, analyses of three marker rings derived from chromosome 17 also contain different breakpoints, all of which were facilitated by low copy repeats (LCRs). This study demonstrates several important findings regarding ring and marker chromosomes: (1) There are specific chromosome preferences in constitutional ring chromosomes, due either to an associated phenotype or the inherent chromosome structure (2) both types of ring chromosomes exhibit breakpoint heterogeneity and (3) the vast majority of breakpoints appear to be facilitated by at least one repetitive region of DNA: LCRs and pericentromeric repeats in the case of chromosome 17, subtelomeric regions in chromosome 9 and the acrocentric short arm regions. These results suggest that the underlying mechanism involved may be more complex than the classic model of homologous recombination.

Identification of a gene expression signature and an increased plasticity in periosteal fibroblasts from Apert syndrome patients. *R. Fanganiello[1], A.L. Sertie[1], N. Oliveira[1], E.M. Reis[2], E. Yeh[1], D. Bueno[1], N. Alonso[4], S. Cavalheiro[3], I. Kerkis[5], S. Verjovski-Almeida[2], M.R. Passos-Bueno[1]* 1) CEGH-IBUSP, Brazil; 2) IQ-USP, Brazil; 3) UNIFESP, Brazil; 4) FM-USP, Brazil; 5) Inst. Butanta, Brazil.

FGF-FGFR signaling is critical in skeletal growth and development. One of the most severe forms of craniosynostosis is Apert syndrome (AS), caused by mutations in *FGFR2*. The signaling pathways activated by FGFR2 are responsible for the processes of cell growth and differentiation at the sutural margins and alterations in these pathways can lead to the premature fusion of these margins. To better understand the signaling pathways and transcription factor networks unchained by FGFR2 activation we investigated, through oligonucleotide microarray technology (Codelink system), the gene expression of the coronal suture periosteum fibroblasts of seven AS patients (S252W mutation) and compared them to those of seven wild type cultured periosteal fibroblasts. We found changes (1.8 fold difference) in the expression profile of 271 genes with a SNR|0.4| and pvalue0.05. Among this group, 63 and 17 genes were found to be diferentially expressed in at least 50% and 100%, respectively, of the 14 groups of genes generated using a leave-one-out statistical procedure, with a SNR|0.75|. In accordance to these data, 6 genes were found differentially expressed between control and mutant cells in quantitative Real Time PCR experiments. This data were also confirmed by an independent experiment where primary cultured control periosteal fibroblasts were treated with high concentration of FGF2, used to simulate the phosphorylation status of mutant *FGFR2*. Furthermore the periosteum cells of one AS patient and one control were submitted to bone differentiation protocols, and surprisingly, only the AS cells were able to differentiate into osteoblasts. This data lead to the identification of an expression profile signature involved in the molecular mechanisms of AS. In addition, our results suggest that the *FGFR2* mutation lead to an increased cell plasticity. CEPID / FAPESP; CNPq robertofanganiello@yahoo.com.

Population screening for fragile X syndrome and sex chromosome aneuploidies by quantification of methylated FMR1 DNA. *B. Coffee[1], I. Albizua[1], M. Friez[2], R. Stevenson[2], S.T. Warren[1]* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Greenwood Genetics Center, Greenwood, SC.

The vast majority of fragile X syndrome is due to aberrant changes in chromatin structure, as a consequence of CGG repeat expansion, that silences expression of the FMR1 gene. One of the epigenetic changes concomitant with CGG repeat expansion is DNA methylation. We have developed a rapid high-throughput quantitative methylation sensitive PCR method to assess FMR1 methylation in DNA from dried blood spots to screen for fragile X syndrome. In addition, this screen will detect sex chromosome aneuploidies when there is a deviation from the expected FMR1 DNA methylation pattern. Detection of methylated FMR1 DNA in males would be consistent with either fragile X, Klinefelter Syndrome (or its variants), or 46,XX males. In females, absence of methylated FMR1 DNA would be consistent with Turner Syndrome or 46,XY females. An increase in FMR1 DNA methylation would be consistent with either fragile X, 47,XXX and its variants. The Q-MSP method is very sensitive and easily detects low levels of methylated FMR1 DNA. The sensitivity of the assay allows for the detection of mosaic fragile X and Klinefelter Syndromes. In addition, the sensitivity allows for the pooling of male samples into large groups, permitting the simultaneous screening of up to one hundred males in a single experiment. To determine if Q-MSP can be used to screen for fragile X syndrome in females, we screened a cohort of full mutation carrier females. Greater than 80% had a FMR1 DNA methylation index greater than 2 SD above the mean normal FMR1 methylation index. In summary, the Q-MSP method can be used for population screening for fragile X syndrome and sex chromosome aneuploidies in a single assay by detection and quantification of methylated FMR1 DNA.

A Novel Multivariate Method for the Analysis of Psychometric and Genotype Data. *T.A. Greenwood[1,2], L.M. Evans[1], S.G. Liang[1], J.R. Kelsoe[1], N.J. Schork[1,2]* 1) Department of Psychiatry, University of California, San Diego, La Jolla, CA; 2) Center for Human Genetics and Genomics, University of California, San Diego, La Jolla, CA.

Novel statistical methods are needed to model the complex interaction of personality and genetics. Traditional strategies that condense psychological exam or psychometric data (e.g., translating items on a questionnaire into global scales) do not take full advantage of the data. We describe a method for testing the relationship between variation in a similarity matrix constructed from items on a psychometric exam and ancillary information, such as genotypes, collected on a sample of individuals. This procedure does not rely on data reduction strategies, such as factor or cluster analysis. This method is also the perfect companion for heat map and tree-based representations of the item data as organized by some feature or grouping factor (e.g., genotypes) meant to reveal the relationship between the items. We have applied this method to a sample of bipolar subjects that have genotypic data for 160 SNPs within a 2.8Mb region on chromosome 22. These subjects have also completed the Cloninger Temperament and Character Inventory (TCI) and Akiskals TEMPS-A. The TCI distinguishes four dimensions of temperament (harm avoidance, novelty seeking, reward dependence, and persistence) and three dimensions of character (self-directedness, cooperativeness, and self-transcendence). The TEMPS-A assesses four types of temperament, hyperthymia, dysthymia, cyclothymia, and irritability, and includes a measure of anxiety. Using this technique, we have identified a number of associations. We also compare our method with other methods.

Hierarchical Modeling in Linkage Disequilibrium Mapping. *G. Chen, E. Jorgenson, J. Witte* Institute for Human Genetics, UCSF, San Francisco, CA.

The completion of the HapMap project and advances in high-throughput genotyping methods has made feasible genome-wide association (GWA) studies. Such studies generally evaluate the relationship between hundreds of thousands of single nucleotide polymorphisms (SNPs) and one or more phenotypes. A critical unresolved issue in GWAs is how to analyze the enormous amount of information generated in a manner that is most likely to detect causal variants. The conventional analysis approach entails estimating the association between each SNP (or multiple SNPs) and a phenotype, and then using the corresponding p-values to prioritize the results. This approach, however, ignores existing information about the SNPs, can lead to spurious results as well as suffer from low power. To address these issues, we propose here a hierarchical model: adding a prior model that incorporates known information about the SNPs into a conventional analysis. In particular, we develop a hierarchical model that uses the following information on the SNPs: 1) potential functionality; 2) whether non-synonymous; 3) evolutionary conservation; 4) previously associated or in linkage region; 5) LD with neighboring SNPs. We show empirically how integrating this information in a hierarchical model may improve the ability of GWAs to determine the location of causal variants.

Translocation of neo(20qter->q13.2) to 22qter detected in prenatal diagnosis samples. *R.E. Falk[1], D.L. Van Dyke[2], R.G. Meyer[2], R.A. Mota[2], D. Krakow[1], R.R. Schreck[1]* 1) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Cytogenetics Laboratory, Mayo Clinic, Rochester, MN.

A healthy 40-year old G2P1 woman presented for CVS at 11+4 weeks of gestation. Cytogenetic analysis of cultured villi showed mosaicism with additional material at distal 22q [specifically, add(22)(q13)] in seven of 22 cells. FISH with a probe set for the TUPLE1 and ARSA sequences showed normal number and orientation of the signals. A whole chromosome 22 painting probe, which was used to investigate the possibility of an inverted duplication of chromosome 22 versus origin from of the extra material from a different chromosome, failed to hybridize to the add(22)(q13) segment. The couple was counseled regarding the high likelihood of confined placental mosaicism. However, evaluation of amniocytes confirmed mosaicism with the add(22)(q13) in 15 of 18 colonies. Multicolor-FISH (M-FISH) showed hybridization of the wcp20 to the add(22)(q13) region. Confirmation studies with subtelomeric FISH probes for chromosomes 20 and 22 showed a normal signal pattern on each chromosome 20 and on the normal chromosome 22. The add(22) showed a 22qter signal proximal to the added segment, a 20qter signal immediately distal to the 22q subtelomeric probe signal and a second 20qter signal at the terminal end of the add(22) segment. Correlation of the FISH and G-banding patterns suggested that the additional material on chromosome 22 represented an inverted duplication of the region 20q13.2 to 20qter. Hence, the abnormal cells had four copies (partial tetrasomy) of distal 20q. Fetal ultrasound assessment showed a flat midface, absent nasal bone, abnormal ear shape/position, possible mild tricuspid regurgitation, echogenic bowel, generally decreased muscle tone, clenched hands and mild unilateral equinovarus foot position. Limited fetal evaluation after pregnancy termination confirmed strikingly dysmorphic facies and abnormal foot position. Tetrasomy of distal 20q is extremely rare. One possible etiologic mechanism of this abnormality is formation of a neochromosome 20q that subsequently attached to distal 22q.

Comprehensive linkage disequilibrium mapping of schizophrenia candidate genes in a large European-ancestry sample. *J. Duan[1], M. Martinez[2], A.R. Sanders[1], G. Burrell[1], C. Hou[1], D. He[1], D. Schwartz[1], N.G. Buccola[3], B.J. Mowry[4], R. Freedman[5], F. Amin[6], D.W. Black[7], J.M. Silverman[8], W.F. Byerley[9], R.R. Crowe[7], C.R. Cloninger[10], D.F. Levinson[11], P.V. Gejman[1]* 1) ENH & Northwestern Univ, Evanston, IL; 2) INSERM, Toulouse, France; 3) LSU Health Sciences Center, New Orleans, LA; 4) QCSR and University of Queensland, Brisbane, Australia; 5) Univ. of Colorado Health Sciences Center , Denver, CO; 6) Atlanta VA Med Ctr & Emory Univ, Atlanta, GA; 7) Univ. of Iowa, Iowa City, IA; 8) Mt. Sinai School of Medicine, New York, NY; 9) UCSF, San Francisco, CA; 10) Washington University, St. Louis, MO; 11) Stanford Univ, Palo Alto, CA.

Linkage, association and cytogenetic data have nominated plausible schizophrenia (SZ) candidate genes, but replication studies have produced mixed results, and there is no definitive evidence for a DNA sequence with an identifiable pathogenic mechanism. We have studied 14 SZ candidate genes (AKT1, ARVCF, CHRNA7, COMT, DAOA, DISC1, DRD2, DTNBP1, HTR2A, NRG1, PPP3CC, RGS4, and the STX7-TAAR6 gene cluster) in a European-ancestry sample of 1,673 cases with final diagnoses of SZ or schizoaffective disorder and 2,146 controls (screened by self-report to exclude those with possible psychotic or bipolar disorders). We used SNPlex and Taqman methods to genotype comprehensive maps of each gene (800 SNPs in 2.2 Mb of sequence) consisting of a framework of HapMap SNPs to tag common variation and additional SNPs that had been reported as associated to SZ, or are missense or within functional elements; and 187 ancestry-informative markers (AIMs) for continental populations, analyzed in relation to self-reported ancestry. We achieved high call rates and low error rates. Analysis of AIMs demonstrated minimal case-control allele frequency differences. We have analyzed 118 SNPs in ARVCF, COMT, DRD2 (Ser311Cys), HTR2A, NRG1 (core SNP haplotype), and TAAR6. We observed nominal p-values <0.05 for SNPs located in HTR2A, NRG1 and TAAR6. Interpretation of the findings will require completion of analyses of the remaining genes and of empirical gene- and experiment-wise p-values, as well as further analyses of possible population substructure.

GALNT3 mutations cause familial tumoral calcinosis by decreasing intact FGF23. *H.J. Garringer[1], H. Boztepe[3], R. Tankakol[3], S.M.J. Mortazavi[2], F. Esteghamat[2], M. Malekpour[2], K.E. White[1]* 1) Med & Mol Gen, IUSM, Indianapolis, IN; 2) Imam Khomeini Univ Hosp, Tehran, Iran; 3) Istanbul Univ, Istanbul, Turkey.

Phosphate homeostasis, required for normal bone development and maintenance, is dependent upon complex endocrine interactions. Disruption of these regulatory pathways disturbs serum phosphate levels, and leads to disorders such as familial tumoral calcinosis (TC). TC is characterized by high serum phosphate concentrations, severe ectopic calcifications, and results from mutations in either fibroblast growth factor-23 (FGF23) or GalNac transferase-3 (GALNT3). FGF23 is critical in the regulation of renal reabsorption of phosphate, however the molecular pathogenesis of TC is unknown. TC patients with FGF23 mutations have low/low-normal serum levels of biologically active FGF23 when analyzed with an ELISA specific for full length FGF23 protein. In contrast, these patients have markedly elevated serum levels when assessed with an ELISA that recognizes intact FGF23 as well as C-terminal fragments. GALNT3 initiates O-glycosylation of proteins within the Golgi. Mature FGF23 requires O-glycosylation, thus, we hypothesized that mutations in GALNT3 cause TC via decreasing serum levels of active FGF23 protein. Herein we identified novel TC mutations in GALNT3: a nonsense mutation (W487X), and a frameshift mutation (S368fsX375) that result in severely truncated GALNT3 protein products. To determine the molecular etiology of TC in these GALNT3-null patients, we analyzed serum levels of FGF23. In this regard, mean serum intact levels of FGF23 were low-normal whereas the C-terminal FGF23 concentrations were 20 fold the normal mean, thus the serum FGF23 profile of these patients with GALNT3 mutations is similar to the serum profile of TC patients with FGF23 mutations. In summary, our findings demonstrate that decreased serum levels of intact, active FGF23 protein lead to the TC phenotype, and the inability to produce sufficient amounts of biologically active FGF23 is a result of loss of function mutations in either FGF23 or in GALNT3. Thus, due to improper processing of FGF23 in GALNT3-TC patients, we conclude that GALNT3 has a critical regulatory role on FGF23 glycosylation and production.

A Parkinson's Disease Mutation genotyping Array for the parkin Gene. *L. Clark[1], E. Haamer[2], H. Mejia-Santana[3], J. Harris[4], S. Lesage[5], A. Durr[5], S. Janin[5], K. Hedrich[6], E.D. Louis[3,4], L.J. Cote[3,4], H. Andrews[4], C. Waters[4], B. Ford[4], S. Frucht[4], W. Scott[7], C. Klein[7], A. Brice[5,8], H. Roomere[2], R. Ottman[9], K. Marder[3,4]* 1) Dept Pathology & Taub Inst, Columbia Univ, New York, NY; 2) Asper Biotech, Tartu, Estonia; 3) Gertrude H. Sergievsky Center, Columbia Univ, New York, NY; 4) College of Physicians and Surgeons, Columbia Univ, New York, NY; 5) INSERM U679, Neurology and Experimental Therapeutics; 6) Department of Neurology, University of Lübeck, Lübeck, Germany; 7) Duke University Medical Center, Durham, NC; 8) Hôpital de la Pitié-Salpêtrière, AP-HP, Paris; 9) NYS Psychiatric Institute, Columbia Univ, New York, NY.

Parkin mutations account for the majority of familial and sporadic early-onset Parkinson's Disease (EOPD) cases with a known genetic association. In both cases, >100 mutations have been described in the parkin gene, many of which are recurrent and have been observed in different ethnic groups. We have designed a parkin genotyping array (PGA) that includes published parkin sequence variants and allows their simultaneous detection. The PGA (gene chip) was constructed by arrayed primer extension technology (APEX). A total of 132 DNA samples, 85 PD cases and 47 controls, previously screened for parkin mutations were used to validate the parkin array. We tested the sensitivity and specificity of the parkin genotyping array as a mutation screening method for the detection of 65 different mutations. Investigators at AsperBiotech performed analysis blind to the mutation status of subjects. Excluding whole exon deletions and duplications, the array detected all disease-associated alleles in PD cases and all parkin SNPs that were included on the chip. We envision several potential uses for the chip. 1) In mutation screening of the parkin gene when used in combination with DHPLC and semi-quantitative PCR to ensure detection of all mutations and 2) As a mutation screening tool for recurrent mutations and risk alleles in epidemiological studies. In summary, the genotyping array is an efficient screening tool for detection of known mutations and may be developed to simultaneously capture genetic information in several genes at once.

Acute in vivo exposition to curcumin and copper by means of comet assay. *A. Corona-Rivera[1,4], P. Urbina-Cano[1], L. Bobadilla-Morales[1], M.A. Ramírez-Herrera[2], M.L. Mendoza-Magaña[2], P. Díaz-Ezquivel[3], R. Troyo-Sanromán[1], J.R. Corona-Rivera[1]* 1) Laboratorio de Citogenética y Genotoxicidad, Instituto de genética Humana Dr. ECR, Dep. Biol. Mol. and Genomics, CUCS, University of Guadalajara. Guadalajara, Jalisco, Mexico; 2) Laboratorio de Neurofisiología, Dep.de Fisiología, CUCS, University of Guadalajara. Guadalajara, Jalisco, Mexico; 3) Bioterio, Dep.de Fisiología, CUCS, University of Guadalajara. Guadalajara, Jalisco, Mexico; 4) Unidad de Citogenética, OPD, Hospital Civil de Guadalajara.

Curcumin is a phytochemical extracted from Curcuma longa L, with anti-inflammatory, antioxidant and anti-carcinogenic properties. In vivo studies, indicate that curcumin is not genotoxic and even genoprotective, mainly due to its antioxidant activity. Curcumin had also showed a pro-oxidant effect in the presence of copper causing DNA breaks. The aim of the present study was to study the effect of in vivo exposition to curcumin in the presence of increasing concentrations of copper on DNA by means of comet assay. Eight groups with six BALB/c mice randomly distributed were set under the following administration scheme: control no-treated group, copper 65ppm, copper 130ppm, copper 390ppm, curcumin 0.2%, curcumin 0.2%+copper 65ppm, curcumin 0.2% +130ppm, curcumin + 390ppm. Blood samples were obtained after 48hr and processed to perform the comet assay. We used whole blood on two layers of agarose per microgel and dehydration to be storaged until observation and propidium iodide stained. Tail length was measured in m from fifty nucleoids in triplicate. The in vivo exposition to curcumin for 48 hr did not cause genomic damage. Copper 390ppm was genotoxic. DNA damage increased (163%) for copper 390ppm exposition. While curcumin in the presence of copper 390ppm showed a decrease of DNA damage. It was also evident that curcumin did not induced DNA damage alone or in combination with copper. We agreed with other studies that the differences observed for in vivo exposition is related with complexes interactions, that decreases the blood and tissue concentration until excretion. Curcumin protected against DNA damage induced by copper 390ppm, showing a genoprotector effect.

Inhibition of proteasome and SGG/GSK3 kinase prevents clearance of phosphorylated tau in *Drosophila*. *O. Blard, T. Frebourg, D. Campion, M. Lecourtois* Inserm U614, Faculty of Medicine, Rouen, France.

Tauopathies, including Alzheimers disease (AD), are a group of neurodegenerative disorders characterized by the presence of intraneuronal filamentous inclusions of abnormally phosphorylated tau protein. In AD brains, it has been shown that the level of abnormally phosphorylated tau is higher than in age-matched control brains, suggesting that abnormally phosphorylated tau is resistant to degradation. Using a *Drosophila* model of tauopathy, we studied the relationship between tau phosphorylation and degradation. We showed that *in vivo* reduction of proteasome activity results in an accumulation of high molecular weight forms of hyperphosphorylated tau. We also found that GSK3-mediated hyperphosphorylated forms of tau are degradable by the proteasomal machinery. Unexpectedly, GSK3 inactivation resulted into a massive accumulation of high molecular weight species consisting of hyperphosphorylated tau. This results suggests that, depending on the kinase(s) involved, tau phosphorylation state affects its degradation differently. We thus propose a model for tauopathies whereby, depending on toxic challenges (e.g. oxidative stress, exposure to amyloid peptide, etc.), abnormal phosphorylation of tau by kinases distinct from GSK3 leads to progressive accumulation of hyperphosphorylated tau oligomers that are resistant to degradation.

Investigating *HOX* genes as autism susceptibility loci using an integrative approach of comparative genomics and genetic analysis. *N. Gharani, R.A. Zimmerman, B.J. Smith, S. Murray, J. Raincrow, C-H. Chiu* Dept Genetics, Rutgers Univ, Piscataway, NJ.

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder with a complex genetic basis. Homeodomain proteins are key regulators of early embryonic development and some members play a critical role in the specification of discrete regions of the central nervous system. We previously demonstrated that the homeodomain transcription factor engrailed 2 (*EN2*) is associated with ASD. The aim of this study was to investigate members of the *HOX* homeodomain gene family, encoded within the four *HOX* gene clusters (*HOXA-HOXD*), as ASD susceptibility loci using association methods and 167 families (n=753) from the autism genetic resource exchange (AGRE). Each of the 4 *HOX* gene clusters, including 5 and 3 flanking sequences cover >300kb of DNA and contain many hundreds of single nucleotide polymorphisms (SNPs). We have taken an integrative approach that combines comparative genomics with linkage disequilibrium (LD) map data to select and prioritize a subset of informative tagSNPs for further analysis. Here we illustrate this approach and present data for the analysis of the *HOXA* cluster on chromosome 7p15. Comparative genomics and the criterion of evolutionary conservation were previously used to identify Phylogenic Footprint Clusters (PFCs) inferred to be putative *HOXA* cis-regulatory sequences (Chiu et al 2002 PNAS 99:5492-5497). Here we used the dbSNP resource to identified 17 potentially functional SNPs within PFCs, intronic, or protein coding sequences. Next we used empirical HapMap SNP data together with the Tagger program to select a subset of 42 informative tagSNPs based on pairwise SNP LD data (r20.8) and inclusive of the 17 potential functional SNPs. 20 SNPs have thus far been genotyped in the AGRE families and analyzed for evidence of association with ASD using the pedigree association program PDTPHASE 2.404. Nominal significant association has been obtained for 2 SNPs both individually and as a haplotype (*rs1801085* P=0.041; *rs10486494* P=0.013; haplotype P=0.0045). These preliminary data suggest that variation in specific *HOXA* genes may play a role in the etiology of ASD.

Fragile X prenatal analyses show full mutation females at increased risk for mosaic Turner syndrome: Loss of maternal X? *C. Dobkin, G. Radu, X. Ding, W.T. Brown, S.L. Nolin* Dept Human Genetics, NYS Inst Basic Research, Staten Island, NY.

Analysis of 475 prenatal samples for fragile X revealed 5 with 45,X/46,XX mosaicism for Turner syndrome among 86 females that carried the full mutation (>200 CGG repeats). In two cases 50% of the cells were 45,X and in the other three 14%. None of the other 160 female fetuses was found to be mosaic for the X chromosome. This highly significant association of Turner mosaicism and the fragile X full mutation is much more common than expected. Isolated cases of mosaic Turner syndrome in full mutation females have been reported previously but an increased prevalence was not apparent from these reports (Shapiro et al., AJMG 51:507, 1994; Tejada et al., J Med Genet 31:76, 1994; Wilkin et al., Prenat Diagn 20:851, 2000).

We were interested to determine whether the maternal chromosome with the full mutation or the paternal chromosome was lost. Analysis of polymorphisms identified the parental origin of the lost chromosome in 3 of the 5 cases. Interestingly analysis of the two cases with 50% 45,X showed that the maternal X had been lost. Since approximately 75% of Turner syndrome cases show a loss of the paternal X, our results suggest that the presence of the fragile X mutation on the maternal chromosome may result in its loss.

A new genetic isolate with a unique phenotype of syndromic oculocutaneous albinism: clinical, molecular and cellular characteristics. *A. Blumenfeld[1], N. Schreyer-Shafir[1], M. Huizing[2], Y. Anikster[3], Z. Nusinker[1], I. Bejarano-Achache[1], G. Maftzir[1], L. Resnik[1], A. Helip-Wooley[2], W. Westbroek[2], L. Gradstein[4], A. Rosenmann[1]* 1) Ophthalmology Dept., Hadassah - Hebrew Univ. Hospital, Jerusalem, Israel; 2) National Human Genome Research Institute, NIH, Bethesda, MD; 3) Metabolic Disease Unit, Safra Children Hospital, Sheba Medical Center, Tel Hashomer, Israel; 4) Ophthalmology Dept., Soroka Medical Center, Beer-Sheva, Israel.

An extended, highly consanguineous Israeli Bedouin family with at least 20 individuals exhibiting a unique phenotype of oculocutaneous albinism (OCA) was identified. All known OCA genes were excluded in this family. Electron microscopic analysis of platelets revealed absence of dense bodies, suggesting a diagnosis of Hermansky-Pudlak syndrome (HPS). HPS is a rare autosomal recessive disorder of lysosome-related organelle biogenesis, clinically characterized by OCA and platelet dysfunction, sometimes accompanied by other systemic pathologies. All human HPS genes (*HPS1-8*) and 5 genes corresponding to murine HPS models were evaluated. Haplotype analysis and homozygosity mapping of the *HPS* loci revealed linkage to chromosome 10 in the studied family. Subsequently, a novel insertion mutation, c.1066-1067insG was identified in *HPS6*. Most frameshift mutations generating premature termination codon cause mRNA nonsense mediated decay (NMD), while intronless genes like *HPS6* are usually not monitored by NMD. Expression analysis revealed no mRNA decay in patient's fibroblasts, hence truncated protein is most probably produced. Confocal microscopy revealed abnormal distribution of LAMP-3 (lysosomal associated membrane protein-3) in fibroblasts from the patients, indicating abnormal trafficking of lysosomal lineage organelles. So far, a single HPS-6 patient phenotypically similar to HPS-3 and HPS-5 has been identified. The HPS-6 phenotype in the studied family is unique since it resembles OCA and not HPS. Therefore, our finding broadens the phenotypic definition of HPS. Two major genetic isolates of HPS-1 and HPS-3 patients were previously diagnosed in Puerto-Rico. The extended Bedouin family is the largest isolate of non-Puerto-Rican HPS patients.

Skewed X-inactivation and X-linked recessive lethal infantile spinal muscular atrophy (*XL-SMA*) as co-inherited traits in a Spanish pedigree: possible clues to disease gene identification. *M.E. Ahearn[1], F. Martinez[2], J. Tarleton[3], J. Laursen[3], K.O. Yariz[1], Y.S. Fan[1], H. Zhu[1], J. Ramser[4], A. Meindl[4], L. Baumbach[1]* 1) Miller Sch Med, Univ. Miami, Miami, FL; 2) Instituto se Biomedicina, Valencia, Spain; 3) Fullerton Genetics Ctr. Lab, Asheville, NC; 4) Gynaekologische Tumorgenetik Ismaningerstr, Munchen, Germany.

Our group has previously described *XL-SMA* syndrome (MIM 30021) and our efforts in disease gene identification. Consistent with other X-linked recessive disorders, only *XL-SMA* males families are affected; obligate carrier females are asymptomatic. Recent cytogenetic and molecular analyses of one *XL-SMA* Family 3 (from Spain) have provided possible new clues. Clinical features of Family 3 *XL-SMA* males include those common to all affected males (AMs); severe congenital hypotonia, congenital contractures of all extremities, muscle biopsy with neurogenic atrophy, and neonatal/infant death from respiratory insufficiency. Family 3 AMs display dysmorphic facies seen in other *XL-SMA* males, but evidence additional dysmorphic findings and clinical features not described in other *XL-SMA* families. Their disease course is more severe with death within the first 24-72 hrs postpartum and represents the most severe disease phenotype. Linkage studies using microsatellites and SNPs have demonstrated that the family links to the current XL-SMA diseasse region (Xp11.3-q11.2). Due to severity of disease presentation, X-inactivation patterns were analyzed in Family 3 using standard androgen receptor methylation assays. These studies were independently performed in two laboratories using identical patient materials. Carrier females and selected non-affected males were tested. Each carrier female showed skewed X-inactivation, with ratios ranging from 86:14 to 90:10. Based on constructed haplotypes, skewed inactivation occurs of the at-risk X chromosome. In hopes of detecting a microdeletion, we are analyzing this family with Array CGH and high density SNP mapping. Skewed X-inactivation has been observed in selected other X-linked disorders, however, families with stably transmitted X-inactivation are rare, and may provide important clues to gene discovery.

Human Cholestryl Ester Transfer Protein (TaqIB) Polymorphism among Filipinos with Cardiovascular Risk Factors. *E.C. Cutiongco[1], R.S. Santos[2], F.R. Punzalan[2], F.B. Geronimo[2], R.V. Tangco[2], R.G. Sy[2]* 1) Institute of Human Genetics, National Institutes of Health Manila, Philippines; 2) Lipid Research Unit, University of the Philippines-Philippine General Hospital.

BACKGROUND:HDL-C has emerged as an important independent predictor of cardiovascular disease. The FNRI and NNHes Study Group in the Philippines reports a high prevalence of low HDL among Filipinos. Most cases of low HDL-C are associated with secondary causes like Metabolic Syndrome. A primary cause of reduced HDL-C such as increased Cholesteryl Ester Transfer Protein activity has been identified.. OBJECTIVES: 1. To determine the phenotype and frequency of Cholesteryl Ester Transfer Protein (TaqIB) polymorphism among Filipinos with cardiovascular risk factors. 2. To determine the association of TaqIB polymorphism with HDL-C levels among Filipinos with cardiovascular risk factors. DESIGN: Cross-sectional Study METHODOLOGY: Fifty patients were included in this pilot study and were examined with respect to genotype, lipid profiles, blood sugar and other cardiovascular risk factors. Polymerase Chain Reaction (PCR), Restriction Fragment Length Polymorphism (RFLP) and Agarose Gel Electrophoresis techniques were used to determine the CETP TaqIB Polymorphism. Analysis include descriptive statistics, Chi square test and Fishers correlation test using Stata version 6. RESULTS: Out of 50 patients, 66% were females and 34% were males with a mean age of 55 y/o and a BMI of 27 kg/m2. The following risk factors were identified: hypertension (92%), dyslipidemia (88%), obesity (68%), smoking (50%), diabetes mellitus type 2 (18%) and family history of premature CAD (14%). The genotype frequencies of B1B1; B1B2; B2B2 were 40%, 50% and 10% respectively. The B1B1 homozygote was associated with lower HDL-C levels (45.358.82 mg/dl) compared to B1B2 (48.9610.10mg/dl) and B2B2 (48.9910.13 mg/dl)). CONCLUSIONS CETP-TaqIB Polymorphisms exist among Filipinos with cardiovascular risk factors. The frequency of TaqIB polymorphism among Filipinos with cardiovascular risk factors were B1B1 (40%), B1B2 (50%) and B2B2 (10%). B1B1 polymorphism is more common than B2B2 and associated with low HDL-C.

Association of *PON2* variants with PON activity in systemic lupus erythematosus (SLE). *S. Dasgupta[1], F.Y. Demirci[1], R.L. Minster[1], M. Kenney[1], P. Shaw[2], A. Kao[2], C. Kammerer[1], F. Bontempo[3], S. Manzi[2], M.I. Kamboh[1]* 1) Dept Human Genetics; 2) Lupus Center of Excellence; 3) Dept Medicine, Univ Pittsburgh, Pittsburgh, PA.

Several studies have implicated the association of low paraoxonase (PON) activity with coronary artery disease (CAD). SLE is a chronic autoimmune disease and patients with SLE are known to have increased morbidity and mortality from CAD. Two SNPs in the PON1 gene (codon 55 and codon 192) are known to be major regulators of serum PON activity, though the extent of contribution from subsequently characterized PON2 and PON3 genes remain to be determined. The purpose of this study was to test the impact of *PON2* SNPs on SLE risk and PON activity. For this purpose, 345 Caucasian SLE patients and 450 healthy control women were genotyped for five *PON2* tagSNPs using either Pyrosequencing or restriction analysis. None of the SNPs were associated with SLE risk. However, in single-site analyses, two SNPs (codon 311 and rs11982486 SNPs) showed significant gene-dosage effects on serum PON activity (p=5.24E-09 and p=0.0096, respectively). When all five *PON2* SNPs and two *PON1* SNPs (codon 55 and codon 192) were included in a multiple linear regression model, the significant effect of *PON2* SNP rs11982486 was lost (p=0.98) but it remained significant for *PON2*/codon 311 SNP (p<0.0001) and for two *PON1* SNPs (p<0.0001). On the other hand, the association with an additional *PON2* SNP (rs17876193), which was not significant in the single-site analysis, became significant using the multiple regression (p=0.0028). The contribution of the *PON1*/codon 192, *PON1*/codon 55, *PON2*/codon311, and *PON2*/rs17876193 SNPs on PON activity was 28.6%, 4.8%, 2.8% and <1%, respectively. These data indicate that in addition to the known effect of *PON1* on PON activity, genetic variation in *PON2* also contributes towards PON activity. Since the PON1 and PON2 genes are clustered in a segment of chromosome 7, their combined genetic effects appear to explain the bulk of variation in PON activity. Further analysis of additional *PON2* polymorphisms will reveal the exact roles of *PON2* variants in both the SLE risk and serum PON activity.

A genome-wide portrait of gene copy number variation spanning over 60 million years of human and primate evolution. *L. Dumas[1], Y. Kim[2], A. Karimpour-Fard[1], M. Cox[1], J. Hopkins[1], J. Pollack[2], J. Sikela[1]* 1) Human Medical Genetics, University of Colorado Health Sciences Center, Aurora, CO; 2) Department of Pathology, Stanford University, Stanford, CA.

Gene duplication and loss are key evolutionary forces that can underlie the emergence of important species-specific traits. A previous genome-wide cDNA array-based comparative genomic hybridization (aCGH) analysis we reported, involving pair-wise comparisons between human and four great ape species, identified over 1,000 genes that showed lineage-specific gene copy number variations (gCNVs) in these species. As a further step toward development of an evolutionary history of primate gene duplication and loss, we have now applied cDNA aCGH to more distant primate species that span over 60 million years of primate evolution. Using human as the reference sample in all experiments and using human cDNA arrays (>41,000 cDNAs) covering 24,473 genes, we identified 1,960 lineage-specific aCGH-predicted gCNVs for these 10 species: 67 in human, 54 in bonobo and chimp, 65 in gorilla, 67 in orangutan, 334 in gibbon, 243 in Old World monkeys (macaque and baboon), 367 in marmoset and 763 (increases) in lemur. For each species except lemur, gene copy number increases consistently outnumbered decreases (861/336), suggesting that sequence divergence did not significantly interfere with copy number predictions. Q-PCR was used to confirm aCGH-predicted changes for several genes, including a number that are potentially relevant to important species-specific traits. Interestingly, aCGH-predicted gene copy number increases in distant primates must reflect expansions that were sufficiently great enough to overcome any reduction in hybridization that was due to sequence divergence. Such gene increases represent excellent candidates to be important to biological traits unique to these distant species. Finally, because the reference DNA is kept constant for all comparisons, cDNA aCGH datasets from a wide range of species can all be interrelated to one another and an evolutionary portrait of gene copy number gain and loss for over 24,000 human genes can be assembled that spans much of human and primate evolutionary history.

Towards the characterization of modifier genes for glaucoma in a huge French-Canadian pedigree carrying the K423E myocilin mutation: identification of clusters for age at onset of the disorder. *P. Belleau[1], K. Lebel[1], R. Arseneault[1], J.L. Anctil[2], A. Duchesne[1], G. Côté[2], M.A. Rodrigue[1], V. Raymond[1]* 1) Ocular Genetics & Genomics, CREMO, Laval University Hospital (CHUL) Res Ctr, Québec City, PQ, Canada; 2) Ophthalmology Dept, St-Sacrement Hospital, Québec City, PQ.

Glaucoma is the 2nd leading cause of blindness worldwide. 11 loci and 3 genes have been characterized for its most common form, primary open-angle glaucoma (POAG). We reported a huge autosomal dominant POAG pedigree in which carriers of the K423E MYOC mutation displayed wide phenotypic variability for age at onset (AAO). As a 1st step towards characterization of modifier gene(s) responsible for this variability, we analyzed if sub-phenotypes for the disorder clustered in particular regions of the pedigree. Of the 709 individuals studied, 145 were mutant heterozygotes. Complete ophthalmologic records were obtained for 103 of the carriers. 86 were diagnosed POAG while the 17 other heterozygotes displayed intraocular hypertension (OHT), a symptom always preceding glaucoma in the family. AAO of the disorder (either POAG or OHT) ranged from 8 to 63 years old. Mean AAO was 27 years old (men: 25, women: 29). Penetrance was 73% in carriers aged 35. We defined the neighborhood of each carrier as a set of pedigree members where the kingship coefficient between the carrier and other members was 0.0625. For each heterozygote, we next calculated the median of age at onset for this carriers neighborhood. Each heterozygote was classified into 3 categories according to this median (25, 26 to 34 or 35). We observed 5 distinct clusters relative to AAO. In clusters 1, 2 and 3 (43 carriers), the majority of heterozygotes showed a median for AAO relative to their neighborhood 35. In clusters 4 and 5, this median was 25. In each cluster, descendants originated from 1 distinct ancestor. Our study confirmed that age at onset displayed wide phenotypic variability in this kindred. Interestingly, heterozygotic carriers clustered into large extreme groups relative to age at onset. The observation of age-related clusters strongly suggests the presence of at least 1 modifier gene for MYOC-associated glaucoma in this pedigree.

Molecular and functional analysis of paraplegin gene (*SPG7*) mutations in patients with spastic paraplegia. *D. DiBella[1], F. Lazzaro[2], M. Plumari[1], C. Gellera[1], C. Mariotti[1], M. Muzi-Falconi[2], S. Baratta[1], F. Taroni[1]* 1) Division of Biochemistry and Genetics, IRCCS Istituto Neurologico Carlo Besta, Milan, Italy; 2) Department of Biomolecular Sciences and Biotechnologies, University of Milan, Italy.

Hereditary spastic paraplegias (HSP) are a clinically and genetically heterogeneous group of neurodegenerative disorders. Mutations in the *SPG7* gene are responsible for autosomal recessive HSP with both pure and complex phenotypes. This gene encodes paraplegin, a major component of the hetero-oligomeric ATP-dependent m-AAA metalloprotease located in mitochondria and involved in proteolytic and chaperone-like functions. We have sequenced the paraplegin gene in 57 unrelated index cases, including 41 isolated cases and 16 cases compatible with an autosomal recessive pattern of inheritance. The majority of patients exhibited a complex phenotype characterized by spastic gait and signs of cerebellar involvement. Pathogenic mutations (3 frameshift, 4 nonsense, and 3 missense) were found in 8/41 (19.5%) sporadic patients but in none of the familial cases. The mutations were not found in a large control population. Four patients (4/8, 50%; 4/41, 9.8%) had mutations on both alleles, a proportion higher than that in previously reported series. Of the remaining 4 patients, 3 carried a single heterozygous missense mutation, suggesting the possibility of a dominant effect of the mutated protein. We have modelled the identified *SPG7* missense mutations in a yeast system in which the human m-AAA is functionally reconstituted by coexpressing its two components AFG3L2 and paraplegin. Notably, functional analysis clearly indicated that the mutation Ala510Val, previously described as a polymorphism (McDermott 2001; Wilkinson 2004) and more recently identified in numerous HSP patients (Elleuch 2006), produces a respiratory-deficent phenotype in yeast cells expressing the mutant protein. Investigation on the dominant effect of the Ala510Val substitution and functional analysis of the remaining missense mutations is in progress. [Partly supported by grants FIRB RBNE014HJ3010, Telethon-UILDM GUP04009, and Fondazione Mariani R0544 to FT].

High-throughput gene expression analysis of skin from psoriatic patients and normal controls. *J. Ding[1], J.E. Gudjonsson[2], R.P. Nair[2], P.E. Stuart[2], D. Ghosh[1], J.J. Voorhees[2], G.R. Abecasis[1], J.T. Elder[2]* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Dermatology, Univ Michigan, Ann Arbor, MI.

Gene expression has been proposed as an intermediate phenotype that can increase power in complex trait gene-mapping studies. Psoriasis, an immune-mediated, inflammatory and hyperproliferative disease of the skin and joints, provides an ideal model system to evaluate this paradigm since the disease tissue is readily accessible. Susceptibility to psoriasis is influenced by multiple genetic and environmental factors, notably including HLA-Cw6.

To characterize global expression in psoriatic patients, we collected involved and uninvolved skin from psoriatic patients and normal skin from controls (40 patients and 40 controls in total, corresponding to 120 skin samples) and performed microarray experiments using Affymetrix U133 Plus 2.0 arrays. Principal Component Analysis (PCA) on all samples showed that involved psoriatic skin could be perfectly separated from uninvolved psoriatic skin and normal skin while the latter two groups were mixed together. Genes involved in immune response, epidermal cell differentiation and cell proliferation regulation were significantly enriched in a list of 666 up-regulated transcripts. When PCA was applied only to uninvolved skin and normal skin, the two groups could be separated with a small fraction of misclassified samples, indicative of distinguishable but not dramatic differences in gene expression between the two groups. In this comparison, we identified only 2 consistently up-regulated transcripts and 7 consistently down-regulated transcripts. The genes encoding these transcripts present excellent candidates and may be involved in modulating susceptibility to psoriasis.

HLA-Cw6 has been shown to be the major genetic risk factor that confers susceptibility to early-onset psoriasis. HLA-Cw6 carriers have a 5 to 20-fold increase in susceptibility. We contrast gene expression differences between HLA-Cw6 positive and negative psoriatics. Our results illustrate the potential use of gene expression as an intermediate phenotype in gene-mapping studies and further the genetic dissection of psoriasis.

Penoscrotal transposition and other anomalies in patients with distal 13q deletion syndrome. *J.R. Corona-Rivera[1,2], J. Acosta-León[2], V.A. Gutiérrez-García[1], E. López-Marure[2], A. Corona-Rivera[1], L. Bobadilla-Morales[1]* 1) Instituto de Genética Humana, CUCS, Universidad de Guadalajara, Guadalajara, México; 2) División de Pediatría, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca", Guadalajara, México.

Complete or partial penoscrotal transposition (PST) is a rare abnormality, frequently associated with other malformations involving the genitourinary, cardiovascular or skeletal systems. Deletions of different portions of chromosome 13 are related with variable features of 13q deletion syndrome as well as with complete or partial PST. We report a patient with del(13)(q32) and partial PST and review the 13q breakpoints previously related to PST. The propositus was born to 20-years-old G2, P2 mother and 37-years-old healthy non-consanguineous father. He was born at term after uncomplicated pregnancy and delivery. Birth weight was 1,800 g and length 44 cm (both below 3rd centile). He presented delayed development of motor skills. Physical examination showed weight 2200 g (-4.7 SD), height 47.5 cm (-3.4 SD), OFC 31.2 cm (-4.8 SD). He had a 1.3 cm cystic mass just below the posterior fontanelle, broad nasal bridge, upward obliquity of the palpebral fissures, small receding chin, short neck, hearth murmur, single palmar crease on both hands, extra digital creases on some digits and hiperconvex nails. He also had partial PST with bifid but well developed scrotum and testis, hypospadias and a perineal sinus. Ultrasonographic evaluation of cranial cystic mass suggested a dermoid cyst. An echocardiogram showed patent foramen ovale. Cystography and abdominal ultrasound did not show other renal or genitourinary anomalies. Cranial CT scan showed mild atrophy. Karyotype was 46,XY,del(13)(q32). The overall phenotype in our patient was strikingly similar to those previously reported in patients with different deletion of chromosome regions located betweeen 13q22-13q34. Since some previous reports of PST had a similar pattern of defects of the facial, genital, cardiovascular and limb regions, but with apparent normal karyotype, we speculate that cryptic deletions of the PST critical region may be related to this cases.

Could Glucocerebrosidase mutations affect alpha-synuclein aggregation by toxic gain-of function? *O. Goker-Alpan[1], D. Urban[1], B. Stubblefield[1], M. Cookson[2], B. Giasson[3], E. Sidransky[1]* 1) MGB/NHGRI, NIH, Bethesda, MD; 2) NIA, NIH, Bethesda, MD; 3) UPenn, Philadelphia, PA.

Accumulation of protein aggregates are linked to many diseases, including the neurodegeneration associated with Parkinson disease. Recent clinical studies implicate an association between mutations in glucocerebrosidase (GBA), the lysosomal enzyme deficient in Gaucher disease, and the development of parkinsonism. GBA mutations are identified at an increased frequency in subjects with different synucleinopathies. Certain GBA mutations exhibit temperature-sensitive activity changes that indicate protein misfolding. In fibroblasts from patients with Gaucher disease, these GBA mutations resulted in improper trafficking. Growth at 30C corrected the trafficking to the lysosomes, restoring enzyme activity and increasing steady-state protein levels. To explore whether misfolded glucocerebrosidase (GC) has an effect on alpha-synuclein aggregation, brain samples from five subjects with parkinsonism who carried GBA mutations were examined. Mutant glucocerebrosidase was present in alpha-synuclein positive inclusions in both GBA hetero- and homozygotes with parkinsonism. Both ubiquitinated and non-ubiquitinated aggregates showed immunoreactivity for GC, and GC positive aggregates were localized with lysosomal markers. Next, the functional relationship between these proteins was examined by co-expression of A53T-synuclein and wild-type or mutant GBA in COS7 cells. Overexpresion of mutant GBA induced the formation of juxta-nuclear LB-like inclusions. These synuclein- and GC-positive inclusions stained positive with aggresome markers and altered the distribution of intermediate filaments in the cell. Deposition of misfolded proteins into aggresomes is a common feature of neurodegenerative diseases associated with a toxic gain-of-function mechanism. These results suggest that mutations in GBA may likewise enhance synuclein aggregation by this mechanism.

Use of C8-DCH--glucopyranoside for high-throughput screening of modulators of lysosomal -glucosidase in intact cells. *E. Goldin[1], D. Urban[1], K. Hruska[1], S. Ziegler[1], E. Sidransky[1], C.R. Kaneski[2]* 1) MGB/NHGRI, NIH, Bethesda, MD; 2) DMNB/NINDS, NIH, Bethesda, MD.

Recently, a new substrate for lysosomal -glucosidase (GC) based on 2,3 dicyanohydroquinone (DCH) has been reported. This substrate, 4-octyl-2,3-dicyano-1,4-hydroquinonyl--D-glucopyranoside (C8-DCH--glu), is hydrolyzed by living cells to a highly fluorescent product (C8-DCH) that can be detected using a standard microplate reader (excitation: 380 nm, emission: 445 nm). A Flp-in-CHO system expressing wild-type or mutant constructs of human glucocerebrosidase (GBA) cDNA with a V5 tag was used to test the use of this substrate for high-throughput screening. CHO cell lines carrying wild-type GBA or one of two common Gaucher mutations, N370S and L444P, were generated. Expression of the mutant and wild-type GC constructs was similar when measured by Western blot with anti-V5 antibody. When incubated with C8-DCH--glu, intact cells expressing the mutant constructs had negligible activity above the baseline found in vector-transfected cells, but the wild-type construct demonstrated a time-dependent increase in fluorescence. Glucocerebrosidase activity in intact cells exposed to the C8-DCH--glu substrate corresponded well to the levels measured in cell homogenates using a standard 4MU method. Hydrolysis of C8-DCH--glu was completely suppressed by the known GC inhibitor, CBE. The difference in activity observed between cells expressing wild-type and mutant GC suggests that this system will enable the determination of changes in GC activity in its native environment and will be useful in monitoring the response to treatments *in vivo*.

Radiation induced genomic damage in the presence of curcumin by comet assay in a murine model. *L. Bobadilla-Morales[1], R. Silva-Cruz[1], K. Contreras-Venegas[1], C. Ortega-de la Torre[1], L. Ruvalcaba-Ortega[1], J.J. Vargas-Lares[1], M.A. Ramírez-Herrera[2], M.L. Mendoza-Magaña[2], J.R. Corona-Rivera[1], A. Corona-Rivera[1,3]* 1) Laboratorio de Citogenética y Genotoxicidad, Instituto de genética Humana Dr. ECR, Dep. Biol. Mol. and Genomics, CUCS, University of Guadalajara. Guadalajara, Jalisco, Mexico; 2) Laboratorio de Neurofisiología, Dep.de Fisiología, CUCS, University of Guadalajara. Guadalajara, Jalisco, Mexico; 3) Unidad de Citogenética, OPD, Hospital Civil de Guadalajara.

Introduction: ionizing radiation is mutagenic to DNA. Curcumin behave anti-oxidant and anti- inflammatory proprieties. Previous studies suggest that curcumin may decrease genetic damage due to ionizing radiation. The goal of this work is to test the radioprotective effect on genetic material of gradual doses of curcumin by comet assay. Methods. We established 6 groups (n=36) of 5 weeks male Balb-C mice, as follow: (1) negative control, (2) exposed to 6 Gy of gamma radiation, (3) curcumin 0.1%, (4) 6 Gy of gamma radiation + curcumin 0.01%, (5) 6 Gy of gamma radiation + curcumin 0.1%, (6) 6 Gy of gamma radiation + curcumin 0.5%. After 24 hs. Comet assay was performed measuring tail length, total length and qualitatively (categories 0 to 4). Results. The observed frequency of damage was similar between control and curcumin 0.01%. Statistical increase was observed in radiated mice. Increased values of damage were observed in radiation + curcumin 0.1% and 0.5% versus control and similar to radiation condition. Conclusions. Genomic damage due to ionizing radiation using comet assay was reduced in the presence of curcumin at doses of 0.1% and 0.5%. This indicate that curcumin was radioprotective of genetic damage.

ChIP on CHIP analysis of neocentromere inner kinetochore chromatin domain structure. *A.L. Alonso[1], F. Cheung[1], D. Hasson[1], B. Fritz[2], A. Ladurner[2], P.E. Warburton[1]* 1) Mount Sinai Sch Medicine, New York; 2) EMBL, Heidelberg.

Human neocentromeres are fully functional variant centromeres that have arisen epigenetically in ectopic chromosomal locations and are devoid of alpha satellite DNA. Neocentromeres allow detailed studies of centromeric DNA and chromatin organization not possible at endogenous centromeres. We have used chromatin immunoprecipitation (ChIP) and genomic microarray (CHIP) analyses with antibodies to three Centromere Proteins CENP-A, -C and -H to define the inner kinetochore chromatin domains at different resolutions on chromosome 13-derived neocentromeres. Using a contiguous 126 BAC genomic microarray spanning 14Mbp from 13q31.3 to 13q33.1, we have mapped the centromere-specific histone H3 variant CENP-A to distinct chromatin domains of 130kb, 215kb and 275kb in three independent 13q32 neocentromeres, suggesting little role for primary DNA sequence in neocentromere formation. Further analysis of two neocentromeres on the BAC array showed that both CENP-C and -H colocalize to the same chromatin domains as CENP-A, defining a distinct inner kinetochore chromatin structure. We then generated a high resolution microarray containing 257 unique PCR fragments that cover ~350kb including the 130kb CENP-A domain, with lower density coverage extending about 1 Mbp on either side. ChIP CHIP analysis on this PCR array showed that the 130kb CENP-A domain defined by the BAC array consisted of two distinct domains of ~102kb and ~7.8kb, both of which showed precise colocalization with CENP-A, -C and -H. These two domains were separated by an ~149kb devoid of these CENPs, which fits with current higher-order chromatin looping models. Finally, to investigate the CENP-A chromatin structure at a nucleosome level, we designed an oligo array that contains overlapping 70mers to two unique sequences of 1540 bp, within the ~102kb domain. Hybridization of CENP-A ChIP DNA enhanced for mononucleosomes showed one CENP-A nucleosome in one region versus three CenpA nucleosomes in the other. These data show that CENP-A chromatin is not contiguous within the kinetochore domain. Instead, CENP-A is interspersed throughout kinetochore chromatin with different CENP-A nuclesome density.

False interphase FISH result due to chromosomal heteromorphism. *L. Dong[1], A. Hajianpour[1], R. Habibian[1], D. Burkhardt[1], S. Kou[1], B. Diaz[1], Q. Huang[1], J. Chang[1], B. Huang[1,2]* 1) Genzyme Genetics, Monrovia, CA; 2) Genzyme Genetics, Orange, CA.

FISH using chromosome-specific DNA probes on uncultured specimens is an efficient method for expanding the capabilities of prenatal cytogenetics & PGD. The clear advantage of interphase FISH is the rapid availability of results; however, chromosomal heteromorphisms can give rise to a result that is discordant with the cytogenetic analysis. We present two cases. Case 1: Transabdominal CVS was performed on a 36 year old at 11 weeks gestation. FISH studies were performed using the AneuVysion assay kit that includes -satellite probes for chromosomes X, Y, & 18 centromeric regions, as well as locus specific probes for chromosomes 13 & 21. Of 82 interphase cells evaluated, the majority showed one signal for chromosome 18 but in ~30% of the cells there was a questionable tiny signal in addition to an intense larger signal. The conventional cytogenetic result was normal. Further investigation using the same probe on metaphase cells revealed that one chromosome 18 had a consistently diminished signal. The false positive monosomy 18 interphase FISH result was therefore attributed to polymorphism of one of the individuals chromosome 18 centromeres. Similar cases have been reported in the literature with findings of false positive monosomy 18 & false negative trisomy 18. Case 2: Pre-PGD FISH studies were performed on a 29 year old female due to a balanced translocation involving chromosome 15 found in her partner. One of the probes initially tested was -satellite DNA probe D15Z4 at 15p11.1-q11.1 (Vysis, Inc.); 50 interphase & 5 metaphase cells were analyzed. One chromosome 15 showed diminished signal in metaphase cells, while only one signal was detectable in most interphase cells. Consequently, a probe for chromosome 15 which does not include the polymorphic region was selected for evaluation. These cases show that careful interpretation of interphase FISH analysis is necessary & that conventional cytogenetic analysis should be performed whenever possible. For PGD cases, the best approach is to perform pre-PGD FISH studies on both parents in order to prevent false PGD results.

Genome assembly comparison to identify structural variation in the human genome. *L. Feuk[1], R. Khaja[1], J. Zhang[1], J.R. MacDonald[1], Y. He[1], A.M. Joseph-George[1], J. Wei[1], M.A. Rafiq[1], L. Armengol[2], X. Estivill[2], C. Lee[3], S.W. Scherer[1]* 1) Dept Genetics & Genomic Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Genes and Disease Program, Center for Genomic Regulation, Barcelona, Catalonia, Spain; 3) Department of Pathology, Brigham and Womens Hospital, Boston, MA, USA.

The most sensitive method for identifying all variation existing between two DNA donors is through direct comparison of accurately completed sequence assemblies of the genomes under study. We developed a new algorithm and applied it for comparison of two existing human genome assemblies, Celera's R27c compilation and the human Build 35 reference sequence. The differences identified range from single nucleotide changes to large structural changes. These include variants where sequence is gained or lost in one assembly compared to the other, as well as inversions. Fluorescence in situ hybridization and PCR based assays were used for experimental validation of assembly differences. Using a combination of literature, database and experimental analyses, we validated 100 structural variants and more than 1.5 million SNPs. In some cases the differences were simple insertion and deletions, but when copy number variants, segmental duplications, or repetitive DNA were involved the relationship was more complex. The results also show that 3Mb of sequence from the R27c assembly can be used to partially fill euchromatic gaps in the reference sequence. Our results highlight the need for comprehensive annotation strategies in order to fully interpret data from CNV-scanning and personalized sequencing projects.

The HR-Amp: A closed-tube mutation scanning and genotyping platform for genetic analysis. *D.A. David[1], C.T. Wittwer[2], J.T. Mckinney[1], S.F. Dobrowolski[1], V.E. Dujols[1], L.M. Nay[1], R.J. Pryor[2], D.D. Hawks[1], S.K. Marland[1]* 1) Idaho Technology Inc., Salt Lake City, UT; 2) University of Utah, Salt Lake City, UT.

HR-Amp is a new instrument that combines rapid-cycle PCR and high-resolution melting analysis (Hi-Res Melting). Genotyping and mutation scanning are enabled without labeled probes or separations by the saturating DNA binding dye (LCGreen PLUS). Rapid cycle PCR is performed within LightCycler glass capillary tubes for optimal speed, optical clarity and temperature homogeneity. The HR-Amp amplifies 32 samples at the same time within 15-30 min. High-resolution melting is performed immediately after PCR in the same instrument without any separation or reagent addition steps. Each sample is automatically translated into a precision thermal block and high-resolution melting performed and analyzed similar to our single sample platform, HR-1. Major applications include mutation scanning and genotyping. Heterozygous sequence alterations of amplified DNA are detected by melting curve shape, providing a homogeneous method for mutation scanning based on heteroduplex formation. Genotyping is enabled by either small amplicon melting or unlabeled probe analysis. The melting signature of both the amplicon and the probe are obtained during the same melting acquisition, taking only 1-2 minutes per sample. Single base changes, as well as small insertions or deletions are easily analyzed. Sensitivity and specificity for single base changes are 100% for amplicons up to 400 bases with a sensitivity of >96% and a specificity of >98% for 400-1,000 bp amplicons. No allele-specific amplification or real-time PCR monitoring are necessary. Several alleles can be genotyped from one melting analysis. Advantages of HR-Amp as a genotyping platform include speed (PCR in 20 min, analysis in 1-2 min/sample), solution-based closed-tube analysis, no need for sample transfers or reagent additions, both scanning and genotyping capability, and nondestructive analysis with the sample immediately available for sequencing in the rare case that it is necessary. Indeed, by combining scanning and genotyping capabilities, we estimate that 99% of the need for sequencing will be eliminated.

DNA repair capacity as a lung cancer risk predictor in never smoker probands and their first degree relatives. *O. Gorlova, S.-F. Weng, Y. Zhang, C. Amos, M. Spitz, Q. Wei* Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX.

We present estimates of risk of lung cancer associated with suboptimal DNA repair capacity (DRC) in lifetime never smokers, and estimates of risk of lung and other cancers in first degree relatives of never smoking individuals (lung cancer cases and matched controls) associated with probands DRC status. We use the data from one of the largest lung cancer case-control studies that included 2701 first-degree relatives of 348 never smokers (163 lung cancer cases and 185 controls) for whom the data on DRC was available. To evaluate whether there was an excess risk of cancer among first-degree relatives of individuals with suboptimal DNA repair capacity (below the control median or the first quartile) measured by host-cell reactivation assay, we performed unconditional logistic regression using generalized estimating equations, accounting for relatedness within families, adjusting for age and gender of proband and of relative, ethnicity of proband, type of relationship to proband, smoking status of relative, birth cohort of relative, and case-control status of the relative. Suboptimal DRC level (below the control median) conferred a significantly increased lung cancer risk in never smokers (OR=1.81, 95%CI [1.17-2.81], p=0.007). There was a 3.75-fold risk for individuals in the first (lowest) quartile of DRC (95%CI [1.97-7.14]) compared to individuals in the highest quartile. Relatives of probands that had lowest DRC (first quartile) were significantly more likely to be diagnosed with lung cancer (OR=5.05, 95% CI [1.51-16.9]), but not with snoking-related or all cancers compared to relatives of probands with highest DRC (fourth quartile). The case-control status of the proband turned out not to be significant when probands DRC status was included in the model. Relatives of probands with DRC below the control median had a significantly earlier age at diagnosis with lung cancer and a smoking related cancer than relatives of probands with DRC above the control median (p=0.019 and 0.026, respectively). No effect of probands DRC was found on age at diagnosis with all cancers.

Clinical relevance of *KRAS* mutation detection in metastatic colorectal cancer treated by Cetuximab plus chemotherapy. *F. Di Fiore[1,2], F. Blanchard[3], F. Charbonnier[2], F. Le Pessot[2,3], M-P. Gallais[4], L. Bastit[5], A. Killian[2], R. Sesboüé[2], J-J. Tuesch[2,6], A-M. Queuniet[7], B. Paillot[1], J-C. Sabourin[2,3], F. Michot[2,6], T. Frebourg[2]* 1) Department of Gastroenterology, University Hospital, Rouen, Northwest Canceropole, France; 2) Inserm U614, Faculty of Medicine, Rouen, Northwest Canceropole, France; 3) Department of Pathology, Rouen University Hospital, Northwest Canceropole, France; 4) Department of Hepato-Gastroenterology, Caen University Hospital and Francois Baclesse Centre, Caen, Northwest Canceropole, France; 5) Oncology Unit, St Hilaire Medical Centre, Rouen, France; 6) Department of Surgery, Rouen University Hospital, Northwest Canceropole, France; 7) Department of Hepato-Gastroenterology, Elbeuf Hospital, France.

The variability of the metastatic colorectal cancer (MCRC) clinical response to anti-EGFR agents, such as cetuximab, has highlighted the urgent need to identify reliable predictive markers. We therefore evaluated the recently suggested predictive value of *KRAS* mutation in MCRC patients treated with cetuximab plus chemotherapy. Fifty nine patients with a chemotherapy-refractory MCRC treated with cetuximab plus chemotherapy were included. *KRAS* exon 2 and *TP53* exons 5-8 were directly sequenced from tumor DNA and the presence of *KRAS* mutation in a small fraction of tumor cells was assessed by the PCR-LCR method. A *KRAS* mutation was detected in 18/59 of the tumors and, in 2 cases, was missed by sequencing analysis. Among the patients with a *KRAS* mutation, 15 presented a progressive disease. No *KRAS* mutation was found in the 12 patients with clinical response. *KRAS* mutation was therefore associated with disease progression ($p = 0.0005$). Among patients without detectable *KRAS* mutations, *TP53* mutation was associated to a clinical response ($p=0.01$). This study confirms that mutation of *KRAS*, downstream of the EGFR pathway, is highly predictive of a non-response to cetuximab plus chemotherapy in MCRC, highlights the need to use sensitive molecular methods to detect somatic mutations conferring resistance and suggests that sequential detection of *KRAS* and *TP53* mutations may have a potential use in clinical practice.

Compromised mRNA processing and epilepsy in Brunol4 mutant mice. *W. Frankel, Y. Yang, C. Mahaffey, T. Maddatu, G. Cox, J. Graber* The Jackson Laboratory, Bar Harbor, ME.

Idiopathic epilepsy is a common disorder with a strong genetic component, usually exhibiting complex inheritance. While both complex and monogenic seizure-prone animals have been reported, multigenic models with well-defined genetic lesions have yet to be developed. Here we describe frequent-flyer mice, in which a transgene insertion disrupts expression of the Bruno-like 4 gene. *Brunol4* haploinsufficiency results in dominant, recurrent limbic and tonic-clonic seizures in older, relatively healthy mice. Null homozygous mutants, which are small and do not thrive as well as littermates, have a more severe phenotype including both convulsions and absence seizures with frequent spike-wave discharges. Both genotypes show low seizure threshold before overt seizure onset. All mutant phenotypes are affected by strain background. *Brunol4* encodes a brain-specific RNA binding protein. Its expression is concentrated in neurons of brain regions controlling synchronization and oscillation (e.g. cerebral cortex, hippocampus, thalamus), suggesting it is involved in the maintenance of normal neuronal rhythmic activities. Using microarrays we identified multiple transcripts with altered expression in mutant brain, some of which were implicated in epilepsy by prior studies and others which are novel. At least four molecules critical to neuronal excitation (HTR2C, SYN2, SNCA and NSF) are selectively reduced at transcript and protein level. Analysis of the 3 UTR of these genes identified a highly conserved U/G rich motif. RNA-protein immunoprecipitation in neurons suggests direct interaction between BRUNOL4 and this sequence, the consequences of which on the target RNA are being investigated in primary culture using reporter and mRNA decay studies. We suggest that BRUNOL4 modulates neuronal excitability at the RNA level through fine-tuning the stability of transcripts encoding proteins critical to neuronal excitation. *Brunol4* mutant mice represent the first animal model where compromised mRNA processing leads to epilepsy. They also demonstrate how a single gene disruption can lead to multiple, more incremental molecular disturbances, mimicking a genetically complex disorder.

A genome-wide association study of putative functional SNPs leads to the identification of two psoriasis loci - IL12B and IL23R - in 3 independent white North American sample sets. *A.B. Begovich[1], S.J. Schrodi[1], M. Leppert[2], G. Krueger[2], M. Cargill[1]* 1) Celera, Alameda, CA; 2) University of Utah, Salt Lake City, UT.

To identify psoriasis-susceptibility loci, we carried out a multi-tiered, case-control association study focusing on functional SNPs. We screened 466 cases and 500 controls (Discovery) in disease phenotype-based pools with 26,644 gene-centric SNPs, ~70% of which were missense. SNPs associated with disease (P<0.05) were evaluated in a replication study (498 cases/498 controls) using a similar strategy. These studies identified a disease-associated IL12B 3UTR SNP which was confirmed by individual genotyping (P = 1.89E-04, OR 1.59 and P = 7.59E-07, OR 1.81, respectively). A Monte Carlo simulation addressing multiple testing showed this result was unlikely to be a type I error. IL12B was resequenced in 96 cases. A combination of 30 functional and tagging SNPs for the IL12B region were genotyped in both studies identifying a second, independent risk allele located ~60kb upstream of the IL12B transcription start site. Together these 2 SNPs mark a common psoriasis-risk haplotype (Pcomb = 8.94E-08, ORcommon = 1.46) as well as a less frequent protective haplotype (Pcomb = 4.19E-11, ORcommon = 0.53); we saw no evidence that the other two haplotypes influenced disease risk. Because IL12B encodes the beta subunit of both IL12 and IL23, we individually genotyped 17 markers in genes encoding the alpha chains of these cytokines (IL12A, IL23A) as well as their receptors (IL12RB1, IL12RB2, IL23R). Single-marker and haplotype analyses identified two IL23R missense SNPs that marked a common disease-associated haplotype in both studies (Pcomb = 7.56E-05, ORcommon = 1.47). Individuals homozygous for both the IL12B and IL23R predisposing haplotypes appear to be at substantially increased risk for psoriasis (Pcomb = 3.8E-08, ORcommon = 1.78). Both the IL12B and IL23R risk haplotypes have now been replicated in a third independent study (481 cases/424 controls; P=0.006 and P=0.003, respectively) suggesting that these genes play a fundamental role in psoriasis and implicating the IL23 pathway in psoriasis risk.

Detection of muscular dystrophy genotypes via universal condition direct sequencing (UCDS). *R.R. Bennett[1], H.E. Schneider[1], C. Feener[1], A. Lakdawalla[2], P.S. Lai[3], C.E. Barrett[1], V. Lip[1], B.L. Wu[1], B.T. Darras[1], A. Beggs[1], L.M. Kunkel[1]* 1) Dept Genetics, Children's Hosp, Boston, MA; 2) Applied Biosystems, Foster City, CA; 3) Department of Pediatrics, National University of Singapore, Singapore.

In order to provide a high throughput, low cost molecular diagnostic technique for the detection of mutations in any type of muscular dystrophy, we have developed UCDS (Universal Conditions Direct Sequencing). In collaboration with Applied Biosystems, Foster City Ca. and its VariantSEQr resequencing team, we have designed and tested primers to amplify all regions of interest (coding and non-coding exons, promoters, splice variations and UTRs) for the following list of genes: DMD, CAV3, TRIM32, CAPN3, FKRP, FCMD, DYSF, SGCA, SGCB, SGCD, SGCG, LMNA, TCAP, TTID. These assays have been designed and tested to be sure that they all amplify at a single set of PCR conditions so that a 384 well plate containing any combination of them can be assembled by a robot and placed in a thermal cycler for amplification. By using M13F and M13R tails on the primers, a universal sequencing plate can be utilized for sequencing these assays. More than 90% of the assays for all these genes have been tested for good amplification and for good sequencing. In the last year many assays have been redesigned to avoid SNPs and for better amplification and double stranded sequence coverage. We are in the final stages of automation decisions and have tested several robots to determine the best robot for this process. Robot script flow diagrams have been created and are currently being tested. Detection of mutations is facilitated rapidly using SeqScape v2.1 software (Applied Biosystems, Foster City Ca.). This software incorporates a consensus sequence based on the NCBI database, complete gene annotation of all NCBI and Celera transcripts for the gene of interest and a tab process for tabing through all variations between patients and consensus. It also features rapid identification of known polymorphisms versus unknown variants as well as insertions and deletions. Several patient mutatons have been found.

Performance of Whole Genome Amplified DNA on the Affymetrix GeneChip Human Mapping 500K Array Set.

C. Guiducci[1], R. Tewhey[1], B. Blumensteil[1], M. DeFelice[1], I. Pe'er[1,2], P. deBakker[1,2], S. Gabriel[1], L. Groop[3], N.P. Burtt[1], D. Altshuler[1,2,4,5,6] 1) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 2) Center for Human Genome Research, Massachusetts General Hospital, Boston, MA; 3) Department of Endocrinology, University Hospital MAS, Lund University, Malmö, Sweden; 4) Diabetes Unit, Massachusetts General Hospital, Boston, MA; 5) Department of Medicine, Harvard Medical School, Boston, MA; 6) Department of Genetics, Harvard Medical School, Boston, MA.

In recent years, several technologies for whole genome association studies have been validated. Critical to the success of these studies and an often underrated factor is the quality and quantity of input DNA. Whole genome amplification (WGA) is a robust method that utilizes 29 DNA polymerase and multiple strand displacement to generate high-fidelity copies of the genome when genomic DNA stocks are limited (Dean et al, 2002). While the performance of wgaDNA on the Affymetrix 10K GeneChip has been tested (Paez et al, 2004), the more recent 500K Array Set has not been formally investigated. We evaluated the success of WGA product on the Affymetrix GeneChip Human Mapping 250K Sty Array by assessing call rate and concordance. Ten samples (isolated from whole blood) were genotyped in tandem for both genomic DNA (gDNA) and amplified DNA (wgaDNA) on 238K SNPs. We also genotyped a reference Promega DNA in duplicate, to establish a baseline average for call rate and concordance (97.5%, 99.6%). The average call rates for the gDNA and wgaDNA were 96.1% and 93.82% respectively. The genotype accuracy between gDNA and wgaDNA samples was 98.71%, compared to the observed concordance rate of 99.8% in gDNA. To further investigate the cause of this decrease in genotyping success, we also evaluated call rates and accuracy for input wgaDNA under varied conditions: increasing concentration, mixing two independent WGA products of the same DNA, and purifying the wgaDNA. Lastly, we will present data that may suggest chromosomal regions are susceptible to poor genotype performance as a result of the WGA process.

A non-glycine sequence variant (P435T) of the COL3A1 gene associated with an autosomal dominant syndrome of joint hyperlaxity, easy bruising, pelvic organs prolapses, premature rupture of the membranes and rectal bleeding. *D.P. Germain* Department of Genetics, HEGP, Paris, France.

Vascular Ehlers-Danlos syndrome (OMIM 130050) is a life-threatening inherited disorder of connective tissue causing severe arterial and intestinal fragility and rupture. Mutations in the COL3A1 gene have been shown to underlie the phenotype. In addition to mutations resulting in haploinsufficiency, missense mutations affecting the glycine residue of the Gly-X-Y triplet of the alpha1(III) procollagen chain result in the incorporation of structurally altered molecules into fibrils and account for 2/3 of the pathogenic mutations. In contrast, no mutations have been found in the X or the Y position of the Gly-X-Y triplet (http://archive.uwcm.ac.uk/uwcm/mg/hgmd0.html). Here, we report a 14-year-old female proband presenting with a syndrome of extensive easy bruising, stretch marks, translucent skin with visible veins, and rectal bleeding. Of note, her 20-year-old sister and her 44-year-old mother both had joint laxity, distinctive facial features with thin lips and lobeless ears, and multiple pelvic organs prolapses (rectal, uterine and vaginal). The mother had premature rupture of membranes on two pregnancies. There was no history of arterial or intestinal complication. A heterozygous c.1906 C>A change was found during cDNA analysis of the probands COL3A1 gene, changing the codon CCT for proline to a codon ACT for threonine at amino acid position 435 of the alpha1(III) chain and confirmed by genomic DNA analysis (exon 25). Whether the identified sequence change located at a Y position of the Gly-X-Y repeat of collagen III triple-helical domain is a pathogenic mutation or a rare variant is unclear since 6 of the 14 threonines normally found in the type III collagen triple-helical domain occupy the Y position. However, the mutation segregated with the phenotype within the family and was absent in the probands unaffected brother. Additional molecular and clinical investigations are ongoing to establish the exact functional importance of the P435T variant. If pathogenic, whether the mutation may lead to the occurrence of life-threatening complications of vascular EDS is unknown.

Global profiling of aberrant splicing in myotonic dystrophy using the Affymetrix human exon array. *L. Bachinski[1], K.A. Baggerly[1], S. Tsavachidis[1], S.E. Olufemi[1], M. Sirito[1], J. Gamez[2], G. Bassez[3], B. Eymard[4], T. Ashizawa[5], J. Mendell[6], B. Udd[7], R. Krahe[1]* 1) Dept. Cancer Genetics, M. D. Anderson Cancer Ctr, Houston, TX; 2) Dept. Neurology, General Hosp. Vall d'Hebron Univ. Barcelona, Spain; 3) Dept. Pathology, Henri Mondor Univ. Hosp., Créteil, France; 4) Myology Inst. Salpêtrière Hosp., Paris, France; 5) Dept. Neurology, Univ. Texas Medical Branch, Galveston, TX; 6) Dept. Neurology, Childrens Hosp. Columbus, Ohio State Univ., Columbus, OH; 7) Dept. Neurology, Vasa Central Hosp. and Tampere Univ. Hosp., and Folkhälsan Inst. of Genetics, Univ. of Helsinki, Finland.

Myotonic dystrophy (DM) is the most common muscular dystrophy in adults. DM1 and DM2 are caused by similar unstable microsatellite repeat expansions - in DM1 a (CTG)n in DMPK in 19q13.3, in DM2 a (CCTG)n in ZNF9 in 3q21.3. The developing paradigm is that DM is a toxic RNA disease, mediated by the expansion of normally polymorphic microsatellites with a (CTG)n-like motif. Transcription of the mutant repeats into (CUG)n/(CCUG)n containing RNAs is necessary and sufficient to cause disease. Mutant RNAs accumulate in ribonuclear inclusions and interfere with RNA splicing, transcription and/or translation of a number of effector genes, resulting in the pleiotropic phenotype characteristic of this disease. To identify genes that are aberrantly spliced as the result of DM expansions, we used the Human Exon 1.0 ST Array (Affymetrix) to profile skeletal muscle biopsies of patients with DM1 and DM2, DM of unknown etiology, and normal (N) individuals. Altogether 184 genes were identified as potentially aberrantly spliced. We have validated two genes, TTN and SSBP3, using fluorescent RT-PCR followed by capillary electrophoresis. Peak heights were quantified using Genotyper 3.7, and isoform ratios were calculated. The isoform ratios for DM and N samples were significantly different for TTN (p-value=0.032396) and for SSBP3 (p-value=0.0023034). Validation of additional candidate genes is ongoing. Since many aspects of the pleiotrophic phenotype in DM are believed to be due to aberrant splicing, a detailed catalog of genes aberrantly spliced in DM will provide valuable entry points for the design of rational therapies.

Mutations in the gene encoding the 3'-5' DNA exonuclease TREX1 cause Aicardi-Goutières syndrome - a Mendelian mimic of congenital viral infection - at the AGS1 locus. *Y.J. crow[1], A.P. Jackson[2], P. Lebon[3], D.E. Barnes[4], T. Lindahl[4], The AGS Consortium* 1) Leeds Institute of Molecular Medicine, University of Leeds, St Jamess University Hospital, Leeds, LS9 7TF, UK; 2) MRC Human Genetics Unit, Edinburgh, United Kingdom; 3) Service de Virologie, Hôpital Cochin, St Vincent de Paul, 82 Avenue Denfert Rochereau, 75674, Paris, France; 4) Cancer Research UK, London Research Institute, Clare Hall Laboratories, South Mimms, Hertfordshire EN6 3LD, UK.

Aicardi-Goutières syndrome (AGS) typically presents as a severe neurological brain disease and is a genetic mimic of the sequelae of transplacentally acquired viral infection. Evidence exists for a perturbation of innate immunity as a pathogenic event in the disease phenotype. Herein, we show that TREX1, encoding the major mammalian 3'?5' DNA exonuclease, is the AGS1 gene; and AGS-causing mutations result in abrogation of TREX1 enzyme activity. Similar loss of function in the Trex1-/- mouse leads to an inflammatory phenotype. These observations suggest an unanticipated role for TREX1 in processing or clearing anomalous DNA structures, failure of which results in the triggering of an abnormal innate immune response. Taken together with our finding of mutations in the RnaseH complex in AGS patients, we are now in a position to define the phenotypic spectrum of the disease, which is considerably wider than previously recognised.

DNA pooling for whole genome association studies on the Illumina Infinium Assay arrays. *A.E. Baum[1], N. Akula[1], I. Cardona[1], W. Corona[1], A. Singleton[2], J. Hardy[2], S. Detera-Wadleigh[1], F.J. McMahon[1]* 1) Genetic Basis of Mood and Anxiety Disorders Unit, National Institute of Mental Health, National Institutes of Health, Bethesda, MD; 2) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD.

Conceptualized a decade ago, genome-wide association studies have only recently become practical in large samples. Costs are still a limiting factor. An initial screen which measures allele frequencies between pools of cases and controls, instead of between individuals, would greatly reduce costs. DNA pooling has been used successfully on several platforms, but has not yet been demonstrated on the Illumina Infinium system. We tested the accuracy of standard pooling methods on the Infinium I chip (109K SNPs) with DNA from 88 Caucasian control subjects who had already been genotyped individually. Three replicate pools of all 88 subjects were made from equimolar quantities of DNA as measured by pico-green. Each pool was concentrated and genotyped in duplicate. One pool was genotyped on 2 different BeadStations. Minor allele frequencies were estimated from raw intensity data (MAF=A/(A+B) or 1- A/(A+B) if A/(A+B)>0.5) and these frequencies were compared with those calculated from the individual data (MAF_{88}). As expected, MAF_{raw} only weakly correlated with MAF_{88} (r=0.86). Results were corrected for each SNPs true heterozygote intensities (k_{snp}=average(A:B) in known heterozygotes), so that MAF_k=A/(A+kB). k-corrected values were also normalized to the true positions of the homozygotes (MAF_{norm}). These transformations greatly improved the correlation between pooled and individual frequencies (MAF_{88} and MAF_k, r=0.98; MAF_{88} and MAF_{norm}, r=0.92). Variance between replicate pools was low (3-5.4%), as was variance between chips run on the same BeadStation (3.9%). Absolute error in allele frequency estimates was about 3-4%. We are now testing pooled Alzheimers Disease samples on the 550K chip to determine whether the well-known ApoE4 polymorphism can be detected.

Role of Notch Signaling in Bone Development. *F. Engin[1], G. Zhou[1], T. Yang[1], T. Bertin[1], M. M. Jiang[1], Y. Chen[1], Z. Yao[3], B. Boyce[3], B. Lee[1,2]* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute; 3) Department of Pathology and Lab Medicine, University of Rochester Medical Center, Rochester, NY.

Notch signaling is a central mechanism for controlling embryogenesis. Mutations of Notch signaling in human cause patterning defects of skeleton including Spondylocostal Dysostosis. However, Notchs *in vivo* function during bone development and pathology is poorly understood. In order to understand Notchs role in bone development, we generated osteoblast-specific transgenic mice in which Notch1 intracellular domain (N1ICD) expression was driven by Col1a1 promoter. In this gain of function model, transgenic mice showed severe, osteosclerosis and dwarfism. Histomorphometric analyses of these mice demonstrated increased mineralization and high bone mass. There was dramatic increase in the number of osteoblastic cells and abundant matrix characterized by an immature woven bone. Quantitative RT-PCR analyses showed upregulation of early osteoblast markers, while mature osteoblast markers such as osteocalcin were significantly decreased in transgenic mice. In these mice, Notch stimulated early osteoblastic proliferation by up regulating *Osterix* and *Cyclin D*, and *Cyclin E*. To elucidate the loss of function of Notch signaling, we also generated osteoblast-specific *Presenilin1, Presenilin2 (PS1/PS2)* double knockout mice. In contrast to our gain of function model, these mice showed significant osteoporosis. Histomorphometric and *ex vivo* culture studies showed decreased mineralization and accelerated differentiation of osteoblasts into osteocytes in double knockout mice, due in part to gain of *Runx2* function. These data highlight a novel central role of Notch signaling in the regulation of two distinct phases of bone formation, i.e., proliferation of early osteoblastic compartment vs. terminal differentiation into osteocytes. Hence, dysregulation of Notch signaling may account for low vs. high bone mass and/or proliferative phenotypes in humans.

The Machado-Joseph disease protein ataxin-3 interacts with NEDD8. *A. Ferro[1,2], A. Carvalho[3,4], A. Teixeira-Castro[5], C. Almeida[4], R. Tomé[4], J. Sequeiros[1,2], S. Macedo-Ribeiro[4], P. Maciel[5]* 1) UnIGENe-IBMC, Porto, Portugal; 2) Dpt of Population Studies-ICBAS, Porto, Portugal; 3) Dpt of Zoology, Coimbra, Portugal; 4) Centre for Neuroscience and Cell Biology, Coimbra; 5) Life and Health Sciences Research Institute, School of Health Sciences, Braga, Portugal.

Machado-Joseph disease (MJD/SCA3) is an autosomal dominant neurodegenerative disorder caused by the expansion of a CAG tract in the coding portion of the *ATXN3* gene. It is unknown how the resulting expanded polyglutamine (polyQ) tract in ataxin-3 (ATXN3), an ubiquitously expressed protein, triggers the disease, and why only some sub-populations of neurons are affected. The presence of ubiquitin-positive aggregates of the defective protein in affected neurons is a hallmark of most polyQ disorders. Accumulation of NEDD8, a ubiquitin-like protein in these inclusions in MJD brains was recently reported. The goal of our work was to determine if wild-type ATXN3 could interact with NEDD8. For this, we tested two normal isoforms of human ATXN3 that differ in their C-terminal (MJD1.1, MJD2.1), and N-terminal portions of the protein, which are common to both isoforms and exclude the polyQ tract, using the yeast two-hybrid and GST pull-down assays. The ceatxn-3 homologue was also tested using these assays. We observed interaction of ATXN3, encoded by both isoforms, and ceatxn-3 with NEDD8. The N-terminal part of ATXN3 seems to be sufficient for the interaction to occur since we saw interaction only with its Josephin domain (JD), indicating that this interaction is not dependent on the UIMs or the polyQ tract of ATXN3. *In situ* co-localization and His-tag pull-down assays confirmed this interaction in eukaryotic cells. The conservation of the interaction with NEDD8 in the nematode suggests a biological and functional relevance for this interaction. Molecular docking studies of the NEDD8 molecule to the JD suggest that NEDD8 interacts with ATXN3 in a substrate-like mode; our preliminary *in vitro* studies suggest that recombinant ATXN3, a known ubiquitin hydrolase, also displays deneddylase activity. Further studies must be carried out to characterize this function and to deepen the implications of these new observations for MJD.

A Markov Chain Approach to Estimating Kinship Coefficients. *K.L. Ayers[1], E. Sobel[2], K. Lange[1,2,3]* 1) Departments of Biomathematics; 2) Human Genetics; 3) Statistics, UCLA, Los Angeles, CA.

We propose a Markov chain method to estimate kinship coefficients between related individuals from dense SNP genotyping data. The output of the chain enables estimation of kinship coefficients, both globally and locally along the human genome. These in turn come into play in QTL mapping and association studies. The chain has 12 possible identity by descent states that mimic the condensed IBD states of Jacquard and Cotterman. Likelihoods can be efficiently computed via forward and backwards algorithms and optimized for maximum likelihood estimation of the underlying kinetic parameters. The equilibrium distribution permits computation of the theoretical (global) kinship coefficients. Posterior probabilities for each state at a particular marker permit estimation of local kinship coefficients. This abstract extends the model discussed in the abstract "Estimating Kinship Coefficients from High-Density SNP Genotypes for QTL Mapping and Association" by Day, Sobel and Lange. The current model is more computationally intensive, but may yield more precise estimates than the Day et al. model.

A Bardet-Biedl syndrome type 1 (BBS1) M390R mouse model results in ventriculomegaly, leptin resistance and a defect in regulation of neuronal cilia synthesis. *R.E. Davis[1], K. Agassandian[1], K. Rahmouni[1], R.F. Mullins[1], A.R. Philp[1,2], C.C. Searby[1,2], D.Y. Nishimura[1,2], M.P. Andrews[1,2], M. Tayeh[1], M.D. Cassell[1], B. Yang[1], E.M. Stone[1,2], V.C. Sheffield[1,2]* 1) University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a pleiotropic, heterogeneous disorder resulting in obesity, retinopathy, polydactyly, cognitive impairment, renal dysplasia and reproductive tract anomalies. Eleven BBS genes have been identified. The *BBS1* M390R mutation is the most common human BBS variant and accounts for ~25% of BBS cases. We have developed a novel knock-in mouse harboring the *BBS1* M390R mutation (*Bbs1*$^{M390R/M390R}$)and have extensively characterized this model. The *Bbs1* knock-in mouse model develops retinopathy and obesity as seen in human BBS patients. Histological analysis of the retina reveals degeneration of the outer nuclear layer (ONL) by 16 weeks of age, with severe attenuation increasing with age. Electroretinogram analysis confirms a progressive deterioration. Immunocytochemical analysis shows mislocalization and accumulation of rhodopsin in the ONL. In initial studies to understand the mechanism of obesity, we demonstrated elevated serum leptin levels in *Bbs1*$^{M390R/M390R}$mice. We show these mice have leptin resistance based on failure to respond to peripheral and direct central nervous system injection of exogenous leptin. Immunohistochemical analysis shows mislocalization of the leptin receptor in the hypothalamus of *Bbs1*$^{M390R/M390R}$ mice. Evaluation of the brain using magnetic resonance imaging demonstrates ventriculomegaly in these mice. Notably, a single M390R allele results in significant ventriculomegaly. Electron microscopic evaluation indicates abnormalities in ependymal cell motile(9+2) and primary(9+0) cilia of the hypothalamus consistent with a defect in retrograde intraflagellar transport and abnormal regulation of ciliogenesis. These data indicate additional phenotypes that should be evaluated in human BBS patients. We demonstrate the utility of the *Bbs1* knock-in mouse model for defining the pathological mechanisms of the BBS phenotypes and its importance for further analysis of BBS1 protein function.

Long term follow up of a 21 y/o female with methylcobalamin-treated methionine synthase deficiency. *D. Adams[1], B. Brooks[5], J. Sloan[1], J. Filiano[2], H. Levy[3,4], C. Venditti[1]* 1) NHGRI, NIH, Bethesda, MD; 2) Dept of Pediatrics and Medicine, Dartmouth Medical School, Hanover, NH; 3) Div. of Genetics, Children's Hospital, Boston, MA; 4) Dept of Pediatrics, Harvard Medical School, Boston, MA; 5) NEI, NIH, Bethesda, MD.

We present a 21 y/o female with methylcobalamin-treated methionine synthase deficiency (cblG). She was diagnosed at 5 m/o after a course marked by failure to thrive, irritability, and megaloblastic anemia. Visual evoked potential (VEP) testing showed impaired visual pathway conduction. Therapy with methylcobalamin was initiated. Shortly after diagnosis she developed infantile spasms with hypsarrythmia. Anti-epileptic medications (AEDs) were trialed without success. The seizures were only controllable by AEDs after a course of ACTH. VEPs gradually returned to normal, presumably due to optic nerve/tract remyelination. However, developmental delay and cognitive impairment persisted. Current therapies include methylcobalamin 500 mcg twice per week, L-methionine 25 mg twice daily, betaine 3 grams per day, folate and leukovorin. Urine organic acid analysis shows minimal excretion of 3-methylglutaconic acid and 3-methylglutaric acid. The total plasma homocysteine level is between 22 and 26 umol/L. The plasma methylmalonic acid level is normal at 0.15 umol/L. Plasma GAA and creatine are normal. Retinal exams are normal bilaterally; there is no evidence of optic atrophy. There is bilateral, asymmetric clonus at the ankles. A brain MRI shows normal brain structure. Magnetic resonance spectroscopy shows decreased NAA in some gray matter areas including the basal ganglia. The young woman described provides an example of the long term outcome of methionine synthase deficiency treated with methylcobalamin. Her overall course appeared to stabilize with the institution of therapy. Open issues include: 1) the contribution of her infantile spasms and hypsarrythmia to her present cognitive delays, 2) the progressivity of her lower extremity spasticity, 3) the metabolic basis of the 3-methylglutaconic and 3-methylglutaric acid excretion, and 4) the course of eye disease in treated cblG given the apparent reversal of visual tract damage.

Gene promoter methylation, genomic deletions and amplifications in biopsies from patients with hereditary breast cancer. *M.P. Carvallo[1], C. Alvarez[1], T. Tapia[1], M. Vallejos[1], S. Smalley[1], M.L. Solis[2], A. Corvalán[2], M. Alvarez[2], E. Rozenblum[3], D. Munroe[3]* 1) Department of Cell and Molecular Biology, Faculty of Biological Sciences, Pontificia Universidad Catolica de Chile, Santiago, Chile; 2) Faculty of Medicine, Pontificia Universidad Catolica de Chile, Santiago, Chile; 3) Laboratory of Molecular Technology, SAIC-Frederick Inc., NCI, National Institutes of Health, Frederick,MD, USA.

We have previously screened 54 families with breast/ovarian cancer for mutations at BRCA1 and BRCA2 genes. Close to 80% of these families did not present a mutation in either gene. In an attempt to search for other tumour suppressor genes involved in the progression of breast cancer, we began an analysis of genomic DNA from breast tumour biopsies of non BRCA1/BRCA2 patients. We analyzed the methylation status of BRCA1 and ATM promoters two genes known to be involved in breast cancer. The analysis of the promoter methylation of these two genes in 30 biopsies from women affected with hereditary breast cancer, revealed an 87% of methylation only for ATM. Besides, only 6 biopsies showed methylation in the BRCA1 promoter. There is evidence that most BRCA1 mutated tumours are negative for estrogen receptor (ER) and ERBB2. Consistent with this information, we found 4/6 breast tumour biopsies, ER negative and ERBB2 negative, showing BRCA1 promoter methylation, suggesting a possible role of this gene in tumour's progression. We performed an array-CGH analysis on 8 of these biopsies to analyze genomic deletions and amplifications. The most frequent deletions found involve: 1p31, 3q28, 6p12, 13q14, 13q33, 15q2, and the most frequent amplifications segments comprised are: 3p21, 2p23, 12q14, 10p12. Some interesting genes included in the deleted regions are: BAG2 (Bcl2 associated athanogen 2), RB, ITM2B (Integral membrane protein 2B), and TUSC3 (Tumour suppressor candidate 3) and in the amplified regions: jun, ALK (Anaplastic Lymphoma Kinase), HMGA2 (High mobility group AT-Hook 2) and MAP3K3 (Mitogen-Activated Protein kinase kinase kinase 3).Financed by Fondecyt 1040779.

Large-scale genetic investigation of genome-wide transcriptional profiles. *H.H.H. Göring[1], J.E. Curran[1], M.P. Johnson[1], T.D. Dyer[1], J.B.M. Jowett[2,3], M.C. Mahaney[1], J.W. MacCluer[1], G.R. Collier[3], E.K. Moses[1], J. Blangero[1,3]* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) International Diabetes Institute, Melbourne, Australia; 3) ChemGenex Pharmaceuticals, Geelong, Australia.

Quantitative differences in gene expression are thought to contribute substantially to phenotypic differences among individuals. While environmental stimuli influence the location, timing, and level of gene expression, genetic differences among individuals are also important. Here we sought to localize major genetic determinants of expression of individual transcripts located throughout the human genome. Using Illuminas Sentrix Human-6 gene expression bead chips, we measured the expression levels of 47,289 different transcripts in stored lymphocyte samples from 1,240 members of 40 randomly ascertained Mexican American families in the San Antonio Family Heart Study. 20,413 transcripts (43%) passed quality control. The levels of virtually all transcripts were found to be significantly heritable, validating these measures as potentially useful biological indicators. In order to localize transcript-specific regulators of gene expression, we performed genome-wide variance components-based linkage analysis on the expression levels of all transcripts. At a false discovery rate of 33%, 2,957 autosomal transcripts (15%) were found to be *cis*-regulated, i.e. a significant point-wise lod score was obtained at the genomic location of the gene. This suggests that a substantial proportion of genes harbor genetic variants that influence their own transcription levels. While *trans*-regulation was also found to be important, most of the major genetic factors influencing gene expression appear to be located in *cis*, with >95% of lod scores ?5 being located in the vicinity of the genomic location of the assessed transcript. This is the largest study todate on the genetics of human gene expression, both with regard to the number of phenotyped individuals and the number of investigated transcripts. Our results indicate that identification of *cis*-regulated genes may be of great utility for prioritization of positional candidate genes.

A genome-wide scan for variation in the polyadenylation signal and correlation to expression levels. *L.R.L. Davies[1], C.J. Cotsapas[1,2], R.R. Graham[1,2], D. Altshuler[1,2]* 1) Program in Medical and Population Genetics, Broad Institute of Harvard and the Massachusetts Institute of Technology, Cambridge, MA; 2) Center for Human Genetics Research and Molecular Biology, Massachusetts General Hospital, Boston, MA.

Gene expression levels, which are both heritable and highly variable across populations, may play an important role in interindividual variation, including risk to disease. Several genome-wide scans have concluded that many genetic determinants of expression levels are *cis*-acting variants. The causal alleles of these variants, however, remain undefined.

We are investigating variations in a near-ubiquitous gene feature, the polyadenylation (polyA) signal. This is a short, highly conserved 6 bp motif in the 3UTR that is bound by the cleavage and polyadenylation specificity factor (CPSF). CPSF is part of a complex responsible for cleavage of the mRNA 15-30 bp downstream of the polyA signal and subsequent polyadenylation of the transcript. We have hypothesized that variations in the polyA signal may disrupt the binding of CPSF, altering the expression levels of some transcripts by affecting the rate of polyadenylation and/or forcing the use of alternate signals downstream. In the latter case, the altered 3UTR length may have further effects on transcript stability, binding of 3'UTR proteins, or the length of the polyA tail.

Here we describe a scan of all 32,000 RefSeq isoform 3UTRs for common variation in the canonical form of the polyA signal (AATAAA). Within these coordinates, dbSNP revealed multiple single nucleotide polymorphisms (SNPs) that we predict may alter CPSF binding. We are currently genotyping these variants in the 270 International HapMap Project samples to determine their population frequencies. We will then experimentally validate whether these alleles do in fact alter the length of the 3UTR or mRNA expression levels using northern blots from EBV-transformed B cell lines derived from the HapMap samples. This scan will provide a new resource of functional alleles that may play a role in disease susceptibility.

Fine mapping and candidate gene screening within a major familial Ménière disease locus on human chromosome 14. *M.E.S. Bailey[1], Y. Lowe[1], C. MacKay[1], A.W. Morrison[2], G.A.J. Morrison[3]* 1) Div. of Molecular Genetics, IBLS, Univ. of Glasgow, Glasgow, U.K; 2) Dept. of Otolaryngology, Royal London Hospital, London, U.K; 3) Dept. of Otolaryngology, Guys and St Thomas Hospitals, London, U.K.

Ménière disease (MD) is a relatively common, complex disorder characterised by episodic hearing loss, tinnitus, and rotatory vertigo with nausea and vomiting, probably caused by increased pressure in the cochlea and vestibular system resulting from endolymphatic hydrops. MD has mid-life onset and leads to a significant reduction in quality of life. Approx. 7% of cases are familial, most compatible with autosomal dominant inheritance. Recently, a locus for familial MD on chr.12 has been reported. We have completed the fine mapping phase of a genome scan using a set of 18 MD families. Linkage analysis of 5cM scan data from all the families gave a maximum multipoint HLOD of 2.90 (? = 55% of families linked, 80% penetrance) indicating potential linkage to a single locus in chromosome 14q21-q22. Fine mapping in the linked families using additional markers has led to enhanced evidence for linkage (HLOD 4.19, ? = 55%, 80% penetrance). Meiotic recombination analysis has enabled us to delineate a bipartite critical region that must contain the causative gene. The minimum critical region (defined using recombinant unaffecteds) of 3 Mbp contains only 2 known genes, *MAMDC1* and *RPL10L*, and a putative expressed locus, *LOC645178*. All exons and putative promoters of these genes have been screened by SSCP and sequencing of patients from linked families. A maximum critical region (using only affected recombinants) of 5 Mbp containing 16 genes has also been delineated. Screening of the next best candidate gene in this region, *BTBD5*, has also been completed. No candidate causative variants have been discovered. Additional candidate genes are being screened and novel markers genotyped, but at present the identity of the predisposing gene at this locus remains elusive. Identification of the gene in the linked families should suggest candidates to screen in the remaining families and illuminate pathways contributing to susceptibility to the more common, sporadic cases of MD.

MOM-PAP-A detects ultra rare deletions and demonstrates that normal lung contains the EGFR microdeletions commonly found in lung cancers. *Z. Chen, J. Feng, S. Sommer* Molec Gen & Molec Diagnosis, City of Hope Natl Med Ctr, Duarte, CA.

In-frame deletions of 15 or 18 bp in the EGFR gene are common in non-small-cell lung cancers and predict response to the tyrosine kinase inhibitors. We hypothesized that these common deletions in tumors derive from rare mutations that occur during lung development and are enriched in normal histological lung tissue by positive selection. To test this Selection Hypothesis for EGFR Deletions (SHED), we developed Multiple Oligonucleotide Mismatch PAP-A (MOM-PAP-A), a sensitive and specific form of Pyrophosphorolysis-Activated Polymerization for Amplification of specific alleles (PAP-A) for detecting mutations other than single base substitutions, including deletions and complex mutations. MOM-PAP-A has the sensitivity to reproducibly detect one mutant molecule in mammalian DNA and can amplify the mutant segment about 4 trillion-fold without nesting. The selectivity of detection was >1×109 wild-type genomes when PAP oligonucleotides mismatch the wild-type at 2-5 bases. MOM-PAP-A revealed that the common 15 and 18 bp somatic EGFR deletions were enriched in normal lung far above that normally expected frequency for 15 and 18 bp common deletions. The common 15 and 18 bp deletions were found in about 6 per ten million normal human lung cells but not in blood cells. An EGFR exon 3 deletion and an EGFR2 deletion homologous to the EGFR 15 bp deletion were not detected in either lung or blood. EGFR and EGFR2 assays were developed for rat, revealing that only the homologous 15 and 18 bp EGFR mutations are present in lung at about 2 per million cells, but not in liver. Mutation frequencies increase ~50-fold from rat pups to adulthood and are similar in young and old adult rats despite a six-fold difference in age, consistent with substantial positive selection occurring before adulthood. The human cells with 15 and 18 bp EGFR deletions may be viewed as premalignant cells in that they are roughly 300,000 times more likely than average adult cells to give rise to lung cancer. PAP-based testing of EGFR mutations potentially offers an approach for rapid, low cost, early screening for early detection of a subset of lung cancer.

The BCL2 gene and aetiology of autoimmune disease. *K. Gendall, C. Guja, A. Colgan, R. Rodger, M. Merriman, P. Chapman, E. Gale, K. Gillespie, P. Gow, A. Harrison, J. Highton, P. Jones, J. ODonnell, S. Pearce, D. Smyth, J.A. Todd, T. Merriman* University of Otago, New Zealand.

Background Human chromosome 18q12-q23 has been linked to several autoimmune diseases, including type 1 diabetes (T1D), rheumatoid arthritis (RA) and Graves disease (GD). This may represent a common susceptibility gene or genes. The BCL2 gene is a candidate in the region due to its function as a negative regulator of apoptosis. Association of *BCL2* in autoimmune diseases has been found in two out of four published studies.

Aim To test the BCL2 gene for association in five independent autoimmune sample sets.

Results Ten *BCL2* SNPs were tested for association in a NZ autoimmune case-control cohort (1,187 RA, T1D and GD cases; 913 controls). Two were nominally associated with autoimmunity in a combination of all three case samples (rs1481032, OR = 0.87, $P = 0.03$; rs2849382, OR = 0.72, $P = 0.001$). These two SNPs were then typed in three UK case-control cohorts (384 T1D cases, 259 controls; 1,919 T1D cases, 1,772 controls; 465 GD cases, 376 controls) and a Caucasian cohort of ~2,000 T1D families. rs2849382 showed no evidence of association in any of the T1D samples (small case-control OR = 0.84, $P = 0.31$; large case-control OR = 1.12, $P = 0.184$; families OR = 1.11, $P = 0.12$) or in the UK GD sample (OR = 1.17, $P = 0.27$). The minor allele of rs1481032 was undertransmitted in the T1D families (%T = 46.8, OR = 0.88, $P = 0.04$), and some association with disease was found in the small T1D case-control group (OR = 0.62, $P = 0.02$). However, rs1481032 was not associated in the large T1D case-control group (OR = 1.01, $P = 0.90$) or the GD samples (OR = 0.83, $P = 0.18$). Meta-analysis of these data using Fishers method found some evidence of association (rs2849382 $P = 0.002$; rs1481032 $P = 0.008$).

Conclusion Nominal evidence of association with *BCL2* was found. However, a more thorough testing of markers in the gene is required.

CRYPTIC INVERSION X UNBALANCED RECOMBINATION IN NEW BORN MALE. *I. GADI*[1], *J. TEPPERBERG*[1], *R. SLOTNICK*[2], *V. JASWANEY*[1], *J. KESLER*[1], *T. ROYESTER*[1], *C. BULLEN*[1], *T. SAPP*[1], *P. PAPENHAUSEN*[1] 1) Cytogenetics, Laboratory Corporation of America, RTP, NC; 2) Robert Slotnick, Washoe Medical Center, 77 Pringle Way, Reno, NV 89502.

We report a newborn baby boy with effective nullisomy for the distal short arm of the X chromosome. The baby was born with multiple anomalies to a 33 year old white female gravida 1, para 1. The head circumference of the baby measured 32.5 cm (10th percentile), inter canthal distance=2.25 cm (about 50th percentile), outer canthal distance=6 cm (about 25th percentile), palpebral fissures=1.75 cm (50th percentile). The pregnancy was unremarkable until the 2nd trimester when the second trimester test showed an elevated risk of Down syndrome (1 in 177). Amniocyte and postnatal blood chromosome analysis revealed an apparently normal karyotype. Second trimester ultra sound showed short long bones (humerous, ulna, radius, femur, tibia and fibula) all measured at less than the 5th percentile for the gestation age. There was neonatal persistence of short limbs particularly of the long bones. Lower extremities and feet were normal, but the upper extremities showed posturing of both hands. The left hand showed ulnar deviation of the first finger and bilateral clinodactyly. Chest was normal in size, although the nipples were widely spaced and hypoplastic. External genitalia appeared normal except cryptorchidism and a suggestion of mild hypospadias. An opthalmology examination identified ocular albinism. Ancillary subtelomere FISH on the postnatal chromosomes showed a deletion of the X chromosome short arm subtelomere, and an extra copy of X chromosome long arm subtelomere attached to the distal Xp short arm. Maternal chromosome FISH revealed a pericentric inversion of an X chromosome suggesting unbalanced recombination as the cause of the abnormal X chromosome in the child. Additional FISH showed loss of loci for STS, Kallmann and presumably the genes associated with X-linked ocular albinism and Leri-Weil dyschondrostesis from the distal short arm of the X chromosome.

Knocking-Down KIF3A in Neural Crest Cells Results in Crainofacial Dysmorphologies. *N. Allen, S. Brugmann, J.A. Helms* Surgery, Stanford University, Palo Alto, CA.

KIF3A, a member of the kinesin-2 anterograde motor transport protein family, is involved in intracellular transport of molecules. It is required for cilia formation and maintenance, as well as successful signal transduction of the Hedgehog (Hh) pathway (Huangfu, 2005). We analyzed KIF3A expression patterns in wild-type mice during the growth and development of the craniofacial prominences. KIF3A is robustly expressed in both the cranial neural crest (CNC) derived mesenchyme and overlying surface ectoderm at the distal tip of the developing frontal nasal process (FNP). It is also expressed throughout the dorsal neuroectoderm in both the ventricular and marginal zones. Knocking-out KIF3A in CNC cells using the Wnt-1 Cre recombinase system produces a mutant with a myriad of craniofacial defects. At e12.5 the mutant has a significantly larger head compared to its wildtype littermates, which either causes or is the result of an extremely enlarged brain. In addition, the survival of neural crest is compromised, as the number of CNC cells within the FNP is significantly reduced in mutant embryos. By e16.5 numerous skeletal defects are evident. The nasal septum is severely truncated and is bifurcated along the sagittal axis. Furthermore, the width of lateral cartilages of the nasal capsule is significantly increased relative to the stage matched wild-type animal. We are currently performing molecular analyses in an attempt to elucidate how precluding normal KIF3A expression in CNC generates the observed phenotype.

High Frequency of Neurexin 1 Signal Peptide Structural Variants in Patients with Autism. *J. Feng[1], R. Schroer[2], J. Yan[1], W. Song[1], C. Yang[1], E. Cook, Jr.[3], C. Skinner[2], C. Schwartz[2], S. Sommer[1]* 1) Department of Molecular Genetics, City of Hope National Medical Center, Duarte, CA; 2) J.C. Self Research Institute, The Greenwood Genetic Center, SC; 3) Institute for Juvenile Research, Department of Psychiatry, University of Illinois at Chicago, IL.

Neuroligins are postsynaptic membrane cell-adhesion molecules which bind to -neurexins, a family of proteins that act as neuronal cell surface receptors. To explore the possibility that structural variants in the -neurexin genes predispose to autism, the coding regions and associated splice junctions of three -neurexin genes were scanned with DOVAM-S (Detection of Virtually All Mutations-SSCP) in 72 Caucasian patients with autism. In addition, segments of the neurexin 1 gene were sequenced in 131 additional Caucasian and 61 African American patients with autism from South Carolina and the Midwest. Two putative missense structural variants were identified in the neurexin 1 gene in four Caucasian patients with autism and not in 535 healthy Caucasian controls (4/203 vs 0/535, P=0.0056). Initial family data suggest that incomplete penetrance may occur. In addition, no structural variant was found in the neurexin 2 gene or the neurexin 3 gene. In the context of all available data, we conclude that mutations in the neurexin 1 gene may contribute to about 2% of autism cases.

MOLECULAR CHARACTERIZATION OF LOW AND HIGH-GRADE OLIGODENDROGLIOMAS. *M. Gadji[1], A.M. Tsanaclis[2], D. Fortin[3], R. Drouin[1]* 1) Service of Genetics, Dept of Pediatrics; 2) Dept of Pathology, Centre Hospitalier Universitaire de Sherbrooke (CHUS); 3) Service of neurosurgery, Dept of Surgery, Faculty of Medicine and Health Sciences, CHUS, Universite de Sherbrooke, Sherbrooke, QC, Canada.

Malignant gliomas are the most common primary brain tumors and include astrocytomas, oligodendrogliomas, and oligoastrocytomas. Oligodendrogliomas constitute about 5% to 30% of all gliomas and their pathogenesis is largely unknown. Molecular studies have identified loss of chromosomal arms 1p and 19q in 50-70% and 65-80% of oligodendrogliomas, respectively. The combined loss of 1p and 19q has proven to be a powerful predictor of a favorable chemotherapeutic response and survival in oligodendrogliomas. We have undertaken a retrospective study of oligodendroglial tumors followed at the CHUS using cytogenetic and molecular genetic techniques. The patient population was composed of 25 persons including 34.3% males and 64.7% females ranging in age from 18 to 77 years with a median age of 40.9 years. Fluorescent In Situ Hybridization using LSI 1p36/1q25 and LSI 19q13/19p13 probes was performed on 21 paraffin embedded tissues retrospectively. The results displayed 16 1p/19q-combined deletions (1p-/19q-); one patient displayed 1p- only, one patient displayed 19q- only and three cases did not show any deletion. To define the deletion length, we performed LOH (Loss Of Heterozygosity) screening with microsatellite marker mapping 1p and 19q after standard PCR-based LOH. Tumor DNA was extracted from 7 paraffin-embedded tissues and from three surgical biopsies. Constitutional DNA was extracted from peripheral blood leukocytes and from saliva in five cases. The preliminary results map the deletions between D1S2795 (1p36.31) locus and D1S2722 (1p34.2) locus and between D19S412 (19q13.32) locus and D19S422 (19q13.13) locus. Kaplan-Meier curves depicting the survival of patients between 0.3 and 262 months and bearing 1p-/19q- displayed a median survival time of 146 months and 136.5 months for oligodendrogliomas and anaplastic oligodendrogliomas, respectively. The average survival obtained in our study is longer than that from previously published studies, possibly due to our more aggressive treatment approaches.

Independent replication of autism association in several neuronal connectivity genes. *J.A. Duvall[1,2], J.L. Stone[1], R.M. Cantor[1], S.F. Nelson[1], D.H. Geschwind[1,2]* 1) Department of Human Genetics, University of California, Los Angeles; 2) Department of Neurology, University of California, Los Angeles.

Autism is a neurodevelopmental disorder which has a significant genetic component and that is characterized by language difficulties, social deficits, and repetitive, stereotyped behaviors. Recently we presented the results of a high density association analysis of 35 neuronal connectivity genes in 224 AGRE autism trios and identified nine genes in which nominal association was observed and for which follow-up analysis was warranted. Here we present the results of an independent follow-up analysis. From the nine genes of interest previously identified, GABRB3, NRXN1, NRXN3, NLGN4, EFNB2, SLIT1, NTN4, SEMA3A, and PLAUR, we genotyped 125 SNPs in an additional 343 AGRE autism trios. The Transmission Disequilibrium Test (TDT) was performed on individual SNPs to determine autism association. Four SNPs showing significant autism association (TDT p0.05) in both the original analysis and the follow-up analysis were identified in three genes: NRXN3, SLIT1, and GABRB3. These findings indicate that genes involved in neuronal connectivity pathways may contribute to autism in some individuals, but also suggest that the contribution from each of these variants is likely to be small. This study presents the first attempt to provide comphrehensive genetic evidence for disruption of biological pathways related to neuronal connectivity in autism pathogenesis. Association analysis using haplotype blocks and testing of other pathway members is ongoing.

***VR22* and *LRRTM3* genes have susceptibility alleles with replicable association in multiple Late-Onset Alzheimers Disease (LOAD) series.** *N. Ertekin-Taner[1,2], M. Allen[3], S. Younkin[3], L. Younkin[3], M. Carrasquillo[3], F. Zou[3], N. Graff-Radford[4], B. Boeve[2], R. Petersen[2], S.G. Younkin[3]* 1) Dept Neuroscience, Mayo Clinic, Rochester, MN; 2) Dept Neurology, Mayo Clinic, Rochester, MN; 3) Dept Neuroscience, Mayo Clinic, Jacksonville, FL; 4) Dept Neurology, Mayo Clinic, Jacksonville, FL.

Alpha-T catenin (*VR22*) on chromosome 10 is an excellent functional and positional candidate LOAD gene. Leucine rich transmembrane protein 3 (*LRRTM3*) resides within the seventh intron of *VR22*. We genotyped 8 SNPs within *LRRTM3* and analyzed them in 3 independent LOAD case-control series. Due to weak linkage disequilibrum (LD), the 8 *LRRTM3* variants formed 20 haplotypes with allele frequencies >1%, accounting for 86% of all *LRRTM3* haplotypes. *LRRTM3* single SNPs or haplotypes did not reveal significant association with LOAD with logistic regression controlling for age, gender and ApoE. The *LRRTM3* haplotype pairs formed 25 common multilocus genotypes (MLGs) which occurred 10 times in the combined series (ages 60-75). In the exploratory series, 6 protective MLGs were identified. Compared to this set of protective MLGs, the remaining MLGs were significantly risky in the exploratory series with an OR of 3.91 (1.61-9.48, p=0.003). Remarkably, this finding was replicated in both follow-up series where the risky MLGs had ORs of 2.99 (1.37-6.54, p=0.006) and 1.97 (0.99-3.94, p=0.055). In the combined series, the OR for the set of risky multilocus genotypes was 2.71 (1.68-4.37) with a p=0.000019. The set of protective *LRRTM3* genotypes are found in 15% and the risky set in 85% of control subjects. This yields a substantial population attributable risk of 59%. The entire *LRRTM3* gene is contained within *VR22*. Functional studies are underway to determine if the risky *LRRTM3* genotypes are associated with altered LRRTM3 and/or VR22 mRNA levels. We have shown that *VR22* has variants that account for the chromosome 10 A42 linkage signal we previously reported. These *VR22* variants and the *LRRTM3* variants are not in LD, suggesting independent effects. Our ongoing analysis suggests that *VR22* also has variants that independently influence risk for LOAD.

Eight genes associated with non-syndromic x-linked mental retardation: the whole is the sum of its parts. *H. Gao[1], K. Gonzalez[1], J. Filiano[2], J. Zheng[1], L. Chen[1], L. Moore[1], V. Kimonis[3], S. Sommer[1]* 1) Clinical Molecular Diagnostic , City of Hope Medical Center, Duarte, CA; 2) Dartmouth Hitchcock Medical Center, Lebanon, NH 03756; 3) Boston Children Hospital, Boston, MA 02115.

X-linked mental retardation (XLMR) has a prevalence of 2.6 cases per 1,000 in the general population, accounting for over 10% of all cases of mental retardation. It is estimated that 2/3 of X-linked mental retardation is non-syndromic (mental retardation without other distinguishing features). Recently, multiple genes have been implicated in non-syndromic XLMR. We have selected eight genes with solid evidence and high attributable rate for a non-syndromic XLMR panel. This panel includes ARX (Aristaless Related Homeobox), DLG3 (Discs, Large Homolog 3), FACL4 (Fatty Acid CoA Ligase 4), FTSJ1 (FTSJ Homolog 1), JARID1C (Jumonji/ARID domain-containing protein 1C), PQBP1 (Polyglutamine Binding Protein 1), TM4SF2 (Transmembrane 4 Superfamily Member 2) and ZNF41 (Zinc Finger Protein 41). Based on publications on individual genes, the estimated detection rate of this XLMR panel is 15-25% of non-syndromic XLMR patients, assuming little or no publication bias. We performed the first multi-gene survey. Since the XLMR panel was offered for clinical testing, 101 clinical samples had been analyzed for the 8 genes. Among them, 38 patients have X-linked family history of mental retardation or developmental delay (class I); 27 patients are sporadic cases (Class II); 36 patients lack clinical information or family history (class III). We identified eight putative mutations in class I and one in class III patients. The detection rate is 12-23% depend on what proportion are X-linked in class III patients. PQBP1 and JARID1c were the most frequently mutated genes. Current data suggests that these eight genes do account for 15-25% of XLMR mutations.

Population genetics and comparative genomics of FUS, a gene involved in malignant translocation. *V. Bekker[1], N. Orr[1], S. Chanock[1,2,3]* 1) Section on Genomic Variation, Pediatric Oncology Branch, Center for Cancer Research, NCI, Bethesda, MD; 2) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 3) Core Genotyping Facility, NCI, Gaithersburg, MD.

The somatic t(11;22) translocation resulting in the fusion of *EWS* and *FLI1* is present in over 85% of cases of Ewings Sarcoma (ES). The remainder of cases arises when *EWS* fuses to one of five members of the ETS gene family (of which *FLI1* is also included). *FUS*, an oncogene found as a fusion partner in liposarcoma and acute myeloid leukemia, has been reported in rare instances to replace *EWS* in ES. Comparison of the genomic structures of *EWS* and *FUS* has revealed highly similar exons. We have characterized population genetic variation in *FUS* to gain further insight into the similarities between these two genes.

Having identified a region of striking conservation in the *EWS* breakpoint region, we conducted a similar analysis for *FUS*. We found a region of 3.2 kb which had a conservation score of 0.712 using the phastCons17way algorithm. Of the small number of cases of ES involving *FUS* reported, all breakpoints occurred in this region, of which we have resequenced 1.6 kb in the SNP500 Cancer population (32 Caucasians, 24 African Americans, 23 admixed/Hispanic and 23 Pacific Rim individuals). Six SNPs were detected and one major haplotype accounted for 93% of the total. Nucleotide diversity, pi, was $9x10^{-5}$ and population mutation frequency, theta, was $51x10^{-5}$. We detected no signatures of recent selection. We compared the linkage disequilibrium and haplotype block structure of *FUS* using HapMap phase II data. LD patterns in both the Caucasian and combined Chinese and Japanese populations were similar, with *FUS* lying at the 5-prime end of blocks of 106 kb and 87 kb respectively. There is evidence for recombination in the Yoruba population in which *FUS* resides in a 47 kb block. Overall haplotype diversity was low (Hd =0.131) and was, as expected, highest in the Yoruba and relatively low in the other populations. These data suggest no sign of recent selection and similar to *EWS* limited haplotype heterozygosity. Further studies are warranted to investigate the population genetic of *FUS*.

Clinical Abnormalities in a Woman with Interstitial Deletion of the Short Arm of Chromosome 11. *D.S. Bonner[1], B.A. Pletcher[1], G.A. Toruner[2], D.L. Streck[2], F. Alcid[3], F. Desposito[1]* 1) Dept Pediatrics, Cytogenetics, UMDNJ/NJ Medical Schol, Newark, NJ; 2) Dept Microbiology and Molecular Genetics, UNDNJ/NJ Medical School, Newark, NJ; 3) North Jersey Developmental Center, Totowa, NJ.

This report describes a 46 year-old female with dysmorphic features and severe mental retardation (MR) who has a de novo interstitial deletion of the short arm of chromosome 11. In addition, she has peripheral edema, significant kyphoscoliosis, and bipolar disorder. MRI of the brain showed arachnoid cysts in the frontal regions, enlargement of ventricles and cortical sulci, as well as a thin rim of hyperintense T2 signal in the periventricular white matter. She has a history of hypothyroidism, chronic sinusitis and chronic bronchitis. Quantitative immunoglobulins are normal, but IgG subclass studies are still pending. These tests may help to explain her recurrent respiratory infections. The patient has three other siblings who are well and without developmental problems. The cytogenetic analysis revealed an interstitial deletion in the short arm on one chromosome 11, with a karyotype designated 46,XX,del(11)(p11.2p13). Although the patient does not appear to have parietal foramina or exostoses generally found in Potocki-Shaffer syndrome (PSS), high density comparative genomic hybridization (CGH) demonstrated a 14 Mb deletion including the EXT2 and ALX4 loci. Other genes contained in this deletion are GYLTL1B, ACP2, MDK, and SLC35C1, which are associated with many of the clinical features in this patient, including MR, growth failure, kyphoscoliosis, and immunodeficiency. A review of the literature revealed a few similar cases with identical breakpoints, but mostly in newborns or young children. This patient appears to be the first reported case of an older individual with this deletion.

An Inexpensive Bead-Based Oligonucleotide Ligation Assay for SNP Genotyping. *S.E. Bruse[1], N. McGregor[1], M.A. Azaro[1], B. Xu[1], L.M. Brzustowicz[1,2]* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) New Jersey Medical School, UMDNJ Newark, NJ.

Candidate gene studies typically involve genotyping of dozens of SNPs within a relatively small region. This requires a flexible technology that is inexpensive in the medium throughput range. One such technology is a bead-based assay combining the oligonucleotide ligation assay (OLA) with the Luminex flow cytometry platform. We have introduced some modifications to the standard OLA/Luminex protocol that reduce the cost per genotype, including: (1) use of far fewer beads than previously published reports (2) use of a universal biotinylated oligonucleotide for capture of the reporter molecule (3) use of FlexMAP (Luminex Corporation) microspheres and (4) incorporation of a highly multiplexed PCR. This system is capable of scoring 50 SNPs simultaneously, processing a 96 well plate in about an hour. The cost is less than $0.10 per genotype for a set of 1000 subjects. In addition to the low assay cost, the initial cost of the platform is ~$50,000, versus other platforms whose cost typically exceeds $250,000. We will present data assessing the validity and reliability of the technique, by comparison of the OLA/Luminex method with both direct sequencing and Pyrosequencing. We will present data focusing on issues of intra-well, inter-well, and inter-plate variability and the negligible impact that using fewer beads has on the accuracy of genotype calling. Finally, we will assess assay conversion rates and assay call rates by presenting data from dozens of multiplexed assays that have been used in candidate gene studies of neuropsychiatric disorders.

Genome-wide association scans identify SNPs associated with Metabolic Syndrome risk factors. *K.A. Frazer[1], J.S. Kooner[2], C.A. Aguilar-Salinas[3], D.A. Hinds[1], C.L. Hyde[4], J.C. Chambers[2], G.R. Warens[4], J. Scott[2], D.S. Lee[4], P.M. Milos[4], D.R. Cox[1], J.F. Thompson[4]* 1) Perlegen Sciences, Mountain View CA; 2) Imperial College of Medicine, London; 3) National Institute of Medicine, Mexico City; 4) Pfizer, Groton CT.

Metabolic syndrome is characterized by a cluster of health risks, increased blood pressure, insulin resistance, abdominal obesity, low HDL cholesterol, and increased triglycerides, in one individual resulting in increased risk for heart disease, stroke and diabetes. Although each of these health risk factors has genetic components, it is unclear whether metabolic syndrome is a distinct heritable medical condition. To identify regions of the genome associated with Metabolic syndrome and its subphenotypes, we performed two whole-genome association studies, individually genotyping DNA from 500 individuals with Metabolic syndrome and 500 matched controls for over 200,000 SNPs in each study. Both studies used individuals living in West London, UK, one cohort was composed of males of South Asia ancestry and the other cohort was composed of males of Northern European ancestry. For the replication phase a set of 5000 SNPs associated with Metabolic syndrome or a subphenotype in the initial two whole-genome studies was genotyped in 4000 additional individuals. Four cohorts were included in the replication phase: South Asia females, Northern European females, Mexican females, and Mexican males. Stratification into the subphenotypes confirmed significant associations of many SNPs, including some located in genes previously shown to be associated with HDL cholesterol and triglycerides levels. Several novel associations of SNPs in genomic intervals not previously identified as associated with the various subphenotypes were also observed. However, no SNPs were significantly associated with Metabolic syndrome, suggesting that it may not have a strong heritable components as currently defined. Interestingly, from the SNPs associated with the various subphenotypes we are able to select a panel of SNPs that may be valuable for predicting individuals predisposed to metabolic syndrome and ultimately improve its definition.

Use of challenging sample types on oligo aCGH microarrays. *F. Cifuentes[1], M. Nair[1], C. Rizzo[2], R. Taylor[3]* 1) Genomics Marketing, Agilent Technologies, Santa Clara, CA; 2) Genomics Marketing, Agilent Technologies, Wilmington, DE; 3) Genomics Research and Development, Agilent Technologies, Wilm., DE.

The use of microarray technology has been growing rapidly over the past decade. Array comparative genome hybridization (aCGH) has become the method of choice for the detection of copy number changes in tumors and genetic disorders. When working with patient samples, there are often significant challenges to overcome to obtain useful data from microarray experiments. Examples of the more problematic sample types include limited starting material, tissue heterogeneity, and formalin mediated crosslinking of nucleic acids. We have developed an optimized protocol for preparing genomic DNA samples to be hybridized to our 60mer oligonucleotide CGH microarrays. The improved method does not require a DNA amplification step and the digestion and labeling reactions have been streamlined, resulting in a shorter processing time without compromising array performance. The protocol has been validated on our aCGH microarray platform using DNA from commercial sources, DNA isolated from cell lines, and DNA isolated from frozen tissues or formalin-fixed, paraffin-embedded tissues. Analysis of DNA isolated from colon carcinoma cell line HT29 (ATCC) successfully detected previously identified aberrations in chromosomes 8 and 18 when using as little as 200 nanograms of input DNA. A comparison of frozen and FFPE samples from breast tumor tissue identified the same HER2+ aberration among others. In titration experiments in which normal cells and cancer cells were mixed we could reliably identify aberrations at 30% purity using Agilent 44K and 185K Human CGH microarrays and our CGHAnalytics software, demonstrating the high sensitivity of the platform.

Why is the Internal Thoracic Artery Resistant to the Development of Atherosclerosis? *S. Archacki, G. Angheloiu, D. Schmitt, C. Moravec, S. Hazen, Q. Wang, Cleveland Clinic Foundation* Molecular Genetics, Cleveland Clinic, Cleveland, OH.

Why is the Internal Thoracic Artery Resistant to the Development of Atherosclerosis? Stephen R. Archacki, George Angheloiu, Dave Schmitt, Christine S. Moravec, Stan Hazen and Qing Wang/The Cleveland Clinic Foundation. Background: We used genetics as a tool to answer the question: Why is internal thoracic artery (ITA) resistant to atherosclerosis? The answer to this question has remained a mystery, until now. Amazingly, the worldwide incidence of disease is estimated to be less than 1 percent. We hypothesize that the endothelial cells (EC) of the ITA respond differently to agents such as oxidized-LDL. Methods and Results: We used intact, human ITA and compared its expression profile intact proximal LAD coronary arteriesthe site of most life-threatening disease causing sudden death. With this approach, we identified the underlying mechanisms which demonstrate why this artery does not develop atherosclerosis. The EC from ITA had a different expression of PECAM-1 (+3.0-fold; $p < 1.45 \times 10\text{-}5$) and enhanced expression of RGS-5, a vasodilator (+5.9; $p < 0.003$) and testin-2 (+4.3; $p < 0.039$), a marker for endothelial cell regeneration. In smooth muscle cells, the expression of three genes was markedly up-regulated in ITA: HSP-70 (+6.1), NOT-1 (+6.5), and ATF-3 (+8.3), which have been shown to reduce atherosclerosis. When we harvested EC from these tissues and exposed these pure cell lines to ox-LDL, we found a significant down-regulation of cell surface adhesion molecules on the ECs from the ITA: VCAM-1 (-18.1), ICAM-1 (-62.4), P-Selectin (-122.0) and E-Selectin (-15.3)--all of which can contribute to inflammation of the artery and generate atherosclerosis. These findings were also demonstrated with immunostains on these arteries and Western Blots. Finally, we analyzed a subset of these genes in large case-control studies to generalize the findings of this genetic profile to the American population at large. Conclusion: We have solved the mystery and answered the question as to why the ITA does not develop atherosclerosis. It resists inflammation.

Oculoauriculofrontonasal syndrome in a mexican patient. *LE. BECERRA[1,2], L. ARNAUD[1,2], M. DIAZ[1,2], JM. MANTILLA[1,2], JA. NASTASI[1,2], M. ORTIZ[1,2], JE. GARCIA[1,2], LE. FIGUERA[1,2]* 1) Departamento de Genetica, CIBO, IMSS; 2) Doctorado en Genética Humana, CUCS, Universidad de Guadalajara, Guadalajara, Mexico.

Oculoauriculofrontonasal (OAFN) syndrome was first report in 1968. This syndrome displays an association of features of frontonasal dysplasia and Goldenhar syndrome. Here we report an 8 year-old boy with OAFN syndrome. He was product from second pregnancy from young healthy unrelated parents; his mother had a previous miscarriage with a hydrocephalic fetus. The propositus was obtained after a full term uneventful pregnancy; birth weight was 3,000 gr. Height and Apgar were not recorded. At birth, there were evident bilateral preauricular tags, macrostomia and a tumor mass in right frontal region. Psychomotor development was normal. Actually he is studying elementary education. Physical exploration: head circumpherence 51.4 cm (40th percentile), height 120 cm (3-10 th percentile), weight 23.5 kg (20-30 th centile). The head show a scar in coronal region, right frontal bossing by osseous prominence and low hairline on this side, left facial asymmetry, sparse eyebrows, the right has a triangle form, to palpation there is a lost of continuity on supra-orbital bridge, telecanthus, and bilateral epicanthic folds. There are two epibulbar dermoids in both eye, the biggest is on the right eye. The nose has a medial scar; the nasal bridge is prominent, broad and bifid nasal tip, and long philtrum. Mouth, superior lip with partial harelip, oral cavity with high and narrow palate, superior gum with a medial cleft, crowded teeth (central incisors above lateral), macrostomia, long right oral commissure and this is down turned, long chin; large ear lobules. No other abnormalities were identified. Radiographic studies did show not evidence of spinal defects. Renal ultrasound is normal. The present case has features of OAFN syndrome. This rare syndrome has common manifestation from Frontonasal dysplasia and Goldenhar syndrome (telecanthus, broad and bifid nasal tip and ocular dermoids, preauricular skin tags, and macrostomia). It is considerate a different syndrome, however, it has been proposed as a spectrum of a same entity, as our patients demonstrate.

Nucleocytoplasmic shuttling defects in heterotaxy. *J.E.J Bedard, S.M. Ware* Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Missense, frameshift, and nonsense mutations in the zinc finger transcription factor ZIC3 cause heterotaxy and have also been identified in patients with isolated congenital heart disease. Previously, we developed transactivation and subcellular localization assays to test the function of ZIC3 point mutations in vitro. Aberrant cytoplasmic localization in a subset of mutants suggested that the pathogenesis of ZIC3 mutations results, at least in part, from failure of appropriate cellular trafficking. To further investigate this hypothesis, the nucleocytoplasmic shuttling properties of ZIC3 were examined. Subcellular localization assays designed to span the entire open reading frame of wild type and mutant proteins identified the presence of nucleocytoplasmic transport signals. Three potential nuclear localization signals (NLS) were identified in ZIC3 and site directed mutagenesis was utilized to alter critical residues. The results demonstrate failure of nuclear localization, with the largest decrease occurring when all three NLS sites were mutated, suggesting that these elements may operate jointly to facilitate proper nuclear targeting. Additionally, we identify a cryptic CRM1-dependent nuclear export signal and identify a mutation within this region in a patient with heterotaxy. These results provide the first evidence that control of cellular trafficking of ZIC3 is critical for function and suggest a possible mechanism for transcriptional control during left-right patterning. Identification of mutations in mapped NLS or NES domains in heterotaxy patients demonstrates the functional importance of these domains in cardiac morphogenesis and allows for integration of structural analysis with developmental function.

The Apoptotic Pathway and Idiopathic Talipes Equinovarus. *A.R. Ester[1], X. Tang[1], A. Scott[2], S.H. Blanton[3], J.T. Hecht[1,2]* 1) University of Texas Medical School at Houston, Houston, TX; 2) Shriners Hospital for Children, Houston, TX; 3) Duke University Medical Center, Durham, NC.

Idiopathic Talipes Equinovarus (ITEV), also known as clubfoot, is a common birth defect occurring in 1/700-1000 live births. Approximately 4000 newborns are diagnosed in the US each year. ITEV is a complex disorder in which multiple genes and environmental factors are postulated to play an etiologic role. Several chromosomal deletion regions, 2q31-33, 3q23-24, 4p14-16, 7p22, 13q33-34 and 18q22-23, have been associated with ITEV; these chromosomal regions may harbor genes that contribute to the phenotype of ITEV. Previously, eight microsatellite markers spanning the 2q31-33 deletion region were genotyped and two, GATA149B10 and D2S1371, showed linkage with association to ITEV. Three candidate genes near GATA149B10, caspase 8 (CASP8), 10 (CASP10) and CFLAR, which are involved in the regulation and activation of apoptosis, were genotyped. rs3731714 in CASP10 showed significant linkage with association (p-value of 0.002). These results suggested that variation in genes in the apoptotic pathway, which are important in limb morphogenesis, play a role in the development ITEV. To test this hypothesis the genes downstream of the CASP8 and CASP10 in the apoptotic pathway were identified: CASP3, CASP9, Apaf-1 and Bid (pro-apoptotic genes) and Bcl-2 (anti-apoptotic gene). Eight SNPs in CASP3, 6 in CASP9, 7 in Apaf-1, 8 in Bid, and 5 in Bcl2 were genotyped in 156 multiplex families with ITEV and 255 simplex trios. The Caucasian and Hispanic allele frequencies were different except for the SNPs in CASP9 and CASP10. All of the SNPs except those in CASP 9 were in HWE. Suggestive results for one or more SNPs were found in the following genes: BID, CASP3, CASP9 and CASP10. Additional analyses are underway and gene interactions are being tested.

Mutation Analysis of the Retinoic Acid Receptor Alpha Gene (RARA) in Autism. *A. Eran[1,4], I. Eisenberg[1,2], D. Pinedo[1,4], K. Graham[1,2], M. Galdzicki[1,4], I.A. Holm[1,3], I.S. Kohane[1,3,4], L.M. Kunkel[1,2,3]* 1) Children's Hospital Boston; 2) Howard Hughes Medical Institute; 3) Harvard Medical School; 4) Harvard-MIT Division of Health Sciences and Technology.

Autism is a common neurodevelopmental disorder with a significant genetic component, characterized by a spectrum of social deficits and repetitive behaviors. Retinoic acid plays a crucial role during development of the vertebrate nervous system through interactions with retinoic acid receptors. The retinoic acid receptor alpha (RARA), located on 17q21, controls cell function by directly regulating gene expression when bound to retinoic acid. A strong linkage peak for autism has been recently fine-mapped to 17q21.

To test whether genetic variations in RARA contribute to this linkage peak, we sequenced RARAs conserved elements in autistic and normal individuals, with the autistic population subdivided into individuals that did and did not contribute to this 17q21 linkage peak. Evolutionary conservation, as an index of functionality, was determined by multiple whole genome alignments; Functionality, in the sense of regulatory mechanisms, was predicted computationally. Screened conserved sequences include both non-coding and coding elements, such as microRNA binding sites, transcription factor binding sites (TFBSs), exons, and splice junctions.

Preliminary results suggest that mutations in TFBSs upstream of the RARA gene might be associated with autism. Unknown variants were found in several individuals that contribute to the 17q21 autism linkage peak. We are presently validating these and other findings in a larger number of individuals.

Fine linkage mapping of a cognitive trait to chromosome 14. *S. Buyske[1, 2, 3], M.E. Bates[2, 5], N. Gharani[3], T.C. Matise[3], J.A. Tischfield[2, 3, 4, 5], P. Manowitz[5]* 1) Statistics Dept, Rutgers Univ, Piscataway, NJ; 2) Center of Alcohol Studies, Rutgers Univ, Piscataway, NJ; 3) Genetics Dept, Rutgers Univ, Piscataway, NJ; 4) Pediatrics Dept, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ; 5) Psychiatry Dept, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ.

The Digit Symbol Substitution Test (WAIS-R) is a test of cognitive processes and relies on working memory, sustained attention, perceptual scan, and visual-motor coordination. In one of the first genome scans of a non-language cognitive trait (Behavior Genetics 36(1):65-76, 2006), we previously reported that a 10cM genome linkage scan yielded significant lod scores on chromosome 14 for the Digit Symbol test in the Collaborative Study on the Genetics of Alcoholism (COGA) sample.

We have since followed up with much denser SNP genotype data on a subset of the original sample. Genotyping was provided by Affymetrix and Illumina, originally for the Genetic Analysis Workshop 14. The sample consisted of 1193 individuals in 111 families, averaging 10.8 individuals in 2.8 generations per family. About 62% of the individuals were phenotyped and 79% at least partially genotyped. The mean inter-marker distance was .35 cM.

Using Merlin-Regress with linkage disequilibrium modeling, we found a peak lod score of 3.5 on 14q31 in a well-defined peak with locus-specific heritability of 38%. The 2-unit-of-lod support interval, 53 cM in the previous study, is now 10 cM or about 6.0 megabases wide. Lod scores are above 1.0 over much of chromosome 14 and we are investigating epistatic effects on this chromosome. This data provides further support for the presence of a specific gene(s) involved in human cognition on chromosome 14; identification of such genes will further our understanding of cognitive functioning under both normal and psychiatric conditions.

Clinical diagnostic testing for autosomal recessive polycystic kidney disease. *J. Dong[1], M.A. Chen[1], S. Nolet[1], M.P. Herbst[1], S. Yao[1], Y. Su[1], R. Sayer[1], L. Guay-Woodford[2], L.M. Messiaen[1]* 1) Dept of Genetics, University of Alabama at Birmingham, Birmingham, AL; 2) UAB Depts. of Medical Genetics and Translational Medicine, Birmingham, AL.

Autosomal recessive polycystic kidney disease (ARPKD) (OMIM #263200) is an hereditary renal cystic disease with an incidence of 1 in 20,000 to 1 in 40,000. The disorder occurs primarily in infancy and childhood and is characterized by enlarged kidneys and congenital hepatic fibrosis. There is no evidence for genetic heterogeneity and *PKHD1* is the only gene known to be associated with ARPKD. The *PKHD1* gene spans approximately 470 kb of genomic DNA on 6p and encodes a 4074 amino acids transmembrane protein known as fibrocystin or polyductin. Due to the severe course of the disease, there is a great need for sensitive and reliable genetic testing in families with a child who has the disease. Linkage based testing using 7 microsatellite markers encompassing a 5 cM region of the *PKHD1* locus is available, but can only be applied when the clinical diagnosis was firmly established in the proband. If in doubt about the clinical diagnosis or if no material was stored for DNA testing from the deceased proband, only mutation analysis of the *PKHD1* gene may allow preparation for prenatal diagnosis in the future. So far, 22 unrelated families (including 20 probands and four obligate carrier parents of deceased individuals) have been tested, in which the diagnosis of ARPKD was suspected based on clinical findings. Genomic DNA was extracted from various tissues, including lymphocytes, fresh or frozen liver and kidney samples, and cultured amniocytes. By PCR and bidirectional sequencing of the longest *PKHD1* open reading frame, 23 mutations were identified. These included 2 nonsense, 12 missense, 2 splice site, and 6 frameshift mutations (FS). 4 new potential pathogenic missense alterations were found so far. The algorithms used to evaluate these novel missense alterations for their pathogenic effect will be discussed.

Complex chromosome 10q rearrangement with terminal deletion in a patient with multiple congenital anomalies.
C. Daly, J. Mester, S. Hassed, S. Li, K. Casas Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

De novo chromosome 10q terminal deletions are rare. Wulfsberg et al. (1989) proposed a chromosome 10q deletion syndrome that includes patients with terminal deletions, interstitial deletions, and other chromosome rearrangements involving chromosome 10q; however, it has been difficult to characterize due to the small number of patients and wide variation in clinical features. Scigliano et al. (2004) reviewed 41 cases of *de novo* 10qter deletions, excluding interstitial deletions of 10qter and deletions associated with other chromosome rearrangements. The patients showed characteristic prominence of the nasal bridge; hypertelorism; abnormal ears; congenital heart disease; anogenital, renal tract, and limb abnormalities; and behavior problems. We report a 7-month-old female with global developmental delays; she was not yet smiling or rolling. She also had a high pain tolerance, chronic otitis media, and shaking spells. EEG was negative and brain MRI showed Chiari malformation. On physical examination, her weight was below the 5th centile. She had a prominent forehead; deep set eyes with trichiasis; kyphosis; scoliosis; sacral dimple; lower extremity spasticity with hammertoe of the great toes; and two café-au-lait macules. Chromosome analysis of metaphase cells showed extra material on chromosome 10q. Subtelomeric FISH analysis proved a *de novo* deletion of 10q. Parental karyotypes were normal. Further investigation with G-banding and whole chromosome painting revealed the extra material is possibly a tandem duplication of 10q26. The atypical phenotypic manifestations of this patient may be due to the breakpoint locus of the terminal deletion or possible 10q26 tandem duplication. *FGFR2* is part of a recombination cluster on 10q26 and has been associated with craniofacial features seen in our patient (Chiari malformation, high forehead, eyelid and lacrimal anomalies, and chronic otitis media). Further characterization of the deletion and possible duplication with molecular cytogenetic studies may provide insight into the specific presentation of the chromosome 10q deletion syndrome.

Analysis of Transforming Growth Factor 3 gene (*TGFB3*) in Pierre Robin Sequence patients. *D. Bueno[1], L.D. Lopes[2], C.E.R. Amaral[3], M.R. Passos-Bueno[1]* 1) Instituto de Biociencias, USP, Sao Paulo,Brazil; 2) Centro de Reabilitacao das Deformidades Faciais,Brazil; 3) SOBRAPAR,Campinas,Brazil.

Pierre Robin sequence (PRS) consists of at least one of these clinical findings: micrognathia, glossoptosis, obstructive apnea, and cleft palate. The pattern of inheritance of the non-syndromic forms is unknown, and both multifactorial inheritance or rare mutations can be responsible for a proportion of the cases. This etiopathological heterogeneity of PRS has made it difficult to identify genes associated to PRS. In an effort to find these genes, we screened the *TGFB3* gene, a transforming growth factor involved in palatogenesis and Meckel cartilage and bone formation, in patients with non-syndromic PRS. The Tgfb3 knockout animal was described as a model for isolated cleft palate associated with respiratory difficulties. Association between polymorphism in *TGFB3* and cleft lip and/or palate remains controversial. Considering the expression pattern of *TGFB3* and the knockout phenotype, we considered *TGFB3* as a good candidate for PRS. Our sample consisted of 48 unrelated patients with non-syndromic PRS. All of them were excluded for deletions at 22q11 (Velocardiofacial syndrome) by microsatellite marker analysis. All the 7 *TGFB3* exons and their neighboring intronic regions were analyzed by dHPLC or SSCP and abnormal patterns were sequenced. We found three rare altered migrating patterns. Sequence analysis of these last ones revealed that they correspond to two previously described mutations: c.1501GA (rs4252346), detected in two of our patients, and c.1500 CT (rs3917215), found in another patient. Although these mutations were not found in 200 control alleles of our population, a frequency of 1,2% and 0,7 % respectively are described by others (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=Snp). We have analysed the parents of each of these affected patients and we verified that all of them were *de novo* changes. Considering the rarity of these mutations and that they are *de novo*, it is possible that they are involved with PRS. Further studies will be performed to elucidate its possible functional effect. CEPID/FAPESP- CNPq.

Genetic heterogeneity in schizophrenia evidenced by co-occurring obsessions and compulsions: A candidate gene study. *P.L. Belmonte[1], M.D. Fallin[2], G. Nestadt[3], A.E. Pulver[3], P.P. Zandi[1]* 1) Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD.

Schizophrenia is a highly heritable psychiatric disorder for which no susceptibility genes have been definitively identified. One reason for difficulty in identifying disease genes is genetic heterogeneity. Obsessions and compulsions frequently co-occur with schizophrenia and obsessive-compulsive spectrum disorders aggregate in schizophrenia families. We used obsessive-compulsive disorder (OCD) and symptoms (OCS) as markers of genetic heterogeneity in schizophrenia and tested candidate genes for association with schizophrenia in the presence of such heterogeneity. Our sample included 261 Ashkenazi Jewish case-parent trios from the Epidemiology-Genetics Program in Psychiatry at Johns Hopkins University. A total of 64 genes were selected for testing based on prior linkage, association, or biological plausibility for schizophrenia or bipolar disorder. Of these, 16 are involved with the glutamate system. These are of particular interest as glutamate has been implicated in both schizophrenia and OCD. A total of 440 single-nucleotide polymorphisms (SNPs) were typed with an average of 6.9 SNPs per gene. We performed single-SNP and haplotype-based transmission-disequilibrium tests. Analyses were performed using stratification by OCD or OCS status and differences in association were confirmed by tests of interaction. In stratified analyses, we found highly suggestive evidence (p0.01) of association for the gene *TUBA8* with schizophrenia in those with OCD. Associations of *GRID1* and *GRIN2B* with schizophrenia were highly suggestive in those with OCS. Of the non-glutamate genes, we found highly suggestive evidence of association with schizophrenia in those with OCD or OCS for *SCA1*, *KIF13A*, *ADRA1A*, *DPYSL2* and *GRFA1* (all p0.01). Associations of *PNOC* with schizophrenia was highly suggestive in those without OCD or OCS. These results suggest genes contributing to the risk of schizophrenia may differ for those with and without OCD/OCS.

Frequency of Fabry disease family histories in a prenatal genetic counseling population. *D. Cutillo[1], H. Travers[2], E. O'Rourke[2], E.R. Wassman[3], D. Ramsey[1], A.E. Donnenfeld[1]* 1) Genetic Services, Genzyme , Philadelphia, PA; 2) Genzyme Therapeutics, Cambridge, MA; 3) Genzyme, Westborough, MA.

Recent developments in enzyme replacement therapy (ERT) for Fabry disease have had a significant impact on the treatment of patients with this disorder. Therefore, patients who have a family history of this disorder need to be identified and counseled appropriately. One recent newborn screening study indicates that the incidence of Fabry disease may be as high as 1 in 2750. The purpose of this abstract is to report on the frequency of genetic counseling sessions in a prenatal population in which a family history of Fabry disease is discovered. Between January 2003 and April 2006, 197,475 patients were seen at Genzyme Genetics for prenatal genetic counseling at geographically diverse locations within the United States. The patients were referred for genetic counseling from obstetric or perinatal physician practices. There was no referral relationship or selection bias of patients between the product team or clinical providers of ERT and the genetic counseling service. During this time period a total of 50 patients were counseled for a family history of Fabry disease. This yields a frequency of approximately 1/4000 prenatal patients. In 23/50 families there was a first or second degree relative of the patient affected with Fabry disease. In 27/50 families the patient or partner (40.7%) or a first degree relative (59.3%) was reported to be a carrier for Fabry disease. Only 14/50 patients were aware of ERT availability for Fabrys disease prior to the counseling session. Of all the patients counseled for a family history of Fabry disease, 50.0% of patients were referred for another indication and only 28.0% of patients had some advance knowledge of enzyme replacement therapy for Fabry disease. We conclude that in an unselected population of prenatal patients, a family history of Fabrys disease will be uncovered in approximately 1/4000 families. Primary health care providers and genetic counselors should be kept up-to-date on advances in treatment for Fabry disease and be familiar with specialized referral centers as a resource for these patients and their families.

Very complex, de novo chromosomal abnormality in a newborn with multiple congenital defects - a counseling challenge. *A. El-Hattab[1], M. Velinov[2], G. Valencia[1], A. Perenyi[1]* 1) Department of Pediatrics, SUNY Downstate Medical Center, Brooklyn, NY; 2) Department of Gene and Cell medicine, Mount Sinai School of Medicine, New York, NY.

Introduction: A case of complex, de novo chromosomal anomalies (terminal 1q and interstitial 2p deletions and 1p duplication) in a newborn with dysmorphic features, agenesis of corpus callosum, cholestasis, and vesicouretral reflux. **Clinical report:** This was the third pregnancy of a 32 years- old healthy mother with unremarkable family history. Prenatal Ultrasound revealed absence of corpus callosum. Amniosentesis chromosomal analysis revealed 46,XY,der(1)del(1)(q42) dup(1)(p22p34) dup(1)(p36.1p36.3) t(1:14)(p22:q32) der(2)del(2)(p23) ins(2:1)(q31:p36.1p36.3) ins(2:1)(q35:?) inv(2)(p23q31). Baby boy was born at term, with birth weight of 3.115 Kg (25th-50th centile) and HC=35 cm (75th-90th centile). Dysmorphic features include high forehead, ridged metopic suture, coarse and rounded face, hypertelorism, prominent eyes, micrognathia, broad depressed nasal bridge, long flat philtrum, low set ears, short neck, prominent occiput, polydactyly, clinodactaly, flexion deformities of the hand fingers, and small hypoplastic nails of the toes. Eye exam revealed retinosclerosis. VCUG revealed bilateral grade 3 vesicouretral reflux. Direct hyperbilirubinemia developed, HIDA scan was suggestive of biliary atresis. **Discussion:** Terminal chromosome 1q deletion, chromosome 1p duplication and chromosome 2p interstitial deletion each is a definable syndrome with few reports on each. This case is the first reported case that has the combination of all these chromosomal abnormalities and features from these syndromes plus other features- such as the cholestasis- that were never reported with any of these syndromes. This very rare/unique case illustrates the difficulties that such complex chromosomal abnormality may present to genetic counseling and care, since it would be difficult/impossible to predict the phenotypic consequences of this abnormality. Further molecular evaluations using Comparative Genome Hybridization may contribute for more precise determination of the chromosomal unbalance in such cases.

A rare single nucleotide polymorphism within mature miR-125a alters its biogenesis. *R. Duan[1], C. Pak[1,2], P. Jin[1,2]*
1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Program in Genetics and Molecular Biology, Emory University, Atlanta, GA.

microRNAs (miRNAs) are ~22-nucleotide non-coding RNAs that inhibit expression of specific target genes at the posttranscriptional level. miRNAs are initially transcribed as long primary transcripts (pri-miRNAs) that are then processed to ~65 nucleotide hairpin precursor miRNAs (pre-miRNA). pre-miRNAs are subsequently exported from the nucleus and cleaved by the RNaseIII Dicer to generate mature miRNAs. Since polymorphisms within miRNA genes could influence the biogenesis and/or target selection of miRNAs, we screened all known miRNAs in the human genome for single nucleotide polymorphisms (SNPs). Of the 462 known human miRNAs we have identified the presence of 14 SNPs. Interestingly, a G-T polymorphism was identified at the eighth nucleotide of mature mir-125a (mir-125a-SNP). While the 2^{nd}-8^{th} nucleotides of mature miRNAs have been proposed to act as seed sequences critical for miRNA-mediated translational control, we have found that this SNP does not influence mir-125a-mediated translational modulation. However, subsequent expreiments revealed a significant reduction in mature mir-125a-SNP levels *in vivo*. RNA folding analysis indicated altered secondary structure of pri- and pre-mir125a-SNP that may affect the biogenesis of this miRNA. Consistent with this prediction, we have found that this SNP alters processing of pri-mir-125a-SNP to pre-mir-125a-SNP. To further validate the role of the altered secondary structure in miRNA processing we generated a double mutant (mir-125a-DM) that contained the G-T polymorphism in addition to a complementary C-A base change that should preserve the seconday structure of pri- and pre-mir-125a. We have found the mir-125a-DM is processed normally. Together, these data suggest that instead of altering translational modulation, the SNP associated with mature mir-125a could alter the secondary structure of pri- and pre-mir-125a and specifically affect processing of pri- to pre-mir-125a. Furthermore, identification of SNPs associated with miRNAs will facilitate understanding of the biogenesis of miRNAs and miRNA-mediated gene regulation.

Linkage study of familial thoracic aortic aneurysms and dissections to known chromosomal loci. *D.C. Guo[1], H. Pannu[1], V.T. Tran-Fadulu[1], N. Avidan[1], R.K. Yu[3], A.L. Estrera[2], H.J. Safi[2], M.C. Willing[5], D. Divecha[1], J.H. Chen[1], J. Yuan[1], R. He[6], S.E. Scherer[4], S. Shete[3], D.M. Milewicz[1]* 1) Dept Internal Medicine, Univ Texas/Houston Med Sch, Houston, TX; 2) Dept Cardiovascular Surgery, Univ Texas/Houston Med Sch, Houston, TX; 3) Dept Epidemiology, Univ Texas M.D. Anderson Cancer Center, Houston, TX; 4) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas; 5) Dept Pediatrics, Univ Iowa, Iowa City, Iowa; 6) Dept Internal Medicine, Medical College of Shanghai Jiaotong Univ, Shanghai, China.

Aortic aneurysms and dissections are the major diseases affecting the aorta, and a leading cause of morbidity and mortality in the United States. Genetic studies of familial thoracic aortic aneurysms and dissections (TAADs) have identified five chromosomal loci, TAAD1, TAAD2 (TGFBR2), TAAD3 (15q24-26), FAA1, and TAAD/PDA (MYH11) and three genes, TGFBR1, TGFBR2, and MYH11 that are responses to familial TAAD. To investigate genetic conditions predispose individuals to TAADs, our laboratory has recruited 345 TAAD families with 2 or more affected family numbers. Twenty percent of families have no living affected family members and half of the families have only 1 affected family member or are parent-child combination. Multipoint linkage analysis was performed on 59 families that have DNA samples collected from more than three affected individuals on known TAAD loci including TAAD1, TAAD3, and FAA1. Based on families with lod scores greater than 0.6 for these loci, 10% of families show linkage to TAAD1, 5% to TAAD3, and one family to FAA1, with total lod scores of 5.5, 5.05, and 0.6, respectively. Twenty-two families showed low positive lod scores (<0.6) to at least one locus. In addition, sequencing analysis was performed for TGFBR1, TGFBR2, and MYH11 on sampled collected from 100, 200, and 96 affected individuals from unrelated TAAD families, respectively. Mutations were found in 1 family for TGFBR1, 6 families for TGFBR2, and 2 families for MYH11. Interestedly, in 11 families, no linkage to any known loci provides evidence indicating 1 or more TAAD loci yet to be identified.

Molecular and clinical characterization of patients with putative Li Fraumeni Syndrome sent for p53 molecular diagnostic testing. *K.D. Gonzalez, C.H. Buzin, K.A. Noltner, D. Gu, W.A. Scaringe* Dept of Molecular Diagnosis, City of Hope Natl Medical Center, Duarte, CA.

Li Fraumeni Syndrome (LFS) is an autosomal dominant inherited cancer predisposition syndrome caused by germline mutations in the p53 gene. Classic LFS is characterized by a proband with a bone or soft tissue sarcoma diagnosed under 45, a first degree relative with cancer diagnosed under 45, and another first or second degree relative with cancer under 45 or a sarcoma at any age. Patients with a germline p53 mutation have a 90% risk by age 60. There are less strict clinical criteria which have been developed for Li Fraumeni-like syndrome (LFL; Birch criteria, Eeles criteria). We analyzed clinical samples that were submitted to the Clinical Molecular Diagnostic Laboratory (CMDL) at City of Hope for diagnostic testing of the p53 gene. We identified 91 positive families from 550 submitted samples, and clinically categorized 264 families (61 positives, 204 negatives). Several interesting and novel findings have emerged. All positive families had one of four core cancers: adrenocortical carcinoma, choroid plexus carcinoma, sarcoma, or breast cancer. All families which lacked these core cancers were negative. Among all families who met classic LFS, 62.5% were positive and among families meeting the Birch and Eeles criteria (LFL), 16% and 19%, respectively, were positive. Interestingly, 20% of families who did not meet LFS or LFL criteria had a p53 mutation. **Four de novo mutations were identified.** All have either an adrenocortical carcinoma or a choroid plexus carcinoma, or both. Additionally, there are nine other possible new mutations based on negative family histories. We conclude that new mutations are more prevalent than previously thought. In addition, choroid plexus tumors are due to p53 germline mutations until shown otherwise. All eight patients (100%) with choroid plexus carcinoma had a p53 mutation and all had negative family histories. Based on the experience gained from this largest single set of patients with identified p53 mutations, we propose a comprehensive set of clinical criteria for predicting the likelihood of p53 germline mutations.

Is Ménières disease associated with polymorphisms in KCNE1 or KCNE3 in the United States? *C.A. Campbell*[1,2], *C.C. Della Santina*[3], *N.B. Smith*[3], *J.P. Carey*[3], *L.B. Minor*[3], *R.J.H. Smith*[1,2] 1) Dept of Otolaryngology, University of Iowa, Iowa City, IA; 2) Interdepartmental PhD Program in Genetics, University of Iowa, Iowa City, IA; 3) Dept of Otolaryngology, Dept of Biomedical Engineering, and Dept of Neuroscience, The Johns Hopkins University, Baltimore, MD.

Ménières disease (MD) is a complex disorder of unknown etiology characterized by the symptoms of vertigo, sensorineural hearing loss and tinnitus. Its incidence in Caucasians is 1-2 per 10,000 and in the Japanese, 35-160 per 1,000,000 (Morrison 1995). Although candidate genes studies focused on COCH (coagulation factor C homology), ATQ1 (antiquitin) and AQP2 (aquaporin 2) have been unsuccessful in identifying disease-causing allele variants of these genes, Doi and colleagues have reported that two single nucleotide polymorphisms (SNPs) in KCNE1 and KCNE3 are associated with MD in Japanese patients (Doi et al. 2005). These two genes encode potassium channels that are expressed in the stria vascularis and endolymphatic sac, respectively. Their role in ion transport and their expression pattern suggest that they may be important in inner ear homeostasis.

To establish whether a similar association exists in the Caucasian MD population, we sequenced the coding regions and exon-intron boundaries of both genes in ~90 persons with MD and compared results to 168 ethnically matched CEPH controls. Neither of the two reported SNPs were significantly associated with MD (KCNE1, p=0.49; KCNE3, p=0.70). Furthermore, comparison of allele frequencies between the Japanese MD population and our study population revealed no significant difference between groups (KCNE1, p= 0.72; KCNE3, p=0.40), suggesting that the significant differences reported in the Japanese study arose from their control population. Consistent with this possibility, we found allele frequencies between the two control populations to be significantly different (KCNE1, p=0.00; KCNE3, p=0.0008). A comparison of the KCNE3 SNP allele frequency in their control population and the HapMap JPT population is also highly significant (p=0.00). Our data show that SNPs in KCNE1 and KCNE3 are not associated with MD in Caucasians.

Function Follows Form: Differential respiratory capacity of mitochondrial complex I mutants in *C. elegans*. *M.J. Falk[1,2], J. Rosenjack[3], M.A. O'Riordan[2], M.M. Sedensky[1,3], P.G. Morgan[1,3,4]* 1) Depts of Genetics; 2) Pediatrics; 3) Anesthesiology; 4) Pharmacology, CASE SOM and Univ Hosp of Cleveland, Cleveland, OH.

Nuclear gene mutations are postulated to be the major cause for mitochondrial oxidative phosphorylation disorders. However, the majority of causative genes are not yet identified and the mechanisms by which their dysfunction results in clinical disease are not known. The nematode, C. elegans, is a useful translational model in which to study the genetic and biochemical basis of mitochondrial dysfunction. We used this model to investigate whether respiratory dysfunction is differentially caused by particular nuclear DNA encoded components of mitochondrial complex I, the largest and most commonly implicated complex in human mitochondrial disease. At least 82% of the 39 nuclear genes encoding human complex I subunits share extensive homology in C. elegans. Utilizing a feeding RNA interference gene knockdown approach, we generated C. elegans mutants for 13 complex I structural subunits. RNA knockdown was confirmed by qRT-PCR. Integrated respiratory capacity of freshly isolated mitochondria from complex I mutants was assayed by polarography. We show that individual nuclear-encoded complex I subunits vary significantly in their impact on integrated complex I-dependent oxidative phosphorylation capacity. Reactive oxygen species damage, as assayed by mitochondrial protein 4-hydroxynonenol antibody staining, also varies by subunit. Importantly, function appears to follow form. Subunits with the greatest impact on respiratory capacity appear to localize to subcomplexes involved in electron transport through complex I. In contrast, subunits known to localize to the membrane-bound arm of complex I minimally impact respiratory capacity. This model organism approach is useful to aid in the rational identification of candidate gene subsets to investigate in human patients with biochemical evidence of mitochondrial complex I dysfunction. It further permits investigation into mechanisms by which individual nuclear genes, when mutated, contribute to human mitochondrial disease.

Functional characterization of an R488H mutation in the plasma membrane carnitine transporter OCTN2, identified in a patient with moderate but symptomatic carnitine deficiency. *R. Gallagher[1, 2], T. Urban[1], C. Morgan[2], S. Packman[2], K. Giacomini[1]* 1) Department of Biopharmaceutical Sciences, Univ California, San Francisco, San Francisco, CA; 2) Department of Pediatrics, Univ California, San Francisco, San Francisco, CA.

During an investigation of the etiology of carnitine deficiency in a symptomatic patient R488H was identified in one OCTN2 allele. R488H had been identified previously only in *cis* with another mutation, A142S. The doubly mutant transporter was reported to be retained in the Golgi and to have very low transport activity in CHO cells. We hypothesized that R488H resulted in the mislocalization. We developed HEK cell lines stably transfected with wild-type and mutant OCTN2 transporters fused to GFP. Transporter localization was assessed by confocal microscopy. Transport assays were performed to determine function.

Both wild-type and R488H transporters localized to the plasma membrane. In contrast, A142S and A142S/R488H transporters showed *both* intracellular retention *and* plasma membrane staining, indicating a partial trafficking defect in HEK cells. This suggests that the mislocalization of the double mutant is due primarily to A142S.

In transport assays the single mutant OCTN2 transporters had mildly reduced function; the double mutant showed an additive effect: A142S: 65% of wild-type, R488H: 74%, A142S/R488H: 48%. Thus, in HEK cells, in contrast to CHO cells, the doubly mutant transporter had significant residual function.

Fractional excretion of carnitine in the parents of the proband indicated that the non-R488H allele caused a more marked reduction in function than the R488H allele. This suggests that the non-R448H allele contributed more significantly to the patient phenotype.

Our results demonstrate the importance of functional assays in establishing the pathogenicity of a nucleotide change. We further conclude that different heterologous cell systems may yield different results, and that these must be correlated with *in vivo* data.

A human fetal cartilage-specific gene expression profile. *V. FUNARI[1], A. DAY[2], D. KRAKOW[1], Z. COHN[1], S. NELSON[2], D. COHN[1,2]* 1) Medical Genetics Institute at Cedars-Sinai Medical Center, LA, CA; 2) Dept. of Human Genetics at UCLA School of Medicine, LA, CA.

Cartilage plays a critical role in human skeletal development, and mutations in many genes uniquely expressed in cartilage are associated with skeletal dysplasias. However, surprisingly little is known about developing cartilage gene expression. To identify genes differentially regulated in human fetal cartilage, 6 fetal cartilage expression profiles were compared to expression profiles from 15 different organs using 46 Affymetrix U133 Plus 2.0 microarrays. Using Significance Analysis of Microarrays, 2,337 probes were identified with significantly higher expression in cartilage. These probes were further validated by comparing their expression in two fetal cartilage samples to 32 non-cartilage containing tissues using 223 Affymetrix U133A/B and 2.0 Plus microarrays. For validation, the signal in cartilage was required to be well measured (intensity >100), and at least five-fold higher than the median expression in non-cartilage tissues. Probes were then ranked by cartilage-specificity, using an analog of coefficient of variation (CV) derived from the non-cartilage tissues. Only probes with a CV of <50% were considered cartilage-specific. By this measure, 177/2,337 probes, representing 146 genes were validated as specifically expressed in cartilage. Many of these genes encode known cartilage-specific extracellular matrix structural proteins and transcripts previously identified in a fetal cartilage EST library, providing confidence that these methods identified fetal cartilage-specific genes. Notably, 12/146 cartilage-specific genes are regulated by NF-KB, including BMP2, LIF, FN1, iNOS, and RELB. This unique expression profile suggests an important but poorly characterized NF-KB regulatory network in growth plate cartilage. Importantly, 23%(33) of the cartilage-specific genes encode unannotated proteins. Overall, these data indicate that the set of genes preferentially or exclusively expressed in cartilage has been greatly underestimated. Many of these genes are likely to have important roles in skeletogenesis and may be candidate genes for skeletal disorders.

Identification of a New Class of 1p36 Deletion Patients Using Array-CGH. *C.A. Bacino[1], S.-H.L. Kang[1], A. Scheffer[2], P.A. Eng[1], J.T. Appleberry[1], J. Li[1], S. Vacha[2], E.R. Roeder[3], V.B. Enciso[3], S. Braddock[4], S.W. Cheung[1]* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Agilent Laboratories, Palo Alto, CA; 3) Division of Genetics and Metabolic Disorders, University of Texas Health Science Center at San Antonio, San Antonio, TX; 4) Division of Medical Genetics, University of Missouri, Columbia, MO.

Monosomy 1p36 is the most common terminal deletion syndrome with an estimated occurrence of 1 in 5000 live births. This deletion results in mental retardation, developmental delay, hearing loss, seizures, cardiac anomalies, in addition to distinct facial features such as large anterior fontanel, deep-set eyes, flat nasal bridge, asymmetric ears, and pointed chin. The rearrangements causing 1p36- are typically observed cytogenetically as a telomeric deletion spanning <10 Mb from 1pter-1p36.23. We report four patients with atypical interstitial deletions proximal to band 1p36.23 detected by array-comparative genomic hybridization (array-CGH). Three patients carry large overlapping deletions of approximately 11.39-14.69 Mb. One patient however, carries a small 2.97 Mb deletion that overlaps with the larger deletions observed in the other three patients. Interestingly these patients manifest clinical characteristics that are different from those seen in classical Monosomy 1p36 deletion syndrome. The clinical presentations in our patients included: prenatal growth deficiency, poor post-natal growth and failure to thrive, feeding difficulties necessitating gastrostomy or NG feedings in some instances, seizures, developmental delay, congenital heart disease, microcephaly, dysmorphic features and limb anomalies including brachydactyly, digital contractures, and/or 5th finger clinodactyly. The dysmorphic features included frontal and parietal bossing, abnormally shaped and posteriorly rotated ears, hypertelorism, arched eyebrows, and prominent and/or broad nose. All children also displayed hirsutism. Similar features have been described in previously affected children with such interstitial deletions suggesting that this chromosomal abnormality may constitute yet another deletion syndrome distinct from the classical distal 1p36 deletions.

Single Nucleotides Polymorphisms (SNPs) in head and neck cancers. *M.T. Ruiz[1], M. Floria-Santos[2], L.M. Alvarenga[1], E.C. Pavarino-Bertelli[1], P.E.M. Guimarães[3], E. Dias-Neto[3], M.J.C. Ruback[1], J.V. Maniglia[1], E.H. Tajara[1], E.M. Goloni-Bertollo[1]* 1) Molecular Biology Department, FAMERP, Sao Jose do Rio Preto, Brazil; 2) The University of Sao Paulo College of Nursing at Ribeirao Preto, Brazil; 3) The University of Sao Paulo School of Medicine, Brazil.

Purpose: To evaluate SNPs from KISS-1 (GA), NINJURIN (A C) and TAX1BP1 (T A) genes in patients with head and neck cancers, and to compare their frequencies within a control population. Methods: We evaluated 186 patients with head and neck cancer and 175 without neoplasia history. The molecular analysis was done after extract DNA from peripheral blood using PCR-SSCP and PCR-RFLP techniques. We used descriptive statistics and Fisher test. Results: Variables analysis showed that the majority of the cases was men (82.07%), Caucasoid (83.33%), 88.72% used tobacco, and 64.4% used alcohol. The most frequent primary site was oral cavity (38.36 %). We did not find statistical differences for the allelic variants from the studied genes, between patients and the control group (KISS-1 gene p=0.2025; NINJURIN gene p=0.1269; TAX1BP1 gene p=0.8434). Conclusion: We did not find association between the studied polymorphisms and head and neck cancers. Therefore, we recommended that the sample number should be increased in order to investigate those variants. The understanding of the mechanisms involved on the tumorigenic process can contribute for individualized treatments and disease prevention. Supported by: CNPq, FAMERP-FUNFARME and FAPESP.

Duodenal Atresia: Prenatal Imaging and Autopsy Findings. *t. Ben-Omran, a. Moore, e. Cutz, r. Windrim, s. Viero, d. Chitayat* Clinical and Metabolic Genetic, The Hospital for Sick Children, toronto, on, Canada.

Duodenal atresia (DA) is the most common type of small bowel atresia with an incidence of 1:10,000 births. DA is a malformation and associated with other anomalies in approximately 30-50% of cases, including gastrointestinal, cardiac, renal, and skeletal abnormalities. DA can be diagnosed prenatally, as early as 18 weeks gestation; however, it may be delayed until after 24 weeks. Mitchell et al., (2004) reported two families with a hitherto new autosomal recessive condition including IUGR, duodenal/ jejunal atresia, annular pancreas, absent gall bladder, neonatal diabetes and dysmorphic features. Here, we report the antenatal ultrasound and MRI findings done on one of the families reported which diagnosed a recurrence. This was the fourth pregnancy of this couple who already lost two children with this condition. Fetal ultrasound done at 18 weeks gestation showed a "double-bubble" sign as an indication of DA. Fetal MRI revealed DA and an absent gall bladder which suggest that this fetus likely have the same condition. Attempts are made to find the gene associated with this autosomal recessive condition but in the meantime the only way we can diagnose the condition prenatally is by fetal ultrasound and MRI which seem to be reliable.

Alternative pathway therapy, nutritional support, and hemodialysis and/or continuous renal replacement therapy (CRRT) in the treatment of neonatal hyperammonemia. *T.H. Cushing[1], N. Baugh[2], C. Wong[1], S.R. Alexander[1], G.M. Enns[1]* 1) Pediatrics, Stanford University, Stanford, CA; 2) Clinical Nutrition, Lucile Packard Children's Hospital, Stanford, CA.

Neonatal hyperammonemic crises are associated with high morbidity and mortality. Alternative pathway therapy (APT), high-calorie nutritional support and hemodialysis (HD) are the mainstays of treatment. In order to understand better the therapeutic effects of these modalities, we describe the clinical course of 15 hyperammonemic neonates treated between 1998 and 2006. Eight patients had organic acidemias (OA)(5 MMA, 3 IVA) and 7 had urea cycle defects (UCD)(2 CPS, 2 citrullinemia, 2 OTC females, 1 OTC male). Patients were treated with protein restriction, high concentration IV dextrose, and intralipids to provide approximately 100 to 120 kcal/kg/day. Three of 8 OA patients required continuous renal replacement therapy (CRRT). We used continuous veno-venous hemodiafiltration to optimize and sustain ammonia removal without rebound. Three of 7 UCD patients required HD, CRRT, or both. No complications occurred with HD or CRRT. Peak ammonia levels ranged from 75 mol/L (IVA patient) to 2653 mol/L (OTC male). The highest ammonia level that responded to therapy without HD/CRRT was 486 mol/L for UCD and 627 mol/L for OA. Two of 15 patients (OTC female and CPS) died in the neonatal period, giving an overall neonatal survival rate of 87%. Two of 13 surviving neonates died in early childhood (MMA and OTC male). Two MMA patients were lost to follow-up. Six patients showed mild (OTC female, CPS, IVA) to severe (3 MMA) developmental delays on follow-up from 8 months to 5 years and 4 were normal on follow-up from 7 months to 6 years. Although survival is good for both groups, patients with UCDs appear to have better developmental outcome. We stress the importance of immediate transport of hyperammonemic neonates to centers with experience in all aspects of therapy, including APT, nutritional support, and HD/CRRT. Based on our limited cohort, supportive care, APT and nutritional support have the potential to be effective at ammonia levels around 600 mol/L in neonates.

Neonatal RDS and Polymorphisms in the Corticosteroid Metabolism Pathway. *K.S. Borowski[1], J.M. Dagle[2], J.C. Murray[2]* 1) Obstetrics and Gynecology, University of Iowa, Iowa City, IA; 2) Neonatology, University of Iowa, Iowa City, IA.

Respiratory distress syndrome (RDS) is a clinical diagnosis made in newborn infants with symptoms of respiratory distress, characteristic x-ray findings and an oxygen requirement. The incidence of RDS is inversely related to the gestational age at delivery. Rates of RDS are affected by the rate of premature delivery as well as by antenatal corticosteroid admninistration. Risk factors for RDS also include maternal diabetes, race and gender. A genetic component to RDS has been clearly identified with gene mutations in SP-B and ABCA3 leading to fatal RDS. Given the known genetic associations with RDS, as well as a decreased incidence with corticosteroid administration, we hypothesized that genetic variability in the glucocorticoid pathway in mothers and infants may alter the risk of neonatal RDS.

Using a candidate gene approach, 5 genes in the glucocorticoid metabolism pathway were analyzed using tagging single nucleotide polymorphisms (SNPs)-NR3C1, HSD11B1, HSD11B2, CYP3A4 and SerpinA6. Inclusion criteria were enrollment in the Disease Variability in the Newborn study at the University of Iowa from 2/01 to 3/06 with available DNA, diagnosis of RDS and gestational age 33-41 weeks. Genotyping was performed using TaqMan assays from Applied Biosystems. 241 affected neonates were analyzed, along with 225 mothers of affected neonates. A sample of anonymous term control infants and mothers were also used for case-control analysis. The results were analyzed with a transmission disequilibrium test (FBAT) as well as with Fisher's exact test for the case-control data. FBAT was performed for all SNPs with none reaching significance. Significance was found in the infant cases compared to controls for variations in the following SNPs: HSD11B2 rs5479 ($p=0.002$), CYP3A4 rs2242480 ($p=0.000012$) and HSD11B1 rs2235543 ($p=0.0016$). Significance was found in the maternal cases with CYP3A4 rs2242480 ($p=0.004$), HSD11B1 rs2235543 ($p=0.0076$) and HSD11B1 rs2282739 ($p=0.0076$). These results suggest that genetic variability in the glucocorticoid metabolism pathway may alter the risk of neonatal RDS.

Expression profiling of blood in Autism. *M. Galdzicki, A. Eran, I. Eisenberg-Loebl, A.T. Kho, H. Peters, K. Graham, S. Brewster, R. Hundley, E. Hanson, J. Ware, L. Rappaport, I.A. Holm, L.M. Kunkel, I.S. Kohane* Children's Hospital Boston, Boston, MA.

Autism Spectrum Disorder (ASD) is a developmental disorder which includes impairment of communication skills, social interactions and repetitive and stereotyped behavior. Twin and family studies give strong evidence suggesting a genetic susceptibility to ASD. We expect an interplay between genetic and environmental factors to be the underlying cause. As part of our integrative genomic approach to understand the causative mechanism responsible for ASD we have established genome-wide gene expression profiling study in children with ASD using in Peripheral Blood Mononuclear Cells (PBMCs) from affected children and control individuals.

More than fifty blood samples from children diagnosed as ASD affected, based on the ADOS/ ADI-R criteria, were collected to date and we expect five-hundred by the end of the year. Twelve affected samples were processed as a preliminary data set on Affymetrix U133 Plus 2.0 microarrays. We were able to distinguish two separate classes of ASD samples based on their expression signature. A short list of differentially expressed transcripts and pathways was found in the analysis and will be further discussed.

With increased sample numbers we expect to find a set of genes that can be used to help diagnose ASD and further divide the ASD into subcategories based on experimentally quantifiable means. We expect that the analysis will lead to the identification of individual genes and/or entire molecular pathways that are abnormally expressed in the affected population indicating possible pathological mechanisms. The identified genes will be examined as high priority candidates for sequencing. Ideally, our goal is to collect upwards of 1000 samples in each group. Parental samples will be classified in the future among the subcategories of ASD determined.

The Development of a High-Throughput Pharmacogenomic Warfarin Genotyping Assay. *A.M.K. Brown, I. Mongrain, Y. Renaud, M.S. Phillips* Université de Montréal Pharmacogenomics Centre, Montréal, Québec, CANADA.

The drug Warfarin is a frequently used medication that reduces the formation of blood clots in patients who have suffered a heart attack or stroke. Experience and routine blood work are currently the only tools physicians have at their disposal to assist in bringing blood concentrations to a therapeutic range. Presently, wide ranges of therapeutic doses are observed in Warfarin patients and traditional indicators such as age, sex and body weight, only account for about half of this variation. It has been shown that polymorphisms in two genes in particular can explain most of the genetic variation observed in patients. The first gene, cytochrome P450 enzyme 2C9 (CYP2C9), is the primary drug-metabolizing enzyme that is responsible for the pharmacokinetic effects of the drug. Reduced function in this gene due to specific polymorphisms can account for a lower required initial dose. The second gene encoding the Vitamin K oxide receptor complex-1 (VKORC1) is the target receptor of Warfarin. Low expression of the receptor due to allelic variation also accounts for lower initial dose. Recently, the FDA has issued guidance for Warfarin use in patients that recommends that genetic screening should be utilized to assist in determining initial dose. Thus, we have developed several high-throughput genotyping assays for multiple technological platforms that can test for the major differences in the CYP2C9 and VKORC1 genes simultaneously. We are presently assessing the cost effectiveness of each of these technologies. Further still, we have determined the haplotype structures found in different populations by testing hundreds of samples from diverse populations, including family trios in some instances, to create a software analysis tool that can be predictive of an individuals proposed phenotype. A molecular profiling assay such as ours will revolutionize the way in which Warfarin is prescribed. The resulting data will provide guidance to physicians as the trend of pharmacogenomics aiding in the therapeutics of medication grows and continues to increase efficacy and reduce adverse drug reactions.

Bidirectional expression of the SCA8 mutation: evidence for polyglutamine inclusions and CUG RNA gain-of-function effects. *R.S. Daughters[1], Y. Ikeda[1], D.L. Tuttle[2], T. Zu[1], M.L. Moseley[1], J.W. Day[1], M.S. Swanson[2], L.P.W. Ranum[1]* 1) Institute of Human Genetics, University of Minnesota, Minneapolis, MN; 2) University of Florida, Gainesville, Florida.

We previously reported that a (CTG)n expansion causes spinocerebellar ataxia type 8 (SCA8). SCA8 BAC-Exp mice show a loss of cerebellar GABAergic inhibition and similar to human patients have 1C2-positive Purkinje cell inclusions. Recently we discovered transcripts spanning the repeat are expressed in both directions (CUG and CAG) and CAG transcripts encode a pure polyglutamine expansion protein (ataxin 8). The expression of non-coding CUG transcripts and previous work in myotonic dystrophy suggest that SCA8 CUG expansion transcripts may contribute to disease pathogenesis by dysregulation of Mbnl and CELF proteins through an RNA gain of function mechanism. To understand the role of SCA8 CUG expansion transcripts on Mbnl dysregulation we crossed SCA8-BAC-Exp mice to heterozygous Mbnl1 isoform knockout mice. Doubly mutant $SCA8^{+/-}$;$Mbnl1^{+/E3}$ animals show significantly enhanced rotorod deficits compared to single mutant $Mbnl1^{+/E3}$ ($p=0.003$) and SCA8-BAC-$Exp^{+/-}$ ($p<0.001$) mice. In addition, we have begun to investigate downstream effects of the CUG expansion on genes normally regulated by MBNL and CELF proteins. The loss of GABAergic inhibition in our SCA8 mice led to the prioritization of a gene identified as a CUG-BP1 binding target by crosslinking/immunoprecipitation (CLIP) analysis, the *GABA-A transporter 4* (*Gabt4*) gene. If upregulated, Gabt4 could lead to decreased cerebellar inhibition by reducing synaptic GABA. Consistent with this hypothesis, cerebellar Gabt4 is significantly upregulated at the RNA ($p<0.001$) and protein ($p<0.001$) levels in both SCA8 BAC-$Exp^{+/-}$ and $Mbnl1^{E3/E3}$ knockout animals and in SCA8 human brain. Additionally, transient transfections using human SK-N-SH cells show upregulation of endogenous GAT4 is triggered by SCA8 CUG, but not SCA8 CAG, expansion transcripts ($p<0.001$). These data provide functional evidence in mice, humans and cell culture that CUG expansions can trigger GAT4/Gabt4 dysregulation through an RNA gain-of-function mechanism in SCA8.

Searching for novel genes predisposing to breast cancer: a high-density linkage scan at the telomeres. *S. Casadei, T. Walsh, J. Higgins, K. Roach, S. Stray, M.K. Lee, M.-C. King* Departments of Medicine and Genome Sciences, University of Washington, Seattle, WA.

Genes involved in inherited predisposition to breast cancer include *BRCA1* and *BRCA2*, *CHEK2*, *TP53*, and *PTEN*. The genes differ in associated phenotypes and penetrance. A substantial fraction of families with four or more cases of breast cancer are wildtype at all these genes, strongly suggesting the existence of other genes responsible for breast cancer predisposition. Previous genome-wide scans for breast cancer genes have not yielded consistent regions of linkage. While this may reflect extraordinary locus heterogeneity of remaining breast cancer susceptibility genes, it is also possible that genomic problems have led to linkages being missed. In particular, recombination rates are high near telomeres, so that conventional linkage scans fail to adequately interrogate these genomic regions. To address this problem, we set up a high-density linkage scan at the telomeres and subtelomeres. We developed sets of 3 to 6 microsatellite markers at 500 kb to 1.0 MB density at the ends of all chromosomes. Our first scan is being carried out on 16 extended kindreds, each including 4 or more cases of breast cancer and yielding potential lods scores greater than 1.0 per family. Mutations in all known breast cancer genes have been excluded by sequencing, MLPA and related methods, and linkage. Promising regions of linkage identified in these families will be followed by targeted scans in more than 300 additional high-risk families.

Testing for association between type 2 diabetes and 225 candidate genes in 2357 Finnish cases and controls. *K.J. Gaulton[1], K.N. Conneely[2], Y. Li[2], A.U. Jackson[2], L.J. Scott[2], W.L. Duren[2], P.S. Chines[3], N. Narisu[3], L. Bonnycastle[3], A. Swift[3], T.T. Valle[4], J. Tuomilehto[4], R.N. Bergman[5], F.S. Collins[3], M. Boehnke[2], K.L. Mohlke[1]* 1) U North Carolina, Chapel Hill, NC; 2) U Michigan, Ann Arbor, MI; 3) NHGRI, Bethesda, MD; 4) Natl Public Health Inst., Helsinki, Finland; 5) U Southern California, Los Angeles, CA.

Type 2 diabetes (T2D) is a complex disorder with a strong genetic component, although the underlying genes are incompletely known. As stage 1 of a 2-stage T2D association study (which includes a genome-wide association (GWA) study, see abstract from Scott *et al.*), we are genotyping 3378 SNPs from 225 candidate genes in 1171 T2D cases and 1186 normal glucose tolerant controls from the Finland-United States Investigation of NIDDM Genetics (FUSION) study. Genes were selected using CAESAR, our algorithm that uses text and data mining to integrate annotations from 11 databases and rank human genes based on their potential function. To test the ability of CAESAR to successfully select complex trait genes, we used the algorithm to rank genes for 11 complex traits. Of 17 tested genes previously implicated in these traits, 8 were present in the top 2% of ranked genes. We used CAESAR to select 209 candidate genes for T2D and genotyped SNPs in these and 16 other genes based on prior evidence of association in FUSION. 1850 SNPs within 10 kb upstream and 5 kb downstream of these genes are present on the GWA panel. 1528 additional SNPs were selected to more completely cover variation in these genes based on linkage disequilibrium (r^2>.8) and annotation. The 3378 SNPs tag an additional 7099 SNPs using the same r^2 threshold. Preliminary results using the 1850 GWA SNPs in 885 cases and 885 controls indicate that the most significant SNP lies in the *ARID2* gene and has an unadjusted p-value of 1.7×10^{-4} under a multiplicative model. Within each gene, we adjusted for the number of SNPs and the correlation between them and found that 3 genes exhibit p-values<.005, which is consistent with the 1.1 gene expected by chance (p=.1). Our completed stage 1 study will include all SNPs and 2357 samples to further determine the significance of these genes in T2D.

SNP fine mapping in 10q22-23, a region with previous linkage to schizophrenia. *P-L. Chen[1], V.K. Lasseter[2], D. Avramopoulos[2], M.D. Fallin[3], A. Pulver[2], D. Valle[1, 4]* 1) Inst Genetic Medicine, Johns Hopkins Sch Medicine, Baltimore, MD; 2) Dept Psychiatry; 3) Dept Epidemiology, School of Public Health; 4) Howard Hughes Medical Institute.

Schizophrenia, with a prevalence ~1% worldwide, is a complex psychiatric disorder with a strong genetic component. We previously performed a genomewide linkage scan on 29 multiplex families of Ashkenazi Jewish (AJ) descent (Fallin *et al*. Am J Hum Genet 73:601, 2003) with the strongest linkage signal at chromosome 10q22 (NPL score: 4.27, empirical p= 0.00002). *NRG3* (neuregulin 3) and *GRID1* (glutamate receptor, ionotropic, delta1) are strong biological candidate genes in this region. To further narrow down the susceptibility gene(s)/allele(s), we obtained a SNP-based fine mapping study with 1536 SNPs across the 12.5 Mb region in 1771 individuals at CIDR using the Illumina BeadArray system. All subjects are of AJ background and were analyzed as 304 trios in family-based or 478 cases and 531 controls in population-based study. We used the UNPHASED analysis package (Dudbridge, Genet Epidemiol 25:115, 2003) for population-based association and transmission disequilibrium test (TDT) studies, using individual SNP genotypes or constructed haplotypes. We also performed exhaustive allelic TDT (Lin *et al*. Nat Genet 36:1181, 2004) to capture information extending beyond 1 LD block. Around *NRG3*, the strongest association signal was at a 6-SNP haplotype (spanning 49 kb) in intron 1 (nominal p=0.00019) and there were many haplotypes between the 5 upstream region and intron 1 of *NRG3* with association (nominal p<0.01). Around *GRID1*, the best signal (nominal p=0.00049) was a 47-SNP haplotype (spanning 436 kb) 3 downstream to the gene and many haplotypes over the 3region of the gene showed association (nominal p<0.01). Intriguingly, there was a cluster of 8 genes flanked by gene deserts between *NRG3* and *GRID1* that also showed association (nominal p<0.01). We are currently investigating these association signals with independent samples and independent statistical methods.

Familial Aortic and Cerebral Aneurysms: A Common Genetic Basis in a Subset of Aortic Aneurysm/Dissection Families. *V. Fadulu, S.E. Smart, J.H. Chen, H. Pannu, L. Dechtenberg, D. Guo, D.M. Milewicz* IM-Medical Genetics, Univ Texas Medical Sch, Houston, TX.

Aneurysms occur most commonly in the aorta & cerebral arteries. Predisposition to aortic and intracranial aneurysms/dissections can be inherited. Familial intracranial aneurysms (ICA) are linked to 3 loci, and familial thoracic aortic aneurysms/dissections (TAAD) are linked to 5 loci TAAD1, TAAD2, TAAD3, FAA1 and MYH11. We recruited 345 families with 2+ persons w/TAAD involving the ascending aorta. The majority of these families showed autosomal dominant inheritance w/variable expression & decreased penetrance in women (men=66% vs. women= 34%). 57% of families had 1+ person with vascular disease extending beyond the ascending aorta.Medical records on families with TAAD & ICA were reviewed and 37 families (11%) were confirmed to exhibit TAAD & ICA within 1 family and/or within at least 1 family member. The majority of persons with ICA were women (63%). 13 people had both TAAD & ICA (equal number of men (n=7) and women (n=6)). Three unrelated men were diagnosed with aortic dissections at ages 27, 37, and 53. They underwent successful repair of their aorta and died suddenly of an ICA at ages 33, 49 and 56, respectively. 37 families consisted of 46 persons with ICA and 197 persons with TAAD. 57% of families had a parent-child with TAAD/ICA. This suggests that in some families, TAAD & ICA segregate together w/variable expression. Mutation & linkage analysis of the known TAAD loci revealed only 1 family with a TGFBR2 mutation (R460C). The remaining families were not linked to any of the known loci for familial TAAD. These families showed a unique phenotype of both TAAD and ICA.Genetic studies indicate that a novel locus is responsible for this phenotype. First-time occurrence of a deadly ICA in families with initially purely TAAD often causes anger, grief and shock in family members; especially when the family adhered to surveillance guidelines and recommendations for only TAAD. Families with TAAD & ICA should be recommended cerebral & aortic imaging. Individuals in these families with successful repair of TAAD should be imaged for ICAs. A large TAA-ICA family will be described.

Identification of genes contributing to obesity associated cardiovascular disease (OCARD). *Y. Dementieva[1], P. Wehner[1], T.L. Green[1], D.A. Primerano[1], J. Denvir[1], L. Wei[1], M.R. Flood[2], D. Calica[2], B. Freeman[2], M. Huff[2], S. Dodson[2], C. Hill[2], A. Frances[3], C. Taylor[3], B. Connors[3], K. McIntyre[3], R. Kreisberg[3], M. Davis[4], H.M. Lee[4]* 1) Marshall University, Huntington, WV; 2) Fairmont State University, Fairmont, WV; 3) West Liberty State College, West Liberty, WV; 4) West Virginia University, Morgantown, WV.

Obesity is a known risk factor in the development of coronary artery disease (CAD). Based on this finding, we hypothesized that specific genes in overweight or obese individuals potentiate the development of CAD and refer to these modifier genes as obesity associated cardiovascular disease (OCARD) genes. The objective of our study is to identify human OCARD genes using population-based association methods.

In order to identify OCARD genes, we performed case-control studies in groups of overweight [(BMI) 25] and obese [BMI 30] Caucasian individuals from West Virginia. Haploview software was used to select the minimal number of tagging SNPs to be genotyped in each candidate gene. SNP genotypes were determined using either pyrosequencing or TaqMan allelic discrimination. Logistic regression analyses were used to test for association between disease phenotype and SNPs with age, gender, BMI, and smoking as covariates.

We determined the genotypes of 54 SNPs representing 20 cardiovascular candidate genes in 265 human subjects with and without atherosclerosis. Three SNPs [Cholesterol Ester Transfer Protein (CETP) rs4784744 (P=0.014, OR 95% CI 1.14 - 3.11), Low Density Lipoprotein-Related Protein 1B (LRP1B) rs1816608 (P=0.016, OR 95% CI 1.25 - 9.27), and Lipase A Precursor (LIPA) rs1556478 (P=0.013, OR 95% CI 1.17 - 3.83)] met the 0.05 significance level for association with CAD.

CETP, LRP1B, and LIPA are known to play critical roles in lipoprotein metabolism. Our results suggest that defects in these genes may predispose to CAD in overweight and obese individuals. However, further investigations in larger populations and functional studies are required to confirm these findings.

Losartan decreases aortic root dilation in Marfan syndrome. *B.S. Brooke, J.P. Habashi, H.C. Dietz* HHMI & Instit. of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD.

The Marfan Syndrome (MFS) is an autosomal dominant connective tissue disorder caused by mutations in fibrillin-1. The most severe complication of MFS is progressive aortic root enlargement, which leads to dissection or rupture unless surgical repair is undertaken. -blockers are standard medical therapy in these patients and slow aortic growth, but do not prevent the need for surgery. Up to a third of MFS patients are intolerant to -blockers and get switched to other blood-pressure reducing agents during the course of treatment. Recently, data from a mouse model of MFS suggested that over-expression of TGF-signaling contributes to the pathogenesis of aneurysm formation. In this model, aortic dilation was arrested by the use of the angiotensin II type-1 receptor blocker losartan, an antihypertensive medication known to inhibit TGF- signaling. Here, we report the results of an observational study designed to evaluate the effectiveness of losartan therapy in MFS patients with progressive aortic dilation. A total of 12 MFS patients (6 males, 6 females, mean age 86 years) were identified from an institutional database that had been switched from -blocker to losartan between August of 1998 and May of 2006. Serial echocardiographic measurements (mean 10 per pt.) of aortic diameter and corresponding Z-scores were compared for each patient while on -blocker and after initiation of losartan. The mean rate of aortic growth (0.007 cm/yr vs. 0.31 cm/yr; $P<0.005$) and the mean rate of change in Z-score (-1.40 Z-score/yr. vs. +0.81 Z-score/yr.; $P<0.01$) were both significantly decreased for individuals on losartan, as compared to their prior performance on -blockers. After adjusting for confounders using multiple linear regression, losartan therapy independently reduced the rate of aortic growth by 0.28 cm per year [95%CI:-0.46 to -0.09; $P<0.005$]) and reduced the Z-score by 2.14 per year [95%CI:-4.03 to -0.24; $P<0.05$]. In conclusion, these data suggest that losartan therapy offers a significant advantage over -blockers for the treatment of MFS. A prospective randomized trial will be initiated soon and be important to confirm the results of this study.

Lysosomal Disease Network launches research web site. *D. Erickson[1], J. Barranger[2], J. Muenzer[3], C. Eng[4], G. Grabowski[5], J. O'Brien[6], G. Pastores[7], E. Shapiro[1], R. Steiner[8], W. Wilcox[9], S. Walkley[10], B. Davidson[10], S. Patel[10], B. Wedehase[10], C. Whitley[1]* 1) Lysosomal Disease Network, Minneapolis, MN; 2) University of Pittsburgh, Pittsburgh, PA; 3) University of North Carolina, Chapel Hill, NC; 4) Baylor College of Medicine, Houston, TX; 5) Children's Hospital Research Foundation, Cincinnati, OH; 6) Mayo Clinic, Rochester, MN; 7) New York University, New York, NY; 8) Oregon Health & Science University, Portland, OR; 9) Cedars-Sinai Medical Center, Los Angeles, CA; 10) and other LDN member institutions.

The Lysosomal Disease Network is a consortium of basic researchers, clinicians, pharmaceutical industry professionals, and patient advocates devoted to promote and facilitate basic, translational and clinical research in lysosomal diseases (LD). The network is a scalable multi-center consortium of geographically distributed expert medical centers, patient support and corporate partners. The infrastructure, mission and charter were developed through organizational committees; the collaborating medical centers, pharmaceutical and patient support organizations will direct the activities of the network through participation in the Steering Committee. Toward meeting its goals, the LDN has launched its web site www.LysosomalDiseaseNetwork.org to facilitate professional and public education, timely network communication, and develop a data entry mechanism for research projects. In its initial year, the web site has announced its 3rd annual scientific meeting, the WORLD Symposium (Dec. 7-9, 2006) in Orlando, FL, USA. Through the web site, participants have been able to submit abstracts, register for the meeting, and join the growing membership list to receive regular communications. The Network is currently developing longitudinal studies to understand the natural history of LD and treatment outcomes. Long term network goals include: 1) Development of an information management infrastructure to encourage integration of shared clinical experience and relevant longitudinal studies; 2) Investigator training, and 3) Public education. Organizational support has been provided by NIH, NINDS, NIDDK, and ORD, NS49950.

Saturation SNP coverage across the GABRB3 locus refines association to autism. *R.J. Delahanty[1], J.A. Smart[1], J.S. Sutcliffe[1,2]* 1) Department of Molecular Physiology & Biophysics, Centers for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Center for Molecular Neuroscience, Vanderbilt University, Nashville, TN.

Autism is a neurodevelopmental disorder affecting greater than 1 in 500 individuals with deficits in development and use of language, social reciprocity, and patterns of repetitive behaviors and restricted interests. Despite a recognized complex genetic etiology, locus heterogeneity has thwarted efforts to identify loci broadly contributing to the idiopathic condition. Chromosomal duplications, linkage and association findings have implicated the 15q 11-q13 region that harbors a cluster of $GABA_A$ receptor subunit genes (GABRB3, GABRA5, GABRG3). Data have most consistently implicated the GABRB3 gene, although no single region based on linkage disequilibrium (LD) structure has been identified. We previously reported an LD-map spanning the entire 1-Mb $GABA_A$ subunit cluster and identified three LD blocks showing evidence for allelic association (McCauley et al, 2004). Last year, Curran et al (ASHG program #1692, 2005) reported additional evidence for association to SNPs in GABRB3, further suggesting involvement of this gene in autism susceptibility. We report a second-generation analysis of LD and allelic association to autism with a specific focus on the GABRB3 locus. We selected and genotyped 48 SNPs covering a 231kb interval across GABRB3, with an average spacing of 1 SNP per 4.9 kb. SNPs were chosen to thoroughly index all common alleles across at GABRB3, potentially functional SNPs, and markers we previously identified as associated. SNPs were analyzed in 644 combined multiplex and parent-child trio autism families. Analyses to date show that association to a region in intron 3 of the GABRB3 gene is replicated in a much larger set of families than previously assessed by McCauley et al. We will present detailed analysis of LD, single marker and haplotype-based association at GABRB3, as well as analysis of trait-subsets of autism to explore genotype-phenotype relationships. Our results continue to support involvement of GABRB3 in autism susceptibility.

Homozygosity mapping discard genetic linkage to CNGA3, CNGB3 and GNAT2 in a large Colombian family with Achromatopsia. *L.F. Cuesta, M. Gordillo, H. Vega* Universidad Nacional de Colombia, Bogota, Colombia.

Achromatopsia, also referred to as total colorblindness or rod monochromacy is a rare (prevalence of 1 in 30,000) autosomal recessive disorder characterized by loss of function of all cone classes, low visual acuity, severe photophobia under daylight conditions, infantile nystagmus and normal funduscopic examination. This entity is genetically heterogeneous. To date, three loci have been associated to achromatopsia: the alpha-subunit of the cone photoreceptor cGMP-gated cation channel (CNGA3) on 2q11, the beta-subunit of the cGMP-gated cation channel (CNGB3) on 8q21-q22, and the cone photoreceptor-specific alpha subunit of transducin (GNAT2) on 1p13. Together, mutations in these genes are thought to be responsible for only 60 % of patients affected with this disorder suggesting the presence of additional genetic heterogeneity in this disease. We identified a large consanguineous family from an isolated village in Colombia with clinical findings compatible with the diagnosis of achromatopsia. This multigenerational pedigree, including six affected individuals was investigated for association with CNGA3, CNGB3 and GNAT2 by homozygosity mapping. At least three microsatellite markers with the highest LOD scores reported previously during the mapping of each locus and surrounding each of the affected genes were evaluated to identify a region of homozygosity in the affected individuals. We found no evidence of homozygosity at any of the three loci as no more than two patients presented homozygosity for the same chromosomal region. These data discard with a very high probability that mutations in CNGA3, CNGB3 and GNAT2 are responsible for achromatopsia in this family and support the notion that other loci for achromatopsia remain to be identified.

Treatment of CNS lysosomal storage with high-dose intravenous enzyme replacement therapy in tolerant MPS I dogs. *P. Dickson[1], C. Vogler[2], B. Levy[2], M. McEntee[3], M. Passage[1], S. Le[1], S. Snider[1], H. Manuel[1], E. Kakkis[4]* 1) Dept Pediatrics, Harbor-UCLA Medical Ctr, Torrance, CA; 2) Dept. of Pathol., St. Louis Univ., St. Louis, MO; 3) Dept. of Pathol., Coll. of Vet. Med., Univ. of Tenn., Knoxville, TN; 4) Biomarin Pharmaceutical, Inc., Novato, CA, USA.

Intravenous (IV) enzyme replacement therapy had been thought not to cross the blood brain barrier (1,2). Recently, Vogler et al. showed that high dose IV ERT reduced brain storage in a tolerant mouse model of MPS VII (3). In order to assess whether this approach would work in a large animal model of MPS I, we gave 2 mg/kg weekly IV recombinant human -L-iduronidase (rhIDU) to 3 tolerant and 3 nontolerant MPS I dogs age 8-20 months. The MPS I dogs were first tolerized with a novel procedure. All MPS I dogs were then treated for 11-13 weeks and their brains studied 48 hours after the final dose with biochemical assays for iduronidase and glycosaminoglycan (GAG) storage. Iduronidase was present in the brains of MPS I dogs treated with high-dose IV rhIDU. Iduronidase levels in tolerant dogs were 0.165 0.016 U/mg (2% of normal), vs. nontolerant dogs 0.077 0.051 U/mg (1% of normal, p=0.046; Normal 8.26 0.746, Untreated MPS I 0.032 0.004). Brain GAG storage was reduced in tolerant IV-treated MPS I dogs. Brain GAG levels in tolerant dogs were 6.03 0.446 g/mg, near the normal value of 5.40 1.82 and less than that in nontolerant dogs (8.27 0.468, p=0.0039; Untreated MPS I: 8.26 1.23). Blinded ultrastructural evaluation showed reduction in neocortical neuronal storage in 2 of 3 tolerant MPS I dogs receiving high-dose IV rhIDU. High dose IV enzyme replacement therapy treats lysosomal storage in the brain in tolerant MPS I dogs, confirming results in MPS VII mice. It may be possible to use IV ERT to treat lysosomal storage in the CNS.

Prenatal diagnosis of lysosomal storage disorders using biochemical testing: Importance of obtaining parental control samples for correct result interpretation. *M.J. Fietz, S. Chin, P. Clements, B. Fong, P. Leane, V. Muller, K. Nelson, C. Nicholls, J.M. Fletcher* Dept of Genetic Medicine, Women's & Children's Hospital, North Adelaide, SA, Australia.

Aim: To evaluate the need for parental samples in the provision of accurate prenatal diagnoses for lysosomal storage diseases (LSD). Setting: The National Referral Laboratory (NRL), Adelaide Womens & Childrens Hospital. The NRL has provided a specialist and comprehensive diagnostic service for lysosomal storage disorders (LSD) to both Australian and overseas patients for over 30 years. During that period, we have performed over 650 prenatal diagnoses for a total of 29 different LSD, with the most frequently tested disorders including MPS-I, MPS-II, Krabbe disease, Pompe disease, metachromatic leucodystrophy (MLD), GM1-gangliosidosis and mucolipidosis type II (I-cell disease). Our standard procedure is to request parental samples prior to performing prenatal testing. This has been thought to be particularly relevant due to the presence of pseudo-deficiency alleles in disorders such as Krabbe disease and MLD. Cases: In case 1, direct enzyme testing for Krabbe disease on chorionic villus (CV) tissue yielded a value intermediate to our previous affected and non-affected reference ranges. The presence of clearly normal enzyme activity levels in parental cultured fibroblasts allowed us to conclude that the fetus was affected by Krabbe disease. In case 2, biochemical testing for Krabbe disease on cultured CV cells was performed, yielding normal results. However, VNTR analysis performed on DNA from both parents and the fetus clearly indicated that the fetus had an identical VNTR pattern to the mother. Therefore, we concluded that the sample was of maternal origin. Amniocentesis was then performed and the assay repeated on cultured amniocytes. Conclusion: Even in the year 2006, despite increasing availability of mutation data, biochemical analysis is still required for prenatal diagnosis of LSD. In such cases, the provision of suitable parental samples (skin fibroblasts or leukocytes) is required to enable optimal data interpretation and the determination of an accurate prenatal result.

A splice mutation in the small subunit of the AP-1 complex underlie the Erythrokeratodermia variabilis type 3 (EKV3) syndrome. *S. Côté[1], A. Montpetit[2], E. Brustein[3,4], C. Meloche[1], M. Boudreau[2], R. Drouin[5], P. Drapeau[3,4], T.J. Hudson[2], C.A. Drouin[6], P. Cossette[1,7]* 1) Service de Neurologie, Centre Hospitalier de lUniversité de Montréal-Hopital Notre-Dame, Montréal,Qc,Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal,Qc,Canada; 3) Centre for Research in Neuroscience and Department of Biology, McGill University, Montreal,Qc,Canada; 4) Pathologie et Biologie Cellulaire, Pavillon Roger-Gaudry, Université de Montréal, Montréal,Qc,Canada; 5) Département de Pédiatrie, Faculté de Médecine, Université de Sherbrooke, Sherbrooke,Qc,Canada; 6) Centre Hospitalier du Grand Portage, Rivière-du-Loup,Qc,Canada; 7) Department of Human Genetics, McGill University, Montreal,Qc, Canada.

Erythrokeratodermia variabilis 3 (EKV3, MIM 609313) is a rare but often fatal autosomal recessive disorder, characterized by typical skin lesions, peripheral neuropathy, psychomotor retardation, hearing loss and severe chronic congenital diarrhea. The EKV3 gene was recently mapped to chromosome 7q22. Here we report the identification of an A to G homozygous mutation in the acceptor splice site of intron 2 of AP1S1, which encodes the small subunit of the AP-1 complex. RT-PCR analysis of mRNA obtained from patients fibroblasts was compatible with skipping of exon 3, predicting a truncated protein lacking most of its clathrin-adaptor domain. These analyses also revealed that a cryptic splice site is used in these patients, resulting in an in-frame mRNA lacking nine base pairs. Knocking-down of AP1S1 in zebrafish using targeted antisense morpholino oligonucleotides (AMO) revealed striking morphological and behavioural phenotypes, including smaller size, loss of pigmentation, and severe impairment of swimming. Co-injection of wild type human AP1S1 mRNA with AP1S1 AMO resulted in a virtually normal phenotype. In contrast, co-injection of the mutant AP1S1 mRNAs with AP1S1 AMO led to similar morphological and motor deficits, suggesting a loss of function effect of these two mutations. These results are consistent with the mutation in AP1S1 being the underlying cause of EKV3.

Segmental duplications on 10q are linked to complex genomic rearrangements associated with neurobehavioral abnormalities. *J. Balciuniene[1], N.-P. Feng[4], B. Hirsch[3], L. Charnas[2], D. Avramopoulos[5], D. Valle[4], L. Schimmenti[2], S. Selleck[1,2]* 1) Dept of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN; 2) Dept of Pediatrics, University of Minnesota, Minneapolis, MN; 3) Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 4) Howard Hughes Medical Institute and the Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 5) Dept of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD.

Low copy repeats (LCRs) or segmental duplications are genomic features that affect chromosome stability and can produce disease-associated rearrangements including deletions and duplications. We describe members of 3 families with deletions in 10q22.3-10q23.31, a region harboring a complex set of LCRs, providing evidence that rearrangements in this region are associated with behavioral and neurodevelopmental abnormalities including mental retardation, autism, hyperactivity and possibly psychiatric disease. Cowden disease was observed in one patient with a deletion extending telomerically to include the PTEN gene.

We fine mapped the deletions in members of all 3 families using a 10q oligo array and CGH (NimbleGen). Our results demonstrate a different deletion in each family with variable breakpoints mapping both between and outside the LCRs. In one proband the deletion breakpoints are at 84,148592 - 89,875445 with an insert containing non-contiguous segments of chromosome 10 DNA from regions outside the deletion and within the deletion in an inverted orientation. In the other two families breakpoints have occurred in the same LCRs (proximal at 81.62 Mb and distal at 89.14 Mb). In one of these families, the deletion co-segregates with neurobehavioral abnormalities in members of 3 generations.

These results suggest that LCRs produce not only non-allelic homologous recombination events but also influence the stability of nearby genomic regions and promote complex chromosome rearrangements. Our data provide increasing evidence that this genomic region harbors one or more genes important for neurologic development and function.

Large scale DNase I hypersensitivity mapping of the human CFTR gene region. *M.O. Dorschner[1], J. Goldy[1], M. Weaver[1], A. Shafer[1], K. Lee[1], F. Neri[1], A. Haydock[1], P. Sabo[1], R. Humbert[1], M.S. Kuehn[2], J.A. Stamatoyannopoulos[1]*
1) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA; 2) Division of Medical Genetics, University of Washington School of Medicine, Seattle, WA.

Transcription of the cystic fibrosis transmembrane conductance regulator (CFTR) gene is tightly controlled in a complex temporal and spatial pattern. To date, few cis-acting elements have been shown to regulate expression of CFTR in a tissue-specific manner. To identify new regulatory elements, we performed quantitative chromatin profiling of 10 tissues across a 525 kb region containing CFTR and three flanking genes. Several CF-relevant cell types including primary airway, intestinal, pancreatic, mammary and renal epithelial cells were examined. Conventional DNase I hypersensitivity Southern blots had been employed previously by other investigators to survey over 300 kb of the CFTR region in an effort to locate active chromatin elements. We extended this work by scanning a larger region spanning from 210 kb upstream of CFTR to 125 kb downstream of the last exon with a set of 1845 contiguous ~250 base amplicons. This high-resolution, real-time PCR-based approach (Dorschner et al., Nat. Methods, 2004) allowed us to rapidly and precisely map 294 unique DNase I hypersensitive sites (DHSs). 74% of the DHSs were only found in one tissue, while the remaining 26% were found in two or more cell types. Close examination of the DHS patterns across tissues yielded over 20 DHSs that may harbor putative CFTR cis-regulatory elements. These sites were found in multiple airway cells and/or a combination of other CF-relevant cell types. A comprehensive catalog of CFTR cis-regulatory elements provides potential targets for therapeutic intervention as well as sites for the identification of mutations that cause cystic fibrosis or modify disease phenotype.

The genetics of copy number variation in a founder population. *D. Conrad, M. Abney, C. Ober, J. Pritchard* Dept Human Genetics, Univ Chicago, Chicago, IL.

There are now numerous approaches for genome-wide ascertainment of human copy number variants (CNVs). Much less work has been done to integrate such variation into traditional methods of genetic analysis. We used the Affymetrix 500k SNP genotyping platform to scan for CNVs in 750 individuals from a young founder population, all of whom have been phenotyped for 25 quantitative traits. A complete genealogy relating these individuals has been constructed from a 12,000-member pedigree. We have identified nearly 1,000 CNVs, including duplications and deletions, ranging in size from hundreds of base pairs to over 1 Mb. In this presentation, we describe new methodology for integrating CNVs into the study of genetic traits. We leverage the pedigree information relating our samples to increase our power to classify CNVs, and to gain new insight into biological properties of CNVs such as the rate of *de novo* CNV formation, transmission distortion, the location of duplication events, and the relationship between copy-variable genomic regions and the genetic map. We anticipate that our work will help to establish a framework by which CNVs can be incorporated into studies of Mendelian and complex disease.

De novo ring chromosome(13)(p11q13): a case report and review bof literature. *S. Batish[1], P. Koduru[2], G. Haberman[2], S. Gupta[2]* 1) Dept Pathology & Lab Medicine, Weill Med Col of Cornell Univ, New York, NY; 2) Cell Genetics, Laboratory Medicine,North Shore University Hospital, Manhasset, NY.

Ring chromosome are rare constitutional abnormality. Loss of genetic material during ring formation as well as mechanical desruption of ring chromosome during mitosis results in dynamic mosaicism and General Ring syndrome characterized by moderate mental deficiency, marked growth retardation, borderline to minor dysmorphogenesis and sometimes intact fertility. A 9 year old girl was evaluated for dysmorphism, growth retardation and seizures. peripheral blood karyotype was 45,XX,-13/ 46,XX,r(13)(p11q33). FISH analysis confirmed the loss of 13q34 band as well as subtelomeric sequences in ring (13). Mosaicism for the ring chromosome was confiemed, 20% of peripheral blood cells were monosomic for chromosome 13. Ring (13) was first described in 1968 and incidence is reported at 1/58,000 livebirths. Charactetistic features of ring (13) include mental retardation, microcephly, facial dysmorphism, and hand, foot or toe abnormalities. The phenotype of the proband is compared with reported cases of r(13) and mechnism of ring formation is discussed.

Genotype-phenotype correlations in MCADD. *G.L. Arnold[1], R. Erbe[2], K. Verdassdonk[2], P.A. Galvin-Parton[3], D.F. Kronn[4]* 1) Div Pediatric Genetics, Univ Rochester Sch Medicine, Rochester, NY; 2) SUNY at Buffalo, Buffalo, NY; 3) SUNY at Stony Brook, Stony Brook, NY; 4) Medical College of NY, Valhalla, NY.

Objective: To investigate genotype-phenotype correlations in children diagnosed with MCADD by expanded newborn screening (ENBS).

Methods: Cross sectional chart review of all children diagnosed with MCADD from four New York ENBS follow-up centers. Infants were classified in three groups: eleven K304E homozygotes, ten with variant genotypes (one or no copies of K304E), and three with atypical MCADD (C8 levels of 30 with brittle fasting intolerance or sibling death, but not homozygous for K304E).

Results: The mean C8 level on ENBS was 14.9 (range 0.99-31.7) in the K304E homozygotes, compared to 6.0 (0.86 -23.2) in the neonates with variant genotypes (p0.02). Organic acids were diagnostic in six of seven K304E homozygotes, but only one of seven with variant genotype (p0.01). Follow-up C8 acylcarnitine levels were 5.2 (1.9-11.3) in the homozygous and 2.1 (0.53-5.3) in the variant infants (p0.01), and follow-up hexanoylglycine levels were 24.7 (12.7-49.3) in the homozygous infants and 9.1 (3.8-23.2) in the variant infants (p0.001). Several variant infants required both acylcarnitine and acylglycine analyses and/or DNA to clarify their affected status.

Conclusions: Infants homozygous for the K304E mutation are more likely to have higher levels of diagnostic metabolites. The extent to which this predicts clinical outcome merits further study, however the 3 atypical infants with profound fasting intolerance and C8 levels 30 suggest a relationship between ENBS C8 level and vulnerability to metabolic stress. Infants with variant genotypes typically have normal organic acid analyses, and some may require both plasma acylcarnitine and acylglycine or DNA analysis to separate affected from carrier infants.

Autosomal recessive severe Brachydactyly caused by a novel BMPR1B mutation. *O. Agamy[1], I. Abuelaish[2], R. Ofir[1], O.S. Birk[1,2]* 1) The Morris Kahn Laboratory of Human Molecular Genetics at the National Institute of Biotechnology; 2) the Genetics Institute at Soroka Medical Center, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer-Sheva, Israel.

Brachydactylies (BDs) are a group of inherited malformations characterized by shortening of the digits due to abnormal development of the phalanges and/or the metacarpals, usually manifest as autosomal dominant traits. We describe four individuals in a large inbred, consanguineous Arab Israeli family presenting with severe brachydactyly segregating in an autosomal recessive mode of heredity. We performed linkage analysis using microsatellite markers adjacent to five genes known to be associated with Brachydactyly: GDF5, ROR2, IHH, HOXD13 and BMPR1B. Linkage was ruled out for four of the five genes tested. A region of homozygosity containing the gene BMPR1B (bone morphogenetic protein receptor 1B) was identified. Two point linkage analysis using SUPERLINK demonstrated maximum LOD score of [Zmax] = 4.05 at recombination fraction [] = 0.0 at marker D4S1599. Mutation analysis of the BMPR1B gene revealed a novel missense mutation, G377A, resulting in substitution of cysteine to tyrosine at the conserved amino acid 34 (C34Y) in the extracellular ligand binding domain of BMPR1B. All affected individuals were homozygous for the mutation. Heterozygous carriers showed no signs of the phenotype. BMPR1B is the major receptor for GDF5, a signaling molecule of the BMP family that plays a major role in digit formation, joint development, and chondrocyte differentiation. So far few mutations in the BMPR1B gene were described; two heterozygous missense mutations in BMPR1B were previously associated with brachydactyly type A2 through a dominant negative effect. Lately, a homozygous loss of function mutation (del359-366) within the extracellular ligand binding domain of BMPR1B was shown to cause a new subtype of acromesomelic chondrodysplasia with genital anomalies. Functional analysis is undertaken in order to characterize the mutation. Our findings highlight the extreme phenotypic variability generated by different BMPR1B mutations.

A novel FLCN gene mutation in a patient with bilateral renal tumors and no other clinical features of Birt Hogg Dubé syndrome. *C.T. Dvorak[1,2], Y. Lien[1], G. Pridjian[1,2,3]* 1) Human Genetics Program, Tulane Sch Medicine, New Orleans, LA; 2) Department of Pediatrics, Tulane Sch Medicine, New Orleans, LA; 3) Department of OB/GYN, Tulane Sch Medicine, New Orleans, LA.

Birt Hogg Dubé Syndrome (BHD) was initially described as a genodermatosis syndrome in 1977, and since then a number of other clinical features (including renal tumors and spontaneous pneumothorax) have been observed in a portion of affected individuals. We describe a 46 year old female who presented with bilateral renal tumors of the chromophobe type. An analysis of the folliculin gene (FLCN) in peripheral blood lymphocytes revealed a novel frameshift mutation in exon 11 (c.1286dupA) that was similar in location and effect to previously described mutations in patients with BHD syndrome. However, our patient did not exhibit the commonly described skin findings or other phenotypic features of BHD, suggesting a greater degree of clinical variability than is typically described for the syndrome. We argue that BHD should be included (along with Von Hippel Lindau and other hereditary cancer syndromes involving the kidney) in the differential diagnosis of all patients presenting with bilateral renal tumors, even in the absence of other clinical findings. In addition, individuals considering FLCN mutation testing should be counselled regarding the variable expressivity and reduced penetrance that can be observed even among family members with BHD.

A simple and robust method for estimating allele frequencies in pooled DNA samples. *H.H. Chen[1], Y.S. Jou[2], W.H. Pan[1, 2]* 1) Department of Biochemical Science and Technology, Institute of Microbiology and Biochemistry, College of Life Science, National Taiwan University, Taipei, Taiwan, ROC; 2) Institute of Biomedical Sciences Academia Sinica, Taipei, Taiwan, ROC.

In large-scaled association studies, measuring the relative allelic abundances of markers in pooled DNA samples is a cost-effective strategy to pinpoint potential loci for confirmation. For some heterozygous SNPs, one allele tends to be preferentially amplified in polymerase chain reactions (PCR), the correction is often carried out in pooled DNAs study. However not all SNPs exhibit the phenomenon of one-to-one correspondence between actual allelic frequency and the amplified results. Thus using correction may result in biased estimates of allele frequencies in DNA pooling study. The aim of this study is to apply a novel approach using polynomial standard curves (SC) to estimate allele frequencies. We compared the accuracy between estimates derived from the proposed method and those from the correction for multiple types of SNP markers (A/T, A/C, C/T, A/G, C/G, and G/T) with 7 designated actual minor allele frequencies (AMiAFs) (5%, 10%, 20%, 30%, 40%, 45%, and 50%). For the SNPs with A/T, A/C, C/T, and A/G polymorphisms; estimates of the 7 AMiAFs derived from SC were similar to those from correction. The former was slightly more precise and closer to the known than the latter. For SNPs with C/G polymorphism; apparent differences were observed between the estimates derived from the two methods. Similar phenomenon was observed for SNPs with G/T polymorphism. In general, the estimates derived from the polynomial SC method were closer to AMiAFs than those from the correction particularly for SNPs with G/C and G/T polymorphism in the AMiAFs range of 20 to 40%. Our results demonstrated that SC method is more accurate and precise than correction, not requiring adjustment by complex statistical models.

Correlation among poor prognostic indicators in B-cell chronic lymphocytic leukemia (B-CLL). *A.W. Block[1], P.K. Wallace[2], K.C. Miller[3], M.S. Czuczman[3], A.A. Chanan-Khan[3], S. Padmanabhan[3]* 1) Clinical Cytogenetics Laboratory, Roswell Park Cancer Institute, Buffalo, NY; 2) Laboratory of Flow Cytometry, Roswell Park Cancer Institute, Buffalo, NY; 3) Department of Medicine, Roswell Park Cancer Institute, Buffalo, NY.

B-CLL, the most common leukemia in adults, is a malignant disorder characterized by progressive accumulation of functionally incompetent B-lymphocytes. Clinical staging systems are of prognostic importance, but cannot predict outcome of individual patients in early clinical stages. Factors that are independent predictors of disease progression and outcome in B-CLL include genomic aberrations and somatic mutation status in the expressed immunoglobulin heavy chain variable region (IgVH). Using a FISH panel that identified specific numerical and structural abnormalities (+12, del(13q), del(11q), del(17p), 14q32 abn) and ZAP-70 (70-kD zeta-associated protein, a surrogate for mutation status) expression assessed by flow cytometry, we studied peripheral blood and bone marrow from 37 unselected B-CLL patients (pts) to investigate the concordance of high-risk markers in these pts. 20/37 (54.1%) pts (10 males, 10 females; median age 62, range 49-85 yrs) showed ZAP-70 expression in less than 20% of cells (mutated status), and were considered ZAP-70 negative. Genomic aberrations were detected in 12/20 (60%) pts with del(13q) in 9/12 (75%) pts. High risk (del 11q and 17p) features were seen in 3/12 (25%) abn cases. 17/37 (45.9%) pts (12 males, 5 females; median age 69, range 42-85 yrs) exhibited ZAP-70 expression in 20% of cells and were considered ZAP-70 positive (non-mutated status). Genomic aberrations were detected in 14/17 (82%) pts with high risk deletions observed in 5/14 (35.7%) abn cases. To develop risk-adapted strategies, prognostic factors are needed to allow the prediction of individual patient clinical course. In this study, poor risk patients were defined by advanced clinical stage, increased age, male predominance, non-mutated status and high risk cytogenetic aberrations.

BRLMM: an improved genotyping calling method for Affymetrix mapping arrays. *S. Cawley[1], X. Di[1], E. Hubbell[1], S. Lincoln[1], M. Moorhead[1], W. Short[1], T.P. Speed[2,3], C. Sugnet[1], J. Veitch[1], T. Webster[1], A. Williams[1], G. Yang[1]* 1) Affymetrix, Santa Clara, CA; 2) Department of Statistics, University of California at Berkeley; 3) Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia.

Highly accurate and reliable genotype calling is an essential component of any high-throughput SNP genotyping technology. The Dynamic Model (Di *et al*, Bioinformatics 2005) which has been extensively used for the GeneChip Mapping 100K and Mapping 500K sets has proven to be very effective, however it is possible to do better. Rabbee & Speed recently developed a model called the Robust Linear Model with Mahalanobis distance classifier (RLMM, Rabbee & Speed, Bioinformatics 2005) which provided an improvement over DM on the Mapping 100K set. We present here an extension of the RLMM model which provides a significant improvement over DM in two important areas - it significantly improves overall performance (call rates and accuracy) and it equalizes the performance on homozygous and heterozygous genotypes. The main difference between RLMM and this evolved approach is the addition of a Bayesian step which provides improved estimates of cluster centers and variances, the new model is called BRLMM (pronounced B-realm). The performance improvement is achieved by two main advances over the DM model. Firstly, RLMM and BRLMM perform multiple chip analyses, enabling the simultaneous estimation of probe effects and allele signals for each SNP and resulting in lower variance on allele signal estimates. The second main source of improvement is the estimation of genotypes by a multiple-sample classification, borrowing information as necessary from other SNPs to better predict the properties of the underlying genotype clusters. By contrast, the DM approach calls genotypes by analyzing the probe-level intensities one SNP and one chip at a time, using strong assumptions about the behaviour of the underlying probe intensity patterns in the context of each of the genotypes. RLMM and BRLMM make weaker assumptions about the behavior of probe intensities than does DM, making them far more robust in the presence of real-world data.

Comparative analysis on deletion polymorphisms using gene expression data. *S. Gopalakrishnan, Z.S. Qin* Center for Statistical Genetics, Biostatistics, University of Michigan, Ann Arbor, MI.

Recent studies suggested that deletion polymorphisms (DP) are ubiquitous in human genome (Conrad et al. 2006, Hinds et al. 2006, and McCarrol et al. 2006). Deletions have been implicated in previous researches as playing a significant role in human diseases (e.g., DiGeorge and Prader-Willi syndromes). With the increasing resolution of the human genome, ever smaller DPs are being identified. Data from the HapMap project and other large scale studies made it possible for a genome wide survey on the impacts of DPs. In this study, we use DPs identified and mapped on all the HapMap individuals (McCarrol et al. 2006) to study their effect on the expression levels in different populations. We compare and contrast the significant results in the three HapMap populations, CEU, YRI, CHB+JPT. The gene expression data are obtained from two different sources: Affymetrix (Cheung et al. 2005) and Illumina (Stranger et al. 2006). Multiple QTL association studies were performed to analyze the data: namely, linear regression using the unrelated founder individuals in all populations, variance component TDT analysis on CEU and YRI trios. In the CEU sample, regression analysis reveals 7 deletion polymorphisms that are significantly associated with expression levels. In the CHB, JPT and the YRI samples, the number of DPs significantly associated with expression levels are 8, 8 and 5 respectively. When using a p-value threshold of 0.0001, we found 11 significant associations in the CEU, 17 in the CHB, 14 in the JPT and 7 in the YRI samples. Special attention has been paid to genes located near the DP sites to identify any potential cis acting effects. We plan to follow up with a more extensive study when denser deletion polymorphism data becomes available.

High density SNP screening of the major histocompatibility complex in systemic lupus erythematosus. *L.A. Criswell[1], S.L. Clark[2], P.P. Ramsay[2], M.F. Seldin[3], L.F. Barcellos[2]* 1) Univ of Calif, San Francisco, CA; 2) Univ of Calif, Berkeley, CA; 3) Univ of Calif, Davis, CA.

A substantial genetic contribution to systemic lupus erythematosus (SLE) risk is conferred by gene(s) within the major histocompatibility complex (MHC) on chr. 6p21. The most consistent associations are with class I and II genes, including HLA-A*01, -B*08, -DRB1*0301, -DRB1*1501, and -DRB1*08. Genes within the class III and extended MHC regions have also been strongly implicated, and may be independent of class II. Previous studies of MHC variation and both SLE susceptibility and related phenotypes have lacked statistical power and genetic resolution to fully characterize MHC influences. We recently completed comprehensive MHC region SNP genotyping in 492 Caucasian SLE cases and 151 nuclear family members (N=643 individuals). A total of 2,360 MHC SNPs spanning 4.9 Mb with an average density of one SNP/2 kb were investigated, including variants from 159 MHC region genes (average 10.7 SNPs/gene). Analyses of linkage disequilibrium and haplotype diversity for MHC SNPs revealed a complex architecture. A total of 236 distinct haplotype blocks were identified in SLE cases and family members, ranging in size from 0.25-161 kb; 2-14 haplotypes/block were observed, marking common haplotypic variation across this region. The most common DRB1 haplotypes, *0301 and *1501, were present in cases at a frequency of 20.1% and 13.7%, respectively; 12% of cases were either homozygous for high risk DRB1 haplotypes or carried one copy of each. The extended DRB1*1501 haplotype previously observed in SLE (~500 kb) was comprised of 17 strongly associated blocks (116 SNPs). Initial results suggest that centromeric and telomeric boundaries are marked by BTNL2 and DQA1 (320 kb region). Full characterization of SLE-associated DRB1*0301 and *08 haplotypes is underway. Our large family-based study of high-density MHC SNP variation, in conjunction with classical HLA loci genotyping in 800 SLE families (Total N=2,400 individuals) will provide an opportunity to systematically screen and identify all MHC gene(s) and interactions contributing to SLE risk and related phenotypes, such as lupus nephritis.

Investigation of somatic *NKX2.5* mutations in congenital heart disease. *J.M. Draus[1], M.A. Hauck[1], E.H. Austin[1], A. Tomita-Mitchell[2], M.E. Mitchell[3]* 1) Surgery, University of Louisville, Louisville, KY; 2) Bioengineering, University of Louisville, Louisville, KY; 3) Surgery, Medical College of Wisconsin, Milwaukee, WI.

Recent reports suggest that somatic *NKX2.5* mutations found in formalin-fixed human hearts with septal defects are etiologic. To test the hypothesis that somatic *NKX2.5* mutations contribute to congenital heart malformations, we repeated the above study using fresh-frozen tissue. Blood and cardiac tissue samples were collected from 28 patients. Our cohort included patients with atrial septal defects (ASD = 16), ventricular septal defects (VSD = 4), and both (AVSD = 8). Cardiac samples were collected as surgical discards or from explanted hearts from malformed and normal regions. Tissue samples were immediately frozen in liquid nitrogen and stored at -80ºC. gDNA was isolated, amplified and sequenced from 42 pathologic cardiac tissue samples using methods described in the published reports. A novel non-synonymous mutation (A65G) was identified in an ASD patient. This mutation results in a glu-to-arg (Q22R) amino acid substitution and is located just outside of the TN domain. Two novel synonymous mutations (G543A and C852G) were observed in separate ASD patients; G543A and A65G occurred in the same patient. Finally, a common SNP (A63G) was observed in 16 patients in homozygous and heterozygous forms. All of the genetic variants were also detected in gDNA from the same patients blood. Conclusion: No evidence of somatic mutations was found in the present study although additional germ-line *NKX2.5* mutations were identified. The effects of fixation are not well understood at the molecular level. gDNA yield from fresh-frozen tissue (1.3 g gDNA from 5 mg tissue) was greater than five times that of formalin-fixed hearts (0.5 - 1 g DNA from 25 mg tissue). The mutational spectrum of formalin-fixed hearts was significantly different from inherited and somatic mutation databases including HGMD, *p53*, *HPRT*, as well as inherited *NKX2.5* mutations. The earlier reports may reflect post-mortem artifacts of fixation, incorporated as mutations during PCR because of low gDNA yield and damaged gDNA templates.

A genome-wide non-synonymous SNP panel. *L.M. Galver[1], P.C. Ng[1], S. Hunt[2], J. Whitacre[1], R. Shen[1], P. Deloukas[2], S.S. Murray[1]* 1) Illumina, Inc, San Diego, CA; 2) Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

Approximately 90% of all genetic variation in humans is attributed to single nucleotide polymorphisms (SNPs) (Collins *et al*., 1998). Many SNPs are believed to cause phenotypic differences and can be related to an individuals susceptibility to disease. SNPs in coding regions that cause amino acid changes, non-synonymous SNPs (nsSNPs), as well as SNPs in regulatory regions, are believed to have the highest impact on phenotype as they directly affect protein structure and function (Collins *et al*, 1997). We have developed a genome-wide panel of nsSNPs that will be a valuable resource either as a whole genome screen of nsSNPs only, or as a complement to other whole genome or candidate gene association studies.

SNPs were selected for this study by screening public databases for all annotated nsSNPs. Approximately 50,000 SNPs were screened for assay designability on the Illumina BeadArray platform and approximately 38,000 were screened for functionality on 90 CEU (Caucasian) samples from the HapMap project. Greater than 13,000 functional SNP assays were chosen for the final panel that represents greater than 5,800 genes. The final assay panel was designed utilizing a whole genome genotyping assay on Illuminas multi-sample bead chips and 270 HapMap samples were genotyped for validation.

Preliminary results from the analysis of 270 HapMap samples show an average minor allele frequency (MAF) of 0.18 for the CEU population, 0.16 for CHB/JPT and 0.16 for YRI. We observed a significant percentage of nsSNPs monomorphic in a single population were polymorphic in one of the other two populations indicating population level differences and possibly selection. Comparing the d_N/d_S ratio(Nielsen, *et al*. 2005) to the no. of nsSNPs per gene, we observed that highly conserved genes have fewer nsSNPs. We also confirmed that putative-damaging nsSNPs (predicted by SIFT, Ng and Henikoff, 2002) tended to be present at lower MAFs as has been predicted in previous studies (Livingston *et al*., 2004, Leabman *et al*., 2003).

A high density admixture scan in 1,670 African Americans with hypertension and 387 normotensive controls. *R. Deo[1], N. Patterson[2], A. Tandon[1,2], G. McDonald[1,2], C. Haiman[4], K. Ardlie[5], B. Henderson[4], S. Henderson[3,4], D. Reich[1,2]* 1) Dept. of Genetics, Harvard Medical School, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Boston, MA; 3) Department of Emergency Medicine, Keck School of Medicine, Univ. of Southern California, CA; 4) Department of Preventive Medicine, Keck School of Medicine, Univ. of Southern California, CA; 5) Genomics Collaborative, Inc., Cambridge, MA.

Hypertension (HTN) is a devastating disease with a higher incidence in African Americans than European Americans, motivating searches for genetic variants determining this difference. We present results of an admixture scan for genetic determinants of HTN. Admixture mapping involves screening the genome in a population of mixed ancestry such as African Americans, genotyping markers differing in frequency between the ancestral populations to find regions with elevated proportion of ancestry from the population with higher risk for disease. We genotyped 1,165 HTN cases and 387 controls from the Multiethnic Cohort (MEC) and 505 HTN cases from the Genomics Collaborative, Inc. collection (GCI) using a panel of 1,291 polymorphic markers, and evaluated the likelihood of each position as a disease locus using the ANCESTRYMAP program. MEC cases and controls, and GCI cases had respective mean European ancestry of 2414%, 2515%, and 1513%. No significant (LOD5) or suggestive (5>LOD4) loci for association with HTN were found for the MEC or GCI samples, separately, or together. Redefining cases and controls by logistic regression with age and BMI as covariates yielded a suggestive peak at 14q22 (LOD=4.0) for the MEC samples, corresponding to a local excess of 5% European ancestry for cases above their individual mean, and a local decrease of 6% for controls. Inclusion of 199 stringently defined GCI cases decreased the LOD score to 1.2. In a combined MEC/GCI scan, we find limited association with HTN for the two top loci reported in the admixture mapping study by Zhu et al. (Nat Genet. 2005 Feb;37(2):177-81.) with estimated odds ratios for HTN of 0.87 (95% credible interval: 0.77-0.99) and 0.95 (0.83-1.05) for one European allele at the 6q24 and 21q21 loci, respectively.

Crypic out-of-frame translational initiation of TBCE rescues tubulin formation in the syndrome of hypoparathyroidism, mental and physical retardation and dysmorphism (HRD). *G.A. Diaz[1], G. Tian[2], M. Huang[1], R. Parvari[3], N. Cowan[2]* 1) Dept Human Genetics, Mt Sinai Sch Medicine, New York, NY; 2) Dept Biochemistry, NYU Sch Medicine, New York, NY; 3) Dept of Dev Gen and Virology, Ben Gurion Univ of the Negev, Beer Sheva, Israel.

Mutations in the gene encoding TBCE cause a devastating autosomal recessive disorder characterized by hypoparathyroidism, mental and physical retardation, and dysmorphism (HRD syndrome). TBCE is one of five tubulin-specific chaperones termed cofactors A-E (TBCA-E). TBCC, TBCD and TBCE are essential in higher eukaryotes and function as a multimolecular machine that assembles quasi-native - and -tubulin polypeptides into tubulin heterodimers competent to assemble into microtubules. HRD is most common in Middle Eastern individuals who are homozygous for a 12-bp founder deletion in the second coding exon of TBCE that ablates nt 155-166 of the open reading frame. The mutant protein lacks amino acids 52-55 within the cytoskeleton-associated protein glycine-rich (CAP-gly) -tubulin-binding domain. Total tubulin levels in homozygous mutant cells are normal, consistent with residual tubulin chaperone activity in the mutant, but mutations identified in a Belgian pedigree present a more puzzling picture. One allele contains a two-bp deletion at nt 66-67 in the first coding exon and is predicted to yield a 22-amino acid wild type peptide fused to an out-of-frame 26-amino acid nonsense sequence; the second allele contains a nonsense mutation in exon 12 (1113T->A) that would result in a protein lacking the C-terminal 157 (out of 527) amino acids. These compound heterozygous HRD patients would not be expected to produce a functional TBCE protein. Here we identify cryptic translational initiation at each of three out-of-frame AUG codons upstream of the genetic lesion as a unique mechanism that rescues a mutant HRD allele by producing a functional TBCE protein. Our data identify a novel rescue mechanism to explain how affected individuals who would otherwise lack the capacity to make functional TBCE can survive, and point to a limiting capacity to fold tubulin heterodimers de novo as a contributing factor to disease pathogenesis.

Pharmacogenetic analysis of antipsychotics: comprehensive analysis of pharmacokinetic variants. *I. Grossman*[1], *Y. Liu*[2,1], *N. Walley*[1], *J. Dawson*[1], *C. Gumbs*[1], *M. Weale*[1], *P. Sullivan*[3], *D. Goldstein*[1] 1) IGSP Center for Population Genomics and Pharmacogenetics, Duke University, Durham, North Carolina, USA; 2) Bioinformatics Research Center, North Carolina State University, Raleigh, North Carolina, USA; 3) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA.

Clinical implementation of pharmacogenetic testing seems achievable with the development of commercially available genotyping platforms. Current options use genetic tests to predict metabolic phenotypes of a few key drug metabolizing enzymes (DMEs), although the potential utility in clinical practice has yet to be thoroughly investigated. This study was designed to describe comprehensively the effects of known functional genetic variations in DMEs on the response to and dosing of antipsychotics. 756 patients who had participated in the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study were genotyped for 26 genetic variants in *CYP2D6, CYP1A2, CYP3A4, CYP3A5, CYP2C9, CYP2C8, CYP2C19, UGT1A4, FMO3* and *ABCB1*. Drug treatments included the conventional antipsychotic perphenazine, and the atypicals olanzapine, risperidone, quetiapine and ziprasidone. Patients treated with each drug were analyzed separately for association with three phenotypes: optimized dose, safety, and efficacy. ANOVA was used to assess whether gene variants predict optimized dose, while association of these genetic polymorphisms with safety and efficacy measurements was tested by way of contingency tables (^{2} and Fisher's exact tests, as appropriate). Potential covariates were broadly evaluated. No clear significant associations were observed between optimized dose and any genetic variants. We could not replicate an association between the *CYP2D6* poor metabolizer (PM) phenotype and Tardive Dyskinesia. However, a trend was detected between relevant polymorphisms and occurrence of side effects for some of the drugs. In conclusion, our results suggest that any effect of relevant genetic polymorphisms in DMEs on antipsychotics response and dosing is modest.

Genome-wide scan for non-syndromic cleft lip and palate in multigenerational Indian families reveals significant evidence for linkage at 13q33.1-34. *S. Beiraghi[1], U. Ratnamala[2], M. Gaines[3], D. Hutchings[3], S.A. Husain[4], P.S. Gambhir[5], J.J. Sheth[6], F.J. Sheth[6], G.K. Chetan[7], M. Naveed[8], J.V. Solanki[9], U.C. Patel[9], R. Memon[2], G.S. Antonarakis[10], S.E. Antonarakis[10], S.K. Nath[3], U. Radhakrishna[2]* 1) Pediatric Dent 6-150 Moos T, Univ Minnesota, Minneapolis, MN; 2) Green Cross bank and Genetic Research Centre, Paldi, Ahmedabad, India; 3) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, USA; 4) Department of Biosciences, Jamia Millia Islamia Central University, New Delhi,; 5) Department of Pediatrics, B. Box 15881, Dubai, United Arab Emirates; 9) Dept. of Animal Genetics and Breeding, Gujarat Agriculture University, Anand, India; 10) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland.

Non-syndromic cleft lip with or without cleft palate (CL-P),is a common congenital anomaly with incidence ranging from 1/300 to 1/2500 live births. We have analyzed two Indian pedigrees (UR017 & UR019) with isolated, non-syndromic CL-P in which the anomaly segregates as an autosomal dominant trait. A genome-wide linkage scan using ~10,000 SNPs was performed. Non-parametric linkage analysis identified 11 genomic regions (NPL > 3.5, P-Value <0.005) that could potentially harbor CL-P susceptibility variations. Among those, the most significant evidence was for chromosome 13q33.1-34 at marker rs1830756 (NPL = 5.57 and p=0.00024). This was also supported by parametric linkage; MOD-score (LOD scores maximized over genetic model parameters) analysis favored an autosomal dominant model. The maximum LOD score was 4.45 and HLOD was 4.45 (alpha = 100%).Haplotype analysis with informative crossovers enabled the mapping of the CL-P locus to a region of approximately 20.17cM (7.42Mb) between SNPs rs951095 and rs726455. Thus, we have identified a novel genomic region on 13q33.1-34 that harbors a high risk variant for CL-P in these Indian families.

Evidence of Association Between Polymorphism on UCPs and Type 2 Diabetes in a Northwestern Population From Colombia. *L. Franco[1], C. Duque[1], N. Gallego[1], F. Uribe[2], A. Villegas[2], G. Bedoya[1], A. Ruiz-Linares[1]* 1) Biology, Universidad de Antioquia, Medellín; 2) Hospital Universitario Saqn Vicente de Paul, Universidad de Antioquia, Medellín.

The uncoupling proteins (UCPs) are a family of mitochondrial transport proteins that promote proton leakage across the inner mitochondrial membrane, uncoupling oxidative phosphorylation from adenosine triphosphate (ATP) production and releasing energy as heat. In comparison to the established uncoupling and thermogenic activities of UCP1, UCP2 and UCP3 appear to be involved in the limitation of free radical levels in cells rather than in physiological uncoupling and thermogenesis. Moreover, UCP2 is a regulator of insulin secretion and UCP3 is involved in fatty acid metabolism. Variation in these genes has been associated with Type 2 diabetes (T2D). We genotyped six polymorphisms in UCP1, UCP2 and UCP3 in a sample of 190 type 2 diabetic patients and 149 nondiabetic participants. Associations between -866G/A (p=0.0025) of UCP2 and -55C/T (p=0.0005) of UCP3 polymorphisms and T2D were found. Additionally, it was found that haplotype AIAGAC was significantly associated with DM2 (p<<<0.0005 and O.R.= 5.19). These results support a role for UCPs in the development of DM2. This research is funded by COLCIENCIAS 11150416451.

Exclusion of MSX1 and PAX9 gene mutations in four families with anodontia. *P. Gambhir[1], S.K. Nath[2], J.V. Solanki[3], U.C. Patel[3], R. Memon[4], U. Ratnamala[4], U. Radhakrishna[4]* 1) Department of Pediatrics, B. J. Medical College, Pune, India; 2) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, USA; 3) Departments of Animal Genetics and Breeding, Gujarat Agriculture University, Anand, India; 4) Green Cross bank and Genetic Research Centre, Paldi, Ahmedabad, India.

Anodontia is one of the common genetic disorders characterized by partial or complete absence of the primary or permanent teeth. Its genetic basis of development is poorly understood. It is generally associated with a group of non-progressive skin and nerve syndromes. Anodontia is usually part of a syndrome and seldom occurs as an isolated entity. Over 50 syndromes may include tooth agenesis. Most commonly affected are third molars (wisdom teeth), followed by either upper lateral incisors or lower second premolars; agenesis involving first and second molars is very rare. Several studies have shown that MSX1 as well as PAX9 genes play a role in early tooth development (Nature Genet. 24: 18-19, 2000; Nature Genet. 13: 417-421, 1996). We have studied four non-syndromic anodontia families including two with complete and two with partial anodontia. The mode of inheritance is autosomal dominant and the severity of the phenotype was quite variable among and between these families. There was 100% penetrance in these families as no skipping of generation was observed. Some of the partially affected individuals lacked mandibular second premolars as well as mandibular central incisors. Thus far, we have analyzed MSX1 and PAX9 gene coding regions and splice junctions by direct sequencing and excluded these genes as candidates in these four families. This study reveals that genetic heterogeneity exists within anodontia.

Multiple perineural thoracic cysts presenting as "neurofibromas". *K. Gardner[1], J. Boardman[2]* 1) Veterans Administration Pittsburgh Healthcare System, Dept Neurology, Univ Pittsburgh, Pittsburgh, PA; 2) Dept of Neuroradiology, Univ Pittsburgh, Pittsburgh, PA.

We report a case of isolated perineural cysts found along multiple, bilateral thoracic spinal nerve roots that were initially thought to represent neurofibromas. No other conditions associated with dural ectasia / perineural cysts were identified. Localized congenital and post-traumatic or surgical perineural cysts have been described previously though never involving multiple levels as in the case presented here. Incidental "Tarlov" cysts have been described primarily in lumbosacral levels though the frequency of these is quite low according to a recent large sampling of lumbosacral MRI images (1.5%).Dural ectasia, arachnoid, and perineural dilation around multiple spinal roots can also be associated with Neurofibromatosis-1 (NF1) or with Marfan Syndrome. Dural ectasia is one of the major diagnostic criteria for Marfan Syndrome using Ghent nosology, also found usually in lumbo-sacral regions. With NF1 perineural cysts and dural ectasia can occur at any spinal level, are associated with other clinical features for NF1, and are sometimes associated with plexiform spinal neurofibromas. Careful evaluation of MRI imaging signal characteristics is critical to first differentiate cysts from tumors in patients presenting with thickened spinal nerve sheaths. T2 signal should match CSF signal for perineural cysts and T1 signal should match that of nerve root in the case of tumor expansion of nerve sheath (with or without enhancement). Those found to have perineural cysts without enlargement of nerve roots should then be examined carefully to exclude associated conditions looking for stigmata of Neurofibromatosis-1 (NF1) and for connective tissue disorders such as Marfan Syndrome. If thickened nerve roots are truly present then the differential for paraspinous tumor includes NF1, NF2, and schwannomatosis depending on presence or absence of characteristic skin findings, vestibular schwannomas, and other diagnostic features.

A common $_2$ adrenergic receptor haplotype is associated with protection against decrease in receptor sensitivity among smoking men. *X. Bao[1], P.J. Mills[2], J.E. Dimsdale[2], M.G. Ziegler[1]* 1) Dept Medicine, Univ California, San Diego, CA; 2) Dept Psychiatry, Univ California, San Diego, CA.

Cigarette smokers are more likely to develop hypertension than nonsmokers. Blunted $_2$ adrenergic receptor (ADRB2) mediated vasodilation has been implicated in the pathogenesis of hypertension. Both smoking and ADRB2 polymorphisms are associated with vascular responsiveness. However, whether they have interactive effect on the intermediate phenotype of $_2$ adrenergic receptor function is unclear. To investigate this, 10 common single-nucleotide polymorphisms (SNPs) in the promoter and coding regions of ADRB2 were genotyped, and lymphocyte $_2$ adrenergic receptor functions were measured in an unrelated cohort of 187 white men. ADRB2 haplotypes were estimated by expectation maximization (EM) algorithm-based methods. Three common haplotypes (frequency > 5%) were identified. The frequency of the most common haplotype (haplotype 1) is 43%. Lymphocyte $_2$ adrenergic receptor sensitivity did not differ between smokers and nonsmokers who were carrying haplotype 1 (5.1 0.6 vs. 6.0 1.7 pmol/L per 10^6 cells), but was significantly lower in smokers vs. nonsmokers who were not carrying haplotype 1 (3.0 0.4 vs. 7.3 1.4 pmol/L per 10^6 cells, $p < 0.01$). No differences in lymphocyte $_2$ adrenergic receptor density and desensitization were seen between smokers and nonsmoker carrying haplotype 1 or not. Our data indicate that smoking reduces $_2$ adrenergic receptor sensitivity but only in subjects carrying no haplotype 1. Therefore, the common $_2$ adrenergic receptor haplotype 1 is associated with protection against smoking-related decrease in receptor responsiveness, and thus may prevent development of hypertension among smokers.

Widely distributed non-coding selection in the human genome. *S. Asthana[1], W.S. Noble[2], G. Kryukov[1], S. Sunyaev[1], J.A. Stamatoyannopoulos[2]* 1) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Dept. of Genome Sciences, Box 357730, Univ. of Washington, 1705 NE Pacific Street, Seattle, WA 98195.

Evolutionarily conserved non-coding sequences (CNSs) in the human genome have attracted considerable attention for their potential to simplify the search for functional elements and phenotypically important human alleles. A major outstanding question is whether CNSs accurately capture the distribution of functionally significant non-coding variation. We used recently available whole-genome sequence data from chimp, dog, mouse, and rat, to partition the human genome sequence at the nucleotide level into conserved and non-conserved positions based on conservation across four non-human species. Conserved bases are widely distributed, with a majority occurring outside of CNSs. Here we show using analysis of comprehensive human resequencing data that the selective differences observed between CNSs and non-CNS non-coding sequences are recapitulated at the level of individual conserved and non-conserved bases outside of CNSs. Individually conserved positions have lower nucleotide diversity within human population. SNPs in these positions tend to have lower derived allele frequency. This result holds for individually conserved bases not simply outside of genes and conventional CNSs but also in regions with extremely poor overall conservation level. The results indicate that a substantial fraction of active selection in human non-coding sequences is occurring outside of CNSs. This fraction is widely distributed, suggesting that a surprisingly large proportion of the human non-coding genome may be under selection. Analysis in the framework of the infinite number of sites model shows that even assuming very strong heterogeneity of mutation rates at all possible scales and any possible distribution of selection coefficients cannot explain the above observations if less than 20% of individually conserved positions are under selective pressure. Limiting the search for phenotypically important human non-coding variation to CNSs may overlook a large reservoir of functional alleles.

Craniometaphyseal dysplasia associated with de novo complex chromosomal rearrangement 46, XY, der(1)t(1;6;14)(q32;q13q22;q22), der(6)t(1;6),der(14)t(6;14)(q22;q22). *B. Afroze[1], Y.S. Choy[1], A. Mekesat[2], Ruziana[2]* 1) Genetics and Metabolism, Pediatric Institute, Kuala Lumpur Hospital, Kuala Lumpur, Malaysia; 2) Cytogenetic Unit, Kuala Lumpur Hospital, Kuala Lumpur, Malaysia.

Craniometaphyseal dysplasia is a craniotubular bone dysplasia syndrome characterized by craniofacial anomalies presenting in early childhood. It is genetically heterogenous and two loci has been identified. The autosomal dominant type is due to mutations in ANKH gene encoding a protein regulating transmembrane transport of pyrophosphate, mapped to 5p14.1p15.2. The second gene locus responsible for the more severe type was mapped to 6q21-q22 in a large inbred family but not cloned yet. We report here a patient presenting to us at the age of 18 months with craniofacial anomalies typical of craniometaphyseal dysplasia. He had frontal bossing and dolicocephaly with severe hypertelorism, telecanthus, broad nasal bridge and but small short nose. The anterior fontanelle was still widely open. His developmental milestones and growth had been apropriate for age. He was the second twin of a non-consanguineous couple and the first twin was perfectly normal. High resolution karyotype revealed a de novo complex chromosomal rearrangement 46, XY, der(1)t(1;6;14)(q32;q13q22;q22), der(6)t(1;6),der(14)t(6;14)(q22;q22). FISH that was carried out using wcp 1, 6 and 14 probes comfirmed the rearrangement. Karyotype for the parents and the other twin was normal. We concluded that the breakpoint at 6q22 had probably disrupted the gene responsible for craniometaphyseal dysplasia.

SIL1 and SARA2 mutations in a family with Marinesco-Sjogren and Chylomicron Retention Diseases. *G. Annesi[1], P. Tarantino[1], F. Annesi[1], E.V. De Marco[1], D. Civitelli[1], A. Torroni[2], A. Quattrone[1,3]* 1) Inst Neurological Sci, National Research Council, Cosenza, Italy; 2) Dipartimento di Genetica e Microbiologia ,Università di Pavia, Italy; 3) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Marinesco-Sjogren Syndrome (MSS) is an autosomal recessive disorder, characterised by cataracts, ataxia, and growth and mental retardation. Recently, Anthonen et al identified the linkage of the MSS phenotype to 5q31 chromosome in a Finnish family, and identified a homozygous 4-nucleotide duplication 506_509dupAAGA of the SIL1 gene in all investigated MSS patients. Senderek et al using homozygosity mapping in three small consanguineous families with typical MSS narrowed a critical region on 5q31. In this region the authors identified mutations in SIL1 gene in individuals with MSS. In the current study, we further investigated a small Italian pedigree, previously described elsewhere. In this family, two brothers had MSS syndrome, with a very low serum concentration of vitamin E and absence of postprandial chylomicrons, a finding consistent with chylomicron retention disease (CMRD). On a subsequent study , we demonstrated that these two brothers carried a mutation in the SARA2 gene belonging to the Sar1-ADP-ribosylation factor family of small GTPases. On the basis of the recent data on SL1 in MSS, we analyzed the SL1 gene in our patients with MSS and CMRD, in their healthy parents, and in 50 healthy controls from Calabria. Sequencing of the SIL1 gene revealed a C-T homozygous mutation at position 331 in exon 4 resulting in a premature stop codon at amino acid 111 (R111X) in the affected brothers, while both parents were heterozygous for the mutation, and all 100 chromosomes from control subjects were wild-type. In our previous study, we hypothesized that both MSS and CRMD found in the two Calabrian brothers could be due to defects in a gene crucial to the assembly or secretion of the chylomicron particle, leading to a very low serum concentration of vitamin E. The present results, however, demonstrate that CMRD and MSS observed in our patients are distinct diseases due to defects in two different genes, SARA2 and SIL1.

Association of m2 and m4 CYP1A1 polymorphisms with Mexican lung cancer patients. *M. Gallegos[1], V. Peralta[1], AM. Puebla[2], GM. Zúñiga[3]* 1) Laboratorios de Genetica Molecular; 2) Inmunofarmacologia; 3) Laboratorio de Mutagenesis, Division de Medicina Mutagenesis, Div. Med. Mol, CIBO, IMSS. Guadalajara, Jalisco. Mexico.

Lung cancer is the leading cause of death among cancers in Mexicans. Although the etiology of lung cancer has yet to be defined, genetic variability in activities of metabolic enzymes has been correlated with lung cancer. In the present study, the possibility of association of CYP1A1 (m2 and m4) genetic polymorphisms with lung cancer was examined among 159 lung cancer patients and 220 controls in Mexicans. Significant association was observed for m2 and m4 CYP1A1 polymorphism with odds ratio 2.19; confidence interval (CI) 0.89 -5.60) and 13.05 (CI 3.01-117.5) respectively. Our results suggest that the m2 and m4 CYP1A1 polymorphisms are an important risk factor for Mexican lung cancer patients.

High Myopia: A Genetic and Clinical Study Among Egyptian Patients. *H. Elbastawisy, M. Salah* Research Institute of Ophthalmology. Giza, Egypt.

Background: In cases of high or pathological myopia, have errors of -6.00D or greater in one or both eyes. Although in many cases myopia appears to be genetically determined, its precise pathophysiology and development have yet to be elucidated. Both, autosomal dominant and recessive transmissions have been reported for the pathological myopia. Methods: forty-two families (group- I) participate in the study with onset of myopia at < 12 years of age in all affected subjects (parents & offspring); myopia of -6.00 D., and two or more affected generations. Group-II, include cases of high myopia as a part of a known genetic syndrome. Full ocular examination as well as axial length measurements was done. The mode of inheritance was thoroughly studied. Results: The (group-I) high myopia families showed a likely autosomal dominant pattern of inheritance, but were far away from autosomal recessive or X-linked inheritance; while high myopia as a part of a syndrome follows the inheritance of the syndrome itself. Ophthalmologic findings showed in (group-I) that (33.3 %) had high myopia ranging from (- 6.00D : -14.00 D), and (48.8%) were extreme myopes (>-15.00D). Most common fundus associations were peri-papillary temporal crescent (95.2%), RPE-atrophy (83%), posterior vitreous detachment (59.5%), typical lattice degeneration (47.6%), and posterior staphyloma (38.1%); while other visual affecting associations were macular hemorrhage (9.5%), choroidal neo-vessels (7.1%), rhegmatogenous R.D. (4.8%) & macular hole (2.4%). Conclusion: The inheritance of isolated high myopia is mostly autosomal dominant in Egyptian cases, while high myopia as a part of a syndrome is inherited as the mode of inheritance of that syndrome. The higher the degree of myopia, the more the severity of an associated ocular degenerative changes & /or complications.

Frequent tetraploid mosaicism in products of conception. *E.M. Davis[1], T. Alexander[2,3], J. Malone[1], R.V. Lebo[1,3]* 1) Pathology, Akron Children's Hospital, Akron, OH; 2) Pathology, Akron City Hospital, Akron, OH; 3) Northeast Ohio Coll Med. Rootstown, OH.

Tetraploid mosaicism defines some cells with 92 chromosomes that arise by doubling the normal number of 46 and is anticipated to result in abnormality. A 40% frequency of tetraploid mosaicism has been reported in 8-cell preimplantation embryos which are considered to be nonviable. During prenatal diagnosis, most mosaic tetraploid cultured amniocytes are considered to have occurred during tissue culture and are not reported. Our laboratory found mosaic tetraploid chorionic villus cells with unique fetal chromosome patterns in 6% to 8% of the 320 products of conception (POCs)-substantially higher than previously reported. To establish whether these tetraploid fetal cells existed in the spontaneous abortion, tissues were studied prior to cell culture. Initially only a few cells in a small fraction of fixed paraffin embedded fetal tissues could be studied by fluorescence in situ hybridization (FISH) because of substantial DNA degradation. Subsequently flow cytometric analysis analyzed thousands of whole nuclei for tetraploid mosaicism from each case. Flow analysis verified tetraploid mosaicism in chorionic villus nuclei in 12 of 13 cases. The single testable fetal tissue in one of these POCs also had mosaic tetraploid cells. These results confirm the high proportion of cases of true tetraploid mosaicism in spontaneously aborted fetal tissues. These data support the conclusion that mosaic tetraploid karyotypes are a biologically important finding in cultures from spontaneously aborted fetuses and should be reported and followed up when found in any cultured fetal tissue.

The genetic susceptibility to retinopathy of prematurity. *M. Bizzarro[1], N. Hussain[2], B. Jonsson[3], R. Feng[4], L. Ment[1], J. Gruen[1,5], H. Zhang[4], V. Bhandari[1]* 1) Dept Pediatrics, Yale Univ Sch Medicine, New Haven, CT; 2) Division of Neonatology, University of Connecticut Health Center, Farmington, CT; 3) Department of Neonatology, Karolinska University Hospital, Karolinska Institutet, Stockholm, Sweden; 4) Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, CT; 5) Department of Genetics and the Yale Child Health Research Center, New Haven, CT.

Background: Retinopathy of prematurity (ROP) accounts for significant morbidity in preterm neonates. In addition to prematurity and environmental factors, we hypothesized that genetic factors play a significant role in this disease process.

Objective:To isolate and estimate the genetic susceptibility to ROP

Patients and Methods: A retrospective study (1994-2004) from 3 centers was performed using zygosity data from premature twins born at 32 weeks gestational age (GA) and surviving beyond 36 weeks postmenstrual age. ROP was diagnosed and staged by pediatric ophthalmologists at each center. Data analyses were performed using mixed effect logistic regression (MELR) analysis and latent variable probit modeling.

Results: 63 monozygotic (MZ) and 137 dizygotic (DZ) twin pairs were identified and analyzed. Demographic data for GA, birth weight, gender, respiratory distress syndrome, ROP, bronchopulmonary dysplasia, duration of ventilation and supplemental oxygen use, and length of stay were comparable between MZ and DZ twins. In the MELR for ROP, GA (p=0.024, OR 0.65; 95% CI=0.45-0.94) and duration of supplemental oxygen (p=0.003, OR=1.03; 95%CI=1.01-1.05) were significant covariates. After controlling for known and unknown non-genetic factors, genetic factors accounted for 70.1% (95%CI=0.09-1.00; p=0.026) of the variance in liability for ROP.

Conclusion: Besides environmental factors, there is a strong genetic predisposition to ROP.

Evidence of a Hyperhidrosis Risk Gene at 5q11.2. *R.M. Cantor-Chiu[1], F. Chandra[2], N. Dorrani[2], C. Swartling[3], D. Glaser[4], S. Ahn[2]* 1) Department of Human Genetics,; 2) Department of Surgery, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) University of Uppsala, Sweden; 4) Washington University, St Louis, MO.

Hyperhidrosis, a disabling lifelong disorder identified by excessive sweating, is familial and common, afflicting as much as 3% of the general population. Although available surgical and drug treatments can reduce excessive sweating, the etiology of this disorder remains unknown. Segregation analysis of families ascertained through a proband with hyperhidrosis revealed a dominant genetic predisposition with reduced penetrance, indicating genetic complexity. Given this evidence of a genetic contribution, a full genome scan of 500 multiallelic markers was initiated to identify chromosome regions likely to harbor hyperhidrosis risk genes. In the current study, 93 members of 16 3-generation hyperhidrosis families were genotyped and analyzed for multipoint linkage under the model of inheritance revealed by segregation analysis. Evidence of linkage to 5q11.2 was observed with a LOD score of 2.0, and no other locus exhibited a lod score greater than 1.0, making this region the most likely location of a hyperhidrosis risk gene. As is necessary with genetically complex disorders, we are conducting a full genome scan in a second independent hyperhidrosis sample of 93 individuals from this cohort before further molecular studies are conducted to narrow the linked region(s) and assess positional candidate genes.

Linking collagen genotypes to molecular phenotypes. *T.F. Chan[1], N. Addleman[1], A. Poon[1], A. Phong[1], T. Klein[2], P. Byers[3], P.Y. Kwok[1]* 1) Institute of Human Genetics, University of California - San Francisco, San Francisco, CA; 2) Department of Genetics, School of Medicine, Stanford University, Stanford, CA; 3) Department of Pathology, University of Washington, Seattle, WA.

Collagen is a fibrous protein that provides structural and functional integrity in the human body. Types I, II, and III fibril collagens are the most abundant forms and account for 70% of the total body collagens. Mutations in collagen lead to an array of disorders. Osteogenesis imperfecta (OI) is the most common manifestation of mutations in the two type I collagen genes, COL1A1 and COL1A2. Other disorders such as chondrodysplasis and vascular Ehlers-Danlos Syndrome (EDS) are due to alterations in type II collagen (COL2A1) and type III collagen (COL3A1), respectively. Although there is a vast repository of clinical phenotypes of the diseases, relationships between genotypes, molecular and clinical phenotypes are poorly understood. Currently, mutations in the collagen genes are identified using a phenotype-to-genotype paradigm. A patient may be diagnosed with a specific phenotype followed by partial genotyping of the individual and possibly close family members. This provides an incomplete picture and does not allow a systematic analysis in a population. In this study, we are moving to a genotype-to-phenotype paradigm in collagen research. Central to this effort is knowing the baseline sequence variations in an ethnically diverse, non-affected population as well as sequence variations seen in patients with collagen disorders. We have performed deep sequencing of the four collagen genes in 192 individuals from the SOPHIE cohort representing 4 ethnic groups as well as 10 patients with OI. We have identified 415 SNPs in the four collagen genes, with 245 as novel SNPs. Correlating the disease causing mutations in the context of background variations in the genes will help explain differences in disease phenotype and guide our study of sequence-structure-function relationship by molecular-folding simulations. This work is supported by the NIAMS AR051582 (T. Klein, PI).

MECP2 large deletions and exon 1 mutations in RTT patients. *F. Ariani[1], I. Longo[1], F. Mari[1], C. Pescucci[1], K. Sampieri[1], R. Artuso[1], E. Scala[1], R. Caselli[1], M. Bruttini[1], I. Meloni[1], G. Hayek[2], M. Zappella[2], A. Renieri[1]* 1) Medical Genetics, University of Siena, Italy; 2) Child Neuropsychiatry, University of Siena, Italy.

Rett syndrome (RTT) is a neurodevelopmental disorder that represents one of the most common genetic causes of mental retardation in girls. MECP2 mutations account for about 80% of classic RTT cases and for a lower percentage of RTT variants. We investigated 74 clinically well-defined mutation-negative RTT patients by searching for missed MECP2 defects. We searched for MECP2 large rearrangements, not detectable by PCR-based traditional techniques, by Real Time qPCR and for mutations in exon 1, previously considered non coding, by DHPLC. We found 9/74 (12%) patients with MECP2 large deletions and 1/74 (1%) with an exon 1 mutation (c.47_57del). The deletions were found in 7 sporadic cases with classic RTT and in one familial case with two sisters with different phenotypes (one is a classic RTT, while the other is a preserved speech variant). The exon 1 deletion was found in a classic RTT girl. These results indicate that MECP2 large deletions are an important cause of classic RTT and confirm the importance of quantitative studies in a complete diagnostic strategy. Moreover, these data suggest that exon 1 mutations are not common in RTT. We decided to characterize the MECP2 deletions by MLPA. All the deletions involve exon 3 and 4, but not exon 2. Intron 2 contains Alu repeats which probably represent recombinogenic factors. Previous studies found that the distal breakpoint of MECP2 deletions frequently occurs in the DPR (deleted prone region). In contrast, in our patients, MLPA showed that 8/9 deletions extend beyond the DPR. MLPA also showed that the deletion in the two RTT sisters involves exon 3 and partially exon 4, suggesting that they probably harbour the same rearrangement. In this case, modifying factors may explain the different phenotypes. Given that the deletion is absent in parents, in order to explain the origin of the rearrangement in the sisters, we hypothesized that one of the two parents may be a mosaic for the mutation in the gonadic tissue.

Tetrasomy X. Report one Mexican patient. *M. Diaz-Garcia[1], A. García-Huerta,[1], D.M. Mendoza-Ugalde[1], C.F. Martinez-Cruz[2,4], R. Baez-Reyes[3], G. Garcia-Sanchez[1]* 1) Genetica. Instituto Nacional de Rehabilitacion. Mexico, DF; 2) Comunicacion Humana. Instituto Nacional de Perinatologia, Mexico, DF; 3) Genetica. Instituto Nacional de Perinatologia, Mexico, DF; 4) Instituto Mexicano del Seguro Social.Hospital General de Zona 53.

The tetrasomy X is a genetic condition in which females have four X chromosomes instead of the usual two. We present a 9-year-and-4-month-old girl who was referred to genetic because shows significant delay in speech development and articulation, language expression and understanding. Clinical features included speech delay, IQ borderline, skin soft and light laxity, muscle hypotonic, high palate, hypoplasic uvula. Joint fingers hyper laxity and showed bilateral clinodactyly in the fifth finger, dermatoglyphics with alterations. Flutes on the outside of the thighs and buttocks, development of secondary sexual characteristics a seven years-and-6 month-old-age and menarche at eight years-old, normal external genitalia. Chromosome analysis was done in lymphocytes. The GTG banded karyotypes showed one cell line, 48,XXXX in 100% of metaphases analyzed. Tetrasomy X is a type of sex chromosome aneuploidy, which simply means an abnormal number of sex chromosomes. In most cases the extra X chromosomes occur when in cell division, two X chromosomes can remain in the egg. If the same event is repeated at the next division, the egg can end up with three X chromosomes. Fertilized by a single X carrying sperm, the egg will then develop into a tetra X chromosomes. Very occasionally, other processes may be involved, such as a failure of the X chromosome to separate in the normal way during cell division in the fertilized egg after conception. The addition of this extra genetic material in a child affects the major areas of development.

Molecular and biochemical alterations in Human Intrauterine Growth Restriction. *L. Guo[1,2], J. Ferreira[1,2], S. Choufani[1], D. Chitayat[1,3], C. Shuman[1], S. Keating[4], J. Kingdom[3], R. Weksberg[1]* 1) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Institute of Medical Sciences, University of Toronto, ON, Canada; 3) Maternal-Fetal Medicine Division, Department of Obstetrics & Gynaecology, Mount Sinai Hospital, Toronto, ON, Canada; 4) Department of Pathology, Mount Sinai Hospital, Toronto, ON, Canada.

We hypothesize that epigenetic programming of the genome during embryonic and fetal development affect gene expression patterns and can cause IUGR. The objective of this study is to verify if in IUGR, there is epigenetic dysregulation of some of the imprinted genes on human chromosome 11p15 that are known to be associated with growth alterations. Following informed written consent, placenta samples and cord vein blood from less than 10th percentile birthweight infants (cases) and controls were collected and DNA/RNA extraction was performed using standard procedures. We assessed the regulation of the imprinted genes on chromosome 11p15 H19 (non-coding RNA) and IGF2 (insulin-like growth factor 2 gene) and the associated imprinting control center (ICR1): methylation status of the genes involved by Southern blotting and bisulphite sequencing, mRNA expression level by quantitative real-time RT-PCR, and allelic specific expression by single-nucleotide primer extension assay (SNaPshot). Our results showed that: 1) IGF2 and H19 expression is downregulated in placentae of infants who are small for gestational age. 2) In both IUGR and controls, the H19 promoter and IGF2 DMR2 are hypomethylated in placentae, but normally methylated in cord blood. 3) ICR1 is hypomethylated in some placentae samples from IUGR and maintain its normal methylation status in blood. The decreased IGF2 and H19 gene expression in IUGR versus control placentae is of great interest since these two genes significantly impact placental growth. This decrease of the expression in human IUGR placentae doesnt seem to be regulated by the methylation status of the chromosome 11p15 region. Thus, the cause for IGF2 and H19 downregulation in IUGR is unknown and may be caused by altered histone modification or dysregulated transacting factors.

Evidence of interaction between DTNBP1 and IL3 in schizophrenia. *T. Edwards[1], X. Wang[2], B. Wormly[2], B. Riley[2], A. O'Neill[3], D. Walsh[4], K. Kendler[2], M. Ritchie[1], X. Chen[2]* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN 37232; 2) Virginia Institute for Psychiatric and Behavioral Genetics and Department of Psychiatry, Virginia Commonwealth University, Richmond, VA 23298; 3) The Department of Psychiatry, The Queens University, Belfast, Northern Ireland, UK; 4) The Health Research Board, Dublin, Ireland.

Schizophrenia is a psychotic mental disorder with a lifetime prevalence of approximately 1%. Heritability estimates of approximately 80% indicate this disease is largely genetic. Reports of risk loci and an epistatic model in the literature suggest a complex genetic etiology. In this study, we explored gene-gene interactions in population-based (657 cases: 414 controls) and family-based (269 families; 654 cases: 737 controls) datasets of English or Irish ancestry. Sixty markers in 8 genes were genotyped in families and thirteen markers in 3 genes were genotyped in population data. Results from the family dataset had an intermediate disease definition and the case control sample used the DSM-IIIR schizophrenia diagnosis or poor outcome schizoaffective disorder. Multifactor Dimensionality Reduction Pedigree Disequilibrium Test (MDR-PDT) was used to explore epistasis in families. A highly significant 3-locus interactive model was identified. The 3-locus family interactive model was between genes IL-3, RGS4, and dystrobrevin-binding protein 1 (DTNBP1) (rs2069803, rs2661319 and rs2619539 respectively), $p = 0.006$. To verify these findings, we used MDR on the case-control dataset containing the same markers typed in the 3 genes. While we could not replicate the 3-locus interaction, we saw evidence of a joint effect of IL3 and DTNBP1 with different markers (rs31400 in IL3 and rs760761 in DTNBP1), $p < 0.001$, odds ratio = 1.25, 95% CI [0.95, 1.65]. This is the first report of gene-gene interaction associated with schizophrenia in both population-based and family-based association studies.

A canine model of pontocerebellar hypoplasia with anterior horn cell disease. *J.C. Fyfe[1], R.J. Castellani[2], D. Rosenstein[1], D. Goldowitz[3], P.S. Henthorn[4]* 1) Laboratory of Comparative Medical Genetics and Small Animal Clinical Sciences, College of Veterinary Medicine, Michigan State University, East Lansing, MI; 2) Dept. of Pathology, University of Maryland School of Medicine, Baltimore, MD; 3) Dept. of Anatomy & Neurobiology, University of Tennessee, Memphis, TN; 4) Section of Medical Genetics, University of Pennsylvania School of Veterinary Medicine, Philadelphia, PA.

Pontocerebellar hypoplasia type I is a rare genetic disorder, and there are insufficient patient and family resources for gene identification by linkage analysis. In such cases, a disease model in a species with sufficient genome mapping resources may provide the first opportunity for molecular diagnosis. Onset of fetal akinesis in late gestation was observed in a colony of laboratory dogs. Affected puppies exhibited global stereotypical positioning of limbs, scoliosis, arthrogryposis, and respiratory failure at birth. Regional hypoplasia was apparent grossly in the central nervous system, most strikingly as underdeveloped cerebellum and mid and caudal brainstem, mild microcephaly, and reduced spinal cord diameter with attenuated nerve roots. Histopathologic abnormalities included axonal dystrophy and reactive gliosis throughout the brainstem and tracts of the spinal cord; reduced foliation, patchy loss of Purkinje cells, and failure of external granular cell migration in cerebellum; and a dearth of myelinated axons in ventral spinal roots. The disorder thus appears to be a homologue of human pontocerebellar hypoplasia type I. Breeding studies demonstrated that the canine disorder segregates as a fully penetrant, simple autosomal recessive trait. A whole genome scan for linkage is ongoing. This work has been supported by grants NS41989, RR02512.

Genetic Dissection Of A Complex Trait: Advantages of Using Multivariate Phenotypes Over Clinical Binary End-Points. *S. Ghosh*[1], *L.J. Bierut*[2] 1) Human Genetics Unit, Indian Statistical Inst, Kolkata, India; 2) Dept of Psychiatry, Washington Univ Sch of Medicine, St. Louis, USA.

A complex trait is usually a function of a multivariate phenotype comprising correlated quantitative variables. Since clinical end-point traits are usually binary in nature (affected/unaffected) and hence contain minimal information on variation within trait genotypes, it may be statistically more powerful to use a correlated multivariate phenotype for identifying genes for the complex trait. Mapping a multivariate phenotype traditionally uses some function of quantitative values of sib-pairs or other sets of relatives as a response variable and marker identity-by-descent scores as explanatory variables. In these analyses, linkage inferences depend strongly on the assumed probability distributions of the quantitative variables, particularly for variance components approaches. We propose, along the lines of Sham et al. (2002), a linear regression formulation in which the response and explanatory variables are interchanged. Analyses do not require apriori modeling of the covariance structure of the multivariate phenotype vector or any data reduction technique such as principal components. It can simultaneously incorporate qualitative and quantitative traits and can use data on n siblings as (n-1) independent observations. Monte-Carlo simulations are performed to evaluate the power of the proposed method under different genetic models. We find that this method yields more power than using binary end-point traits as well as the Haseman-Elston regression and the reverse regression approaches based on principal components. An application of the method is illustrated using data on alcoholism related phenotypes from the Collaborative Study On the Genetics Of Alcoholism project, each of which has provided evidence of linkage near the *ADH* gene cluster on Chromosome 4 using univariate analyses.

Characterization of the haplotypes, loss of heterozygosity and expression levels of glycine N-methyltransferase gene in prostate cancer. *Y.M.A. Chen[1], Y.C. Huang[1], C.M. Lee[1], Y.P. Shih[1], M.Y. Chung[2,3], Y.H. Chang[4,5], J.S.W. Huang[4,5], M.T.D. Ho[5,6], C.C. Pan[5,6], T.T. Wu[7], J.M. Hsu[8], S. Yang[8], M.W. Lin[1]* 1) Institute of Public Health, National Yang-Ming University, Taipei, Taiwan; 2) Faculty of Life Sciences and Institute of Genome Sciences, National Yang-Ming University, Taipei, Taiwan; 3) Department of Medical Research and Education, Taipei Veterans General Hospital, Taipei, Taiwan; 4) Division of Urology, Taipei Veterans General Hospital, Taipei, Taiwan; 5) Faculty of Medicine, National Yang-Ming University, Taipei, Taiwan; 6) Department of Pathology and Laboratory Medicine, Taipei Veterans General Hospital, Taipei, Taiwan; 7) Division of Urology, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; 8) Department of Urology, Mackay Memorial Hospital, Taipei, Taiwan.

Glycine N-methyltransferase (GNMT) affects genetic stability by regulating the DNA methylation level and interacting with environmental carcinogens. Previously, through genotypic analysis, we demonstrated that GNMT is a tumor susceptibility gene for hepatocellular carcinoma. In this report, we used a case-control study to study the association between different haplotypes of GNMT and the susceptibility to prostate cancer (PCa) in Chinese population. The results showed that more than 92% of the subjects had three major GNMT haplotypes: A, 16GAs/DEL/C (58%); B, 10GAs/INS/C (19.9%) and C, 10GAs/INS/T (14.5%). Compared to persons with haplotype A, people carrying haplotype C had significantly lower risk for PCa (OR, 0.68; 95% CI = 0.48-0.95). Phenotypic analysis using luciferase reporter constructs showed that among three haplotypes, haplotype C had highest level of promoter activity and the differences were statistically significant (ANOVA test, p = 0.001). In addition, 38.1% (8/21) of prostatic tumor tissues had loss of heterozygosity of GNMT gene. Immunohistochemical staining showed that GNMT expressed abundantly in benign prostatic hyperplasia tissues, while its expression was diminished in 86% (37/43) of the prostatic tumor tissues. Therefore, GNMT is a tumor susceptibility gene for prostate cancer.

Four novel MLH1 and MSH2 mutations in Korean patients with HNPCC. *J.R. Choi[1], S. Park[1], N. Kim[2], D. Lee[3]* 1) Laboratory Medicine, Yonsei University College of Medicine, Seoul, Korea; 2) General Surgery, Yonsei University College of Medicine, Seoul, Korea; 3) Seoul Clinical Laboratory, Seoul, Korea.

Hereditary non-polyposis colorectal carcinoma (HNPCC) is one of the most common hereditary cancer-susceptible syndromes which inherits in an autosomal dominant pattern and is predisposed to the early development of colorectal and endometrial cancer as well as a range of other tumor types. Germline mutations in the DNA mismatch repair (MMR) genes, particularly MLH1, MSH2, and MSH6, are associated with the clinical phenotype of HNPCC. In this study, we report the analysis of 4 patients including a family with two affected individuals (a mother and her son). All patients had been previously diagnosed with colorectal cancer. Genomic DNA was extracted from whole blood and tested by PCR, DHPLC, and direct sequencing methods. One patient had a novel nonsense mutation in exon 3 of the MLH1 gene (c.256CT) and another patient had a frameshift mutation in exon 9 of the MSH-2 gene (c.1413delA). The mother had a missense mutation in exon 3 of MSH-2 gene (c.505AG) whereas the son had a slightly different missense mutation in exon 3 of MSH-2 gene (c.380AT), both of which have not been previously reported. In addition, both the mother and son had an identical splice mutation that had already been published in databases in exon 13 of the MSH-2 gene (c.2006-6TC). This is the first report of 4 novel mutations, according to the Human Gene Mutation Database (HGMD) in 4 patients with a history of colorectal cancer.

Informatics for next-generation DNA sequencing using single molecule clusters and sequencing-by-synthesis (SBS). *C. Brown, A. Cox, L. Davies, C. Goddard, N. Spiridou, K. Maisinger, M. Parkinson, D. Bentley* Computational Biology & IT, Solexa Ltd, Saffron Walden, United Kingdom. CB10 1XL.

Solexa has developed a new generation of DNA sequencing technology that promises to transform the economics of sequencing, offering advantages in both cost and throughput of two orders of magnitude or more. Recently Solexa successfully validated its Cluster-SBS technology by resequencing first the Phi-X 174 bacteriophage and then a 162 kb region of the human. Eventually the vast majority of differences between an individuals genome and the human reference sequence will be detectible from a single sample of fragmented human DNA either following re-alignment of the resulting reads or re-assembly. We will describe the high-throughput bioinformatics pipeline we have developed to match the unprecedented rate of sequence generation. The raw output of a Solexa machine is a large number of CCD images, from which sequences and associated quality metrics must first be extracted. These reads are then aligned to a reference genome or assembled, allowing for errors. Custom solutions enable us to run these computationally intensive tasks on modest hardware. A final consensus calling stage detects differences between the reference genome and the target genome being sequenced, providing confidence measures for each mutation found and, for a diploid genome such as the human, distinguishing heterozygotic from homozygotic variation. To determine the read length necessary for single-sample human resequencing, we computed a whole-genome alignment for each 25 base fragment in the human genome. This exhaustive study shows that good quality 25 base reads suffice to detect variation in around 82% of the genome, the remaining 18% being largely comprised of known repeats. Importantly the impact of well-calibrated base scoring schemes, coverage biases, error rates and the resulting yield of primary data underpinning these calculations are defined. Solexa collaborates with the European Bioinformatics Institute on the integration of resequencing data into Ensembl and with Imperial College London on exploiting the new possibilities for genetic analysis presented by this data.

Epidermal expression of the Hutchinson-Gilford progeria syndrome mutation in transgenic mice. *M. Eriksson[1], H. Sagelius[1], Y. Rosengardten[1], M. Hanif[1], M.R. Erdos[2], R. Varga[2], B. Rozell[3], F.S. Collins[2]* 1) Karolinska Institutet, Department of Biosciences and Nutrition, Stockholm, Sweden; 2) Genome Technology Branch, NHGRI/NIH, Bethesda, MD; 3) Karolinska Institutet, Department of Laboratory Medicine, Huddinge, Sweden.

Hutchinson-Gilford progeria syndrome (HGPS) is a rare disorder characterized by features of premature aging. Clinical findings in the skin include scleroderma, alopecia, and loss of subcutaneous fat. HGPS is caused by mutations in *LMNA,* a gene that encodes two major proteins of the inner nuclear lamina, lamin A and lamin C. The predominant cause of progeria is a single nucleotide change in exon 11, 1824C>T, which results in the activation of a cryptic splice site that produces a lamin A protein with an internal deletion of 50 amino acids. We have generated tetracycline inducible transgenic lines containing a minigene incorporating exons 1-11, intron 11, and exon 12 of human *LMNA*, under the control of a tet-operon. The two lines differ only in nucleotide 1824, where one minigene carries the wild-type sequence of *LMNA,* and the other carries the mutation. After breeding with a mouse line carrying the K5tTA, expression of the minigene is directed to keratin 5 expressing tissues, including hair follicles and the epidermis. Histopathological examination of transgenic mice expressing the HGPS mutation reveals progressive changes in the skin compared to wild-type minigene transgenic controls. Early stages are characterized by slight epidermal hyperplasia and concomitant mild hypergranulosis and hyperkeratosis. More severe regions show severe epidermal hyperplasia, with extensive immature hyperparakeratos, as well as enlarged and displaced sebaceous glands. The severe changes are associated with dermal inflammatory infiltrates. End stage disease is characterized by epidermal hypoplasia with resting hair follicles and associated hypoplastic sebaceous glands. Severe abnormalities include a well developed fibrosis, absence of detectable hypodermal adipocytes, and premature death. Taken together, this system provides a good model for studying molecular mechanisms leading to skin abnormalities in HGPS and other related disorders.

MCA/MR patients and array CGH analysis: report of 14 cases. *R. Caselli[1], C. Pescucci[1], F. Mari[1], C. Speciale[1], MA. Mencarelli[1], M. Bruttini[1], O. Zuffardi[2], R. Artuso[1], F. Ariani[1], E. Scala[1], A. Renieri[1]* 1) Medical Genetics, University of Siena; 2) Medical Genetics, University of Pavia.

We report here the analysis of 14 cases by array CGH. Patients were selected for having mental retardation and facial dysmorphisms. One major anomaly was present in about half of cases: eye coloboma and polydactily in 1 case, hypospadia and dolichocolon in 1 case, cleft palate and sandal gap in 1 case, and retinoblastoma in 3 cases. In one case a pericentric inversion of chr.15 was inherited from the healthy mother. In this selected population we identified segmental deletions in 6/14 patients (about 40%). In 4 cases we identified known deletion syndromes. Two out of three patients with retinoblastoma had the 13q deletion syndrome (13q13.3-q21.2 and 13q14.11-31.1). In these cases the specific facial feature and the presence of retinoblastoma strongly indicated this diagnosis on clinical ground. On the contrary, the diagnosis of 22q11.2 and 15q11-q13.1 was quite unexpected. The 22q11.2 deletion was found in a 18 year-old girl with eye coloboma (both iris and retina), upper postaxial polydactyly, CLP, IVD and stereotypic hand movements and an inherited pericentric inversion of chr.15 . In this case, the adult age and the uncommon abnormalities of the patient such as eye coloboma have made more difficult the diagnosis on a clinical ground. The 15q11-q13.1 deletion was found in a 4-year old boy with hypospadia, dolichocolon, gastroaesofageal reflux and epilepsy. A posteriori re-evaluation of the patient identified features compatible with Angelman syndrome.In 2 cases there were two uncommon deletion syndrome of the long arm of chr. 2. A 4 year-old girl with cleft palate, sandal gap and epilepsy has a 10 Mb deletion in 2q32.1-32.3. Comparison with other case of the literature suggested that a specific phenotype of this syndrome may be defined. A 14 year-old boy with criptorchidism, aggressiveness and self-mutilation has a 12 Mb deletion in 2q24.3-31.1. Previous studies have demonstrated the association of this region with autism. Recently, four cases with an overlapping deletion have been described. All the patients showed similar facial dysmorphisms and behavior disorders.

GNPTA Disorders: Mutations in 25 patients with Mucolipidosis II and III. *R. Bargal[1], M. Zeigler[1], A. Abu-Libdeh[2], V. Zuri[1], H. Mandel[3], Z. Ben Neriah[1], F. Stewart[4], N. Elcioglu[5], T. Hindi[6], M. Le Merrer[7], M. Penttinen[8], G. Bach[1], A. Raas-Rothschild[1]* 1) Human Genetics , Hadassah Hebrew University Medical Center, Jerusalem, Israel; 2) Department of Pediatrics, Makassed Hospital, Al-Quds University, Jerusalem, Israel; 3) Metabolic Unit, Meyer Childrens Hospital, Rambam Medical Center,Haifa, Israel; 4) Northern Ireland Regional Genetics Service, Belfast City Hospital, Ireland; 5) Department of Pediatric Genetics, Marmara University Hospital, Istanbul, Turkey; 6) Department of Pediatrics, Augusta Victoria Hospital, East Jerusalem, Israel; 7) Departement de Genetique Humaine, Necker Enfants-Malades, Paris, France; 8) Clinical Genetics Unit, Turku University Central Hospital, Turku, Finland.

Mucolipidosis II (MLII) and Mucolipidosis III (MLIII) are autosomal recessive disorders of lysosomal hydrolases trafficking due to the deficiency of the multimeric enzyme, UDP-N-acetylglucosamine-1-phosphotransferase. The / subunits encoded by the GNPTA gene are catalytic subunits while the GNPTAG encodes the recognition gamma subunit. We report on the GNPTA mutations in 22 ML II and 3 ML III patients. 21/22 ML II patients were homozygous and one was compound heterozygous for the disease-causing mutations. The ML II causing mutations were scattered along the GNPTA gene, in the subunit (3 patients) and in the subunit (19 patients). The various GNPTA mutations found in the ML II patients are predicted to damage profoundly the protein structure. Two ML III patients carried the same splice-site mutation IVS17 + 6T>G in compound heterozygosity with two severe mutations [c.3502_3delCT;R1189X]. A third MLIII patient was compound heterozygous for an -subunit missense mutation [c.1196C>T] and a -subunit deletion (c.3502_3delCT(suggesting that there is no GNPTA intragenic complementation. The results of this study show that the severity of the mutations, rather than their localization in the or subunits correlate with the severity of the phenotype and confirm that ML III is genetically heterogeneous. We suggest that MLII and MLIII diseases due to mutations in GNPTA represent the same entity with a severe to moderate clinical continuum.

Facioauriculovertebral spectrum on 250 Mexican patients. *A. Garcia-Huerta[1], L.M. Rosales-Olivarez[2], M. Diaz-Garcia[1], C.F. Martinez-Cruz[3,4], G. Garcia-Sanchez[1]* 1) Genetica. Instituto Nacional de Rehabilitacion, Mexico,DF; 2) Cirugia de Columna. Instituto Nacional de Rehabilitacion. Mexico, DF; 3) Departamento de Seguimiento Pediatrico. Comunicación Humana. Instituto Nacional de Perinatologia Mexico, D.F; 4) Instituto Mexicano del Seguro Social.Hospital General de Zona 53.México, D.F. E mail:guillegs@yahoo.com.mx.

250 Mexican patients with Facioauriculovertebral spectrum. This study compares the clinical, radiologic, audiometric and genealogic findings on 250 patients with aural Facioauriculovertebral spectrum, seen in the Department of Genetics at the National Institute of Rehabilitation, from January 2004 to December 2005. We made clinical story, pedigree, spine X rays and audiometry, on each patient. The range of age was 1 to 35 years old, with a sex ratio: 2:1, been predominant in males. We found bilateral microtia in 41%, atresia of external auditive meatus in 79.8%, facial asymmetry:17.2%, preauricular tags:13.3%, submucous cleft palate:7%, vertebral anomalies 18.8%, severe hearing loss:70.7%, mainly conductive and 41.8% had adverse prenatal factors, such as bleeding during the early pregnancy. We found 38.7% affected relatives with Facioauriculovertebral spectrum, 57.4% were sporadic cases, 26.6% had autosomal recessive inheritance and 12.1% autosomal dominant inheritance. Molecular studies were made on 11.3%, but they were not conclusive. We discuss the clinical differences with previous reports. We also confirm the variability in expression and the need of a detailed clinical examination to all first degree patients relatives in order to find a mild expression of Facioauriculovertebral spectrum, and give them an accurate genetic counseling.

An *EVC2* mutation is associated with Weyers acrofacial dysostosis and severe EvC syndrome in the same pedigree. *M. Galdzicka[1], E.W. Jabs[2], E.I. Ginns[1]* 1) Pediatric Neurology, Univ. of Massachusetts Medical School, Shrewsbury, MA; 2) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD.

A novel premature stop mutation has been identified in exon 22 of *EVC2* in a four-generation family. The proband has Ellis-van Creveld syndrome (EvC; MIM225500) while other affected individuals have features of Weyers acrofacial dysostosis (MIM193530) (Howard TD et al. 1997). Weyers acrofacial dysostosis is an autosomal dominant condition with dental anomalies, nail dystrophy, postaxial polydactyly, and mild short stature. The autosomal recessive EvC syndrome is similar to Weyers but has additional features of disproportionate dwarfism, thoracic dysplasia, and congenital heart disease. Although the proband's phenotype fits EvC syndrome, the phenotype in other affected family members resembles Weyers acrofacial dysostosis. *EVC* and *EVC2* gene mutations have previously been identified in both disorders (Xiaoqian Y et al. 2006; Galdzicka M et al. 2002), but this is the first instance where a mutation is associated with both phenotypes. Other than predicted transmembrane domains, no homologies/motifs give clues about either protein's function. The genes are divergently transcribed with transcription start sites separated by only 1.6kb, and have multiple start sites and numerous splice variants. These genomic features may reflect a transcriptional regulatory scheme that coordinates expression of these two genes in a way that is critical to normal skeletal and cardiac development. All exons and intron-exon boundaries were amplified from genomic DNA and sequenced. The heterozygous *EVC2* mutation, SER1245STOP (S1245X; 3734C>A; NCBI reference sequence AY185210) was present in 7 affected but not in 12 unaffected family members, and was absent in 100 normal individuals. Even though we anticipated finding a compound heterozygous mutation in the proband, only the S1245X has been identified. Our findings support the hypothesis that mutations in either *EVC* or *EVC2* cause a wide variety of manifestations, ranging from mild Weyers acrofacial dysostosis to the more severe EvC syndrome, and that individuals carrying either *EVC* or *EVC2* mutations can have clinically indistinguishable presentations.

Complex chromosome rearrangement maps ectrodactyly-deafness (OMIM 220600) to chromosome 7q21.13. *B. Dallapiccola[1], L. Bernardini[1], C. Palka[2], C. Ceccarini[1], A. Capalbo[1], R. Mingarelli[1], A. Novelli[1]* 1) CSS-Mendel Institute, Rome, Italy; 2) "La Sapienza" University, Rome, Italy.

Two-chromosomes translocations occur in about 0.1-0.2% individuals, while complex rearrangements with >2 breakpoints are extremely rare. While most of these individuals are healthy and phenotypically normal, clinical abnormalities are found in about 6% of them. We report on a 5-year-old girl, evaluated because of psychomotor delay, deafness, ectrodactyly of right hand and feet, craniofacial dysmorphisms, cleft palate and tetralogy of Fallot (TF). She had also macrocephaly, sparse hairs and eywbrows, wide nasal bridge with piriform nose, long philtrum and micrognathia. Ears were prominent, low-set and abnormally shaped, with crumpled helices. The right 5th finger was short, with hypoplastic palmar and distal interphalangeal flexion creases. Severe bilateral sensorineural deafness was corrected by prosthesis. Standard karyotype suggested a small intrachromosomal duplication of long arm of chromosome 7, but an array-CGH analysis with an average 1 Mb resolution excluded any genomic imbalance. The chromosomal rearrangement was characterized by m-BAND analysis, which disclosed a reciprocal interstitial translocation t(7q21;8q24). FISH analysis using specific clones, and an high resolution array-CGH analysis (44K Agilent chip, Agilent Technologies Inc., Palo Alto, CA) disclosed a paracentric inversion of 7q and a microdeletion of 7q21.13. Parents had normal chromosomes. A few patients with ectrodactyly and other defects, including deafness, have been found presenting with structural rearrangements affecting 7q21-q22. The imbalance found in the present patient narrows the candidate region of ectrodactyly-deafness (OMIM 220600)to sub-band 7q21.13. Interestingly, this girl had some facial features reminescent of tricho-rhino-phalangeal syndrome (TRPS) and one chromosome breakpoint involved band 8q24, where the TRPS locus has been mapped. In addition, FOG1 gene, which had been implicated in a subset of subjects with TF, maps to chromosome 8q23. Thus, cryptic chromosome deletion and, likely, position effects account for the complex phenotype observed in this unique patient.

Retrospective study of Clinical and histological manifestations of IP in Adults. *C. Bodemer[1], A. Rimellla[1], S. Fraitag[2], Y. de Prost[1], J.P. Bonnefont[3], A. Smahi[3], S. Hadj-Rabia[1]* 1) Dermatology,Hôpital Necker-Enfants Malades,Paris,France; 2) Pathology, Hôpital Necker-Enfants Malades,Paris,France; 3) Genetics, Hôpital Necker-Enfants Malades,Paris,France.

Introduction Incontinentia pigmenti (IP) is a rare X dominant genodermatosis related to mutations of NEMO gene. Itt affects mostly female patients and is usually lethal for males in utero. It is a multisystem disorder, primarily of ectodermal origin, accompanied by dental, ocular, and central nervous system disorders. The skin lesions may occur in 4 classically successive diagnostic stages: erythema and vesicles, (stage 1); verrucous lesions (stage 2); linear hyperpigmentation (stage 3); and pallor and scarring (stage 4).In adults, manifestations are skin involvement (stage 4) and teeth and nail anomalies. Patients and Methods Among the 325 patients with molecular diagnosis of IP, the adult females (age over 18 years) were contacted for clinical examination. Skin, ocular, neurological and stomatological manifestations were recorded using a standard form. Skin biopsy was performed. Results 25 patients fulfilled the criteria : the diagnosis was made in adulthood in 52%of the patients. Stage 4 was constant (100%) stage 3 and 2 were found in 11 and 1 patients respectively. Other manifestations were: woolly hair (44%), nails (84%), teeth (92%), ocular (48%), mammary (28%) and neurological (12%) anomalies. Histology shows apoptotic kératinocytes, absence of follicles and sweat glands (stages 3 and 4), hypopigmentation and atrophic epidermis (stage 4). Discussion Diagnosis of IP was delayed in 52% of the patient and based on the constant presence of stage 4 cutaneous lesions. Extracutaneous manifestations, such as teeth anomalies and mammary malformation, are frequent. During the first and second stages of IP, keratinocyte apoptosis is classical on skin biopsy. Interestingly, we demonstrate that keratinocyte apoptosis persists in adults and is associated with absence of both sweat glands and follicles. Histology may be helpful for the diagnosis of IP in adults and should be include in the IP criteria defined by Landy and Donnai. Late apoptosis may explain rare manifestations of IP in adults.

Molecular cytogenetic analysis of 149 breakpoints in 76 cases with apparently balanced chromosome rearrangements. *D.R. FitzPatrick[1], J.A. Fantes[1], E. Borland[2], J. Ramsay[1], D. Donnai[2], J. Clayton-Smith[2], V. van Heyningen[1], G. Black[2]* 1) Medical Genetics Section, MRC Human Genetics Unit, Edinburgh, United Kingdom; 2) Dept of Medical Genetics and Regional Genetic Service, St. Marys Hospital, Hathersage Road, Manchester M13 0JH.

De novo apparently balanced chromosome rearrangements (DN-ABCRs) are detected in 1 in 2000 amniocenteses with a 3-10% risk of serious malformations and learning disability. Currently predicting the phenotype associated with a DN-ABCR is not possible. We ascertained 76 cases (46 cases with clinically significant phenotypes, and 30 cases without) through two UK regional Genetics Centres. A total of 149 breakpoints (BP) were mapped by a FISH strategy scanning 10-20 Mb around each cytogenetic BP using the Sanger 1 Mb clone set to identify flanking clones. A contig of tiling path clones were then used to identify a breakpoint-spanning BAC clone. 23% of all BP were fine-mapped with fosmid clones or long-range PCR products. Analyses of the results from the two groups of patients and have delineated a number of differences:

1. Microdeletions were only identified in cases with a clinical phenotype. Three of the six deletions detected were some distance (6-30 Mb) from the translocation BP.

2. The BP disrupted genes in a similar percentage of cases both with and without a phenotype, however in cases with a phenotype the disrupted genes were more commonly transcription factors or DNA binding proteins.

3. In cases without a phenotype, there are fewer than expected breakpoints mapping to R-bands.

4. BP regions in abnormal cases tend to be more evolutionarily conserved

This is the largest systematic study of DN-ABCRs which includes a control group of clinically normal cases. The four molecular features with discriminant power may be useful in prenatal counselling particularly if our rapid and effective strategy for DN_ABCR mapping can be implemented in clinical cytogenetic labs.

Clinical genetics service for the psychiatric population. *E.W.C. Chow*[1,2], *A.L. Rideout*[1], *A.S. Bassett*[1,2] 1) Centre for Addiction and Mental Health, Toronto, ON, Canada; 2) Department of Psychiatry, University of Toronto, Toronto, ON, Canada.

Psychiatric genetics is an emerging field in clinical genetics that is attracting more and more interest among psychiatric clinicians. Genetic testing for syndromes or conditions associated with psychiatric and behavioral manifestations are increasingly available. The Clinical Genetics Service (CGS) was set up in July 2005 at a psychiatric hospital to address issues in clinical psychiatric genetics including genetic testing, behavioral phenotypes, and genetic counseling. So far, we have provided services to 25 probands (11 M, 14 F; mean age 25.6 years, SD 13.1 years) and/or their families. Primary psychiatric diagnoses for these individuals included schizophrenia (n=6), autistic spectrum disorders (n=6), mental retardation (n=4), anxiety disorders (n=3), depression (n=2) and other diagnoses (n=4). We have assessed 17 individuals for genetic testing; 10 of these individuals were seen for testing for 22q11.2 deletion syndrome (22q11DS), six for fragile X syndrome, and nine for other potential genetic syndromes. In addition, we provided genetic counseling to four families, three of which were for various psychiatric disorders and the fourth due to a history of a familial cardiac condition. Four individuals were referred for a consultation on behavioral phenotype for previously diagnosed genetic syndromes such as 22q11DS, oculo-auriculo-vertebral spectrum and Borjeson-Forssman-Lehmann syndrome. Establishing a psychiatric genetics clinic at a psychiatric hospital has proven a feasible means of providing genetic services to the psychiatric population.

Genotype Fidelity within DNA Extracted from Archival Tissue. *J. Breyer[1], P. Schuyler[2], B. Elmore[1], B. Yaspan[1], K. Bradley[1], D. Page[3], W. Dupont[2], J. Smith[1]* 1) Deptartments of Medicine and Cancer Biology, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Biostatistics, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Pathology, Vanderbilt University Medical Center, Nashville, TN.

Formalin-fixed paraffin embedded human tissue is a rich potential resource for genetic investigation of cancer. However, the limiting quantity and poor quality of DNA extracted from archival tissues presents a challenging obstacle. We have conducted investigations of SNP genotyping accuracy and whole genome amplification fidelity within DNA extracted from archival tissue of the Nashville Breast Cohort. Each of the 7,772 women in this cohort underwent biopsy for benign breast disease and have been followed for over 17 years for the subsequent development of breast cancer. Among them 552 women have progressed to breast cancer. We conducted a matched study of 47 women from the cohort. DNA from archival tissue was compared with DNA of the same subjects obtained from recently collected saliva. We demonstrate that direct genotyping of extracted DNA from the benign entry biopsy is extraordinarily accurate using the high-throughput Illumina GoldenGate assay, even with very limiting amounts of DNA. The genotype concordance rate was 99.7% between DNA from paraffin embedded tissue samples and from recent saliva samples of the same individuals. Of 99,546 genotypes sought from these samples, 99,292 (99.7%) were obtained. We further observe that protocols for whole genome amplification can fail to replicate the source genome for accurate genotyping and highlight the need for improved methods.

A genome-wide scan suggests a region on chromosome 16p is a determinant of serum ferritin after adjusting for *HFE*: The HEIRS Family Study. *R. Acton[1], B. Snively[2], J. Barton[1], C. McLaren[3], P. Adams[4], S. Rich[2], J. Eckfeldt[5], R. Press[6], P. Sholinsky[7], C. Leiendecker-Foster[5], G. McLaren[3,8], M. Speechley[4], E. Harris[9], F. Dawkins[10], V. Gordeuk[10]*
1) University of AL, Bham, AL; 2) Wake Forest University, Winston-Salem; 3) University of CA, Irvine, CA; 4) London Health Sciences Ctr, Ontario; 5) University of MN, Minneapolis, MN; 6) Oregon Health & Science University, Portland, OR; 7) National Heart, Lung and Blood Institute, Bethesda, MD; 8) VA Long Beach Healthcare System, CA; 9) Kaiser Permanente Ctr for Health Research, Portland, OR; 10) Howard University, Washington, DC.

1/200-1/400 whites of northwestern and central European descent have hemochromatosis (H), of whom 60%-100% are *HFE* C282Y homozygotes whose iron overload (IO) phenotype is variable. We recruited family members of H and IO probands for a genome-wide linkage scan of potential quantitative trait loci (QTL) that contribute to variation in transferrin saturation (TfSat), unsaturated iron-binding capacity (UIBC), and serum ferritin (SF). Participants with elevated TfSat and SF, and all C282Y homozygotes who attended a clinical exam, became probands if a qualifying group of first-degree relatives 19 years old were also available. Linkage scan genotyping utilized 402 microsatellite markers with average spacing of 9 cM; the largest gap between adjacent markers was 18 cM. 943 individuals, 76% of whom were white, were evaluated from 174 families. After adjusting for age, gender, and race/ethnicity, the strongest evidence for linkage with UIBC (LOD = 9.52), TfSat (LOD = 4.78), and SF (LOD = 2.75) was in the Ch6p region containing *HFE* (each P <0.0001). After adjusting for *HFE* genotype, recruitment site, body mass index, menopausal status, history of phlebotomy treatment, hepatitis B or C positivity, alcohol intake, and C-reactive protein, evidence of linkage was also observed for SF in a region of Ch16p (LOD = 2.63, P = 0.0007) that includes the heme oxygenase 2 gene. Thus, we found evidence of QTL(s) on Ch16p that contributes to SF variation, and the expected QTL(s) on Ch6p that contributes to UIBC, TfSat, and SF variation.

Experience of Discrimination Among Persons who Have Undergone Predictive Testing for Huntingtons Disease.

C. Erwin[1], E. Penziner[2], J. Williams[2], A. Wallis[2], Y. Bombard[3], M. Hayden[3], J. Paulsen[2] 1) Family Medicine, University of Texas Houston , Houston, TX; 2) Psychiatry, University of Iowa Carver College of Medicine, Iowa City, IA; 3) Center for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, BC.

Little is known about the actual long-term consequences of genetic testing for genetic conditions that may lead to discrimination. The consequences of genetic discrimination generate social, health, and economic burdens for those at genetic risk and for society as a whole. The objective of this study was to better understand experiences of genetic stigmatization and discrimination among persons who have undergone predictive testing for Huntingtons disease (HD). Using a semi-structured interview and computerized qualitative analysis, 15 presymptomatic persons with a positive gene expansion for HD were interviewed with regard to treatment following predictive testing. The sample was comprised of 11 women and 4 men, mostly married, ranging in age from 22 to 62 years. Participants lived in eight U.S. States and resided in urban, rural and suburban settings. Participants reported consequences following disclosure of genetic test results in three main areas: employment, insurance and social relationships. Although the majority of employed participants had revealed their test results to their current employers, nearly all of them reported that they would not disclose this information to future employers. Most of the sample disclosed their test results to their physician, but a similar majority did not disclose their genetic status to insurers. Most participants had openly disclosed the test results to family and peers although patterns of disclosure varied widely. Study findings provide a better understanding of factors influencing individuals acceptance of genetic tests and suggest the need for further examination of this important population. Data collected in this study will guide development of a survey to examine the long-term effects of genetic testing in a larger study cohort. Ultimately, these findings will improve understanding of communication preferences, patient-provider processes, and health outcomes.

Mosaic aneuploidies in the developing and adult brain. *J. Chun* Department of Molecular Biology Helen L. Dorris Child and Adolescent Neuropsychiatric Disorder Institute The Scripps Research Institute 10550 North Torrey Pines Rd ICND-118 La Jolla, CA 92037.

The brain is remarkable for its enormous cellular diversity and complex organization that may be unique for each individual. This uniqueness might in part explain behavioral differences between people, or contribute to the sporadic presentation of most major neurological and psychiatric diseases. A possible contributing mechanism to produce brain uniqueness is the existence of mosaic aneuploidies that have been shown in recent years to be pervasive throughout the developing and adult brain. Although the functions of mosaic aneuploidies in normal brain remain unknown, constitutive aneuploidies, like Trisomy 21 (Down syndrome), have proven associations with cognitive function, providing proof-of-concept for functional consequences of neural aneuploidies in humans. Using human and/or mouse models, aneuploidies have been documented throughout the neuraxis. During neurogenesis, over 1/3 of mitotic, neural progenitor cells are aneuploid, and assessment by spectral karyotyping (SKY) identifies a wide range of different aneuploidies that include chromosome gain, loss and combinations of the two. The number of aneuploid cells can be altered by growth conditions in culture as well as by genetic deletion of DNA repair/surveillance genes like Atm and Xrcc5. The generation of neural aneuploidies can, at least in part, be attributed to well-known chromosome missegregation mechanisms. In postmitotic neurons that do not have discernible chromosomes, the actual karyotype of individual neurons is not known in detail. However, use of FISH with chromosome-specific point probes indicates that even for a single locus, approximately one to several percent of cells are aneuploid, representing a substantial population when accounting for all chromosomes. Aneuploid neurons have been shown to be integrated into functional neural circuits, raising the possibility that these mosaic aneuploid cells can produce distinct neural outputs. Recent data on some of the functional consequences of aneuploidy will be presented. This work was supported in part by the National Institute of Mental Health.

A systematic genome wide association study of 19,779 coding SNPs with putative function identifies a novel susceptibility gene for Crohn disease. *A. Franke[1], J. Hampe[2], P. Rosenstiel[1], A. Till[1], K. Huse[3], M. Albrecht[4], G. Mayr[4], F.M. De La Vega[5], J. Briggs[5], M. Wenz[5], S. Guenther[5], D.A. Gilbert[5], N. Prescott[6], T. Lengauer[4], C. Matthew[6], M. Krawczak[7], S. Schreiber[1]* 1) Institute for Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany; 2) Department of General Internal Medicine, Kiel, Germany; 3) Leibniz Institute for Age Research - Fritz Lipmann Institute, Jena, Germany; 4) Max Planck Institute for Informatics, Saarbruecken, Germany; 5) Applied Biosystems, Foster City, CA, USA; 6) King's College London School of Medicine, London, UK; 7) Institute of Medical Statistics and Informatics, Kiel, Germany.

Use of a comprehensive panel of coding SNPs may enable fast identification of susceptibility variants for complex phenotypes. A subset of 19,779 putatively functional SNPs was selected from over 60,000 candidate nsSNPs compiled from public and private sources. Genotyping in 735 patients with Crohn disease and 368 controls by SNPlex identified 7,832 SNPs as being informative in this population, and these were genotyped in an independent German sample of 386 trios, 946 cases and 1091 controls. Hierarchic analysis identified one significantly disease-associated non-synonymous SNP (p=8.4x10-6 single point allelic case-control, OR=1.70 [95% CI: 1.33-2.16], p=2.9x10-5 TDT). The association was replicated in a British (661 controls, 515 cases) and another independent German (736 controls, 736 cases) sample. Full mutation detection failed to detect any other cSNP that explained the association. The novel susceptibility variant interacts with known variants in CARD15 (Breslow Day test, p=0.046 evaluating homozygous and compound heterozygous carriers of CARD15 risk alleles). The predicted function suggests that the variant leads to an impairment of the killing of intracellular bacteria. Direct association analyses with a comprehensive set of nsSNPs can lead to the direct identification of susceptibility variants for complex phenotypes. Genome-wide nsSNP panels are therefore a valuable addition to other LD-based mapping approaches. The identified novel disease gene adds to the understanding of Crohn disease as an innate immune disorder.

Unraveling the genetic aetiology of stroke in Pakistan. *P.M. Frossard, D. Saleheen* Dept Biological & Biomed Sci, Aga Khan University, Karachi, Pakistan.

Stroke, the most common cause of disability and the third cause of death worldwide, represents an enormous public health problem which is rapidly spreading in developing countries. In search of quantitative trait loci underlying the etiology of ischaemic stroke (IS) in Pakistan, we designed an association study at candidate gene loci chosen from various atherosclerotic pathways. Our study population included 210 IS cases and 350 disease-free, age- and gender-matched, controls, recruited at Liaqat National and AKU Hospitals, Karachi, Pakistan. Genotyping of genetic markers (dimorphisms) was done by PCR-RFLP. Associations of the studied dimorphisms with IS were tested by both single-point and haplotype analyses. Three loci are directly associated with clinical IS diagnosis. Phosphodiesterase 4D (PDE4D): we investigated three PDE4D genetic markers (SNP32, 83 and 87, see Gretarsdottir et al., Nat Genet. 2003;35:131-138), and evidenced that TT genotypes of SNP83C>T confer a significant risk for IS on both univariate and multivariate analyses ($P<0.005$). Paraoxonase genes (PON1, 2 and 3): amongst the eight markers included here, PON1 192Q>R, PON2 148G>A and PON2 311C>S are associated with IS, and QAS haplotypes indicate a 1.87-fold increased risk of developing IS ($P=0.01$). ATP-binding cassette transporter A1 gene (ABCA1): we included five intragenic markers, and first established that the RL haplotype (combination of R219K and V825L marker mutations) is strongly associated with decreased HDL-c levels (OR=8.33, $P=0.001$). We then found that allele 774P of mutation T774P showed the strongest direct association with IS (OR=4.06, $P<10\text{-}7$). We further demonstrated that a three-point VPL haplotype (combination of V771M, T774P and V825L markers) is indicative of a very strong increased risk for IS (OR=10.34, $P<10\text{-}7$). Upon applying an overall, single multivariate model, we established that two major gene effects (ABCA1 and PON) and one minor gene effect (PDE4D) account for 65.3% of IS in the studied Pakistani population.

Population-specific abnormal high density of HapMap QC- SNPs in ENCODE regions: from the 1% towards a high-resolution genome-wide analysis of copy number variants (CNVs) of the human genome. *L. Armengol[1], S. Villatoro[1], M. Garcia-Aragones[1], J.R. Gonzalez[1,2], X. Estivill[1,2,3], ENCODE variation analysis group* 1) Genes and Disease Program, Center for Genomic Regulation (CRG), Barcelona, Catalonia, Spain; 2) CeGen Barcelona Node, Barcelona, Catalonia, Spain; 3) Pompeu Fabra University, Barcelona, Catalonia, Spain.

A bulky number of copy number variants (CNVs), ranging from several bases up to many kb, appear to be polymorphic either in copy number or in orientation in different populations. The existence of such structural variants is a putative source of SNP genotyping problems and inconsistencies. When analysing SNPs in such regions, violations of Hardy-Weinberg equilibrium, inconsistencies in Mendelian inheritance, reduced efficiency in genotype calling, discrepancies among different genotyping platforms, and many other problems might arise. The systematic analysis of such SNPs (designated as QC- since they do not fulfil the Quality Control standards) can help in the identification of genomic regions that are polymorphic and that have not yet been uncovered. We have focused on the ENCODE (ENCyclopedia Of Dna Elements) regions to analyse the content of QC- SNPs generated in the HapMap project. We computed the density of QC- along the ENCODE regions using a 25-kb sliding window and identified 42 several population-specific regions having an abnormally high density of QC-. Analysis of these regions using array-based CGH and MLPA provided experimental validation of computational observations. Fifteen of such regions contain transcribed sequences. Fifteen of 30 regions contain CNVs, of which 12 are novel. Four of the newly detected CNVs are polymorphic in the four populations. Population-specific CNV composition differences were detected for the highly polymorphic variants. While this study was initially focussed on 1% of the human genome sequence, the whole genome scan for QC- SNP features in different populations should provide a complete picture of CNVs that cannot be detected by current array screening methods. Supported by Genome Spain and Genome Canada and the Catalan Government. We are in debt with all members of the Hap Map and ENCODE projects.

BBS10 mutations in severe antenatal cases with severe cystic kidneys "Meckel-like" type. *S. Audollent[1], L. Baala[1], R. Khaddour[1], J. Martinovic[1], A. Buenerd[2], G. Leichmeijer[3], M. Le Merrer[1], A. Munnich[1], F. Encha-Razavi[1], M.C. Gubler[4], M. Vekemans[1], T. Attié-Bitach[1]* 1) Genetics, Inserm U-781, Paris, Paris, France; 2) Hopital Edward Herriot, Lyon, France; 3) Klinische Genetica en antropogenetica De Boelelaan, Amsterdam; 4) INSERM U-574 Hopital Necker, Paris France.

Bardet-Biedl syndrome (BBS, OMIM 209900) is a multisystemic disorder characterized by progressive retinal dystrophy, postaxial polydactyly, obesity, hypogonadism, learning difficulty and renal dysfunction. Other manifestations include diabetes mellitus, neurological signs, heart disease, and hepatic fibrosis. The condition is largely genetically heterogeneous and 11 genes have been identified (*BBS1-BBS11*) thus far, mutations of *BBS10* on chromosome 12q21.2 accounting for 30 % of cases. In addition, a complex epistatic inheritance has been established in this disorder, i.e. in some families, 3 mutations at 2 BBS loci are necessary for expression of the disease. We recently showed that fetuses with severe cystic kidneys were indeed prenatal forms of BBS. In the present study, we sequenced the *BBS10* gene in 16 antenatal cases referred as Meckel-like. In 4 cases, we identified a recessive mutation at the *BBS10* locus. Three fetuses had MKS kidney phenotype, whereas liver and brain were normal. As previously reported in foetal BBS cases, although the kidney histopathological findings were similar to MKS, no bile duct proliferation of liver was observed. Interestingly, one case had *situs inversus* and polysplenia suggesting a ciliary dysfunction. In another case, BBS genes screening identified a heterozygous *BBS6* nonsens mutation in accordance with the multigenic inheritance of BBS. These results confirmed that the diagnosis of BBS is underdiagnosed antenatally, and should be systematically suspected in fetuses with severe cystic kidneys leading to oligoamnios and foetal or perinatal death. This study also confirms the high frequency of *BBS10* mutations in BBS.

Analysis of SMS1 mRNA expression in focal cerebral ischemia in rats after treatment with neuropeptide Semax and its C-terminal Pro-Gly-Pro tripeptide. *V.G. Dmitrieva[1], E.V. Torshina[1], O.V. Povarova[2], L.V. Dergunova[1], S.A. Limborska[1], V.I. Skvortsova[2]* 1) Institute of Molecular Genetics RAS, Moscow, Russian Federation; 2) Institute of Stroke RSMU, Moscow, Russian Federation.

It is now well known that ceramide and diacylglycerol (DAG) are signal molecules of apoptotic and antiapoptotic pathways of cell regulation. Being element of sphingomyelin cycle sphingomyelin synthase 1 (SMS1) controls the synthesis of ceramide and diacylglycerol which relative concentrations are responsible for balance between cell death and surviving. It is established that apoptosis is involved in mechanisms of cerebral ischemia. Consisting of a fragment of ACTH4-7 and C-terminal PGP tripeptide neuroprotective polypeptide Semax is used for acute therapy of stroke. To investigate the expression of SMS1 the brains of male Wistar rats were analyzed at three time points following permanent middle cerebral artery occlusion (pMCAO) and treatment either with saline, Semax or PGP: 3, 24, and 72 hours. The intraperitoneal injection of solutions were done at 15 min, 1 h, 4 h and then after every 4 h. Semiquantitative RT-PCR has been used to measure changes in SMS1 expression in the ipsilateral and contralateral frontoparietal cortex and subcortex of rat brains. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as the internal control. In the lesioned cortex, SMS1 mRNA decreased during first 24 h post-MCAO, while at 72 h SMS1 expression returned to control level. During first 24 h the expression of SMS1 in ipsilateral subcortex of sham-operated and ischemic rats was also decreased. The level of SMS1 mRNA in ipsilateral subcortex of ischemic rats continue to be decreased at 72 h post-MCAO. During first 24 h Semax did not change the SMS1 expression neither in frontoparietal cortex nor in subcortex of ipsilateral hemisphere. In contrast to Semax its C-terminal PGP tripeptide during first 24 h increased the level of SMS1 mRNA up to control value. However in the lesioned cortex at 72 h post-MCAO the expression of SMS1 was decreased after treatment either with Semax or PGP. In addition during all three days of treatment Semax decreased SMS1 mRNA expression in subcortex of control rats.

Factor D Deficient Mice as Model of Mesangial Immune Complex Glomerulonephritis. *M.A. Abrera-Abeleda[1,2], Y. Xu[3], M.C. Pickering[4], R.J.H Smith[1,2], S. Sethi[5]* 1) Dept of Otolaryngology and; 2) Interdisciplinary PhD Program in Genetics, University of Iowa, Iowa City, IA; 3) Division of Clinical Immunology & Rheumatology, University of Alabama, Birmingham, AL; 4) Molecular Genetics & Rheumatology Section, Imperial College School of Medicine, London, UK; 5) Dept of Laboratory Medicine and Pathology, The Mayo Clinic, Rochester, MN.

Complement Factor D (CFD) is a serine protease that catalyzes the formation of the C3 convertase of the alternative complement pathway. Mice with a targeted deletion of Cfd (Cfd-/-) have complete inhibition of complement activation through the alternative pathway (Xu 2001 PNAS). Because the complement system plays an important role in the pathogenesis of some renal diseases, we studied the renal pathology in the Cfd-/- mutant mouse and compared findings to renal lesions in the Factor H deficient (Cfh-/-) mouse, which is an established model for membranoproliferative glomerulonephritis (MPGN).

Cfd-/- (n=5), Cfh-/- (n=6) and wildtype (WT) mice (n=5) derived on C57BL/6 background were euthanized at 8 months of age. Prior to euthanasia, renal function was assessed by measuring serum and urine creatinine and albumin, and calculating creatinine clearance. Renal histology was evaluated on formalin-fixed specimens under light microscopy; snap frozen tissue was used for immunofluorescence analysis of C3 and IgM. Ultrastructural comparisons were done by electron microscopy.

In both the Cfd-/- and Cfh-/- mutants, creatinine clearance is decreased and urine albumin is elevated as compared to control animals ($p<0.05$), although the change in renal function is greater in the Cfh-/- mice. Cfd-/- mice had mild-to-moderate mesangial expansion with C3 and IgM deposition in the mesangial region. Cfh-/- mice had mesangial proliferation and thickening of capillary walls with deposition of C3 and IgM, which is characteristic for MPGNII (Dense Deposit Disease). Renal lesions in Cfd-/- are restricted to the mesangium, which suggests that Cfd-/- mutant mice may serve as a model of mesangial immune complex glomerulonephritis.

Family history and electronic medical records in primary care. *W. Feero, E. Piekarz, D. Meyer* Dept Community/Family Med, Maine-Dartmouth Family Pract, Fairfield, ME.

Family history is recognized as an important bridge to the integration of emerging genetic technologies into primary care. Electronic medical records (EMR) are fast becoming the standard of record keeping in primary care, however, little is known about how the use of EMR systems impacts the ascertainment of family history. To examine this, charts of faculty in a rural primary care residency program were reviewed for the quantity of family history data obtained at initial patient visits pre and post EMR implementation. 28 charts total were reviewed using an objective scoring system (0- least information, 4- most information). None of the charts (pre or post EMR) contained a three generation graphical pedigree. Family history was most commonly recorded on a paper- based initial visit questionnaire. Composite family history scores were 2.9 for visits pre- EMR and 2.6 post- EMR implementation. However, if information captured on paper only is excluded for the post-EMR visits, the composite score drops to 1.4. Further studies should be directed at determining if this result can be generalized to other EMR platforms, and if so, how the decrement in the amount of family history obtained in the electronic environment may be avoided.

Examination of Sex and Age of Onset as Important Sources of Variation for Genetic Association Findings in Schizophrenia. *M.D. Fallin[1,6], P. Belmonte[5], V.K. Lasseter[2], N. Cheng[2], D. Avramopoulos[2,3], J. Mulle[2,3], P.S. Wolyniec[2], J.A. McGrath[2], G. Nestadt[2], KY. Liang[6], D. Valle[3,4], A.E. Pulver[2]* 1) Dept Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 2) Department of Psychiatry & Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 4) Howard Hughes Medical Institute; 5) Dept of Mental Health, Johns Hopkins School of Public Health, Baltimore, MD; 6) Dept of Biostatistics, Johns Hopkins School of Public Health, Baltimore, MD.

Schizophrenia (SZ) is a common heritable psychiatric disorder, yet few susceptibility genes have been confirmed. We recently performed SNP genotyping on 64 candidate genes (440 SNPs)in 274 SZ/schizoaffective Ashkenazi case-parent trios. We genotyped 6.9 SNPs/gene (1 SNP/11.9 kb), and reported results for SNPs and haplotypes across all 64 genes (Fallin et al 2005). These initial results did not accommodate sources of heterogeneity such as sex of the case and age of onset, yet both may be very important in the genetics of SZ. We have therefore performed interaction analyses in these trios to assess the impact of sex and age of onset on the association findings for these 64 genes, using covariate terms in conditional logistic regression for each SNP. We show 5 genes that gave suggestive evidence for association with SZ in our original analysis whose SNP signal is further refined by consideration of age of onset (PRODH, GRID1, NRG3, ADRA1A, NOS1) and 7 genes where a signal emerges that was not detected in the original marginal results. We also show 1 gene with suggestive evidence in our prior analyses that is refined by the inclusion of case sex (NOS1), and 4 additional genes with evidence of interaction by sex that were not suggestive in marginal analyses (DISC1, CABIN1, DRD4, RTN4R). Our results are consistent with previous findings of increased risk for DISC1 among women (Hennah et al 2003). These SNP findings were confirmed in haplotype analyses stratified by either age of onset or sex.

Evidence of a new QTL for BMI on chromosome 1 in the isolated population of Campora. *M. Ciullo[1], C. Bourgain[2], V. Colonna[1], C. Bellenguez[2], T. Nutile[1], M. Astore[1], A. Calabria[1], M.G. Persico[1]* 1) IGB A. Buzzati-Traverso - CNR Naples, Italy; 2) INSERM U535, Villejuif, France.

Campora is a geographically isolated village of Cilento, South Italy, with a few founders and inbreeding. Recently, Campora population allowed us to identify a new locus strongly linked to hypertension, encouraging the study of this population for the identification of loci involved in other complex traits. A collection of several quantitative traits related to the cardiovascular system have been measured in this population. The present study is the first linkage analysis of a quantitative trait in this population. Body-mass index (BMI), an obesity-related trait and a risk factor for cardiovascular diseases, was calculated for 394 adult individuals in the population. These individuals, all related through a 2947-member pedigree spanning 15 generations, were genotyped for 1122 microsatellites on the genome (average marker distance: 3.6 cM, heterozygosity 0.70). To perform the linkage analysis, we broke the very complex pedigree into 92 families including 366 phenotyped individuals, with an optimized use of the maximum partitioning approach to pedigree breaking proposed by Falchi and collaborators (2004). With the regression-based linkage statistic proposed by Sham and collaborators (2002), we detect a strong linkage on chromosome 1 (position 176.38, LOD= 4.47, pvalue=0.01), robust to the various trait transformations considered. We also replicated linkage for two known QTLs on chromosome 2 (Deng et al. 2002) and on chromosome 6 (Atwood et al. 2002). The linkage is also detected with a variance component analysis. Again, the result is robust to trait transformation. This study suggests that linkage study of sub-pedigrees carefully chosen in the Campora population is a powerful strategy to detect new QTL. Atwood et al (2002) Am.J.Hum.Genet 71:1044 Deng et al (2002) Am.J.Hum.Genet 70:1151 Falchi et al (2004) Am J Hum Genet 75:1015 Sham et al (2002) Am J Hum Genet 71:238.

Estimating Kinship Coefficients from High-Density SNP Genotypes for QTL Mapping and Association. *A. Day, E. Sobel, K. Lange* Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

The power to detect disease genes can be dramatically increased by including knowledge of the true genetic relationships between individuals in the study sample. Unfortunately for some pedigree-based datasets, or even in case-control studies, there are relationships among the individuals that are unknown to the analyst. This can arise for example from purposefully hidden relationships, loss of historical information, or simply the proper question never being asked.

We have developed a simple, closed-form, likelihood-based algorithm to recover the useful data from these cryptic relationships. The algorithm is based on using the number of identity-by-state matches observed in an extended segment of SNPs as an estimate for the expected number, which is a function of the kinship coefficient. Solving for the kinship coefficient provides an unbiased estimator. For smaller segments of SNPs, this method of moments statistic estimates the conditional kinship coefficient. As the segment length grows, the estimate converges to the theoretical kinship coefficient. Using the very large-scale SNP genotyping tools now available, we can quickly calculate a good estimate for the true theoretical kinship coefficient and reasonable estimates for the conditional kinship coefficients between any two individuals. These kinship coefficients estimates can be used in QTL mapping and association analyses for gene localization.

To test our method we used the Affymetrix 100K SNP set as a representative high-density SNP dataset. We present results based on both simulated and real pedigrees. The results from 1000 simulated runs give excellent agreement to the known true values with very small standard errors. The results on a limited number of real datasets also give reasonable estimates. We are currently gathering more real datasets to demonstrate the usefulness of this method.

DUX4 transcriptionally regulates paired-like homeodomain transcription factor 1. *M. Dixit[1], Y.-W. Chen[1,2]* 1) Center for Genetic Medicine Research, Children's National Medical Center, Washington, DC; 2) Department of Pediatrics, George Washington University, Washington, DC.

Fascioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant disease linked to a partial deletion of the 3.3 kb D4Z4 repeat arrays at chromosome 4q35. The only known transcript encoding a double homeodomain protein, DUX4, in each of the repeat unit was shown likely aberrantly expressed in the muscles of the FSHD patients but not in healthy individuals. In this study, we determined whether paired-like homeodomain transcription factor 1 (PITX1) which were shown specifically up-regulated in FHSD was a direct transcriptional target of DUX4. To test if the DUX4 gene can directly interact with the pitx1 promoter, we first amplified a 318 bp fragment flanking a putative DUX4 binding site in an evolutionally conserved region. We then inserted the fragment to the pGL3-basic luciferase reporter vector. The construct was co-transfected with the pCIneo-DUX4 expression vector and luciferase activities were measured at 24 hours post-transfection. Co-transfection with pCIneo-DUX1 (a non-4q35 homolog of DUX4 gene), pCIneo-DUX4c (a 4q35 homolog of DUX4 gene) expression vectors and the insertless vector alone were performed as controls. The results showed a 110-fold increase (n=4, $p=2.4x10^{-17}$) of the luciferase activity when the pGL3-pitx1 was co-transfected with pClneo-DUX4 compared to samples co-transfected with insertless vector. Co-transfection with DUX1 or DUX4c also lead to up-regulation of the luciferase activity, 1.5 and 5 fold ($p=1.6x\ 10^{-11}$ and $p=2.2x10^{-8}$), respectively but the changes were dramatically lower than DUX4 co-transfection. This is the first report on potential transcriptional target of DUX4 in muscle cells. The fact that the target gene, PITX1, was shown specifically up-regulated in FSHD suggested that aberrant expression of DUX4 in the FSHD patients likely to be responsible for the disease-specific up-regulation of PITX1, which activated down-stream pathways contributing to muscle pathologies in the FSHD patients.

The development of an open platform LIMS solution to address the complexity of genomics and systems biology workflows, data management, and analysis. *D. Bronnikov* GenoLogics Life Sciences Software Inc., Victoria, BC, Canada.

Recent breakthroughs in the development of high throughput technology platforms for large scale gene expression and genotyping studies introduced a new challenge to geneticists: efficient use of the avalanche of data produced. It is becoming an increasingly daunting task to archive, retrieve, share and compare the data generated by different technology platforms and software applications for data analysis. We present a genomics-purposed LIMS software that enables efficient data management, automatic acquisition from instrumentation, and processing of diverse data in a highly customizable and user friendly environment, integrating open data standards and an open technology platform to encourage collaboration. Based on an established LIMS platform, we created flexible in silico solution that accelerates the entire procedure of sample tracking, quality control, workflow optimization, ensure accuracy and reproducibility of the results, hence increasing the productivity of researchers conducting experiments in Genomics and emerging discipline of Systems Biology.

Transmission and instability of the Huntington's Disease CAG repeat length in a large multigenerational Venezuelan pedigree. *D. Brocklebank[1], J. Gayán[1], M. Andresen[3], S. Roberts[2], D. Housman[3], L. Cardon[1], N. Wexler[2], The US-Venezuela Collaborative Research Group* 1) Dept Statistical Genetics, University of Oxford, UK; 2) Columbia University, NY 10032 USA; 3) MIT, Cambridge, MA 02139 USA.

Huntington's disease (HD) is a progressive neurodegenerative disorder caused by an unstable trinucleotide (CAG)n repeat expansion in the gene on chromosome 4 which codes for the huntingtin protein. This CAG repeat shows remarkable instability, changing often in number during transmission from parents to offspring. Normal alleles (fewer than 35 repeats) are generally stable, while expanded alleles (35 or more repeats) can exhibit dramatic instability on transmission to subsequent generations. There is a strong paternal sex bias towards expansion. Repeat lengths of 40 CAGs or greater are fully penetrant and will produce symptom onset if a gene carrier lives a normal lifespan. The instability of the repeat length has important implications for HD since it accounts for approximately 70% of variation in age of onset. We analyzed the instability of the repeat length as it is transmitted from parent to offspring in large Venezuelan (Vz) kindreds, with a particular view to determining the heritability of the instability. We followed the transmission of alleles through multiple generations, and calculated the change in length of each transmitted expanded allele. Paternal transmissions usually feature repeat length expansions, sometimes almost doubling in size. In contrast, female transmissions predominantly display very little change, minor expansions balanced by contractions. For paternal transmissions only, we have also observed a significant relationship between the amount of change in the repeat length and its original size. The extensive Vz kindreds provide a unique resource for detecting any familial effects influencing the instability. Using relative-pair correlations and variance component maximum likelihood methods, we have obtained evidence for a highly significant familiality and heritability for the CAG change on transmission from fathers. This suggests that modifier genes may influence the stability of the repeat length on transmission of the expanded allele from father to child.

Assessment of ALOX5AP in two independent coronary artery disease studies. *D.R. Crosslin[1], J. Rose[1], J.J. Connelly[1], C. Haynes[1], S. H. Shah[1,2], T. Wang[1], D.C. Crossman[3], C.B. Granger[1], J. L. Haines[4], C.J.H Jones[5], J.M. Vance[1], P.J. Goldschmidt-Clermont[6], W.E. Kraus[2], S.G. Gregory[1], E.R. Hauser[1]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Division of Cardiology, Duke University Medical Center, Durham, NC; 3) University of Sheffield, Sheffield, United Kingdom; 4) Vanderbilt University, Nashville, TN; 5) University of Wales College of Medicine, Cardiff, United Kingdom; 6) Miller School of Medicine, University of Miami, Miami, FL.

Leukotrienes are arachidonic acid (AA) derivatives known for their inflammatory properties. In recent years, it has been well-documented that the inflammation process of leukotrienes may play an important role in atherosclerosis and subsequently cardiovascular disease (CAD). Mediating the conversion of AA to an unstable leukotriene precursor (LTA4) is the enzyme 5-lipoxygenase-activating-protein (ALOX5AP, FLAP). Several publications have demonstrated an association between variants in FLAP and other genes in the leukotriene metabolism cascade (Helgadottir, 2004). We performed an association study between these variants in FLAP and CAD in the GENECARD study of early onset coronary artery disease study (438 families) and in the Duke University Hospitals cardiac catheterization CATHGEN (556 Cases with early onset CAD and 256 Controls) sample. Analysis of single SNPs in FLAP showed weak evidence for association (p-val < .10). The four-SNP haplotype (HapA) that conferred a 2 times greater risk of myocardial infarction (MI) and stroke in the Icelandic cohort proved to have a moderate association (global p-val = .03) in the CATHGEN population while controlling for age, race and cardiovascular covariates. This result serves as further validation of the association of HapA in CAD. Interestingly we also detected an association with SNPs in ALOX5 (p-val < .05), the target of FLAP. The GENECARD families do not demonstrate association with either ALOX5 or FLAP. We are exploring additional genes in this pathway, as well as the effects of ethnicity and CAD subphenotype (Helgadottir, 2005). We are also examining evidence for interactions among ALOX5, FLAP and other genes in the AA pathway.

Online Interdisciplinary Healthcare Training: A Model for Genetic Education. *S. DeLany Dixon[1], S. Ashley[1], K. Gordes[2], L. Doucette[2]* 1) Master's in Genetic Counseling Program, University of Maryland,School of Medicine Baltimore, MD; 2) University of Maryland School of Medicine, Baltimore, MD.

Purpose: To increase exposure and understanding of the role of genetic counseling in interdisciplinary healthcare and to educate genetic counseling students in cultural competency, an online interdisciplinary healthcare course with both didactic and clinical components was developed. Allied health graduate students in the medical technology, genetic counseling, and physical therapy programs at the University of Maryland School of Medicine participated. The course focused on areas of health promotion and prevention, geriatrics, long-term care, home health and hospice care, ethics, bioterrorism, multiculturalism, and regulatory updates. Methods: An online interdisciplinary course was offered in the Fall of 2005. Students completed online discussions via Blackboard and written assignments. In the Spring semester, students participated in 10 interdisciplinary wellness fairs targeting the underserved population in inner-city Baltimore. Results: Students completed pre- and post- course tests to evaluate and assess their understanding of interdisciplinary healthcare. Approximately 74% of students demonstrated improvement in the understanding of interdisciplinary healthcare. Additionally, students completed the Inventory for Assessing the Process of Cultural Competence Among Healthcare Professionals-revised (IAPCC-R) to assess their level of cultural competency. Prior to the course, 56% of students were noted to be culturally aware, while 44% of students classified as culturally competent. Following the didactic course and participation in community health fairs, 73% of students improved or maintained their level of cultural competency. Conclusions: Based on evaluation from the students as well as the pre- and post- course exams, online education is effective in training students in interdisciplinary healthcare. Additionally, multicultural educational experiences impact the level of cultural competence in allied health students.

Using next generation technology for human genome sequencing and SNP discovery. *D. Bentley* Solexa Ltd, Little Chesterford, Essex, United Kingdom.

Re-sequencing and characterization of sequence variants in individual human genomes on a large scale is of critical importance for studies of medical genetics and evolution of populations. We have developed a system that is capable of re-sequencing human genomes at two orders of magnitude lower cost and higher throughput than conventional technology. Single molecules of randomly fragmented genomic DNA are attached to a planar, optically transparent surface and amplified in situ to create an ultra-high density array of templates (up to 10 million per cm2) for sequencing. Novel reversible terminators with removable fluorescence are used in a robust four-color DNA sequencing-by-synthesis method. Sequence reads with individual base quality scores are generated and aligned against a reference genome. Genetic differences are called using a specially developed data pipeline. Read alignments, sequence variants and summary statistics are displayed using an implementation of the Ensembl genome browser, and also in the sequence display Staden software gap4. Initial experiments using a human BAC enabled us to generate data with high raw read accuracy (Q20) and to obtain consensus sequence of accuracy 99.99 %, with accurate determination of all homopolymeric tracts, dinucleotide repeats and single base differences when compared to the reference sequence. We are currently sequencing an individual human genome (Yoruba from Ibadan, Nigeria) using a random shotgun approach. Early high-quality datasets matched to the reference sequence reveal an even distribution of reads across all chromosomes. We also demonstrate applicability of the system to generating paired reads, targetted sequencing of human genes and genomic regions and accurate identification and display of single nucleotide polymorphisms.

Clinical Benefit Following Enzyme Replacement Therapy (ERT) with Alglucosidase alpha in Children with Pompe Disease. *D. Corzo[1], C. Spencer[2], B. Byrne[2], M. Nicolino[3], W.L. Hwu[4], N. Leslie[5], H. Mandel[6], E. Wraith[7], P. Kishnani[8]* 1) Genzyme Corp, Cambridge, MA; 2) Shands Hospital at the University of Florida College of Medicine, Gainsville, FL; 3) University Hospital Debrousse, Lyon, France; 4) National Taiwan University Hospital, Taipei, Taiwan; 5) Cincinnati Children's Hospital, Cincinnati, OH; 6) Ramban Medical Center, Haifa, Israel; 7) Royal Manchester Children's Hospital, Manchester, UK; 8) Duke University Medical Center, Durham, NC.

Introduction. Pompe is a metabolic myopathy due to a deficiency of the lysosomal enzyme acid alpha glucosidase. Those with onset of symptoms in the first year of life typically die from cardiac and respiratory failure at a median age of 8.7 months (Kishnani et al., in press). **Methods.** Study 1 enrolled 18 patients <6 months of age; Study 2 enrolled 21 patients >6 to 36 months of age. All patients had onset of symptoms in the first year of life and evidence of cardiomyopathy prior to treatment. **Results.** After 1 year of ERT with rhGAA 18/18 (100%) patients in Study 1 were alive and 15/18 patients (83%) were free of invasive-ventilator support. In Study 2, 16/21 patients (76%) were alive and 11/16 (69%) patients who were free of invasive ventilation at baseline, remained so. All but 2 patients with follow up cardiac echo data demonstrated decrease in LV mass; 2 patients showed LV mass stabilization. Thirteen out of 15 patients (73%) of patients treated at <6 months of age (Study 1) showed acquisition of new motor milestones, in contrast to10/21 patients (48%) of those treated at >6 months of age (Study 2). Thirty five out of 39 patients (90%) developed anti-rhGAA antibodies; in one case antibodies had inhibitory activity (in vitro). **Conclusions.** Administration of alglucosidase alpha to this large cohort of patients with Pompe disease resulted in measurable clinical benefit, even in those patients with advanced stage of the disease at onset of ERT (Study 2). Results from these trials provide further evidence that early initiation of ERT is of paramount importance to maximize the chances of a favorable motor outcome. Patients continue to be treated and followed up in extension studies.

Impairment of the Hypothalamus-Pituitary-Thyroid axis in Patients with Glycogen Storage Disease type I (GSD1): increased prevalence of thyroid autoimmunity and hypothyroidism in GSD1b but not in GSD1a. *G. ANDRIA[1], G. PARENTI[1], R. PIVONELLO[2], M. SIBILIO[1], F. BALIVO[1], R. DELLA CASA[1], R. TAURISANO[1], M. SALERNO[1], G. LOMBARDI[2], G. SEBASTIO[1], A. COLAO[2], D. MELIS[1]* 1) DEPARTMENT OF PEDIATRIC, Federico II University, SERGIO PANSINI 5, Naples, Italy; 2) Department of Molecular and Clinical Endocrinology and Oncology Federico II University, SERGIO PANSINI 5, Naples, Italy.

Background: GSD1 has been supposed to be associated to endocrine dysfunction. Aim: The aim of the current study is to investigate the hypothalamus-pituitary-thyroid axis in patients with GSD1 and to compare it in GSD1a and GSD1b patients. Patients and Methods Ten patients with GSD1a, 7 with GSD1b and 34 sex and age-matched healthy controls entered the study. Results Serum FT4 was significantly lower in GSD1a and GSD1b ($p<0.05$) whereas TSH was significantly higher in GSD1b ($p<0.005$) and slightly higher ($p=0.06$) in GSD1a patients than in controls. Tg and TPO auto-antibodies were significantly higher in GSD1b than in GSD1a patients and controls ($p<0.005$). After TRH stimulation, an enhanced TSH response was found in GSD1a and GSD1b patients ($p<0.005$) compared to controls. The presence of a subclinical or overt hypothyroidism was found in 4/7 GSD1b and in none of GSD1a patients (2=7.47, $p<0.005$), and controls (2=27.2, $p<0.0001$). Conclusions GSD1b patients have an increased prevalence of thyroid autoimmunity hypothyroidism and, whereas GSD1a patients showed only a mild impairment of thyroid function. The results of the study suggest a primitive damage of the thyroid gland although the only slightly elevated TSH levels even in patients with overt hypothyroidism suggest a possible concomitant damage at the level of the hypothalamus or pituitary gland .

Characterization of New SBCAD Gene Sequence Variants in Patients with 2-Methylbutyrylglycinuria Identified by Newborn Screening with Tandem Mass Spectrometry. *J. Alfardan[1,2], N. Majumder[3], D. Matern[5], J. Kant[1,2,4], J. Vockley[1,3,4]* 1) Univ of Pittsburgh School of Medicine/Graduate School of Public Health; 2) Dept Pathology; 3) Dept Pediatrics; 4) Dept Human Genetics; 5) Mayo Clinic School of Medicine, Dept Laboratory Medicine.

Objective: Short/branched chain acyl-CoA dehydrogenase deficiency (*SBCADD*), also known as 2-methylbutyryl-CoA dehydrogenase deficiency, is a recently described autosomal recessive disorder of isoleucine metabolism. Few patients have been reported so far, most due to a founder mutation found in the Hmong Chinese population. While the first reported patients had severe disease, most of the affected Hmong have remained asymptomatic. In this study we describe three non-Hmong patients brought to attention by elevated C5-carnitine in blood spots on MS/MS newborn screening. **Methods:** PCR and bidirectional sequencing was performed on genomic DNA from two of the patients covering the entire *SBCAD* (*ACADSB*) gene sequence of 11 exons along with a control subject. 2-Methylbutyrylcarnitine production by patient fibroblasts was quantitated by incubation with isotopically labeled isoleucine followed by tandem mass spectrometry. **Results:** Fibroblasts from two patients accumulated elevated 2-methylbutyrylcarnitine. Sequence analysis of genomic DNA from each patient identified variations in the *SBCAD* gene not previously reported. The first was a homozygous p.Gln99X nonsense variant in exon 3. The patients parents are first cousins of Indian descent. The second patient was a compound mutant for c.443C>T, p.Thr148Ile in exon 4, and c.1159G>A, p.Glu387Lys in exon 10. Both missense changes are predicted to be deleterious to enzyme function. The patients, now 9 and 10 months respectively, are well and developing normally with no specific therapy. Mutational analysis of fibroblasts from the third patient, who is also well, is pending as are functional studies of the mutant enzymes. **Conclusion:** These findings show *SBCAD* deficiency can be identified through newborn screening by tandem mass spectrometry. Our patients have been well without treatment and call for careful follow-up studies to learn the true clinical impact of this disorder.

Germline CDKN2A coding mutations are rare in the majority of cutaneous melanoma patients. *M.L. Council[1], J. Gardner[1], J. Ivanovich[2], C. Kamp[2], L. Cornelius[3], A. Bowcock[1]* 1) Dept Human Genetics, Washington Univ, St Louis, MO; 2) Hereditary Cancer Core, Washington Univ, St Louis, MO; 3) Div of Dermatology, Washington Univ, St Louis, MO.

Malignant melanoma is the most serious form of skin cancer, and its incidence has tripled in Europeans over the past 30 years. Intensive, episodic UV-exposure is felt to be contributory to this process. Rare germline mutations of CDKN2A, a tumor suppressor located at 9p21, are detected in affected members of some families where cutaneous melanoma is segregating. We have begun a genetic study of cutaneous melanoma at Washington University School of Medicine (St. Louis, Missouri). DNA from a cohort of 110 patients is currently available. These include 75 female and 35 male patients; all are of European origin. Twenty-two patients have at least one other first, second, or third-degree relative with melanoma. The majority (85%) of patients have a first, second, or third-degree relative with a second cancer: breast (40%), lung (27%), and colorectal (25%), most commonly. All patients have been screened for variants in CDKN2A and the overlapping p14 gene with dHPLC and/or direct sequencing. Only one germline mutation was detected within the coding region of CDKN2A (D125H); this mutation has been previously described. As this patient was adopted, we have no additional family history. Two patients had intronic variants of undetermined significance, and one patient harbored an A134A silent change. In summary, less than 1% of our cohort of melanoma patients were found to have a mutation altering the coding sequence of CDKN2A, although 20% of patients have a first, second, or third degree relative with melanoma. This is in agreement with other studies. It suggests that CDKN2A mutations are rare in the majority of melanoma patients and that a search for other susceptibility genes is warranted.

Negative BRCA1 immunohistochemistry and/or reduced RNA expression in ovarian tumors predicts germline BRCA1 mutation status. *A. De Luca[1,2 *], J.Z. Press[3 *], S. Young[2,6], Y. Ridge[6], S. Kalloger[5], D.M. Miller[4], D. Horsman[2,6], C.B. Gilks[2,5], D.G. Huntsman[1,2,5,6]* 1) Center for Translational and Applied Genomics, Provincial Health Services Authority & BC Cancer Agency, Vancouver, BC, Canada; 2) Departments of Pathology and Laboratory Medicine; 3) Obstetrics and Gynaecology; 4) Gynecologic Oncology, University of British Columbia, Vancouver, BC, Canada; 5) Genetic Pathology Evaluation Centre of the Prostate Centre, Vancouver General Hospital, Vancouver, BC, Canada; 6) Hereditary Cancer Program, BC Cancer Agency, Vancouver, BC, Canada.

Germline DNA from 49 consecutive women with ovarian cancer was assessed by dHPLC for BRCA1 mutations, and abnormal peaks were sequenced. BRCA1 RNA expression and loss of BRCA1 protein were assessed by real-time PCR and immunohistochemistry (IHC) [anti-BRCA1 (Ab-1), mouse mAb (MS110)], respectively. Mutation screening revealed 8/49 (16%) germline truncating BRCA1 mutations and 1 somatic BRCA1 mutation. 26/49 (53%) tumors had reduced BRCA1 RNA expression, 23/49 (47%) showed loss of BRCA1 immunoreactivity, and 19/49 (39%) had both. All cases with loss of BRCA1 immunoreactivity were high grade serous or undifferentiated. Frequency of BRCA1 germline mutations was 7/26 (27%) in patients with reduced BRCA1 tumor RNA expression and 8/23 (35%) in patients with negative BRCA1 immunoreactivity. The sole case with a somatic truncating BRCA1 mutation had loss BRCA1 expression at a protein and RNA level. 10/14 of the cancers with loss of BRCA1 immunoreactivity and no mutation had BRCA1 promoter methylation, as detected by methylation-specific PCR after bisulfite treatment. None of the 26 ovarian cancer patients with detectable BRCA1 immunostaining had a BRCA1 germline mutation. The sensitivity and specificity for detection of patients who harbour BRCA1 germline mutations were 7/8 (87%) and 22/41 (54%) for RNA expression, 8/8 (100%) and 26/41 (63%) for IHC. Ovarian carcinomas from BRCA1 germline mutation carriers had loss of BRCA protein expression. BRCA1 IHC in primary ovarian carcinoma specimens could be used to triage women for genetic counseling then BRCA1 mutation testing. *Authors contributed equally to this work.

Partial trisomy 2p with congenital polyvalvular disease. *D.N. Abuelo[1], L. Kochilas[1], U. Tantravahi[2]* 1) Pediatrics, Rhode Island Hospital, Providence, RI; 2) Pathology, Women and Infants'Hospital, Providence, RI.

In congenital polyvalvular disease (CPVD), two or more of the cardiac valves show dysplastic features. It is usually associated with major chromosomal abnormalities, most often trisomy 18, but has been described in other aneuploidy syndromes as well. Here we report CPVD associated with partial trisomy 2p.

The patient was born after an uneventful pregnancy with a birth weight of 2.5 kg. Intermittent cyanosis developed at two hours. Physical examination showed craniofacial dysmorphism (prominent forehead, plagiocephaly, deep-set eyes, unilateral microtia with patent external auditory canal), capillary hemangiomas on the forehead and posterior neck and postaxial polydactyly of the left foot. Cardiac examination showed biventricular and septal hypertrophy, a large conoventricular ventricular septal defect(VSD)and a patent foramen ovale. Both semilunar valves were dysplastic with partially fused and thickened leaflets. Doppler interrogation revealed moderate valvar pulmonary and aortic stenosis, mild aortic regurgitation through the non-coapted dysplastic leaflets and some degree of dynamic subvalvular outflow tract obstruction bilaterally. Because of progressive pulmonic stenosis, she underwent initial pulmonary balloon angioplasty at two months and subsequent pulmonary valvulotomy, VSD closure, resection of infundibular muscle bundles and subaortic septotomy. Psychomotor testing showed global developmental delay for which she receives early intervention services.

Cytogenetic study of peripheral lymphocytes revealed an inverted duplication of bands p24p22 on one chromosome 2, confirmed by FISH analysis using whole chromosome DNA paint probe and 2p telomere DNA probe.

Conclusion: The cardiac abnormalities found in this patient are within the spectrum of defects previously reported in patients with 2p duplication, except for the presence of CPVD. Since our patient has a slightly larger duplicated segment than previously reported cases, we suggest that this additional chromosome region may include genes involved in cardiac valvulogenesis.

Sequence-level population simulations over large genomic regions, with gene conversion, recombination hotspots and selection. *D. Balding[1], J. Whittaker[2], M. De Iorio[1], C. Hoggart[1], T. Clark[1]* 1) Dept Epidemiology/Public Hlth, Imperial College, London, United Kingdom; 2) London School of Hygiene and Tropical Medicine, London, United Kingdom.

Population samples of DNA sequences can be simulated using coalescent-based simulation software, such as Hudsons MS. Coalescent methods work backwards in time, which is computationally efficient but is limited in the amount of recombination that can be incorporated, as well as the flexibility to include important features such as gene conversion and selection. With increased capacity of computers, it is now feasible to implement more flexible, forwards-in-time simulation strategies. We have developed FREGENE, software for forwards-in-time, whole-population simulation of sequence-like data over large genomic intervals. It can incorporate different demographic models, as well as recombination, both crossovers and gene conversions at highly variable rates, and several selection models. As illustrations of its potential uses, we (1) examine the performance of algorithms for identifying recombination hotspots, in the presence of potential confounding by gene conversion and selection, and (2) find approximations for genome-wide significance levels of genetic association studies using high marker density or resequence data, under different assumptions about demography and gene conversion. FREGENE is useful both for population genetics simulation studies, and for realistic power simulations for genetic epidemiology studies.

The characterization of RNA instability mutations in carbamyl phosphate synethetase I (CPSI) through inhibition of nonsense mediated decay. *A. Eeds[1], D. Mortlock[1], R. Wade-Martins[2], M. Summar[1]* 1) Ctr Human Genetic Res, Vanderbilt Univ, Nashville, TN; 2) The Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

Carbamyl phosphate synthetase I (CPSI) is the liver-specific enzyme that catalyzes the first and rate-determining step of the urea cycle. Mutations cause CPSI Deficiency (CPSID), an autosomal recessive disease characterized by hyperammonemia. We have previously identified many patient mutations hypothesized to cause CPSI RNA instability. These genomic variants were present in patient genomic DNA but not detectable in patient RNA, indicating RNA degradation, perhaps due to splicing errors and/or nonsense mediated decay. These mutations included the intronic substitutions c.654-3T>G and c.1210-1G>T, the exonic c.1893T>G mutation which directly creates a nonsense codon, and c.2388C>A which is a translationally silent exonic mutation. Using a model system developed in our lab, we show proper expression of wild-type CPSI and significantly decreased expression of CPSI transcripts containing each mutation, as measured by quantitative RT/PCR assays. To determine if this decrease was due to NMD, it was inhibited by siRNA mediated knockdown of UPF2. Subsequently, relative expression levels of each mutant transcript were increased, indicating these mutations cause degradation via the NMD pathway. In addition, cryptic splice sites activated by intronic mutations were identified. This project supports the proposed prevalence of RNA instability mutations in a severe metabolic disease and demonstrates a mean for examining functional consequences of such mutations including the activation of aberrant splicing and nonsense-mediated decay.

Nucleotide sequence analysis of exon 1 of the MECP2 gene in patients previously found to be negative for mutations in exons 2, 3, and 4. *B. Anderson, F. Quan, A. Buller, M. McGinniss, M. Peng, W. Sun, C. Strom*
Department of Molecular Genetics, Quest Diag Nichols Inst, San Juan Capist, CA.

Rett syndrome (RTT) is a neurodevelopmental disorder most commonly seen in females. RTT is caused by mutations in the X-linked methyl CpG binding protein 2 (MECP2) gene. The MECP2 gene consists of 4 exons and codes for multiple transcripts. The transcript for the MeCP2e2 isoform includes all four exons and utilizes a translation start site in exon 2. This transcript was originally thought to be the only transcript from the MECP2 gene. However, an alternatively spliced transcript that codes for the MeCP2e1 isoform was subsequently identified. This transcript consists only of exons 1, 3, and 4, and uses a translation start site in exon 1. The MeCP2e1 isoform appears to be the predominant isoform in the brain. Most patients with RTT have mutations in exons 3 and 4 of the MECP2 gene, and no patients with mutations in exon 2 have been described to-date. Since exon 1 was originally thought to be non-amino acid coding, we previously performed testing for RTT by nucleotide sequence analysis of exons 2-4 of the MECP2 gene. With the discovery of the transcript for the MeCP2e1 isoform, and the identification of rare RTT patients with mutations in exon 1, we have now modified our assay to include this exon. We report here the results of nucleotide sequence analysis of exon 1 for 400 patients previously found to be negative for mutations in exons 2, 3, and 4 of the MECP2 gene. Our results indicate that mutations in exon 1 detectable by nucleotide sequence analysis are likely not a frequent cause of RTT.

The Guilford Genomic Medicine Initiative (GGMI): Developing a model for personalized medicine. *S. Blanton[1], P. Leitz[2], V. Henrich[3], J. Vance[1], M. Pericak-Vance[1], GGMI Investigators[2,3]* 1) Duke Ctr Human Genetics, Durham, NC; 2) Moses Cone Health Care System, Greensboro, NC; 3) The University of North Carolina at Greensboro.

Genetic and genomic information has the potential to revolutionize medicine by changing it from a discipline that reacts to disease to one that prevents it. The main soldiers of this revolution will be the existing primary and specialty physician practices in the private, not the University, setting. However, in a recent survey, only 8% of medical directors believed they were prepared to provide even the most basic education, decision support and assessment of risks for their patints in a genomic medicine setting. To this end, the Moses Cone Healthcare System of Greensboro, NC, UNC at Greensboro, and the Center for Human Genetics at Duke Univesity have begun the GGMI. Its goal is to create a working model to addresss the specific problems in reengineering current medical systems to be genomic medicine ready. GGMI will create solutions that can be applied to other medical plans, such as the military's. The specific aims are to create first a baseline genomic literacy in the general and medical community and to then use a step-wise implementation of three initial diseases to develop a genomic medicine model. Focus groups, both lay and professional, have been conducted to ascertain the level of education and interest in genomic medicine. For the first aim, a web-based genetic and family history module has been developed for physician education. The diseases considered initially in the second aim are thos in which the genomic inforamtion is clearly and universally agreed to be beneficial as a single test and have wide appeal to the population as a whole. This module inclues acquisition of the patient's medical and family history and risk algorithms which generate recommendations based on the family history. Algorithms for thrombotic disease (Factor V Leiden) and breast and colon cancer have been developed and are being piloted in select private practices. Genomic medicine for pharmacogenetics will be developed next. Update of the progress and model development paradigm will be presented.

Increased prevalence of vitiligo and associated autoimmune diseases in a small inbred Romanian community. *S. Birlea, P.R. Fain, R.A. Spritz* Human Medical Genetics Program, University of Colorado Health Sciences Center, Aurora, CO.

The utility of population isolates for gene mapping and identification is well established, taking advantage of the relative homogeneity of genetic and environmental risk factors in these settings. We have studied a small village in the mountains of northern Romania in which vitiligo, an autoimmune disease characterized by acquired pigmentary loss, occurs at a prevalence of 2.9% (48 cases/1673 inhabitants), ten times more than in the surrounding villages or elsewhere in the world. The village is geographically isolated and was founded ~400 years ago by only three families; three-fourths of villagers today still share those original three family names, with many known consanguineous matings. The vitiligo phenotype in the village is typical, and is highly associated with other autoimmune diseases, including autoimmune thyroid disease, rheumatoid arthritis, and adult-onset autoimmune diabetes mellitus, but the mean age of vitiligo onset (34.8 yrs) is relatively late. There is striking (96%) case clustering among closely related individuals, and most patients derive from two unaffected parents (37/48). The high frequency of vitiligo and associated autoimmune diseases, high rate of consanguinity, and pattern of recurrence among sibs is consistent with multifactorial inheritance involving a major-locus recessive derived from a founder. Genomewide linkage and linkage disequilibrium analysis of this remarkable isolated population provides a unique opportunity to map and identify a major gene conferring susceptibility to vitiligo and associated autoimmune diseases that will likely have application to other populations around the world.

Severe language delay associated with duplication of the Williams-Beuren critical region. *J.S. Berg[1], N. Brunetti-Pierri[1], B. Nowakowska[1,2], E. Obersztyn[2], C-T. Fong[3], A. Summers[4], A. Patel[1], A.L. Beaudet[1], S.W. Cheung[1]* 1) Dept of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 3) Pediatric Genetics, University of Rochester, New York, NY; 4) North Bay Health Unit - Genetics, Ontario, Canada.

The Williams-Beuren Syndrome (WBS) is among the most well-characterized microdeletion syndromes, caused in most cases by recurrent de novo deletions at 7q11.23 mediated by non-allelic homologous recombination between low copy repeats (LCR) flanking this region. Given the presence of numerous LCRs and the frequency with which deletions in the WBS region are observed, one would expect that duplications of the same segment might also occur. This hypothesis was recently demonstrated to be correct with the identification of an eight-year-old male with severe language delay and duplication of the WBS critical region (Somerville, NEJM 2005). However, the degree to which duplications of this region contribute to the overall burden of language delay or other developmental disorders is unclear.

We now report five additional patients with severe language delay associated with 7q11.23 duplications. Two patients with prominent language delay were found to have reciprocal duplications of the classical WBS critical region. One 47,XXY patient with uncharacteristically severe language delay was found to have ~33% mosaicism for a ring chromosome containing material from 7q11.23. Two siblings with dysmorphic features and significant language delay were shown to have ~20% mosaicism for a >10 Mb 7q11-q11.23 duplication. These duplications were all first identified by array-comparative genomic hybridization and confirmed by FISH, thus confirming the initial report of severe language delay seen in duplication of the WBS region and further delineating the phenotypic spectrum of this condition. We propose that duplications of the WBS region may be more frequent than previously suspected and that screening for this duplication is warranted in children with language delay.

Pharmacological Induction of Mitochondrial Biogenesis and Antioxidant Genes in X-linked Adrenoleukodystrophy. *R. Deering[1], G. Dong[2], K.D. Smith[1,2]* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD.

X-linked adrenoleukodystrophy (XALD) is caused by mutations in the peroxisomal membrane protein gene ABCD1. Patients have increased levels of very long chain fatty acids (VLCFA; C>22:0), heterogeneous mitochondrial damage, and increased oxidative stress and damage. They typically present with adrenal insufficiency and cerebral inflammatory demyelination or peripheral axonopathy. Available therapies include bone marrow transplantation or dietary therapy (Lorenzos oil) with variable outcomes. We have been studying 4-phenylbutyrate, trichostatin A (TSA), both histone deacetylase inhibitors and hydroxyurea (HU), a ribonucleotide reductase inhibitor, as possible pharmacological therapies. These drugs reduce VLCFA levels in cultured fibroblasts and XALD mouse models (HU not yet tested), increase mitochondrial biogenesis, and increase peroxisome proliferation. Increased mitochondrial biogenesis is required for reduction of VLCFA levels. In recent RT-PCR studies of XALD fibroblasts, these drugs increased peroxisome proliferator activated receptor gamma coactivator 1 alpha (PGC1) and beta (PGC1), nuclear factor erythroid 2-related 2 (NFE2L2), and basic-leucine zipper transcription factor MAFK mRNA levels. PGC1 is a key transcription factor involved in mitochondrial biogenesis; the role of PGC1 is unknown. Nfe2l2 and Mafk bind to the antioxidant response elements of heme oxygenase (HO-1) and manganese superoxide dismutase genes. Treatment of Nfe2l2 -/- mouse fibroblasts demonstrated that increased mitochondrial biogenesis is independent of Nfe2l2 up regulation. Initial studies of HU and TSA treated XALD fibroblasts, grown under hyperoxic conditions (40% oxygen), reduced HO-1 mRNA levels 2-fold (compared to untreated cells) indicating an increased ability of the cells to handle induced oxidative stress. Understanding how these drugs contribute to organelle biogenesis, alleviate oxidative stress, and understanding the resultant lowering of VLCFA levels may contribute to therapy of XALD and provide means for identifying more effective therapeutic interventions.

High-resolution Melting Curve Analysis - a laboratory tool capable of more than mutation detection only. *J.T. Den Dunnen, R.H.A.M. Vossen, G.J.B. van Ommen* Human & Clinical Genenetics, Leiden University Medical Center, Leiden, Nederland.

Recently, the possibilities to scan DNA sequences for sequence variants with melting curve analysis (MCA) have been improved considerably. Using a combination of improved fluorescent dyes (saturating) and enhanced high-resolution instrumentation, the sensitivity and specificity of the technology have been significantly improved. In our lab hrMCA is developing quickly into a standard laboratory tool, applied to tackle diverse issues. Addition of the intercalating fluorescent dye can be both before and after PCR. Addition prior to the PCR usually demands a small modification of the PCR conditions; usually slightly increasing the Mg^{+2}; concentration and annealing temperature is sufficient. Since MCA is sensitive to variation in DNA concentration and PCR yield, we introduced a post-PCR stabilisation buffer that reduces variation between melting curves and noticeably improves results. Mutation detection in clinical diagnosis was performed in a range of diseases, with excellent results; nearly all known changes could be detected starting with existing PCR amplicons, mostly designed for other mutation detection methods. Using addition of an unlabelled melt-probe we were able to discriminate 10 alleles of a set of 3 SNPs in a 25 bp region. The same approach also facilitated discrimination between VNTR alleles varying between 14 and 21 CA-repeats. Results with hrMCA in relation to SNP discovery were excellent; scanning is simple and simple, and the throughput excellent (over 1600 samples per hour). In addition, upon discovery, it is immediately clear whether hrMCA can also be used for subsequent high-throughput SNP-scoring without the need to design a specific assay. Finally, hrMCA was used successfully to determine the complexity of sets of DNA-clones and -fragments, incl. identifying mutation carrying clones, to follow the efficiency of DNA bisulfite treatment and in relation to clone selection protocols (e.g. phage-display selections).

ArrayCGH reveals complex chromosome 8 rearrangement in a patient with supravalvular pulmonary stenosis.
K. Buysse, B. Menten, B. Callewaert, B. Loeys, A. De Paepe, G. Mortier, F. Speleman Center for Medical Genetics, Ghent University, Ghent, East-Flanders, Belgium.

Recurrent constitutional chromosome 8p rearrangements have been described, in particular the inversion duplication and t(4;8)(p16;p23). For these rearrangements, involvement of olfactory receptor (OR)-gene clusters has been demonstrated. Here we describe yet another chromosomal rearrangement involving both the chromosome 8 short and long arm and which is complex in nature. The proband was born after an uncomplicated pregnancy of 38 weeks. Birth weight was 3150 g (P50), length 49 cm (P90), head circumference 32 cm (P10). A heart murmur was detected at birth. Echocardiography showed a supravalvular pulmonary stenosis. Physical examination at the age of 3 months revealed a baby in good general condition. There was an impression of hypertelorism, strabismus of the left eye, upslanting palpebral fissures and blue sclerae. The hands showed bilateral simian crease. The ears were posteriorly rotated with a preauricular appendix on the left side. There was an intergluteal hairy dimple. Neurological examination was normal and the child showed a normal psychomotor development. Karyotyping revealed an aberrant chromosome 8 with extra material on the short arm. FISH analysis with telomeric probes showed extra material of 8qter on 8pter and a deletion of the distal 8p segment. This was indicative for a recombinant chromosome resulting from a balanced pericentric inversion. However, chromosomal analysis of both parents gave normal results. An arrayCGH analysis was performed in order to delineate the breakpoints. The deletion of 8p and duplication of 8qter material was confirmed. However, an additional gain of material was seen on 8p22. The karyotype was rewritten as 46,XX,der(8)(qterq24.1::p23qter).arr cgh 8p23.1(pterCTD-2629I16)x1, 8p22(RP11-148E1RP11-545M21)x3, 8q24.13(RP11-158K1qter)x3. Further molecular investigation is ongoing to define the exact nature of this unusual rearrangement and particular attention will be given to the possible role of the genomic architecture of 8p which is known to mediate recurrent imbalances such as inv dup(8p).

Screening for APC gene mutations in 23 Chilean families with familial adenomatous polyposis: analysis of extracolonic manifestations. *K. Alvarez[1, 2], M. De la Fuente[2], A. Letelier[2], M. Acuña[2], F. Bellolio[1], F. León[1], F. López-Kostner[1], M.P. Carvallo[2]* 1) Laboratorio de Oncología y Genética Molecular, Departamento de Cirugía Digestiva, Facultad de Medicina, Pontificia Universidad Católica de Chile, Santiago, Chile; 2) Departamento de Biología Celular y Molecular, Facultad de Ciencias Biológicas, Pontificia Universidad Católica de Chile, Santiago, Chile.

Familial adenomatous polyposis (FAP) is an autosomal dominant disease with complete penetrance. It is characterized by the development of hundreds to thousands of adenomatous polyps present mainly in the colon and rectum, and the development of colorectal cancer at 35-40 years old. FAP is caused by mutations in the tumor suppressor gene APC (5q21-22). Different studies in FAP patients have shown a correlation between the site of the mutation and the clinical phenotype, such as the degree of severity and/or the presence of extracolonic manifestations. Desmoid tumours constitute the most frequent extracolonic manifestations in FAP patients, associated with mutations present in exon 15 between codons 1310-2011. We performed the screening of the APC gene in twenty three Chilean families apparently not related. All patients were selected by standard criteria. Exons and intron-exon boundaries of the APC gene were analyzed through Single Strand Conformation Polymorphisms, Protein Truncation Test, and DNA sequencing. Our study revealed 17 different truncating mutations present in 21/23 families (91%), nine of these novel. Fourteen mutations were found in exon 15 between codons 829 and 1570, one in exon 6, one in exon 7 and one in exon 14. Eight families (35%) showed almost one patient affected with desmoid tumours. In these families we found seven mutations among codons 849 and 1533. Four mutations were inside the region associated with desmoid tumours. Three mutations were found upstream of the described region; two of them present in families with almost 100% penetrance for desmoid tumours among relatives. By means of the use of conventional techniques our study has demonstrated a high detection rate of mutations in this gene. FONDECYT 1040827.

A Robust, Scaleable Solution for High Throughput Data Production Using Affymetrix 500K SNP Arrays. *B. Blumenstiel[1], M. DeFelice[1], M. Parkin[1], W. Winslow[1], C. Healy[1], D. Mirel[1], P. Lin[1], B. Handsaker[1], M. Nizzari[1], P. DeBakker[1], M. Daly[1,2], D. Altshuler[1,2], S. Gabriel[1]* 1) Broad Institute, Cambridge, MA; 2) Center for Genome Research, Massachusetts General Hospital, Boston, MA.

Over the past year robust, comprehensive tools for genome-wide association studies have become available. In order to apply these tools to perform association studies of disease it is critical to produce data at high scale and high quality. To meet this need, we have developed an automated lab process for target prep, data management and tracking system to support the Affymetrix 500K SNP array. Initially at a scale of 384 arrays per week in March 2006 the pipeline reached full scale in May 2006 generating 1536 arrays per week. In total over 6,000 arrays (1.5 billion genotypes) have been generated, with quality and accuracy of data maintained throughout the scale up. Overall call rates across different datasets exceed 99% on average and accuracy as assessed by segregation tests in family samples and comparison to the Hap Map is approximately 99.5%. We have implemented quality control tests to take advantage of the product content and the dense genotype data. Routine tests include chip to chip comparison on overlap SNPs and tests for unexpected allele sharing which suggests sample mix up or contamination.

Enzyme replacement therapy in a murine model of mucopolysaccharidosis IVA. *M.A. Gutierrez[1], J.H. Grubb[2], T. Nishioka[1], G. Trandafirescu[1], S. Tomatsu[1]* 1) Department of Pediatrics, Saint Louis University, Saint Louis, MO; 2) Department of Biochemistry and Molecular Biology,Saint Louis University, Saint Louis, MO.

Mucopolysaccharidosis IVA (MPS IVA) is an autosomal recessive disorder caused by a deficiency of N-acetylgalactosamine-6-sulfate sulfatase (GALNS), leading to accumulation of keratan sulfate and chrondroitin-6-sulfate. Preclinical studies of enzyme-replacement therapy for MPS IVA were performed in MPS IVA mice. The pharmacokinetics and biodistribution were determined for recombinant human N-acetylgalactosamine-6-sulfate sulfatase (rhGALNS). The plasma half-life of the phosphorylated rhGALNS was 3 min and disappeared from the systemic circulation of the animals in two phases. After intravenous doses of 250 units/g body weight were administered, the enzyme was primarily recovered in the liver, with detectable activity in other tissues including bone and bone marrow but not in brain. Greater activity levels were reconstituted in various tissues after a high dose (1,500 units/g body weight). Even a single rhGALNS injection reduced remarkably the amount of storage material in the liver and spleen of MPS IVA mice. After intravenous dose of 250 units/g body weight was administered for 12 weeks, MPS IVA mice showed 80-90% reduction of storage in visceral organs, bone marrow cells, osteoblasts, osteocytes, ligaments, and connective tissues surrounding the bone, while the growth plate region showed a little improvement. These preclinical mouse studies demonstrate the clearance of tissue by administered rhGALNS, thereby providing the in vivo rationale and the critical pharmacokinetic and pharmacodynamic datafor the design of enzyme-replacement trials in patients with MPS IVA.

A voxelation map of gene expression in a mouse brain section. *M.H. Chin[1], A. Geng[1], A. Khan[1], W.J. Qian[2], S. Levy[3], R.D. Smith[2], R.M. Leahy[4], D.J. Smith[1]* 1) Depts. Molecular and Medical Pharmacology & Human Genetics, Sch Med, Univ California, Los Angeles, Los Angeles, CA; 2) Biological Sciences Division and Environmental Molecular Sciences Laboratory, Pacific Northwest National Laboratory, Richland, WA; 3) Biomedical Informatics Department, Vanderbilt University, Nashville, TN, 37232, USA; 4) Signal & Image Processing Institute, University of Southern California, Los Angeles, CA.

Gene expression signatures in the mammalian brain hold the key to understanding neural development and neurological diseases. In order to address this problem, we employed voxelation, which involves dicing the brain into spatially registered voxels (cubes) and then assaying gene expression from each voxel using microarrays. Multiple volumetric images of brain gene expression are created, similar to those obtained from biomedical imaging systems. We have reconstructed 2-dimensional images of gene expression for 20,000 genes in a coronal slice of the mouse brain using microarrays in combination with voxelation at a resolution of 1mm. Good reliability of the microarray results were confirmed using multiple replicates, subsequent quantitative RT-PCR, proteomics and publicly available in situ hybridization data. Clustering analysis identified known and novel genes with expression patterns localized to defined substructures within the brain. In addition, genes with unexpected patterns were identified. The genome-scale maps of gene expression obtained using voxelation will be a valuable tool for the neuroscience community.

Identification of cis sequence effects on gene transcription using multiple methods. *A. Bergen[1], A. Baccarelli[1,2], T. McDaniel[3], K. Kuhn[3], E. Chudin[3], P. Bender[4], R. Pfeiffer[1], D. Garcia-Rossi[1,5], K. Jacobs[1,5], B. Packer[1,5], S.J. Chanock[1,5,6], M. Yeager[1,5]* 1) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 2) School of Public Health, Harvard University, Boston, MA; 3) Illumina, San Diego, CA; 4) Coriell Institute for Medical Research, Camden, NJ; 5) Core Genotyping Facility, NCI, Gaithersburg, MD; 6) Section on Genomic Variation, Pediatric Oncology Branch, CCR, NCI, Bethesda, MD.

We investigated the role of sequence variation in cis on gene expression and identified associated SNPs and/or haplotypes in a group of genes commonly studied in cancer research. Three replicate cell cultures of thirty unique individual cell lines drawn from the Caucasian subsample of the SNP500Cancer resource were grown with same-lot cell culture reagents in parallel. Total RNA purified from each sample was amplified and labeled by the method of Eberwine, and gene expression profiling was performed using a custom Illumina Sentrix Array Matrix-96 array. N=32 genes had sequenced verified SNPs in the SNP500Cancer database and sufficient gene expression signal and variance. Association analysis of the quantitative trait of rank-invariant normalized mean RNA transcript level and SNP alleles focused on genes with 2 to 15 tag SNPs. We used 1) the single-point additive model of Mander, 2) SNP-wise regression, and 3) a phylogenetic method (TreeScan), using haplotypes and phylogenetic reconstruction via neighbor joining to evaluate association between partitions of the haplotype phylogeny and gene expression signal. For genes analyzed by all three methods (N=21 genes encompassing N=104 tag SNPs), 3, 5 and 4 genes (a total of N=7 genes encompassing N=43 SNPs) exhibited significant ($p<0.05$) association between one or more SNP genotypes and/or haplotype partitions and RNA transcript level. Two genes were identified using all methods, one gene was identified by the two SNP-wise methods, two genes were identified by the phylogenetic method, and two genes were identified via SNP-wise regression. These results identify candidate SNPs involved in the regulation of transcription and identify strengths and limitations of SNP-wise and haplotype-wise analytical methods.

ANTERIOR CERVICAL HYPERTRICHOSIS: A CASE REPORT. *D. Garcia-Cruz, M.G. Lopez-Cardona, J.R. Corona-Rivera* Instituto de Genetica Humana, Centro Universitario de Ciencias de la Salud, Guadalajara, Jalisco, Mexico.

Introduction: Anterior cervical hypertrichosis (ACH) (OMIM 600457) is a rare form of localized hypertrichosis, Tsukahara and Kajii (1992) described the first Japanese family with 7 affected members in 3 generations, posteriorly Braddock et al. (1995) reported a similar case of anterior cervical hypertrichosis without other abnormalities. Also it has been reports associated to hereditary motor and sensory neuropathy (HMSN), (OMIM 239840), severe chorioretinal degeneration, optic atrophy and recently we described a case with ACH associated with unusual features: moderate mental retardation, abnormal EEG, and mild microcephaly. Methods: We describe clinically a 24 month-old Mexican boy with congenital ACH. Results: Case Report: the propositus is a 24 month-old Mexican boy with congenital ACH, he was the product of a full-term pregnancy and non-consanguineous parents. Clinically he showed hypertrichosis on the forehead, cheeks, cervical anterior just cephalad to the laryngeal prominence, which was noted since birth, low posterior hairline on neck and fine hypertrichosis on posterior thorax. Radiological examination showed megacolon. Discussion: ACH has been considered to be an autosomal dominant phenotype, and/or X-linked. Up to date it is not clear if isolated ACH, ACH-HMSN, or other associated findings reported in some patients with ACH, are part of ACH or fortuitous associations. ACH syndrome is not yet well delineated mainly by the small number of affected patients.

Incorporating linkage information in testing strategies for genome-wide association studies in family-based designs. *D. Fardo[1], S.T. Weiss[2], C. Lange[1]* 1) Deptartment of Biostatistics, Harvard School of Public Health, Boston, MA; 2) Channing Laboratory, Brigham and Women's Hospital, Boston, MA.

Genome-wide association studies have come to the forefront of statistical genetics. A number of analysis approaches for such studies have been suggested but have not yet proven successful. Van Steen et al (2005) suggested a testing strategy that allows the same data set to be used for the screening step and the replication step, bypassing the multiple testing problem and minimizing the effects of study heterogeneity. The approach has been successfully applied to identify a novel SNP for BMI that replicated in 5 additional studies (Herbert et al, in press). One limitation of the testing strategy by Van Steen et al (2005), however, is that linkage information is ignored, which, in practice, will lead to a substantial reduction in power. Our new methodology incorporates linkage information and can use the same data set for both the screening step and the replication step. The approach enables a more powerful analysis of genome-wide association studies in order to detect genetic factors for complex diseases. We assess the power of our approach by a series of simulation studies at a genome-wide level and show that the power gains are of practical relevance. We illustrate the approach by an application to an asthma study.

The genetics of lateral fusion defects during female reproductive tract development. *D.R. Cordero[1,3], H. Kim[2,3], D.J. Donovan[1,3], C.C. Morton[1,3], B.J. Quade[1,3]* 1) Department of Obstetrics, Gynecology and Reproductive Biology, Brigham and Women's Hospital; 2) Department of Molecular Genetics, Massachusetts General Hospital; 3) Harvard Medical School.

Developmental abnormalities involving the female reproductive tract (FRT) manifest at different ages as a heterogeneous group of disorders and may have significant psychological, sexual and reproductive implications. One common group of FRT abnormalities is those secondary to defects in lateral fusion of the Mullerian ducts. However, little attention has been given to the genetic and molecular regulatory mechanism controlling lateral fusion of the Mullerian ducts. We obtained a lymphoblastoid cell line (LCL) from a patient with a didelphic uterus, cleft palate and a structurally abnormal cerebellum who had a balanced translocation involving chromosomes X and 17 (46,X,t(X;17)(p11.2;p11.2) enrolled in the Developmental Genome Anatomy Project (dgap.harvard.edu). Metaphase and interphase chromosomes from the LCL were used for Fluorescence in situ hybridization (FISH) using BAC and fosmid clones to narrow the breakpoints. Refined mapping of the breakpoint region on the X chromosome by Southern blot analysis has narrowed the breakpoint region to a 4kb region on the short arm of the X chromosome. This highly conserved region is several kb away from known genes and may be involved in important gene regulatory functions. Future directions will include suppression PCR to determine the junction fragment. The DNA sequence data obtained from the junction fragment will allow further analysis to determine the contributions of genes on chromosomes X or 17 to normal and abnormal lateral fusion of the mullerian ducts.

.

Genotype-calling algorithm for high-throughput chip-based TaqMan SNP assays. *B.Q. Doan[1], B. Carvalho[2], S.N. Liu-Cordero[3], B. Bishe[1], A. Fink[1], A. Chakravarti[1], R. Irizarry[2], D.E. Arking[1]* 1) IGM/JHMI,Baltimore,MD; 2) Biostat/JHSPH,Baltimore,MD; 3) BioTrove,Woburn,MA.

With the International HapMap Project and discovery of millions of single nucleotide polymorphisms (SNPs) within the human genome, the ability to conduct large-scale genome-wide association studies is being realized. Chip-based technologies and genotype calling software have made possible the systematic generation of genotype data consisting of 1,000s- 100,000s of SNPs. However, little is available for large-scale fine mapping studies that focus on regions needing <100 SNPs, which typically have relied on individual TaqMan assays that are relatively labor intensive with genotype calling heavily reliant upon manual calling. In our study we focus on using a chip-based OpenArray SNP genotyping technology developed by BioTrove using the TaqMan assay to follow up on regions identified from a genome-wide association study on the QT interval. Two advantages are the small amount of DNA required (2.3 ng/sample/SNP) and its high throughput (up 100,000 genotypes/day), allowing for the efficient genotyping of 32 SNPs in 25,000 subjects done in duplicate. To accommodate the throughput, we develop an automated genotype-calling algorithm for the raw data (VIC and FAM dye fluorescence intensities) to systematically control for unwanted sources of variation. First to adjust for differences in the intensities based on the dye, we normalize VIC to FAM. Then we further normalize by samples to adjust for variations in DNA concentrations, and by arrays to adjust for variations in chip performance. We examine several methods including quantile, median, and mean normalizations. Genotype clusters are defined based on known genotypes from HapMap sample controls, and the mean of the log2(ratio of normalized intensities) for each cluster is defined. Study sample genotypes are called from the known genotype cluster mean with the smallest distance to the sample log2(ratio). We are further developing our algorithm to control for other possible systematic variations such as differences in sample well location and in the assay PCR efficiency (based on GC content of the primers, and/or product length).

Reproductive Genetics And Responsibility: The Patient Standpoint. *C. Bouffard* Dept Pediatrics, Univ Sherbrooke, Sherbrooke, PQ, Canada.

The concept of « responsibility » used in bioethics has been neglected, with respect to the patients standpoint. Interest, for the most part, has been directed almost exclusively, so far, toward the impact of genetics on society, as opposed to that of society on genetics. As a sequel to my previous work, this study proposes to examine: 1)different ways in which patients view the notion of responsibility when consulting for reproduction-related genetic problems, 2)the representation they entertain towards these responsibilities, 3)the repercussions of these responsibilities on their decision-making processes, on their lives and that of their unborn child and, 4) the socio-cultural factors that generate these responsibilities. Beyond the acquisition of new information, the consequences of a selective abortion or the birth of a severely ill offspring shall determine responsibilities, which are more of a socio-cultural than genetics in nature: Responsibilities assumed by patients undergoing genetic counselling with respect to reproductive issues, as well as the representations such patients entertain toward these responsibilities, are multiple and determined by cultural, social, institutional, economic, familial and individual factors that are associated more with the collective concept of quality of life than with genetics. Ethnographic multi-sited research design based on participative observation, taped and videotaped interviews of 48 research subjects (or until the data is saturated). Methodology: comparative analysis of resultants from multiple sources like literature review, participative observation, semi-structured interviews, content and discourse analysis. So far, my work showed 7 levels of responsibility from the patients perspective: 1) Assimilating genetic information and knowledge; 2) Making decisions after a genetic counselling session intended to promote an informed consent; 3) Making decisions in a context where alternatives are limited to palliative solutions; 4) Accepting to carry, to transmit or to have transmitted a genetic or chromosome disease; 5) Accepting the psychological, familial, personal or social consequences; 6) Managing reproduction based on health criteria; 7) Transferring knowledge to family members.

SNP Selection for Association Studies. *E.L. Goode, D.N. Rider, W. Liu-Mares, X. Wang, J.E. Olson, M. Wiepert, J.P. Kocher, J.R. Cerhan, F.J. Couch, J.M. Cunningham* Mayo Clinic College of Medicine, Rochester, MN.

The availability of high-throughput genotyping platforms enables investigators to create custom arrays of thousands of SNPs. One cost-efficient SNP selection approach relies on the use of publicly-available data from LD characterization efforts. We developed a LD-based SNP selection system using genotype data from the HapMap Consortium (Phase II), Perlegen, SeattleSNPs, and NIEHS EGP (Panel 2). 1,808,564 SNPs within 5 kb of 25,418 Build 35 genes were included from HapMap; 763,543 SNPs within 5 kb of 23,100 genes were included from Perlegen; 29,287 SNPs within 261 genes were included from Seattle SNPs; and 76,862 SNPs within 171 genes were included from NIEHS EGP. We identified tagSNPs using the LDSelect binning algorithm (Carlson et al., 2004) with a minimum European-American MAF = 0.05 and $r^2 = 0.8$ between assayed and unassayed SNPs. Several factors were considered when selecting the best source for each gene (e.g., N chromosomes studied, N SNPs genotyped, and N bins) and selecting tagSNPs within each bin (e.g., assay conversion metrics, putative function, and MAF). Using predefined criteria, we found that 23,593 genes were best covered by HapMap (985,226 SNPs in 301,451 bins), 1,101 by Perlegen, 190 by SeattleSNPs, and 116 by NIEHS EGP; 1,818 genes had no available SNP genotypes. Comparison of information across LD sources suggests that, depending on intron-exon structure, resequencing projects did not always provide the best coverage. Extensions enabling additional comparisons include the use of more ethnic groups and LD projects, linkage with functional SNP databases, and consideration of multiple tagging algorithms. In current studies of 256 candidate genes within the NFkB pathway, we found that 10,104 SNPs in the public LD projects reduced to 3,007 bins (mean = 12 bins per gene, median = 7, range = 1 to 151). Assessment of the transferability of LD from these public projects to our genotyped study participants is currently underway. Although use of public data reduces the expense of SNP discovery and characterization, one must consider whether the chromosomes studied by these projects are representative of those to be genotyped.

Birt-Hogg-Dube: A syndrome the geneticist should know. *C.D. DeLozier[1, 2], T. Treisman[1], Y. Chang[3], D. Tashjian[4], T. McCalmont[5], C.J. Curry[6]* 1) Genetic Medicine, Central California Faculty Medical Group, Fresno, CA; 2) Genetics Department, Kaiser Permanente Fresno, CA; 3) Urology Department, Kaiser Permanente Fresno, CA; 4) Dermatology Associates, Fresno, CA; 5) Dermatopathology, University of California San Francisco, CA; 6) Department of Pediatrics, UCSF-Fresno Medical Education Program Fresno, CA.

In our full-service genetics consultation we see approximately 200 families/year for assessment of a hereditary predisposition to cancer. Most consultations concern breast/ovarian or colorectal cancers, and most gene testing comes back negative. Although textbooks suggests that rare cancer-predisposition syndromes account for less than one percent of familial aggregation of cancer, our experience suggests that syndromic entities may well be under-diagnosed. One such condition is the Birt-Hogg-Dube (BHD) syndrome, due to mutations in the presumed tumor-suppressor gene folliculin (FCN) on chromosome 17p. BHD is best known to dermatologists because of skin lesions with characteristic histology: fibrofolliculomas, trichodiscomas and acrochordons. Renal tumors, specifically oncocytomas and oncocytic hybrid tumors with both malignant and benign lesions, occur in approximately 30% of BHD patients. The gene mutation also predisposes to spontaneous pneumothorax/pulmonic cysts and to benign and malignant tumors of the uterus, ovaries, breast and colon. We describe here the clinical, genetic and histological features of three families with BHD syndrome presenting to the cancer genetics consultation in the same year. All adults over 30 had typical facial and thoracic skin lesions and each family had at least one person with a benign or malignant kidney tumor. Two families had pneumothorax. A fourth proband presented with primary spontaneous pneumothorax, had no other clinical features at the age of 46. We believe that a thorough physical exam and the conscientious histological verification of benign and malignant tumors in individuals attending the cancer genetics clinic will result in improved detection and management of this under-diagnosed cancer predisposition syndrome.

Fetal DNA from maternal plasma: noninvasive prenatal exclusion of Hemoglobin Bart's Hydrops (--^{SEA}/--^{SEA}).

S.S.Y. Ho[1], S.S. Chong[2,4], E.S.C. Koay[3,4], S. Ponnusamy[1], L.L. Chiu[4], W. Wang[2], A. Roy[1], M. Rauff[1], L.L. Su[1], B. Arijit[1], M. Choolani[1] 1) Department of Obstetrics and Gynaecology, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 2) Department of Paediatrics, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 3) Department of Pathology, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 4) Molecular Diagnosis Center, National University Hospital, Singapore.

Aim

Alpha thalassemia carrier(/--)couples risk having fetuses with fatal hemoglobin(Hb)Barts hydrops(--/--). Invasive prenatal testing procedures can cause miscarriages. We hypothesized that HbBarts hydrops can be excluded noninvasively using fetal DNA in maternal plasma and carriers with unaffected fetuses can avoid unnecessary invasive procedures.

Methods

Two microsatellite markers within the common -^{SEA} alpha thalassemia breakpoints were analyzed in 26 families each consisting of maternal plasma, parental and fetal DNA. Parental microsatellite markers discriminate fetal paternally-inherited alleles from maternal alleles in maternal plasma.

Results

Fetal paternally-inherited microsatellite markers were detected in 9 maternal plasma. Presence of 1 fetal paternally-inherited microsatellite marker(n=4), or both(n=5) excluded HbBarts hydrops. Absence of both markers required further confirmation using fetal DNA. Of these, one fetus was confirmed HbBarts hydrops.

Conclusion

HbBarts hydrops was excluded noninvasively with 100% accuracy using fetal DNA in maternal plasma. Of the 25 unaffected cases, 9 were excluded of HbBarts hydrops noninvasively. As such, 36%(9/25) of screened population would avoid unnecessary invasive prenatal testing.

Deletion 7q with FOXP2 involvement transmitted through a familial complex rearrangement. *P.A. Lennon[1], S.W. Cheung[2], D. Peiffer[3], K.L. Gunderson[3], P. Hu[1], A. Patel[2], C.A. Bacino[2]* 1) School of Health Sciences, UT-MD Anderson Cancer Center, Houston, TX; 2) Medical Genetics Laboratories, Baylor College of Medicine, Houston TX; 3) Illumina Incorporated, San Diego, CA.

Children who demonstrate abnormal language development, in the absence of apparent causative factors, are diagnosed with specific language impairment. Previously, fine mapping of microsatellites within in a large, three-generation family, in which half the members had severe specific language impairment, aided the localization of the SPCH1 locus (thought to be responsible for the speech and language deficits within this family) to 7q31 within markers D7S2459 (107.1 MB) and D7S643 (120.5 MB) (Fisher et al., 1998; Lai et al., 2000). Additionally, chromosome rearrangements of 7q31 and mutational analyses have supported the growing evidence that FOXP2, a gene within the SPCH1 locus, is involved with speech and language development. It is unclear whether the AUTS1 (autistic spectrum 1) locus, highly linked to 7q31, overlaps with the SPCH1 locus. Here, we provide the clinical description of a patient with specific language impairment, but not autism, and a deletion of 7q31.1 -7q31.31 (111.4 MB-120MB). His karyotype is 46,XY,der(7)del(7)(q31.1q31.31)ins(10;7)(q24.3;q31.1q31.31)mat. Our patients deletion, which includes FOXP2, adds to the body of evidence which supports the role of FOXP2 in specific language impairment, but does not support the previously reported role of FOXP2 in autism. A reported association between autism and WNT2, another gene which is deleted in our patient, is likewise not supported by the case we present. Our patients apparent delimiting of the proximal boundary of the previously reported SPCH1 locus (Lai et al., 2000) to 111.4 (MB) and our patients presentation with specific language impairment but not autism, when examined in light of Hutchesons et al (2003) reported critical minimal AUTS1 region between 106.9 and 109.7 MB, strongly supports that the SPCH1 and AUTS1 loci are separate, non-overlapping entities.

Global profile of copy number variation in the human genome. *C. Lee[1], H. Aburatani[2], N. Carter[3], M. Hurles[3], K. Jones[4], S. Scherer[5], C. Tyler-Smith[3], Genomic Structural Variation Consortium* 1) Department of Pathology, Brigham and Woman's Hospital, Harvard Medical School, Boston, MA; 2) University of Tokyo, Japan; 3) Wellcome Trust Sanger Institute, Cambridge, UK; 4) Affymetrix Corporation, Santa Clara, USA; 5) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, Canada.

Copy number variation (CNV) within the human genome is of functional importance and yet remains grossly under-ascertained. To redress this imbalance and generate a CNV map of the human genome, we screened all 270 individuals from the four HapMap populations with ancestry in Europe, Africa and East Asia for copy number variation using two complementary technologies: the Affymetrix 500k SNP genotyping platform and comparative genome hybridisation on a spotted microarray containing ~27,000 BAC clones representing the genome tilepath. We rigourously assessed the rate of false positive CNV calls by several independent means, including the validation of over 100 loci by quantitative PCR and FISH. We identified over a thousand CNVs in these four populations, many of which have not previously been identified, and which contain hundreds of genes and non-coding functional sequences. We ascertained the impact of these CNVs on the reliability of SNP genotypes from the International HapMap Project. We also delineated the linkage disequilibrium properties of hundreds of these CNVs, and identified tagging SNPs. Finally, we identified the genomic regions that show the most dramatic variation in copy number between populations, and explored selective explanations for these observations. Our data is also released in public genome browsers for the clinical genetics and basic research community. This represents a comprehensive, genome-wide assessment of CNV and its relationship to haplotypic structure, providing an important resource for the understanding of how genome structure impacts on biological function.

Asian Nomads traces in the mitochondrial gene pool of Slavs. *B.A. Malyarchuk[1], T. Vanecek[2], M.A. Perkova[1], M.V. Derenko[1], M. Sip[3]* 1) Genetics Laboratory, Institute of Biological Problems of the North, Magadan, Russian Federation; 2) Department of Pathology, Medical Faculty Hospital, Charles University, Pilsen, Czech republic; 3) Faculty of Health and Social Studies, University of South Bohemia, Ceske Budejovice, Czech Republic.

Mitochondrial DNA (mtDNA) variability was studied in a sample of 179 individuals representing Czech population from west Bohemia. MtDNA analysis revealed that the majority of Czech mtDNAs belongs to the common West Eurasian mitochondrial haplogroups. However, about 3 per cent of Czech mtDNAs encompass East Eurasian lineages (A, N9a, D4, M*). Comparative analysis of published data has shown that different Slavonic populations contain small but marked amount of East Eurasian mtDNAs (e.g. 1.3 per cent in Eastern Slavs, 1.8 per cent in Western Slavs, and 1.2 per cent in Southern Slavs). It is noteworthy that Baltic populations (Latvians, Lithuanians and Estonians) have avoided a marked influence of maternal lineages of East Eurasian origin (0.3-0.6 per cent). The two East Eurasian mtDNA haplogroups, Z1 and D5, are present in gene pools of North European Finnic populations (Saami, Finns, and Karelians). Unlike them, Slavonic populations in general are characterized by heterogeneous mtDNA structure, defined, in addition to Z1 and D5, by haplogroups A, C, D4, G2a, M*, N9a, F and Y. Therefore, different scenarios of female-mediated East Eurasian genetic influence on Northern and Eastern Europeans should be highlighted: (1) the most ancient, probably originated in the early Holocene, influx of Asian tribes, which brought a few selected East Asian mtDNA haplotypes (like Z and D5) to Fennoscandia (Tambets et al. 2004), and (2) gradual gene flows of historic times occurred mostly in the Middle Ages due to migrations of nomadic peoples (such as the Huns, Avars, Bulgars, Mongols) to Eastern and Central European territories inhabited mainly by Slavonic tribes. We suggest that the presence of East Eurasian mtDNA haplotypes is not original feature of gene pool of the proto-Slavs, but mostly is a consequence of admixture with Central Asian nomadic tribes, who migrated into Central and Eastern Europe in the early middle Ages.

Mutations in the *CEP290/NPHP6* gene, encoding Centrosomal Protein 290/Nephrocystin-6, cause Joubert Syndrome with Nephronophthisis, blindness, and cerebellar defects. *E.A. Otto[1], J.A. Sayer[1], H. Khanna[1], J.F. O'Toole[1], M.A. Kennedy[2], B.V. Fausett[1], M. Attanasio[1], J. Helou[1], D. Williams[3], Y. Liu[4], L. Ma[5], X. Zhu[5], I. Glass[6], A. Swaroop[1], D. Goldman[1], I. Drummond[4], P. Nurnberg[7], A. Swaroop[1], M.R. Leroux[2], F. Hildebrandt[1]* 1) Departments of Pediatrics, Human Genetics, Neuroscience, and Ophthalmology, Univ Michigan, Ann Arbor, MI; 2) Mol. Biology, Simon Fraser Univ, Burnaby, Canada; 3) Pharmacology, UCSD, San Diego, CA; 4) Renal Unit, Harvard Medical School, Boston, MA; 5) Biochemistry, Inst of Biol Sci, Shanghai, China; 6) Dept of Pediatrics, Univ of Washington, Seattle, WA; 7) Center for Genomics, Univ of Cologne, Germany.

Nephronophthisis, an autosomal recessive cystic kidney disease, is the primary genetic cause for chronic renal failure in children. The molecular basis and its association with retinal degeneration and cerebellar vermis aplasia (Joubert syndrome), are poorly understood. Joubert syndrome is a heterogeneous disorder characterized by cerebellar vermis hypoplasia, mental retardation, ataxia, developmental delay, oculomotor apraxia, and irregular breathing pattern. Variable clinical features include retinal dystrophy and renal anomalies (Nephronophthisis). Applying a positional cloning approach, we identified 9 different mutations in CEP290/NPHP6 in 7 families with Joubert syndrome and nephronophthisis and 1 family with nephronophthisis associated with retinitis pigmentosa without cerebellar defects. We demonstrated that CEP290/NPHP6 directly interacts with and modulates the activity of ATF4/CREB2, a transcription factor possibly implicated in cAMP-dependent renal cyst formation. In a cell cycle-dependent manner CEP290/NPHP6 localizes to centrosomes and to the nucleus in renal epithelial cells. In photoreceptor cells the protein is found in the connecting cilium. Abrogation of the function in zebrafish yields convergent extension defects and recapitulates the renal, retinal and cerebellar phenotypes of Joubert syndrome. Our findings help establish the link between centrosome function and transcriptional control in the pathogenesis of cystic kidney disease, retinal degeneration, and central nervous system development.

Genome-wide scan for split-hand/foot malformation with long bone deficiency (SHFLD) (OMIM 119100) in a large multigenerational UAE family shows a novel susceptibility locus on chromosome 1q42.13-1q43. *M. Naveed[1], M.T. Al-Ali[1], S.K. Murthy[1], S. Al-Hajali[1], N. Al-Khaja[1], U. Ratnamala[2], A. Bottani[3], S.E. Antonarakis[3], M. Gaines[4], J. Golla[4], D. Hutchings[4], S.K. Nath[4], U. Radhakrishna[3]* 1) Center for Arab Genomic studies, Dubai, UAE; 2) Green Cross Blood Bank & Genetic Research Centre, Paldi, Ahmedabad, India; 3) Dept. of Genetic Medicine & Development, University of Geneva Medical School, Geneva, Switzerland; 4) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK, USA.

Split-hand/foot malformation with long bone deficiency (SHFLD) is a very rare severe limb deformity characterized by lack of part or entire tibia with or without split-hand/split-foot deformity. Identification of genetic susceptibility loci for SHFLD has yet remained elusive, due to its rare incidence, variable expression, and uncertain inheritance pattern. This heterogeneous phenotype is usually inherited as an autosomal dominant trait with reduced penetrance although recessive inheritance has been postulated. Genome-wide linkage analysis with the GeneChip Mapping EA 10K Array (Affymetrix) containing ~10,000 SNP markers identified a novel SHFLD locus in a large isolated, non-syndromic, multigenerational, consanguineous UAE national family (UR078) with apparent autosomal dominant inheritance. Multipoint non-parametric analysis indicated significant evidence of linkage for SNP marker rs966302 at chromosome 1q42.3 (NPL = 9.8, P= 0.000065). Multipoint parametric analysis showed a LOD score of 3.20 (= 0) at SNP marker rs950964, supporting linkage in this region. A parametric two-point MLS LOD of 1.95 was detected for SNP marker rs923976 under a dominant mode of inheritance and reduced penetrance. Haplotype analysis with informative crossovers enabled mapping of the SHFLD locus to a region of approximately 18.38cM (8.4Mb) between proximal SNP rs1124110 and distal SNP rs535043. Thus, we have identified a novel genomic region on 1q42.13-1q43 that harbors a high risk variant for SHFLD in this UAE family. To our knowledge, this is the first genome-wide significant linkage results ever reported for SHFLD.

Complex patterns of copy number variation at sites of segmental duplications: an important category of structural variation in the human genome. *H. Kehrer-Sawatzki[1], V. Goidts[1], D.N. Cooper[2], L. Armengol[3], W. Schempp[4], J. Conroy[5], X. Estivill[3], N. Nowak[5], H. Hameister[1]* 1) Human Genetics, University of Ulm, Ulm, Germany; 2) Institute of Medical Genetics, Cardiff University, Heath Park, Cardiff, United Kingdom; 3) Program in Genes and Disease, Center for Genomic Regulation, Barcelona Biomedical Research Park, Barcelona, Spain; 4) Institute of Human Genetics and Anthropology, University of Freiburg, Freiburg, Germany; 5) Department of Cancer Genetics, Roswell Park Cancer Institute, Elm and Carlton Streets, Buffalo, USA.

The structural diversity of the human genome is much higher than previously assumed. To investigate the association between segmental duplications that display constitutive copy number differences (CNDs) between humans and great apes and those which exhibit polymorphic copy number variations (CNVs) between humans, we performed aCGH. Our study documents for the first time that in addition to human-specific gains common to all humans, these duplication clusters also exhibit polymorphic CNVs >40kb. Segmental duplication is obviously an ongoing process during human genome evolution. Importantly, among the CNV-associated genes identified, those involved in transcriptional regulation were found to be significantly overrepresented. Complex patterns of variation were evident at sites of duplications, manifesting as interindividual differentially sized copy number alterations at the same genomic loci. Thus, CNVs associated with segmental duplications do not simply represent insertion/deletion polymorphisms, but rather constitute a wide variety of rearrangements that lead to gene gains and losses with high inter-individual variability. Although the number of CNVs did not differ between Africans and Caucasians/Asians, the average number of variant patterns per locus was significantly lower in Africans. Thus complex variation patterns result from recent genomic rearrangements. The high number of these rearrangements, some of which are probably recurrent, and differences in population size and expansion dynamics, may account for the greater diversity of variation in Caucasians/Asians as compared with Africans.

Evaluating HapMap data transferability in a Shanghai Chinese population. *C. Hu[1], W. Zhang[2], C. Wang[1], R. Zhang[1], Q. Fang[1], J. Lu[1], X. Ma[1], W. Jia[1], International Type 2 Diabetes 1q Consortium* 1) Shanghai Diabetes Institute, Shanghai Clinical Center for Diabetes, Shanghai Jiaotong University Affiliated Sixth People's Hospital, Shanghai, China; 2) Human Genetics Division, University of Southampton, Southampton, UK.

The HapMap project aimed to catalog millions of SNPs in the human genome, in order to facilitate association analysis between phenotypes and disease variants. In this study, we examined the transferability of CHB (Northern Chinese) HapMap data to the Han Chinese in Shanghai (CHS, Southern Chinese). Over 4,500 SNPs in a 21Mb region on 1q21-q25 were genotyped in 80 unrelated Shanghai Chinese subjects as part of the International Type 2 Diabetes 1q Consortium. After removal of SNPs that failed quality control and those not in the HapMap panel, 3,014 SNPs were analyzed. The allele frequencies were highly consistent between the CHB and CHS populations ($r = 0.94$, $P < 0.0001$) whereas they were less consistent between CHS and the other populations ($r = 0.88$ for JPT, 0.46 for CEU and 0.41 for YRI, all $P < 0.0001$). In order to compare linkage disequilibrium between populations, we estimated pairwise r^2 of adjacent SNPs. Higher correlation of r^2 between CHS and CHB ($r = 0.97$, $P < 0.0001$) than that between CHS and the other populations was observed ($r = 0.96$ for JPT, 0.80 for CEU, and 0.64 for YRI, all $P < 0.0001$). SNPs with a minor allele frequency over 0.05 were selected to evaluate the tagging SNP (tSNP) performance in CHS based on the pairwise algorithm of the Tagger program. An r^2 of 0.8 was defined as the threshold for tSNP selection. About 50% of SNPs were selected as tSNPs in the CHB, JPT and CEU populations, and about 75% of SNPs in the YRI population. We found that tSNPs from CHB and JPT were highly informative in the CHS population. Approximately 95% SNPs in CHS were captured by the tSNPs selected from CHB or JPT, whereas less than 90% SNPs were captured by the tSNPs from CEU. Although over 97% SNPs in CHS were captured by the tSNP set from YRI, about 1.5 times more tSNPs were needed. Overall, our study supports the portability of HapMap CHB data to the study of complex diseases in the Southern Chinese population.

Association study in search for genetic backgrounds of myocardial infarction, focused on SNPs in genes encoding molecules that belong to lymphotoxin- signaling cascade. *K. Ozaki[1], H. Sato[2], A. Iida[3], H. Mizuno[2], M. Hori[2], Y. Nakamura[3], T. Tanaka[1]* 1) Laboratory for Cardiovascular Diseases, RIKEN, Tokyo, Japan; 2) Department of Cardiovascular Medicine, Osaka University Graduate School of Medicine, Suita, Japan; 3) Laboratory for Pharmacogenetics, RIKEN, Tokyo, Japan.

Myocardial infarction (MI) has been a principal cause of death in many countries and inflammation is now considered to play a critical role in its pathogenesis. We have previously found that the functional single nucleotide polymorphism (SNP) in the lymphotoxin- gene (LTA), encoding one of the cytokines produced in an earlier stage of vascular inflammatory processes, conferred susceptibility to MI. To further investigate whether the variants in genes which encode molecules of LTA signaling cascade are also associated with susceptibility to MI, we performed a case-control association study using tag SNPs, selected on the basis of the information in HapMap database as well as JSNP database, for genes of LTA signaling cascade. We found one SNP in one LTA related gene conferring risk of MI (2=21.1, P=0.0000044). This association was replicated with another panel of MI and control subjects. The SNP, located within 5-untranslated region of exon 1 in this gene, enhanced the transcriptional level of the LTA related gene. Moreover, suppression of the gene expression level using siRNA in cultured coronary vascular endothelial cells as well as T lymphocyte cell line reduced activation of NFkB, a central mediator of inflammation, by stabilizing phosphorylated IkB. Thus, the levels of this LTA related gene influence the degree of inflammation, indicating that this SNP is a novel genetic risk factor for MI.

Mutation analysis of genes in the RAS-MAPK pathway in 31 patients with Kabuki syndrome. *H. Kuniba[1,2,10], D. Sato[1,3,10], N. Miwa[1,10], N. Kurotaki[1,10], K. Yoshiura[1,10], T. Kondoh[2], T. Matsumoto[2], H. Tonoki[3], H. Ohashi[4], K. Kurosawa[5], T. Nagai[6,10], Y. Fukushima[7,10], N. Okamoto[8], K. Naritomi[9,10], N. Niikawa[1,10]* 1) Dept Hum Genet, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 2) Dept Pediatr, Nagasaki Univ Hosp, Nagasaki; 3) Dept Pediatr, Hokkaido Univ Grad Sch Med, Sapporo; 4) Div Med Genet, Saitama Child Med Ctr, Iwatsuki; 5) Clin Res Inst, Kanagawa Child Med Ctr, Yokohama; 6) Dept Pediatr, Dokkyo Univ Sch Med Koshigaya Hosp, Koshigaya; 7) Dept Med Genet, Shinshu Univ Sch Med, Matsumoto; 8) Dept Planning and Res, Osaka Med Ctr Res Inst for Maternal Child Health, Osaka; 9) Dept Med Genet, Univ Ryukyus Sch Med, Nishihara, Japan; 10) SORST, JST, Kawaguchi, Japan.

Kabuki (Niikawa-Kuroki) syndrome (KS) is a multiple congenital anomaly (MCA)-mental retardation (MR) syndrome characterized by long palpebral fissures with eversion of the lower eyelids, skeletal anomalies, fingertip pads, short stature, and occasional immune abnormalities. Molecular cytogenetic approaches including genome CGH have failed to reveal the etiology. Recently, germline mutations in genes of the RAS-MAPK pathway were shown to be causes of MCA/MR syndromes, i.e., *PTPN11* in Noonan syndrome; *HRAS* in Costello syndrome; *KRAS*, *BRAF*, *MEK1* and *MEK2* in Cardio-facio-cutaneous syndrome. Because of some similar facial features, we hypothesized that KS may be associated with germline mutations in the RAS-MAPK pathway.

Ten selected candidate genes (*RAF1, ARAF, BRAF, ERAS, NRAS, HRAS, KRAS2, GRB2, PTPN11* and *SOS1*) in the pathway were screened for mutations. DNA was extracted from 31 KS patients (15 females, 16 males), and their entire coding regions and splice junctions were sequenced. Consequently, we did not detect mutations in any of the genes and any patients analyzed. Although our results do not totally rule out their role in KS, candidate gene approaches should be tried, since there has been no clue to identify the putative gene causative for KS, especially those involved in signal transduction in an immune system.

Comparison of the mapping coverage provided by model-free and model-based tagging SNP definitions. *M. Nothnagel[1], A. Wollstein[2], M. Krawczak[1]* 1) Institute for Medicical Informatics and Statistics, University of Kiel, Kiel, Germany; 2) Humboldt University, Institute of Informatics, Berlin, Germany.

Genome-wide association studies are regarded as a major tool for fine-mapping the genetic causes of common diseases. Exploiting information redundancy due to associations between single nucleotide polymorphism (SNP) markers potentially reduces the efforts in terms of time and cost for those studies. Initial methods sought to define haplotype blocks and therein SNPs that distinguish between block haplotypes but this approach is unreliable due to the questionable validity of the block concept. Block-free and model-free methods that consider pairwise linkage disequilibrium (LD) to define tagging SNPs are now a standard tool in association studies. A block-free but model-based method has recently been suggested which additionally takes marker information content and marker distance into account for the selection of tagging SNPs. Using the International HapMap data, we assess the ability of both approaches to provide sufficient levels of LD for mapping hidden causal genetic variation in association studies on a chromosomal scale. We demonstrate that both approaches have similar mapping coverage in high-density marker sets but capture partially different sets of genetic variants. We also show that a considerable loss of information results from use of tagging SNPs with either method compared to the use of all available markers.

Genetic testing in autism: How much is enough? *G.E. Herman, A. Sommer, B. Enrile, M. Pastore, S. Fitzgerald, J. Atkin, K.L. McBride* Children's Research Institute and Dept. of Pediatrics, The Ohio State University, Columbus, OH.

79 unrelated patients referred with a provisional diagnosis of an autism spectrum disorder (ASD) were evaluated between 1/105 - 3/706 in our developmental and genetics clinics. 8 patients were excluded because they did not meet criteria for diagnosis. The remaining 71 patients included 57 males and 14 females (ratio 4.1:1) with an age range of 19 months - 15 years. Macrocephaly (HC95%;) was present in 18 (25%). 28 had a formal psychological evaluation. 50 met DSMIV criteria for autism, with the rest being Asperger or PDD-NOS. There were 5 nuclear and 5 extended families with more than a single individual affected with an ASD, 5 extended families with significant psychiatric disease and 1 with both, by history (23% total). The diagnostic yield of testing was 11% (8/71). Two children had visible chromosome abnormalities - one with 47XYY and one with several small marker chromosomes. 2 patients (ages 2 and 4, respectively) with classic autism and significant macrocephaly had different de novo heterozygous mutations in PTEN. One male with autism was noted to have a submicroscopic duplication, detected by DNA CHIP, but not regular chromosome analysis. The rearrangement was noted in an interstitial region on chromosome 1 that is not associated with a defined genetic syndrome. One parent carried the identical genomic rearrangement. Thus, the relevance of the finding to the etiology of autism in the child remains unclear. Finally, 3 females had Rett syndrome, with DNA sequencing of the MECP2 gene confirming the diagnosis in each. Interestingly, metabolic screening (plasma amino acids, urine organic acids, total homosyteine, plasma/urine guanidinoacetate, sterol profiles, uric acid) produced no positive testing results, nor did Fragile X DNA testing. PTEN gene sequencing should definitely be performed in any autistic or delayed child with significant macrocephaly. Further, careful pedigree analysis is likely to reveal a higher frequency of families with psychiatric disease and/or extended realtives with an ASD. Metabolic screening may not be warranted without more specific indications or additional findings.

Neoplasms in Myotonic Dystrophy. *C. Mueller[1], R.T. Moxley[2], J. Hilbert[2], M.H. Greene[1]* 1) Clinical Genetics Branch, DCEG, NCI, NIH, Bethesda, MD; 2) Department of Neurology, Department of Neurology, University of Rochester Medical Center, Rochester, NY.

Myotonic dystrophy type 1 (DM1) is the most common form of muscular dystrophy in adults, affecting about 1 in 8,000 individuals. In addition to muscular weakness, atrophy and myotonia, there are a myriad of clinical features including cardiac conduction defects, respiratory insufficiency, cataracts, diabetes, reduced immunoglobulins, frontal balding, testicular atrophy, and varying degrees of mental impairment. DM1 is the result of an unstable trinucleotide (CTG) expansion in the 3 untranslated region of the *dystrophia myotonic-protein kinase (DMPK)* gene, located on chromosome 19q13.3. In reflecting on our clinical experience, we have wondered whether there might be an increased incidence of tumors in patients with DM1. There have been multiple case reports of DM1 and pilomatrixoma, a benign calcifying cutaneous tumor thought to be derived from hair matrix cells. We present a comprehensive literature review of reported pilomatrixomas and various other neoplasms that have been observed in patients with DM1. We also present our initial analysis of tumors reported by DM1 patients enrolled in the NIH sponsored National Registry of Myotonic Dystrophy and Facioscapulohumeral Muscular Dystrophy Patients and Family Members. Pilomatrixomas emerged as the strongest candidate for a genuine molecular relationship to DM1, which gained support from the occurrence of pilomatrixomas in patients with Rubinstein-Taybi syndrome and Gardner syndrome, both of which are associated with the development of various neoplasms. The other most common tumor types implicated, based on our findings include thymoma, adenomas of the parotid, pituitary, parathyroid, pancreas and thyroid glands, as well as multiple basal cell carcinomas. This constellation of tumors also led us to our hypothesis that dysregulation of the Wnt/-catenin signaling pathway may be the molecular basis for this relationship, as it has been implicated in the development of pilomatrixomas in the disorders under consideration, in sporadic pilomatrixomas, and in a number of the other neoplasms that have been reported in DM1 patients.

Comprehensive genetic analysis of relevant four genes in 49 patients with Marfan syndrome or Marfan related phenotypes. *N. Matsumoto[1,2], H. Sakai[1], A. Nishimura[1], T. Mizuguchi[1]* 1) Dept Human Genetics, Yokohama City Univ Grad Sch Med, Yokohama, Japan; 2) Solution-Oriented Research for Science and Technology, JST, Kawaguchi, Japan.

In order to evaluate the contribution of FBN1, FBN2, TGFBR1, and TGFBR2 mutations to the Marfan syndrome (MFS) phenotype, the four genes were analyzed by direct sequencing in 49 patients with MFS or suspected MFS as a cohort study. A total of 27 FBN1 mutations (22 novel) in 27 patients (55%, 27/49), one novel TGFBR1 mutation in one (2%, 1/49) and two recurrent TGFBR2 mutations in two (4%, 2/49) were identified. No FBN2mutation was found. Three patients with either TGFBR1 or TGFBR2 abnormality did not fulfill the Ghent criteria, but expressed some overlapping features of MFS and Loeys-Dietz syndrome (LDS). In the remaining 19 patients, either of the genes did not show any abnormalities. This study indicated that FBN1 mutations were predominant in MFS but TGFBRs defects may account for approximate 5-10% of patients with the syndrome.

Mosaic status of lymphocytes in Klinefelter syndrome (KFS). *M. Tanwar[1], R. Prabu[1], R. Kumar[2], N. Gupta[2], K. Kucheria[1], R. Dada[1]* 1) Anatomy, AIIMS, N Delhi, India; 2) Urology Department, AIIMS, N Delhi.

KFS is the commonest genetic cause of Infertility. These cases present with hypogonadism and are generally believed to be azoospermic. Recently few studies have shown that Klinefelter cases have 46, XY cell line and in such cases there may be isolated foci of spermatogenesis. Such cases have better prognosis on assisted reproductive techniques (ART) [If it is followed by preimplantation genetic diagnosis]. So we tried to look for low-level mosaicism in ten infertile Klinefelter patients who did not show features of hypogonadism to identify for presence of normal cell line which could not be identifyied on analyzing twenty metaphases. In these cases we analyzed 150 well spread G banded metaphases in each case and found that two cases showed 4.5% 46, XY cell line.This had not been identified on analyzing 2o metaphase spreads. Klinefelter syndrome shows a variation in phenotype and thus diagnosis is often delayed or patients remain undiagnosed. Early diagnosis by karyotyping allows initiation of testosterone substitution therapy to avoid symptoms of androgen deficiency. This may allow future fertility to be preserved for young Klinefelter patients. The main problem with conventional karyotyping is that routinely 20 metaphases are analyzed and counted, this may miss low-grade mosaicism. Such cases may have a normal 46, XY cell line and may have foci of spermatogenesis, which could be used for TESA in ART. Therefore analyzing a large number of metaphases in such cases with no features of hypogonadism may detect low percentage of 46, XY cell line and such cases carry a good prognosis on ART. Recent techniques like FISH (florescence in situ hybridization) are rapid and sensitive and can help in analyzing a large number of metaphases and interphases cells in short time and can detect cryptic and low level mosacism, which may have been missed cytogenetically. In conclusion, infertile Klinefelter patients with no features of are likely to have low-grade mosaicism with 46,XY normal cell line may have successive sperm retrivel even if such cases are azoospermic.

Insertion/Deletion Polymorphisms in Rajasthan Tribal Populations and Rajputs. *S. Kamboj[1], R. Dada[1], S. Bhardwaj[2], K. Kucheria[1]* 1) Anatomy, AIIMS, N Delhi, India; 2) Dept of Zoology, Banswara, Rajathan.

In recent times, polymorphic DNA markers are widely used to study the genomic diversity of Indian populations as most are selectively neutral, more ubiquitous and have higher heterozygosities than polymorphic protein and enzyme markers. As new alleles are not generated at Alu insertion/deletion loci, and as there is no identified selection pressure on these loci, these loci have gained importance in the study of genetic structures of human populations. In the present study six human - specific insertion/deletion polymorphisms were studied in five endogamous tribal populations, namely Minas, Garasiyas, Damariyas, Sahariyas and Bhils of Banswara and Rajputs of Rajasthan. DNA samples from 222 unrelated individuals were analysed. Of these polymorphic markers five are Alu insertion/deletion markers (Alu PV 92, Alu FX III B, Alu D1, Alu APO, Alu ACE and Alu-CD4), while the sixth marker (mt NUC) pertains to a mitochondrial DNA segment, 540 bp in length, which got inserted into human nuclear genome. The results of this study show that all loci are polymorphic in all three populations. Most of the loci showed high levels of heterozygosity in all three populations. Genetic data allow researchers to determine the relatedness of different racial and ethnic groups and to arrange them in an evolutionary or phylogenetic tree. Special statistical packages will be used for statistical analysis of the data.

A comparison of linear and logistic regression-based methods for disease gene identification. *E.D. Kelly* Hitachi Dublin Laboratory, Hitachi Europe Limited, Dublin 2, Ireland.

Simple tests which seek to identify associations between drug response, disease status and individual genetic polymorphisms have been in use for some time. Recently the focus has shifted to considering extended haplotypes, rather than single loci. The attraction of these more complex methods is in the subsequent increased power of the tests, coupled with the belief that the underlying nature of common diseases and drug responses may only be discovered by considering more complex interactions. Regression-based methods have proved effective and powerful tools for the identification of such associations. Fundamental to the regression-based process is the selection of a suitable model. Clinical data commonly feature a binary response, which mathematically lends itself to the logistic regression model. Logistic regression modelling, however, can pose insurmountable computational problems given certain data, and thus linear models have also been investigated as an alternative. We have developed both logistic and linear regression models which are capable of handling long-chain haplotypes and several non-genetic covariates simultaneously. Here we present the results of a comparison between the two models for a variety of data sets. For each data set and each regression model we perform a number of tests. Initially we test the overall null hypothesis that no independent variable (haplotype or non-genetic covariate) is associated with the response. If the resultant P-value proves significant, then each individual independent variable is tested in turn. For the overall P-value we see strong matching between the two sets of results. For the individual covariates the matching is less marked, though qualitatively similar. This suggests that, given the computational difficulties of increased burden and possible insolubility inherent in logistic regression, linear regression may be the preferred initial option for both quantitative and binary response data. If the overall P-value proves significant, it may then be appropriate to consider, for the binary response, the logistic model for the analysis of the individual independent variables.

Identification of distinct QTLs linked to length or weight variability in humans. *S. Heath*[1], *D. Fradin*[2], *J. Lepercq*[3], *M. Lathrop*[4], *P. Bougnères*[5] 1) Dept Epidem & Biostatistics, Centre National de Génotypage, Evry, France; 2) INSERM U561, Paris, France; 3) EA University Paris V and Department of Gynecology Obstetrics, Paris, France; 4) Centre National de Génotypage, Evry, France; 5) INSERM U561 and Department of Pediatric Endocrinology, Paris, France.

Birth length, as well as birth weight, follows a continuous distribution in a given human population, with macrosomia and smallness for gestational age at the two edges of this distribution. Fetal growth is a complex, dynamic, multifactorial process controlled by maternal, placental and fetal factors including interactions between the fetus and intrauterine environment. To approach the genetic factors implicated in the normal variation of birth length and of birth weight, we conducted a genome-wide approach of these two quantitative traits in 220 French pedigrees (412 sib-pairs) using a variance components method. While birth length and weight showed a powerful phenotypic interaction ($r=0.76$, $p<0.0001$), their genetic variability appeared dependent on distinct QTLs. Birth length was linked to two suggestive QTLs on chromosome 2, which encompassed 6 and 11 consecutive markers on 2q and 2p respectively. The first peak spans ~10cM, with a MLS of 2.69 ($p=2.10^{-4}$). The second peak spans ~12cM, with a MLS of 3.57 ($p=2.10^{-5}$). Ten peaks with LOD scores between 1.0 and 2.2 were seen on chromosomes 7q36, 8p23-p21, 10q21, 13q11 and 17q25. Birth weight variability was linked to a QTL on 7q35 (LOD=3.1, $p=8.10^{-5}$). Several other regions showed peaks with a nominal LOD score for birth weight: twelve peaks with LOD scores between 1.0 and 2.2 were found on chromosome 1p36-p35, 1q42-1q44, 2qter, 6q22-q24, 7p21-p11, 8p22, 10p12-p11, 13q31-q33, 14q11, 15q21, 17q24 and 20p13. These QTLs provide a first step towards the identification of the genomic variants involved in the variability of fetal growth in humans. Because of the risk of false positivity, our results should however be considered preliminary until they are replicated in other studies.

Loss of Sprouty gene function leads to dental anomalies by modulating FGF signaling. *O. Klein[1], G. Minowada[2], R. Peterkova[4], H. Lesot[5], G. Balooch[3], J. Jernvall[6], G. Martin[2]* 1) Pediatrics; 2) Anatomy; 3) Biomaterials, Univ California, San Francisco, San Francisco, CA; 4) Institute of Experimental Medicine, Prague, Czech Republic; 5) INSERM, Strasbourg, France; 6) Institute of Biotechnology, University of Helsinki, Finland.

There is growing evidence that activating mutations in the FGF signaling pathway cause a variety of disorders, such as Apert, Noonan, Costello, and cardiofaciocutaneous syndromes. Dental and craniofacial anomalies are central features of several of these conditions. We have modeled gain-of-function of FGF signaling in mice by inactivating members of the Sprouty family. This gene family encodes intracellular proteins that antagonize FGF signaling downstream of the receptor. Our studies in mice show that two Sprouty family member, *Spry2* and *Spry4*, are essential for the formation of the normal number of teeth. In mice, a toothless gap known as a diastema is present between the incisor and molar regions. During embryogenesis, tooth primordia form in the diastema but cease developing and undergo apoptosis. In both *Spry2* and *Spry4* null embryos, a diastema bud develops into a supernumerary tooth just anterior to the first molar, and these two genes function in different tissues: *Spry2* is predominantly expressed in the epithelium and *Spry4* in the mesenchyme. The formation of supernumerary teeth in *Spry2* null mice can be prevented by reducing the dosage of FGF signaling pathway components, indicating that *Spry2* normally reduces the sensitivity of the diastema bud epithelium to FGF signaling. We propose that Sprouty genes modulate two discrete parts of an epithelial-mesenchymal FGF signaling loop in diastema tooth development. Additionally, we demonstrate that when *Spry2* and *Spry4* are inactivated together, dramatic effects on incisor development are observed. These include ectopic deposition of enamel as a result of abnormalities in regulation of ameloblast stem cells. Thus, Sprouty genes are critical regulators of mammalian tooth development. Given the importance of gain-of-function of FGF signaling in human syndromes, it is possible that loss-of-function of FGF antagonists such as Sprouty contribute to human disorders as well.

Constitutional *BCR* gene deletion; a possible new microdeletion syndrome. *F.M. Mikhail[1], M. Descartes[1], A. Piotrowski[1,2], R. Andersson[3], T. Diaz de Stahl[2], J. Komorowski[3], C. Bruder[1,2], J.P. Dumanski[1,2], A.J. Carroll[1]* 1) Dept. of Genetics, Univ. of Alabama at Birmingham, USA; 2) Dept. of Genetics and Pathology, Uppsala Univ., Sweden; 3) Linnaeus Centre for Bioinformatics, Uppsala Univ., Sweden.

We report a 15-year old boy with history of learning and behavior problems. He was diagnosed with ADHD. Developmental milestones were within normal limits, but performance on the VMI test yielded an age equivalent of 8.4 years. Physical examination showed normal growth with slight facial dysmorphism, including short and narrow forehead, flared eyebrows, up-slanting palpebral fissures, cupped ears with small lobules, short philtrum and short neck. HRB chromosome analysis revealed a normal male karyotype. FISH analysis using the subtelomere probe panel showed normal subtelomeric regions, but TelVysion mixture no. 3 containing the 22q subtelomere probe showed an interstitial deletion of the LSI *BCR* control probe (22q11.2). These results were confirmed using the LSI *BCR/ABL* single fusion translocation probe set. In order to determine if the DiGeorge critical region was included in the deletion, we used the *Tuple1* probe (22q11.2), which showed a normal hybridization signal on both chromosomes 22. Using a 32K BAC array CGH chip, we were able to narrow the proximal and distal breakpoints of the deletion. This interstitial microdeletion was estimated to be 1.4-1.7 Mb in size and to span at least ten genes. Both parents proved to be normal cytogenetically and by array CGH. The patients final karyotype was: 46,XY.ish del(22)(q11.2q11.2)(*BCR*-)dn. This microdeletion region is flanked by LCRs containing several modules with a high degree of homology, and therefore could be implicated in its origin. Interestingly, eight patients with the same interstitial *BCR* deletion have been reported in the literature. Common features reported included developmental delay and hypotonia. Our current case as well as the previously reported cases may represent a new microdeletion syndrome on chromosome 22. Further characterization of the microdeletion boundaries as well as comparison of the phenotype of these patients is currently in progress.

Loss of Heterozygosity in Normal and Pre-neoplastic Lung Tissue from High-Risk Patients. *K.L. Meadows[1], D.M. Ducharme[1], C. Markunas[1], R.J. Slebos[2], M.P. Rivera[3], G.P. Flake[1], P. Stockton[1], J.A. Taylor[1,4]* 1) LMC, NIEHS, RTP, NC; 2) Vanderbilt University, Nashville, TN; 3) UNC Hospitals, Chapel Hill, NC; 4) Epidemiology, NIEHS, RTP, NC.

Lung cancer is the leading cause of all cancer-related deaths. To date, there are no effective, early screening tools to identify individuals at high-risk for developing lung cancer. Loss of heterozygosity (LOH) is a common genetic alteration involved in tumorigenesis. In relation to lung cancer, most LOH analyses have examined only cancer cells. As a result, the timing of early LOH events and the possible correlation of these molecular changes to environmental exposure and neoplastic transformation in the lung have not been well characterized. We established a prospective study to assess LOH in individuals lesions that were serially biopsied over time in a group of people at high-risk for developing lung cancer. During each bronchoscopy, lung tissue biopsies were obtained at any areas of abnormality and four standard sites to obtain normal tissue. Follow-up bronchoscopies were scheduled according to the severity of the histology report. In total, 47 patients enrolled in the study, 106 bronchoscopies were performed and over 400 biopsies collected. We have initiated a comprehensive, genome-wide LOH analysis using the Affymetrix 100K SNP chip to determine if there are specific molecular LOH profiles that may be used to: 1) identify those lesions most likely to histologically progress, 2) identify patients at the highest risk of lung cancer and 3) identify patients who have the highest level of chromosome damage following environmental exposure. Preliminary evidence suggests the presence of LOH in the respiratory epithelium of high-risk individuals without lung cancer. The present study provides a rare resource for the detection of early LOH patterns in individuals at high-risk for developing lung cancer. Accordingly, if histological progression and exposure correlate with specific LOH profiles, then LOH may potentially serve as an effective, early screening tool to identify and monitor those persons at highest risk for this disease.

Gene-gene interaction methods for family-based case-control data. *D.B. Hancock, E.R. Martin, Y.J. Li, W.K. Scott*
Center for Human Genetics, Duke University Medical Center, Durham, NC.

Gene-gene interactions are often assessed in familial case-control data, wherein parent ascertainment is difficult for late-onset diseases. Conditional logistic regression (CLR) and generalized estimating equations (GEE) both test for interactions in families with missing parents but adjust for relatives correlations differently to maintain nominal significance. To compare these methods, we used the SIMulation of Linkage and Association program to create datasets of 700 singleton (affected proband), 200 nuclear multiplex (affected sibpair), and 100 extended multiplex (affected cousin pair) pedigrees with sibship sizes of 3 and with no grandparental/parental genotype data. We created 2 disease loci (D_1,D_2) with relative risks (RRs) for main genetic effects of 3 or 1.5 and joint effects of 10 or 3, respectively. We tested 4 scenarios with 5 biallelic markers: linkage but no association (M_1), linkage and association [M_2 in perfect linkage disequilibrium (LD) with D_1 and M_5 in perfect LD with D_2], association but no linkage (M_2), and no linkage or association (M_4). Interactions between M_5 and each M_1-M_4 marker were tested. We built interaction models in SAS program packages and estimated type I error, power, and average odds ratios (ORs) for CLR and GEE across 1000 replicates. The simulations reflect case-control data, so ORs were used to estimate RRs. Both methods were valid tests of association in the presence of linkage. GEE revealed inflated type I error as a test of linkage in the presence of association (23% for RR=10) but offered more power to detect interaction (100% v. 79% for RR=10, 53% v. 33% for RR=3). GEE also offered more power in datasets of reduced size, imperfect LD, and singleton pedigrees only. With large interaction, CLR produced inflated ORs for interaction (11.9-17.4), while GEE produced underestimated ORs (2.0-4.7). With modest interaction, CLR provided more accurate ORs (2.4-2.8); GEE again underestimated effects (1.3-1.8). These data show that GEE achieves more power to detect gene-gene interactions in families with no parents but appears less robust to cases of association but no linkage and underestimates risk as compared to CLR.

A novel mutation at N-terminal of SMN Tudor domain inhibits its interaction with target proteins. *H. Nishio[1], M.J. Lee[1], T. Kotani[1], R. Sutomo[1], A.H. Sadewa[1], T.H. Sasongko[1], Gunadi[1], M. Matsuo[2]* 1) Department of Public Health, Kobe University Graduate School of Medicine, Kobe-City, Hyogo, Japan; 2) Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe-City, Hyogo, Japan.

More than 95% of patients with spinal muscular atrophy (SMA) are homozygous for deletion of the SMN1 gene. However, a small number of SMA patients bear one SMN1 copy with a subtle mutation within the gene. Such intragenic mutations may be helpful, not only in confirming the diagnosis, but also in elucidating the structural and functional domains of the survival motor neuron (SMN) protein. In this study, we describe a novel mutation identified in two Japanese patients who were clinically diagnosed as having SMA. Combination of denaturing high performance chromatography and sequence analysis using genomic DNA and cDNA showed that they harbored a novel intragenic point mutation in SMN1 exon 3, 275G>C, leading to tryptophan-to-serine substitution at amino acid 92 (W92S) at the N-terminal of the SMN Tudor domain. To test whether the W92S mutation destroys the function of SMN, we studied the in vitro interaction of the Tudor domain with SmB protein and fibrillarin. The mutated Tudor domain showed reduced interaction with these proteins, suggesting that the W92S mutation was responsible for the development of the disease. In conclusion, we report that a mutation at the N-terminal of the Tudor domain affects the interaction of SMN with the target proteins.

Robertsonian translocation and Recurrent ICSI failure. *M. Jena[1], R. Kumar[2], N. Gupta[2], R. Prabu[1], K. Kucheria[1], R. Dada[1]* 1) Anatomy, AIIMS, N Delhi, India; 2) Urology,AIIMS, N Delhi, India.

Chromosomal anomalies have been postulated to be one of the principal genetic factors in reproductive failure. Robertsonian translocation is the most common structural rearrangement of human chromosomes occurring in 1% infertile men. Assisted reproductive techniques have served as a boon for infertile males with severe oligozoospermia. However in the present study we found that of 184 infertile men, 4 men had robertsonian translocation between D/G group. The most common treanslocation was t (13;14) whixch was seen in three cases while the fourth case had t (13;13). All these men were oligozoospermic and had recurrent ART/ICSI failure. The wives of these were cytogenetically normal and had no gynaecological or obstretic abnormality. It has been reported that chromosomal rearrangements, particularly robertsonian translocation, could disturb meiotic disjunction of chromosomes not involved in the rearrangements resulting in a predisposition towards trisomy. During meiosis, the robertsonian translocation chromosomes & the two normal homologue synapse as a trivalent. Alternate segregation produces normal or balanced gametes, while adjacent segregation produces two disomic & two nullisomic gametes. These aneuploid gametes result in difficulty in fertilization, poor blastocyst development and implantation failure. This results in severe emotional , physical and financial stress to the couples.These results highlight the need for cytogenetic investigation in the infertile men who opting for ART, as this will help in providing most adapted therapeutics and counseling to such men.

Identification of a unique Alu-based polymorphic locus and its use in human population studies. *D. Kass, N. Jamison, M. Mayberry, E. Tecle* Department of Biology, Eastern Michigan Univ, Ypsilanti, MI.

Alu elements comprise a retrotransposon family of short interspersed DNA elements (SINEs) found in primate genomes. Recent integrations of Alu elements within the human genome have generated presence/absence variants useful as DNA markers in human population studies as well as in forensic and paternity analyses. Besides the ease of use, this type of marker is unique because the absence of the Alu element represents the ancestral form. We have identified a novel Alu-based polymorphic locus that consists of four alleles in which we can predict their evolutionary order. Additionally, we have developed a simple and rapid assay for genotyping individuals for this locus. Thus far, we have analyzed DNA samples comprising four different ethnic groups with at least seventeen samples per group. We have observed variability that was not originally found by simply analyzing the presence/absence forms of this marker. Among the results, all four alleles were common in the African American population, whereas one allele was not found in the Asian population and a different allele was absent in both the European Caucasians and South Americans. The distinctive features of this marker in conjunction with the use of a simple assay system, as well as the initial findings, afford this marker as a unique tool in the study of both global and regional analyses of human populations.

RET proto-oncogene genotyping using unlabeled probes, the masking technique and amplicon high-resolution melting analysis. *R.L. Margraf[1], R. Mao[1,2], W.E. Highsmith[3], L.M. Holtegaard[3], C.T. Wittwer[1,2]* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Department of Pathology, University of Utah Medical School, Salt Lake City, UT; 3) Molecular Genetics Laboratory, Mayo Clinic, Rochester, MN.

Single base pair mutations in the *RET* proto-oncogene can cause multiple endocrine neoplasia type 2 syndromes. The conventional approach for genotyping *RET* mutations is sequencing the exons. A closed-tube *RET* proto-oncogene genotyping assay using a saturating DNA dye, unlabeled probes, and amplicon high-resolution melting analysis was developed. The method required two sequential PCR stages, a primary and secondary assay. The primary assay analyzed *RET* exons 10, 11, 13, 14 and 16 with a total of seven reactions using eight unlabeled probes. The primary assay genotyped wild type exons, a common exon 13 polymorphism and an exon 16 mutation, while other *RET* sequence variation was detected. The primary unlabeled probe data limited the possible genotypes for the detected *RET* sequence variation, which permitted genotyping in a secondary assay with only two to five reactions. Six probes were designed with the masking technique and masked selected sequence variations to allow unambiguous analysis of other mutations elsewhere under the probe. After this two-stage *RET* assay, less than 0.2% of exons tested would require sequencing for genotype. A blinded study generated from 5 wild type and 29 available *RET* sequence variation samples was 100% concordant with sequencing. Amplicon high-resolution melting analysis with unlabeled probes and the masking technique is a fast, accurate method for genotyping the >50 *RET* sequence variations.

Heredity of endothelin secretion: Human twin studies reveal the influence of polymorphism at the chromogranin A locus, a novel determinant of endothelial function. *E.O. Lillie, M. Mahata, S. Khandrika, F. Rao, R.A. Bundey, G. Wen, L. Taupenot, B.K. Rana, D.W. Smith, S.K. Mahata, M.G. Ziegler, N.J. Schork, D.T. O'Connor* University of California San Diego, La Jolla, CA.

Background. Endothelial dysfunction predisposes to vascular injury in association with hypertension. Endothelin (ET-1) is a potent vasoactive peptide that is synthesized and released by the vascular endothelium and is a marker of endothelial function. Chromogranin A (CHGA) regulates the storage and release of catecholamines, and may also have direct actions on the microvasculature. CHGA is a candidate gene for intermediate phenotypes that contribute to hypertension, and shows a pattern of SNP variations that alter the expression and function of this gene, both in vivo and in vitro. **Methods and Results.** In a study of twins (N=239 pairs), plasma ET-1 was 58+/-5% ($p<0.0001$) heritable. Plasma ET-1 was both correlated and associated with chromogranin fragment levels, and the two were influenced by shared genetic determination (rhoG=0.318+/-0.105,p=0.0032). We therefore hypothesized that variation in the CHGA gene may influence ET-1 secretion. Carriers of the CHGA promoter -988 G, -462 A, and -89 A alleles showed significantly higher mean plasma ET-1 than their major allele homozygote counterparts (p=0.02, 0.006, 0.03 respectively). Analysis of a linkage disequilibrium block that spans these 3 SNPs showed a significant association between the GATACA haplotype and plasma ET-1 (p=0.0075). In cultured human umbilical vein endothelial cells (HUVEC), CHGA caused dose-dependent secretion of ET-1. **Conclusions.** These results suggest that common, heritable variation in expression of the human CHGA gene influences endothelial ET-1 secretion in vivo, explained by a CHGA stimulus/ET-1 secretion coupling in endothelial cells in vitro. The findings document a previously unsuspected interaction between the sympathochromaffin system and the endothelium, and suggest novel genetic and cell biological approaches to the prediction, diagnosis, and mechanism of endothelial dysfunction in human disease.

Biological evidence of skeletal dysplasia in ancient Egypt. *C. Kozma* Department of Pediatrics , Georgetown University Hospital, Washington , DC.

The ancient Egyptian civilization originated along the banks of the Nile River spanning three thousand years before the Christian era. Through the monuments and records left by ancient Egyptians, we are well informed about many aspects of their culture including the existence of skeletal dysplasia and in particular achondroplasia. The artistic documentation of dwarfs is plentiful including hundreds of objects. Dwarfs gained a sacred status and two key gods, Bes and Ptah, were dwarfs. The hot and dry climate allowed for excellent preservation of bodies and as a result, Egypt has several partial and complete skeletons of dwarfs. Some skeletal remains are catalogued and published in the medical and archeological literature and some are known from excavators account. There was a burial area near the great Pyramids for high-ranking dwarfs. A skeleton of a female dwarf from the Old Kingdom (2686-2190 BCE) was found with a babys remains in situ. It is believed that she died during delivery. The Badarian skeleton, which dates back to 4500 BCE, is an example of short limbed dwarfism possibly representing an epiphyseal disorder. The remains of dwarfs from ancient Egypt are also present in British museums. They are in the Natural History Museum in London, in Cambridge University, and in the Institute of Archeology. The British Museum has a complete skeleton of a child who was affected with osteogenesis imperfecta. Furthermore, the Natural History Museum has a partial skeleton with osteogenesis imperfecta and a skeleton possibly affected with mucopolysaccaridosis. The ancient Egyptians followed a strict moral conduct as documented in their Wisdom Teaching. Amenemope, a wise man who lived in 1391-1354 BCE said: Beware of stealing from a miserable man, and of raging against the cripple. Do not stretch out your hand to touch an old man, Nor snip at the words of an elder. He moreover recommended respect and tolerance for individuals with disabilities: Do not jeer at a blind man nor tease a dwarf, Neither interfere with the condition of a cripple. Do not taunt a man who is in the hand of God, Nor scowl at him if he errs.

Expression Analysis of Mouse Atherosclerotic Aorta Revealed Significant Dysregulation of Genes in the Calcium Signaling Pathway. *S.K. Mak[1], B. Teng[2], L.C. Shimmin[1], J.E. Hixson[1]* 1) HMG,UT-Houston,Health Sciences Center, Houston, TX; 2) IMM,UT-Houston, Health Sciences Center, Houston, TX.

Atherosclerosis susceptibility results from the interaction of several genetic and environmental risk factors. Our lab generated a LDLR-/-/Apobec1-/-atherosclerotic mouse model(LDb)which had elevated plasma LDL cholesterol profile as in human disease. Aortic lesions of LDb mice at 2-and 8-month old fed on a chow diet had a 0.20% and 20.6% lesion, respectively and a 0.20% and 29.7% when fed on a high fat diet. Histological analysis showed that these lesions were predominantly clustered in the aortic arch where disturbed shear stress(DSS)was implicated. In this study we use a global gene expression approach to identify regulatory pathways that are significantly impacted by the interaction of age,diet,DSS and strain. Mice(n=32)were fed either chow or high fat diet and sacrificed at age 2-and 8-months. RNA was isolated from aortic DSS and non-DSS regions. Using 64 murine Affymetrix chips with 45,000 genes, we profiled differentially expressed genes that have p-value of 0.01,fold change 1.5, FDR 0.05, and analyzed the data by the t-test and ANOVA. Significant genes were subjected to pathway analysis by Pathway Express to assess the significance of differentially regulated pathways in atherosclerosis. This Pathway analysis identified calcium signaling as the leading pathway in which a significant proportion of the genes are differentially regulated in atherosclerosis. Out of 180 genes in the KEGG calcium signaling pathway, we identified 55 genes that are differentially regulated. The expression fold changes were confirmed by real time PCR. In addition,8-month old LDb aortic sinus stained with Alazarin Red indicated positive calcified lesions. Functional annotation further revealed that many of these genes have been implicated in cardiovascular disease. Our study demonstrates that calcium signaling pathway are significantly altered in atherosclerosis. However, further biological and clinical study of calcium signaling genes is needed to assess its role in cardiovascular disease. Clinically, this pathway may serve as an important target for future therapeutic intervention.

Analysis of Segmental DNA Changes in Cancer using GSP-Array7700. *Y. Murayama[1], S. Ozawa[2], S. Asakawa[1], Y. Saikawa[2], H. Hasegawa[2], H. Jinno[2], K. Aiura[2], A. Takayanagi[1], M. Maekawa[3], M. Kitajima[2], N. Shimizu[1]* 1) Dept. Mol. Biol., 144-8 Ogura Saiwai-ku, Kawasaki, Kanagawa, Japan; 2) Keio University School of Medicine, Department of Surgery, Tokyo, Japan; 3) GSP Lab. Inc., Japan.

BAC microarray-based comparative genome hybridization (CGH) provides a highly efficient method to detect deletion or amplification of specific DNA segments in the genomes at individual chromosome basis. We constructed human BAC library (Keio BAC library) in 1994 and since then we have utilized it for the genomic DNA sequencing of human genome. To develop a high resolution BAC microarray, we read the end-sequences of 10,000 BAC clones, mapped them on the human chromosomes using the updated genome sequence data (Build35), and selected 7,718 BAC clones. Then, these BAC-DNAs were spotted on a glass microscope slide in triplicate (GSP-Array7700) so that the resolution of the GSP-Array7700 is about a BAC probe/400kb throughout the human genome. We employed the GSP-Array7700 to detect segmental DNA copy number changes in cancer cells and tissues including epidermoid carcinoma A431 cells, TE-series esophagus cancers cells, and esophagus cancer tissues from patients. We in fact detected copy number changes of various DNA segments, some of which corresponded to oncogenes such as EGFR and CCND1 and suppressor genes such as FAT3. Further analysis of these data would provide new information on the cancer related marker genes.

Homozygosity mapping in the Old Order Amish identifies a region of Chromosome 3 as linked to obesity related traits. *P.F. McArdle[1], J.R. O'Connell[1], A.R. Shuldiner[1,2], B.D. Mitchell[1], M. Abney[3]* 1) School of Medicine, University of Maryland, Baltimore, MD; 2) Geriatrics Research and Education Clinical Center, VA Hospital Medical Center, Baltimore MD; 3) Departments of Human Genetics and Statistics, University of Chicago, Chicago, IL.

We performed genome wide homozygote by descent (HBD) linkage scans of several obesity related traits in an Old Order Amish population from Lancaster, PA (n = 743 subjects). Our analyses relied on a non-zero probability of having parents share at least one common ancestor in this young founder population. The conditional probability of being HBD was based upon complete pedigree information and an individuals multi-locus genotype and was included as a fixed effect in a linear variance component model. We detected consistent linkage to chromosome 3q26 for several obesity related traits including BMI, total cholesterol, LDL, and leptin. Our highest peak in the region was to total cholesterol at 196cM (LOD = 2.2). There was little or no evidence for linkage within this region to the same traits in our standard variance components linkage analysis, although we and others have previously observed linkage of this region with plasma adiponectin levels. Among the relevant candidate genes in this region are APM1, which encodes the gene for adiponectin, and PSARL, variants in which have been shown to be associated with type 2 diabetes and the metabolic syndrome. These analyses suggest that HBD mapping in relevant populations may be a useful technique for mapping complex disease genes. Further investigation is required to determine if variants in the adiponectin gene or other genes are responsible for the HBD linkage to obesity related traits.

Linkage analysis using GeneChip Microarray maps a possible locus for Crohn's disease to chromosome 3p. *N. Magal[1], R. Rahav[1], R. Shapiro[3], T. Shohat[2], M. Shohat[1,2]* 1) Department of Medical Genetics, Rabin Medical Center and Felsenstein Medical Research Center, Petah Tikva, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Israel; 3) Schneider Childrens Medical Center, Institute of Gastroenterology, Hepatology and Nutrition, Petah Tikva, Israel.

We report a large Israeli family in which six out of 12 children have severe Crohn's disease. A dense genomewide linkage search of the family was undertaken using Affimetrix GeneChip Human Mapping 10K array. Initial analysis was performed on DNA from the six affected family members and their parents. The results showed several regions with the same haplotype in all the patients in more than six SNP's in a row. All these regions were excluded except for one locus on chromosome 3p, which was identified in previously published association studies as a candidate locus for Inflammatory Bowel Disease. This interval, which was found to contain the same SNPs profile in all the patients, is 24Mb long and contains 123 genes. Further haplotype analysis using polymorphic markers within this region in affected and unaffected family members enabled us to confirm that all the patients shared the same two alleles, while four out of the six unaffected siblings had a different haplotype. A maximum lod score of 1.8 (theta = 0.00) was found at marker D3S1263. Other known candidate loci for Inflammatory Bowel Disease were analyzed and excluded according to their SNP's profile. The TGF-bR2 (transforming growth factor, beta receptor II) gene, located in this interval, was sequenced but no mutation was detected. This study identified a possible new locus responsible for Crohn's disease located on chromosome 3p.

Biochemical and molecular analysis of 14 patients with thiamine-responsive pyruvate dehydrogenase deficiency.

E. Naito[1,2], M. Ito[3], I. Yokota[3], Y. Kotani[1], K. Shinahara[1] 1) Dept of Pediatrics, Institute of Health Biosciences, The University of Tokushima, Tokushima, Japan; 2) Division of Pediatrics, Tokushima Red Cross Hinomine Medical and Rehabilitation Center, Tokushima, Japan; 3) Dept of Pediatrics, Kagawa Natl Childrens Hosp, Kagawa, Japan.

We report biochemical and molecular analysis of 14 patients with thiamine-responsive pyruvate dehydrogenase complex (PDHC) deficiency. PDHC activity was assayed using two different concentrations of thiamine pyrophosphate (TPP) in cultured lymphoblastoid cells or cultured fibroblasts from 14 patients. These 14 patients displayed very low PDHC activity in the presence of a low ($1x10^{-4}$ mM) TPP concentration. These PDHC activities increased at a high (0.4 mM) TPP concentration. Especially, PDHC activity of seven patients increased within normal range. Therefore, PDHC deficiency in 14 patients was due to a decreased affinity of PDHC for TPP. Treatment with a high dose of thiamine resulted in a reduction in lactate and clinical improvement in these patients, suggesting that these 14 patients have a thiamine-responsive PDHC deficiency and a high dose of thiamine is very effective for patients with this type of PDHC deficiency. The DNA sequence of these patients X-linked E1 subunit revealed a point mutation in all 14 patients including 7 patients in exon 3, one patient in exon 4, one patient in exon 5, two patients in exon 7, and three patients in exon 8 . Seven patients (V71A, R88C, G96S, C101F, S152P, L216F, and L260Q) of them were novel. Two mutations (L216F and R263G) were found in the genomic DNA of the patients mother, and the PDHC activity of these two mothers was decreased in the presence of a low TPP concentration. Half of 14 patients with thiamine-responsive PDHC deficiency were caused by mutations in exon 3 of E1 subunit gene. Therefore, exon 3 in the E1 subunit gene appears to be important in thiamine-responsive PDHC deficiency.

Development and evaluation of a novel single nucleotide polymorphism panel to detect hidden population substructure in individuals of European ancestry. *K.K. Nicodemus[1,2], Y. Yao[2], I. Giegling[3], D. Rujescu[3], N. Stefanos[4], C. Stefanis[4], D.R. Weinberger[1]* 1) GCAP, CBDB/NIMH/NIH, Bethesda, MD; 2) Epidemiology, Johns Hopkins SPH, Baltimore, MD; 3) Psychiatry, Ludwig Maximilians University, Munich, Germany; 4) University Mental Health Research Institute, Athens, Greece.

Several recent disease association studies have demonstrated population stratification (PS) in European-based populations. When genetically distinct subpopulations are unknowingly differentially sampled in cases and controls and the disease rate varies between the subpopulations, false positive association signals may be spuriously inflated and true association may be masked or reversed. Statistical methods have been proposed to detect PS using randomly selected genetic markers. Markers chosen to be ancestry informative may be more effective to detect PS. We selected SNPs likely to be informative in persons of European ancestry using the following SNP sets: ancestry informative SNPs, SNPs under selection in European populations (e.g., LCT), skin pigmentation SNPs, forensic identification SNPs, SNPs reported to be most informative for population ancestry and SNPs with > 10% difference in allele frequency in European samples (ALFRED) for a total of 141 SNPs. Study populations included: western European (German), southern European (Greek), European American (EA), HapMap CEPH trios and the NIMHGI EA schizophrenia families (N=3,538). A Bayesian method and a latent-class method were used to detect PS. Preliminary results suggest the German and EA samples were similar based on skin pigmentation SNPs; however, the NIMHGI family sample showed a higher proportion of ancestral skin pigmentation alleles than other European samples. We are currently examining all subsets of SNPs and evaluating the entire panel for informativeness of PS in European-based populations. In addition, we present a novel method (Genomic Matching) to control PS: cases are matched to controls who share a high proportion of genotypes from our SNP panel before performing association tests. Simulation studies are being conducted to assess how the proposed method performs versus current structured association methods to control for confounding due to PS.

Non-invasive genotyping fetal Kell blood group (KEL1) using cell-free fetal DNA in maternal plasma by MALDI-TOF mass spectrometry. *Y. Li[1], K. Finning[2], G. Daniels[2], W. Holzgreve[1], S. Hahn[1]* 1) Department of Research, University of Basel, Basel, Switzerland; 2) International Blood Group Reference Laboratory, National Blood Service, Bristol, UK.

Alloimmunization against the fetal Kell (KEL1) blood group antigen is gaining in importance and is the second most important cause of haemolytic disease of the newborn (HDN). The KEL*1 gene differs from the highly prevalent KEL*2 allele by a C-to-T base substitution in exon 6, thereby encoding threonine instead of methionine at residue 193. Currently, prenatal diagnosis of KEL1 involves invasive procedures, such as amniocentesis and chorionic villus sampling, which present a risk for both fetus and mother. The discovery of fetal cell-free DNA (cf-DNA) in maternal plasma provides the possibility for non-invasive prenatal diagnosis. However, the detection of fetal gene point mutations is difficult when using conventional PCR-based methods, due to the overwhelming presence of maternal cf- DNA sequences. In this context, it has recently been shown that the MALDI-TOF mass spectrometry-based single allele base extension reaction (SABER) assay may permit the detection of paternally inherited fetal SNPs from cf-DNA in maternal plasma. In this study, we examined KEL*1 from KEL:-1,2 pregnant women using the MALDI-TOF MS-based SABER assay. Thirty maternal plasma samples at risk for KEL1-alloimmunization were taken at 14-35 (mean: 22.8) weeks of gestation. The results were confirmed by serological tests on cord blood or PCR typing on amniocyte-derived fetal DNA. We detected the fetal KEL*1 allele in 11 of the 13 KEL1-positive samples (85% sensitivity). In total, the presence or absence of the paternal KEL*1 allele could be correctly determined in 93% of cases (28/30). Therefore, the MALDI-TOF mass spectrometry-based SABER assay may be useful for the detection of the fetal KEL1 status, but needs to be improved for clinical application. More precise methods, such as size fractionation of cf-DNA approach, might help improve the detection.

Slow acetylator genotype at the N-acetyltransferase 2 gene is a key predictor for adverse events by an anti-pneumocystis drug co-trimoxazole in patients with systemic lupus erythematosus. *N. Kamatani[1], M. Soejima[1], T. Sugiura[1], M. Kawamoto[1], Y. Katsumata[1], K. Takagi[1], A. Nakajima[1], T. Mitamura[2], A. Mimori[3], M. Hara[1], Y. Kawaguchi[1]* 1) Div Genomic Med, Tokyo Women's Med Univ, Tokyo, Japan; 2) Div Inernal Med, JR Tokyo General Hospital, Tokyo, Japan; 3) Div Internal Med, Internatinal Medical Center of Japan, Tokyo, Japan.

Objective. For the individual optimization of the co-trimoxazole (anti-pneumocystis drug) therapy in the patients with systemic lupus erythematosus (SLE), we investigated the genomic polymorphisms in the gene coding for N-acetyltransferase 2 (NAT2). Methods. 51 patients with SLE to whom prophylactic dose of co-trimoxazole had been administered were enrolled in a cohort study, and 54 patients including additional 3 patients who had suffered from severe adverse events by TMP - SMX were analyzed as a case-control study. Haplotypes were estimated using the PENHAPLO program by the EM-based maximum likelihood method to see whether the individuals possess NAT2*4 (wild-type) haplotype that renders the subjects the fast acetylator phenotype. Results. Adverse events occurred in 18 of the 51 SLE patients (35.3%) in the cohort study. Genotyping analysis followed by the haplotype inference of the NAT2 gene indicated that the numbers of fast (with NAT2*4 haplotype) and slow (without NAT2*4 haplotype) acetylator diplotype configurations (combinations of haplotypes) were 44 and 7 patients, respectively. Five (71.4%) out of 7 patients with slow acetylator diplotype configuration experienced adverse events, and the frequency was significantly higher than that in the patients (13/44, 29.5%) carrying fast acetylator diplotype configuration (P = 0.045, RR = 2.42, 95% CI = 1.26-4.65). In the case control study, the frequency of slow acetylator diplotype configuration was significantly higher in patients with severe adverse events (3/5, 60%) than in patients (6/49, 12.2%) without severe adverse events (P = 0.028, OR = 10.7, 95% CI = 1.4-78.0). Conclusions. The NAT2 slow acetylator diplotype configuration as inferred by the EM algorithm is an important predictor of adverse events by co-trimoxazole in the patients with SLE.

A Japanese case of Oto-palato-digital syndrome type II: an apparent lack of phenotype-genotype correlation. *T. Kondoh[1], N. Okamoto[2], N. Norimatsu[1], H. Moriuchi[1]* 1) Dept Pediatrics, Nagasaki City, Nagasaki Univ Sch Medicine, Nagasaki, Japan; 2) Dept Planning and Research, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan.

Oto-palato-digital (OPD) syndrome is characterized by hearing impairment, cleft palate, deformities of extremities and characteristic facies including frontal bossing, marked micrognathia, hypertelorism and downslant palpebral fissures. OPD syndrome is classified into two types from the aspect of clinical severity, OPD I (mild form) and OPD II (severe form). Filamin A gene (FLNA) is the causal gene of OPD I and OPD II as well as Melnic-Needles syndrome and frontometaphyseal dysplasia; however, it is not clear why mutation of the same gene results in different clinical entities. We here report a 12-year-old Japanese boy with OPD II. He was born as the first child of nonconsanguineous healthy parents at 41 weeks and two days of gestation with weight and length of 3,068 g (-0.3 SD) and 50.0 cm (+0.3 SD), respectively. He had various anomalies at his birth, bilateral cataracts, bilateral glaucoma, bilateral severe hearing impairment, congenital heart defect, umbilical herniation, bowling extremities and constrictions of various joints. These clinical features and the whole body X-ray findings were compatible of OPD II. He was also complicated with respiratory failure due to deformed chest and adenoid hyperplasia, urinary tract stenosis, apnea attack and poor weight gain. His mental development cannot be assessed exactly because of skeletal anomalies, hearing loss, and near total blindness. His karyotype was normal, 46,XY. FLNA analysis by ordinary PCR-direct sequencing method showed a C586T (R196W) missense mutation in exon 3. Another patient who also had the R196W mutation was reported previously; however, his clinical phenotype was OPD I (mild form). In addition, a patient with a C586G (R196G) mutation was previously reported as OPD II. Thus, phenotype-genotype correlation of OPD is not clear in those patients. Further clinical and genetic studies are needed to clarify the relationship between phenotype and genotype, or to identify other factor(s) that influence the clinical features.

Nodular hidradenocarcinoma: molecular cytogenetic analysis of a sweat gland tumor in a young male. *B. Horst[1], S. Volpert[2], Ch. Lee[1], HJ. Schulze[3], J. Atzpodien[4], J. Tchinda[5]* 1) Department of Pathology, Columbia University Medical Center, New York, NY; 2) Institut für Humangenetik, Universitätsklinikum Münster, Germany; 3) Fachklinik Hornheide, Department of Dermatology, Münster, Germany; 4) Fachklinik Hornheide, Department of Medicine Oncology, Münster, Germany; 5) Brigham and Womens Hospital, Harvard Medical School, Boston, U.S.A.

Hidradenocarcinomas are among the least common adnexal tumors of uncertain origin. They range from locally recurring, low-grade well differentiated tumors to highly aggressive tumors with potential for local destruction and distant metastasis to lymph nodes, bone and lungs. Data on cytogenetic analysis of these tumors are very limited. Here, we report the case of a 29-year-old man presenting with a nodular hidradenocarcinoma of the toe and filia to the lung. We used array comparative genomic hybridization (aCGH) on paraffin embedded tissue to characterize the tumor. An approximately 39.2 Mb large deletion of the long arm of chromosome 14 was detected as the sole DNA copy number change related to the tumor. The deletion of cell cycle and RNA transcription regulators in this genomic area may have been contributory to tumor formation in this patient. The patient is doing well with no sign of recurrence two years and five months after surgical resection of the primary tumor and lung metastasis.

Hemophilia A: molecular defects and mutation detection rate in severe, mild and moderate affected patients. *J. Horst[1], A. Markoff[2], R. Eisert[4], C. Wermes[4], H. Pollmann[5], A. Todorova[6], U. Nowak-Göttl[3], N. Bogdanova[1]* 1) Chairman, Inst Human Genetics, Univ Muenster, Muenster, Germany; 2) Institut für Medizinische Biochemie, Münster, Germany; 3) Pädiatrische Hämatologie und Onkologie, Münster, Germany; 4) Pädiatrische Hämatologie und Onkologie, Hannover, Germany; 5) Hämophilie Zentrum, Münster, Germany; 6) Laboratory of Molecular Pathology, Sofia, Bulgaria.

Hemophilia A (OMIM 306700) is the most frequent X-linked bleeding disorder affecting 1 to 2 per 10 000 males worldwide. Recently we showed that the mutation detection rate in severely affected male patients is virtually 100% when testing for the common intron 22- / intron 1- inversions and big deletions, followed by genomic sequencing of the F8 gene. We also showed that protein truncating molecular defects are prevalent in those patients [Bogdanova, Markoff et al., 2005, Hum Mutat 26(3):249-54]. Here we report on the spectrum of mutations and their distribution throughout the F8 protein in 136 moderately (n=24) or mildly (n=112) affected patients with hemophilia A. The performed sequencing analysis revealed a molecular defect in 121 (89%) of the patients, whereas 15 (11%) had no mutation in the coding region of the F8 gene, in the exon/intron borders or in the promoter region. All negative patients were mildly affected with exception of one patient with FVIII:C 2-3%. Thirty six of the mutations identified are novel. The vast majority of the detected mutations were missense mutations (n=104). Two molecular changes in the promoter region of the factor VIII gene were detected in two patients with mild hemophilia A. To our knowledge this is the first report on promoter mutations in the F8 gene. Our data show that, in contrast to severe hemophilia A, the analysis on the genomic level fails to detect the molecular defect in about 4% of the moderately and in 12.5% of the mildly affected patients. We postulate that in a part of these patients the reduction of the F8 activity is due to defects in other steps of the coagulation cascade.

Cole-Carpenter as a severe skeletal dysplasia. *G. Nishimura[1], M. Takeuchi[2], M. Nakayama[2], G. Knopfle[3], A. Superti-Furga[4], B. Zabel[4], S. Unger[5]* 1) Department of Radiology, Tokyo Metropolitan Kiyose Children's Hospital, Tokyo, Japan; 2) Department of Pathology, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 3) Institute of Pathology, University Hospital of Bonn, Bonn, Germany; 4) Centre for Pediatrics and Adolescent Medicine, University of Freiburg, Freiburg, Germany; 5) Institute for Human Genetics, University of Freiburg, Freiburg, Germany.

In 1987, Cole and Carpenter reported 2 unrelated children with a previously unrecognized phenotype whose main findings were bone fragility and craniosynostosis. The authors called this disorder a newly recognized type of osteogenesis imperfecta. However, since type 1 collagen analysis was normal, this condition has subsequently been labeled the Cole-Carpenter syndrome (MIM112240). Since that first report, only a few cases have been described and only one which had clinical/radiographic findings closely matching the original patients (Amor et al., 2000). However, unlike the first 2 patients, this third patient was detected prenatally and was abnormal at birth with osteopenia, bowing of the femurs, and a single rib fracture. We report a further 3 sporadic cases who had in utero bowing of the limbs and were suspected of having osteogenesis imperfecta. After delivery, they were found to have pronounced proptosis and midface hypoplasia suggesting craniosynostosis. Post-mortem radiographic examination revealed a strikingly consistent picture of generalized osteopenia, mid-shaft femoral fractures without bone thickening, bowing of femurs, tibias, and fibulas, as well as beaded ribs. Of note, the clavicles were also affected (short, thick, and misshapen) and the sacrosciatic notches were abnormally wide. This case series confirms that (1) the Cole-Carpenter bone fragility-craniosynostosis syndrome is a distinct entity with radiographic findings that allow differentiation from osteogenesis imperfecta; (2) while the two original cases were ascertained in infancy, severe cases can be detected prenatally. Since fetuses with bone fragility tend to be diagnosed as OI, the incidence of Cole-Carpenter syndrome may have been underestimated so far.

Multi Information for Measuring Linkage Disequilibrium among Multiple Loci and its Applications. *L. Luo, M. Xiong* Biostatistics, University of Texas - Houston, Houston, TX.

Measure of linkage disequilibrium (LD) between two loci is a fundamental quantity in genetics and plays an essential role in population genetics, statistical genetics and genetic epidemiology. The traditional LD measures, such as , although they have been applied successfully to genetic studies of complex diseases, they have serious limitations in providing overall information about LD among multiple loci due to the pair-wise feature of the traditional LD measures. Very few generally accepted measures of LD among multiple loci exist in the literature. To develop simple, but efficient measure of LD at multiple loci is urgently needed. In this report, we present a novel concept of multi information that is the extension of mutual information between two variables to measure LD among multiple loci. We demonstrate that multi information on multiple markers is a simple function of pair-wise as well as high order LD among the multiple markers. We also develop conditional multi information and formula for recursively computing multi information. To facilitate the application of multi information in population genetics and association studies of diseases, we investigate their properties and derive his asymptotical distribution. The mean and variance of multi information as well as the relationships with the parameters in the population genetics are also studied. To evaluate the performance of the multi information for measuring LD among multiple loci, we apply it to a HapMap data set. Our computational results from the real data coincide with the theoretical results and demonstrate its widely potential application as a powerful tool in evolution of populations and association studies of diseases.

An analysis of the *GRIK2* Modifier effect in Huntingtons disease. *S. Kishikawa[1], W. Zeng[1], T. Gillis[1], L. Djoussé[2], R.H. Myers[2], M.E. MacDonald[1], J.F. Gusella[1]* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Department of Neurology, Boston University School of Medicine, Boston, MA.

Huntingtons disease (HD) is an autosomal dominant late-onset neurodegenerative disorder caused by an expanded polyglutamine tract in the huntingtin protein. Human genotype-phenotype studies show that while age at neurological onset is primarily determined by polyglutamine length, it is also altered by genetic modifiers. *GRIK2*, which encodes the GluR6 subunit of kainate receptor, is currently the only genetic modifier of HD that has been specifically identified and confirmed in multiple independent studies. Our previous study revealed that affected individuals who have the relatively rare 16 TAA repeat allele in *GRIK2* 3 UTR show an average 5.5 years younger onset age compared with those with other TAA repeat alleles. To identify the mechanism of the genetic modifier effect of *GRIK2*, we checked the sequences of all *GRIK2* exons and flanking regions in four individuals, three with 16 alleles and one with a more extreme 17 TAA repeat allele, all with much earlier age at onset than expected from the length of their HD CAG mutation. Sequencing of all exons showed no coding sequence or boundary changes in the HD samples. Haplotype analysis using microsatellites and SNPs in *GRIK2* suggested no common ancestral origin for the similar TAA repeat alleles, suggesting that the TAA allele itself, rather than a linked polymorphism, is responsible for the modifier effect, possibly through a regulatory effect at the level of *GRIK2* RNA. We have confirmed expression levels of 6 alternative splice variants of *GRIK2* in regions of normal human brain by RT-PCR. Two of the these represent the major isoforms found in human brain and their relative proportions did not vary across brain region, including striatum. We next plan to test the effect of different TAA alleles on the proportion of the *GRIK2* splice and editing forms present in normal and HD brain.

Effects of Raspberries on cAMP-responsive element modulator (CREM) Expression in Rat Testes. *B.H. Lee, H. K. Lee, W.M. Yang, W-N. Kim, D. R. Kim, W. Park, S.K. Park* Prescriptionology, Kyung Hee Univ. College of Oriental Medicine, Seoul, Korea.

Rubi Fructus (RF), the dried unripe fruit of raspberries is used to manage impotence, spermatorrhea, enuresis, asthma, and allergic diseases; it has also been used as a stomachic and tonic in Korean medicine. Rats were treated RF for 56 days consecutively. Animals were sacrificed and the testes were removed. Total RNA was extracted from rat testes using Trizol method. Then we carried out Western blotting assay using anti-CREM antibody. CREM mRNA levels were significantly increased in testes from the rats treated with RF (p 0.05). The relative expression of CREM mRNA in the RF treated group was 189% than that in the normal group. There was significantly enhanced expression of CREM-immunoreactive bands in the RF treated group compared to the vehicle treated group (p 0.05). The relative expression of CREM in the RF group was 112% than that in the normal group. This result confirmed mRNA data. In conclusion, RF has an enhancing effect of CREM expression in rat testes both at mRNA and protein level. These results suggest that RF may have an effect on proliferation and differentiation of germ cells closely related with CREM gene expression.

The Fruit of *Cornus officinalis* Enhances Expression of cAMP-responsive element modulator (CREM) in Rat Testes. *W-N. Kim, J.H. Lee, W.M. Yang, B.H. Lee, D.R. Kim, W. Park, S.K. Park* Prescriptionology, Kyung Hee Univ. College of Oriental Medicine, Seoul, Korea.

Corni Fructus (CF), the fruit of *Cornus officinalis* has long been used as a tonic according to Korean medicine, it nourishes the liver and kidneys. Although many studies have examined how CF affects antioxidative damage and spermatogenesis in vitro, the relationship between CF and its effects on male reproductive malfunction associated with CREM gene expression and spermatogenesis in vivo has not yet been elucidated. Rats were treated CF for 56 days consecutively. Animals were sacrificed and the testes were removed. Total RNA was extracted from rat testes using Trizol method. Then we carried out Western blotting assay using anti-CREM antibody. CREM mRNA levels were significantly increased in testes from the rats treated with CF (p 0.05). The relative expression of CREM mRNA in the CF treated group was 153% than that in the normal group. There was significantly enhanced expression of CREM-immunoreactive bands in the CF treated group compared to the vehicle treated group (p 0.05). The relative expression of CREM in the CF group was 132% than that in the normal group. In conclusion, CF has an enhancing effect of CREM expression in rat testes both at mRNA and protein level. These findings suggest that CF may have a role of improving male infertility related with the sperm alteration and proliferation or differentiation of germ cells closely related with CREM gene expression.

Familial ATP7B Gene Analysis for Wilson Disease. *G. Kaur[1], S. Kumar[2], B.R. Thapa[3], R. Prasad[2]* 1) Dept Physiology, Goverment Medical College, Chandigarh, UT, India; 2) Dept Biochemistry, PGIMER, Chandigarh, UT; 3) Pediatric Gastroenterology, PGIMER, Chandigarh, UT.

Background: A number of PCR based techniques like SSCP, ARMS-PCR, seminested PCR and dinucleotide-repeat markers analysis have been used in the diagnosis of asymptomatic Wilson disease patients and carrier status of Wilson disease families. In present study, we explore the utility of mutation analysis with combination of RFLP in genetic diagnosis of Wilson disease. Aim: The study was planned to provide molecular diagnostic tool for diagnosis of asymptomatic Wilson disease patients as well as assessment of carrier status of Wilson disease families. Subjects and methods: We have analyzed four Wilson disease families in which parents and siblings showed no clinical manifestations and biochemical abnormalities. The parents of Wilson disease patients were not consanguineous and without any family history of Wilson disease. Mutations in ATP7B were characterized using SSCP and DNA sequencing. Further, RFLP was developed for analysis of characterized mutations in ATP7B from Wilson disease patients, their parents and siblings. Results: We have characterized three mutations A3767G, A1003T and I1102T by using SSCP and DNA sequencing in wilson disease patients. These mutations created/deleted restriction site for AccII, Bsh 1236I and EcoRI restriction enzymes respectively. Despite of no clinical manifestations and without any significant alteration in biochemical investigations in thirteen familys members, we have diagnosed 8 carriers and 1 asymptomatic wilson disease patients by restriction digestion analysis. Conclusion: Our report demonstrates that mutation analysis in combination with RFLP is useful for diagnosis of asymptomatic wilson disease patients as well as for elucidation of the carrier status among the patients family members. It is noteworthy here that this combinational methodology provide a positive diagnosis in the siblings/parents where biochemical parameters are ambiguous.

CFTR gene study in African children with cystic fibrosis phenotype: identification of a novel A204T missense mutation and frequencies of common polymorphisms. *L. MUTESA[1], C. VERHAEGHE[1], K. SEGERS[1], J.F. VANBELLINGHEN[1], L. NGENDAHAYO[2], C. OURY[1], L. KOULISCHER[1], V. BOURS[1]* 1) Department of Human Genetics,CHU Sart-Tilman, Center for Biomedical Integrative Genoproteomics (CBIG) University of Liège, Belgium; 2) Department of Anatomy Pathology, CHU-Butare, National University of Rwanda, Butare-Rwandaÿ.

Cystic fibrosis (CF) is one of the most common autosomal recessive disease in Caucasian with an incidence of 1 in 2500 births. However, very little is known about CF in Black population from Africa where this disease has been believed to be extremely rare. Nevertheless, CF is still under-diagnosed in this population. Indeed, clinical features of this disease are often similar to that of other frequent diseases in Africa such as malnutrition, tuberculosis, chronic pulmonary infections and HIV/AIDS. Moreover, molecular analyses, required to confirm the diagnosis, often remain inaccessible in many African countries. We have investigated 60 unrelated Rwandan children patients with CF clinical features. We applied a gene scanning approach using DHPLC and MLPA systems to analyse all exons and flanking intron sequences of the CFTR gene, in order to characterise CF mutations, sequence variations and gross genomic rearrangements. Four different CF-mutations, including one previously undescribed missense mutation (A204T in exon 6a), and 9 polymorphisms were identified. The CFTR-A204T mutation was studied by immunoblotting and pulse-chase in transiently transfected HeLa cells. The results revealed a lower level of CFTR mature protein relative to CFTR-wild type. The frequencies and association of coding single-nucleotide polymorphisms (c.2694T>G, c.4521G>A and c.1540A>G) were compared with control group and previous data. All these results are of interest in designing an appropriate strategy for genetic testing and counselling of CF patients in Africa.

snp.plotter: An R based SNP/haplotype association p-value and linkage disequilibrium plotting package. *A. Luna[1], D.R. Weinberger[1], K.K. Nicodemus[1,2]* 1) GCAP/CBDB, NIH/NIMH, Bethesda, MD; 2) Epidemiology, Johns Hopkins SPH, Baltimore, MD.

snp.plotter is a free and easy-to-use R package which produces publishable-quality plots of p-values using single SNP and/or haplotype data. Main features of the package include options to display a linkage disequilibrium (LD) plot below the p-value plot using either the r2 or D' LD metric with a user-specified LD heatmap color scheme, setting the X-axis to equal spacing or to use the physical SNP map, and specification of plot labels, colors and symbols for desplaying p-values. A major strength of the package is that it can plot multiple datasets simultaneously. Plots can be created using global and/or individual haplotype p-values along with single SNP p-values. R is a free software environment for statistical computing and graphics available for most platforms. The proposed package provides a simple way to convey both association and LD information in a single appealing graphic for candidate gene or whole genome association studies and requires virtually no knowledge of the R programming language - snp.plotter requires only the option for input data file names. In addition, snp.plotter can be used as a point-and-click web-based version at http://cbdb.nimh.nih.gov/~kristin/snp.plotter. The proposed package should facilitate the creation of complex graphics for genomewide or candidate gene association studies.

Preimplantation Genetic Screening for aneuploidy rates in couples undergoing donor egg in vitro fertilization cycles. *W.G. Kearns[1], R. Pen[1], A. Benner[1], K. Richter[2], P. Browne[2]* 1) Shady Grove Ctr for Preimplantation Genetics, Rockville, MD; 2) Shady Grove Fertility RSC, Rockville, MD.

PGD is used to decrease miscarriages, prevent the birth of aneuploid offspring and to potentially increase the implantation rate of preimplantation embryos. All information regarding rates of aneuploidy among human preimplantation embryos comes from PGD of embryos of people with impaired fertility. In this population, aneuploidy screening is suggested for women with recurrent pregnancy loss, those with the transfer of good quality embryos without achieving a viable pregnancy or women of advanced maternal age. Typically women using donor egg IVF have the highest success rates due to the selection of egg donors in a low risk population; less than 34 years of age with normal Day 3 FSH and estradiol levels. Therefore, PGD for aneuploidy screening is not a common recommendation for this patient group. However, embryonic aneuploidy rates occurring within the general human population remain unknown. Therefore, we determined aneuploidy rates in couples undergoing donor egg IVF cycles. 32 couples underwent donor egg IVF-PGD. Laser-assisted embryo biopsy was performed on day-3 and PGD was done on 440 cleaving embryos from 32 initiated cycles. The mean donor age was 26.5 yrs (21-31). Multi-color fluorescence in situ hybridization (FISH) was used to determine aneuploidy for chromosomes 13, 14, 15, 16, 17, 18, 21, 22, X and Y. Clinical outcomes were determined. Pregnancy was defined by ultrasound identification of an intrauterine gestational sac. All 32 women had an embryo transfer. 5% (22/440) of the embryos were not diagnosed due to poor embryo quality. 50% (209/418) of the embryos were abnormal for at least 1 of the 10 chromosomes tested. The clinical pregnancy rate was 66% (21/32) per patient and per embryo transfer. There were no miscarriages, misdiagnosis, or mosaic embryos. These data provides insight into the presence of aneuploidy in a low risk population. Pregnancy rates were similar in these patients to those undergoing donor egg IVF without PGD. The miscarriage rate was 0% which could be due to the PGD testing or alternatively due to the small sample size.

Concurrent deleterious germline mutations in both *BRCA1* and *BRCA2* in a large series of patients. *M. Martin, C. Frye, L.A. Burbidge, A.M. Deffenbaugh, D. Pruss, B.E. Ward* Myriad Genetic Laboratories, Salt Lake City, UT.

Infrequent case reports of individuals with germline mutations in both the *BRCA1* and *BRCA2* genes exist but there has been no systematic analysis of prevalence in a large cohort of patients. The aim of this study was to determine the prevalence and review available personal and family history of individuals with two deleterious germline mutations. The presence of double heterozygotes (DH) was detected in patients analyzed by comprehensive sequencing of *BRCA1* and *BRCA2* (bidirectional sequencing of all exons, splice site junctions of both genes, plus detection of five common large rearrangements in a large proportion of patients) and in Ashkenazi Jewish (AJ) patients who underwent analysis of the three founder mutations (*BRCA1* 185delAG, 5385insC and *BRCA2* 6174delT). Of 76,825 individuals tested by full sequence analysis, 9541 patients were found to have one deleterious mutation and 26 were found to be DH (6 of whom were AJ). Of 19,673 individuals tested for only the founder mutations, 3455 patients were found to have one deleterious mutation and 33 were identified as DH. As expected, the increased incidence of mutations in the AJ population led to an increased frequency of double *BRCA1* and *BRCA2* heterozygotes. Within the total population of DH, 42 of the probands reported a personal history of an HBOC related cancer, including 76% with invasive breast cancer, 7% ovarian cancer and, 14% reported both breast and ovarian cancer, and 2% with DCIS. 15 of the probands reported only familial cancer history and no personal history of HBOC related cancer, and 2 specified only familial history and did not specify personal history. The reported age of diagnosis of breast cancer ranged from 22-63 years, with a mean age of 40.1. The reported age range for diagnosis of ovarian cancer was 41-88 with a mean age of 56. The clinical presentation of personal and family history does not differ significantly from individuals that carry one mutation in either the *BRCA1* or *BRCA2* gene suggesting that the conferred risk for cancer in DH is on the same order of magnitude as that of single mutation carriers.

A practical method of genome screening for population-specific selective sweeps: candidate regions contributing to inter-population phenotypic divergences. *R. Kimura[1, 2], A. Fujimoto[1], K. Tokunaga[1], J. Ohashi[1]* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) JSPS research fellow.

Phenotypic divergences among modern human populations have been produced as genetic adaptation to local environments. To identify genes involved in population-specific phenotypes, therefore, it is significant to search for signs of recent positive selection in the human genome. Although detection of elongated linkage disequilibrium (LD) has been a powerful tool in the field of evolutionary genetics, such current methods are not applicable to identify already fixed loci. Here, we report a new LD-based method of screening for population-specific selective sweeps including already fixed regions. The present method depending on the ratio of observed homozygosity for the haplotypes between populations enables us to measure the inter-population differences in the extent of nucleotide diversity, genetic differentiation, and LD. Another advantageous point of our method is that it does not require haplotype phasing of SNPs that should be determined from family data or estimated from population data with a possibly inaccurate, time-consuming computation. We analyzed the genome-wide SNP typing data form the International HapMap project (Phase I 16c.1) and performed a genome-imitating simulation under neutrality using a well-fitting demographic model. The results suggest that rapid fixations of new advantageous mutations frequently occurred after the "Out of Africa" probably due to environmental changes and to population bottlenecks, while in the African population, advantageous alleles fixed slowly, if any, after generation of the polymorphisms. The present study, detecting the genes already reported to be under strong selection such as *ABCC11* in the Asians, *SLC24A5* and *MATP* in the Europeans, and *FY* in the Africans, provides other candidate regions of population-specific selective sweeps in the human genome that must contribute to a variety of phenotypes among human populations.

Molecular Diagnosis of Norrie Disease. *G. Modabber, M. Houshmand, M.H. Sanati* Medical Genetic, National Institue of Genetic Engineering and Bioth, Tehran, Iran.

G.modabber , M. Hoshmand, M.H.Sanati Iran,National Institue for Genetic Engineering and Biotechnology Norrie disease Norrie disease is a rare X-inked recessive (Xp11.4) condition characterized by congenital blindness in males due to degenerative and proliferative processes in the neuroretina . Retinal dysgenesis occurs early during embryogenesis and is often associated with microphthalmia . The most prominent feature at birth is an intra-ocular mass which can be misdiagnosed for retinoblastoma and ultimately leads to shrinkage of the eye globe . The main histopathological findings are rosettes of immature retinal cells embedded in a vascular connective tissue of hyperplastic primary vitreous . Norrie disease is a rare disorder, its exact incidence is unknown. It is not associated with any specific racial or ethnic group.Mutations in the NDP cause Norrie disease. The NDP gene produces a protein called Norrin , which is believed to be crucial to normal development of the eye , brain , inner ear , nasal epithelium and other body systems. In affected males, mutations in the NDP gene are associated with a spectrum of retinal findings ranging from Norrie disease (ND) to X-linked familial exudative vitreoretinopathy (FEVR), including some cases of persistent hyperplastic primary vitreous (PHPV), Coats disease, and advanced retinopathy of prematurity (ROP).These phenotypes appear to be a continuum of retinal findings with considerable overlap. References: 1. Norrie disease gene sequence variants in an ethnically diverse population with retinopathy of prematurity ,Molecular Vision 2005; 11:501-508 2. Norrie, 1927;Warburg,1966; Warburg,1975.

Sequencing Analysis of two Iranian patients with Allgrove Syndrome. *L. Komeilian[1], Sh. Salehpour[2], H. Tonekaboni[2], M. Houshmand[1]* 1) Medical Genetic, National Institue of Genetic Engineering and Bioth,Komeilian,BS.Houshmand,PhD Tehran, Iran; 2) Mofid Pediatrics Hospital,Salehpour,MD Tonekaboni,MD.

L.Komeilian(1),Sh.Salehpour(2),H.Tonekaboni(2),M.Houshmand(1) 1: National Institute of genetics Engineering and Biotechnology 2: Pediatrics Hospital of Mofid Allgrove syndrom: The triple A syndrome is a rare autosomal recessive disorder (gene locus is on chromosome 12q13, contains 16 exons and code for a 546 amino acid protein which called ALADIN). characterized by adrenal insufficiency,achalasia and alacrima. Material and methods: Patient No1: An 8.5 years old boy, a product of consanguineous marriage with, Alacrima, Achalasia, Short acting ACTH stimulating test showed primary Adrenal insufficiency. A low serum cortisol level, History of an acute encephalopathy, mild ataxia. Generalized skin hyper pigmentation, Epigastric pain, A sensory autonomic neuropathy. Patient No 2 An 2.5 years of old boy, product of nonconsanguineous marriage with , History of poor weight gain, Generalized skin hyper pigmentation, Alacrima, Achalasia ,Dysphagia, Lethargy and Seizure, Hyponatremia(Serum Na=112 meq/lit), Hyper Kalemia(Serum K=5.7 meq/lit), Hypoglycemia(BS=52 mg/dl), Hhypotention. Sensory autonomic neuropathy. Xerophtalmia, Keratosis. DNA Analyzing: PCR and Sequencing methods were used to analyze 12 out of 16 exons in AAAS . The exons :4,5,6,7,8,9,10,11,12,13,14,15. Result: G7329Cmutation was found in IVS7-1 of AAAS gene in both patients. G13504A mutation was found in intron 14 of AAAS gene in patient 2. Conclusion: More investigations need to show pathogeneticity of these mutations.

Acentric supernumerary marker chromosome characterized as inv dup(3)(qter-q26.1::q26.1-qter) in a child with several dysmorphic features. *S.K. Murthy[1], A.K. Malhotra[1], P.S. Jacob[1], S. Naveed[1], E.E.M. Al-Rowaished[1], S. Mani[1], S. Padariyakam[1], R. Pramathan[2], S. Lyndell[2], R. Nath[2], A. Redha[3], M.T. Al-Ali[1], L. Al-Gazali[2]* 1) Department of Genetics, Al Wasl Hospital,DOHMS, Dubai, United Arab Emirates; 2) Department of Pediatrics, Faculty of Medicine and Health Sciences and Al Ain Hospital, UAE; 3) Department of Pathology, Dubai Hospital, DOHMS, Dubai, UAE.

Pure tetrasomy 3q26-qter is an extremely rare observation. We report here our molecular cytogenetic results from an one month old child presenting with several dysmorphic features including depressed nasal bridge, low set ears, micrognathia, prominent hairy forehead, tail like sacrococcygeal appendage, hypoplasia of corpus callosum and streak pigmentation on the lower aspect of the forearm. Initial peripheral blood karyotyping and all-telomere FISH screening showed normal results. Chromosome analysis from fibroblasts obtained from a skin biopsy showed the presence of a marker chromosome in 98% of the cells analyzed. The marker chromosome was C-band and NOR negative. Oligo array-CGH studies showed an amplification of 3q26.1-qter region, confirming the origin of the marker chromosome. Further characterization of the marker by subtelomere FISH studies revealed it to be an inversion duplication of 3q26.1-qter. Only three cases of similar acentric supernumerary marker characterized as inv dup(3q) have been reported so far. Tissue specific mosiacim, a possible activation of neocentromere at 3q26 and genotype-phenotype correlation due to tertrasomy 3q26-qter in our patient is discussed.

The New Zealand Maori Population as a Candidate for Admixture Gene Mapping. *R.A. Lea[1,2], D. Hall[1,3], G.K. Chambers[3], L.R. Griffiths[2]* 1) Institute of Environmental Science and Research Ltd, Wellington, New Zealand; 2) Genomics Research Centre, Griffith University, Queensland, Australia; 3) School of Biological Sciences, Victoria University of Wellington, New Zealand.

The Maori population of New Zealand (NZ) represents the final link in a long chain of island-hopping voyages stretching across the South Pacific - The last of the great human migrations. This indigenous population originated from restricted groups of founding ancestors (~1000 years ago) and underwent rapid growth followed by more recent genetic admixture with British colonisers over the past 200 years (8 generations). Compared to Caucasians the modern Maori population (~15% of NZ) exhibits markedly increased rates of genetically-influenced diseases such as lung cancer, diabetes and gout. It is plausible that these disease differences are partly due to higher frequencies of susceptibility genes in this indigenous group and/or genetic interaction arising from intermarriage with Europeans (admixture). Population-based linkage disequilibrium (LD) studies that incorporate genetic admixture (ie. admixture LD mapping) can be a powerful approach for identifying disease susceptibility genes. Before such studies can be properly designed it is important to understand the genetic structure of the target population. We have conducted statistical analyses of genetic data for the Maori population to show that a) long-range admixture LD (~6Mb) exists and b) the proportion of European genes in Maori is ~40%. We have also found correlations between Maori ancestral variation and clinically important phenotypes such as nicotine metabolic rate and BMI suggesting ancestry-specific genes may modulate variation in these traits. Our genetic research has established valuable baseline genetic information for this unique Polynesian population and, coupled with the marked disease disparities compared to Europeans, suggests that the Maori population is an excellent candidate for admixture gene mapping studies.

An open-label study of long-term miglustat use in adult patients with Type 1 Gaucher disease. *R. Heitner[1], M. Hrebicek[2], D. Elstein[3], C.E.M. Hollack[4], A. Zimran[3]* 1) Department of Paediatrics, University of the Witwatersrand, Johannesburg, South Africa; 2) Institute of Inherited Metabolic Disorders, Prague, Czech Republic; 3) Shaare Zedek Medical Centre, Jerusalem, Israel; 4) Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands.

The objective of this study was to assess the long-term safety and efficacy of oral miglustat (Zavesca) in patients (pts) with Type 1 Gaucher disease (GD1) who had completed one of the prior miglustat pivotal trials. In this Phase IIIb open-label, multinational study, miglustat efficacy was evaluated by assessing liver and spleen volumes, haemoglobin level, platelet count and chitotriosidase activity. Miglustat safety was also investigated. This analysis took into account individual baseline conditions upon entry into the pivotal studies. For organ volume and chitotriosidase activity, statistical significance of change from baseline was assessed using a paired t-test. Twenty-three individuals (74% female) were recruited from four national Gaucher referral clinics. The mean age SD was 39.39.8 years. A total of 14 pts completed the 24 month assessments. Nine pts were withdrawn. Reasons for withdrawal were: loss of follow-up (1 pt), compliance issues (1 pt), switch to commercial drug (2 pts), pt request (pregnancy planning; 2 pts), diarrhoea (1 pt), increased liver volume (1 pt), and a serious adverse event (SAE) (cerebral haemorrhage; 1 pt). Total miglustat exposure including treatment during previous clinical trials ranged from 48 to 72 months. The continuous improvement observed for organ volumes and blood parameters in the pivotal phase (up to 3 years) was maintained in the additional follow up. Chitotriosidase activity declined continuously over time. There were no new cases of peripheral neuropathy or abnormal cognitive function. This study confirms long-term efficacy of miglustat on all standard GD parameters with an additional 2 years of data. The safety profile was also consistent with previous pivotal clinical trials. With a miglustat exposure of up to 6 years, this study represents the longest follow-up of a cohort of GD1 pts in a clinical trial setting.

Novel KRIT1 mutations mediating Cerebral Cavernous Malformations. *N. Limaye[1], N. Revencu[1,2], L. Boon[1,2], M. Vikkula[1], The CCM Study Group* 1) Laboratory of Human Molecular Genetics, Christian de Duve Institute of Cellular Pathology, Université catholique de Louvain, Brussels, Belgium; 2) Cliniques St Luc, Université catholique de Louvain, Brussels, Belgium.

Cerebral Cavernous Malformation (CCM; OMIM 116860) is characterized by lesions of densely clustered, enlarged capillary-like sinusoids lined with an endothelial layer, with no intervening brain parenchyma. They occur in the brain, spinal cord, retina, and as hyperkeratotic cutaneous capillary-venous malformations (HCCVMs) in the skin, and can sometimes cause headaches, seizures, neurological deficits and cerebral hemorrhages. Truncating mutations in three different genes: KRIT1 (CCM1), MGC4607 (malcavernin, CCM2), and PDCD10 (CCM3), have so far been found to cause the familial form of the disease. While the precise functions of the CCM genes remain to be elucidated, KRIT1 has been shown to be critical for arterial morphogenesis and identity in a knockout mouse model. In humans, the KRIT1-containing 7q locus is estimated to account for about 40% of CCM-affected kindreds, with mutations in the gene causing the malformation with a fairly high clinical penetrance of about 62-88%. In the current study, we screened all 16 coding exons of the KRIT1 gene, along with flanking intronic sequence, by dHPLC followed by sequencing, to identify mutations in 40 affected families. We identified 17 different mutations, 11 of which are novel, in 18 families. Five of these new mutations are insertions, three are deletions, two are intronic nucleotide substitutions, and one a nonsense substitution. All of these cause frame-shifts and/or premature termination of the coding sequence. All of the identified mutations co-segregate with the CCM phenotype within the families, with a total of thirty-one affected and four non-penetrant mutation carriers identified. In keeping with earlier reports, KRIT1 mutations account for 45% of the affected families in our study, and invariably cause loss-of-function of the protein. (http://www.icp.ucl.ac.be/vikkula) (vikkula@bchm.ucl.ac.be).

Epistatic Effect Between 11q22 and 17p11 for Attention-Deficit/Hyperactivity Disorder in the Paisa Genetic Isolate. *M. Jain[1,2], F.X. Castellanos[3], D. Pineda[4], F. Lopera[4], J. Palacio[4], K. Berg[1], J. Bailey-Wilson[1], M. Muenke[1], M. Arcos-Burgos[1]* 1) NHGRI/Medical Genetics Branch, NIH, Bethesda, MD; 2) HHMI-NIH Research Scholar, Chevy Chase, MD; 3) NYU, Child Study Center, New York, NY; 4) University of Antioquia, Colombia.

Attention-deficit/hyperactivity disorder (ADHD, [MIM 143465]) is the most common behavioral disorder of childhood. Segregation and epidemiological analyses both suggest genetic factors play a role in the pathogenesis of ADHD. Eighteen multigenerational extended families from the Paisa genetic isolate demonstrate linkage to four regions: 4q13.2, 5q33.3, 11q22 and 17p11. Regions on 5q, 11q and 17p replicate regions found in other populations and suggest that putative causative genes in these regions will have effects across populations. In an attempt to unravel genetic complexities underlying ADHD previous work has confirmed the presence of genetic heterogeneity between families and pleiotropy between ADHD, disruptive behaviors and substance abuse. We examined the possibility of interactive effects between the linked loci in 134 nuclear families from the Paisa genetic isolate using SNPs at a 200kb resolution in these four regions. We used Coxs nonparametric linkage correlation method where linkage in families to a region is evaluated based on the condition that the families are linked to a reference region. Conditioning on families linked to chromosome 17p11 led to a significant increase in the nonparametric LOD on 11q22 from 0.55 to 3.88. Conditioning on families linked to 4q13.2 increased the nonparametric LOD on 11q22 from 0.55 to 3.24. Thorough parametric analysis using the method implemented in TLINKAGE did not disclose an interactive effect, again pointing to the increased power to detect interaction using nonparametric methods compared to parametric ones. These results suggest that candidate genes on 4q13.2 and 17p11 interact with a locus on 11q22 to confer susceptibility for ADHD. Using ADHD as a disease model we have now demonstrated heterogeneity, pleiotropy and epistasis to be important for this seemingly complex trait.

Association between PDE4D genotype/phenotype and young ischemic stroke. *Y.C. Liao[1], H.F. Lin[2], C.W. Liou[3], E. Hsi[1], S.H. Juo[1,4,5]* 1) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Neurology, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 3) Department of Neurology, Chang Gung Memorial Hospital, Kaohsiung, Taiwan; 4) Department of Clinical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 5) Department of Medical Research, Mackay Memorial Hospital, Taipei, Taiwan.

Background: The phosphodiesterase 4D (PDE4D) gene was shown as a susceptibility gene to ischemic stroke in the Icelandic population. Previous studies primarily focused on late-onset stroke. We tested for the association between PDE4D and young ischemic stroke in a Taiwan population.

Methods: Stroke patients with age between 15 and 45 years were recruited from five medical centers. The present study included 156 patients, 130 young (45 years) and 187 old controls (46 years). We selected four SNPs which have been implicated to be associated with stroke in some previous studies: SNP45 (rs12188950), SNP56 (rs702553), SNP83 (rs966221), and SNP87 (rs2910829). Genotype and haplotype effects were evaluated.

Results: The genotypes in cases and controls were in Hardy-Weinberg equilibrium. SNP45 was monomorphic in our population. For SNP56, allele T was relatively common in cases than in controls. After adjusting for age and sex, the OR for the TT genotype of SNP56 was 2.45 (the nominal p = 0.017 and the permutated p = 0.028) between the cases and young controls. Using old participants as control, the statistical results did not reach the significant level, but showed a similar trend. There was no statistical significance for SNP83. The frequency of CT genotype at SNP87 was significantly lower in old controls (OR=1.99, the nominal p = 0.014 and the permutated p = 0.035). We further investigated the haplotypes comprising SNP56 and SNP87. The AC haplotype of SNP56-SNP87 was negatively associated (p=0.006) with young stroke.

Conclusion: our study suggests that the PDE4D gene may play a role in young stroke in the Taiwanese population.

RNA interference-mediated allele-specific silencing rescues sialic acid levels in the dominant disorder sialuria. *E. Klootwijk, P.J. Savelkoul, C. Ciccone, D. Krasnewich, W.A. Gahl, M. Huizing* MGB, NHGRI, NIH, Bethesda, USA.

Sialuria is a rare autosomal dominant disorder caused by a missense mutation in the allosteric site of the rate-limiting enzyme of sialic acid biosynthesis, UDP-GlcNAc 2-epimerase/ManNAc kinase, encoded by the *GNE* gene. This results in loss of feedback inhibition of GNE by CMP-sialic acid, and overproduction of sialic acid. Sialuria patients manifest variable signs and symptoms, including mild hepatomegaly and developmental delay. Since dominantly inherited disease alleles are attractive therapeutic targets for allele-specific silencing mediated by RNA interference (RNAi), we employed this method in fibroblasts of sialuria patients. Small interfering RNA (siRNA) was designed to specifically target a sialuria *GNE* missense mutation (c.787G>T, R263L). This siRNA was transfected into patients fibroblasts and the extent of silencing was assessed after 48 hours. After silencing, allele-specific real-time PCR analysis demonstrated that expression of the mutant *GNE* transcript was decreased by 71 3 (SD) % (*n*=3). Furthermore, HPLC analysis of fibroblast extracts showed that sialic acid levels decreased 59 15% (*n*=3) after silencing. Finally, GNE enzymatic activity measurements showed a 41 6 % (*n*=3) recovery of feedback inhibition by CMP-sialic acid. These results demonstrate that RNAi can correct the underlying metabolic defect *in vitro* in a human inborn error of metabolism. We plan to extend this RNAi study to a mouse model of sialuria that we are generating. Allele-specific RNAi therapeutics in sialuria provides an example for correcting dominant-negative mechanisms through elimination of specific mutant transcripts.

High resolution detection of copy number changes and LOH using the Affymetrix GeneChip 500K Mapping Array on formalin-fixed, paraffin-embedded tumor tissue. *S. Jacobs[1], E.R. Thompson[2, 3], Y. Nannya[4], Y. Go[4], R. Pillai[1], S. Ogawa[5], D.K. Bailey[1], I.G. Campbell[2, 3]* 1) Genomics Collaborations, Affymetrix, Inc, Santa Clara, CA; 2) VBCRC Cancer Genetics Laboratory, Peter MacCallum Cancer Centre, East Melbourne, Victoria, Australia; 3) Department of Pathology, University of Melbourne, Parkville, Australia; 4) Departments of Hematology/Oncology, University of Tokyo, Tokyo, Japan; 5) Department of Regeneration Medicine for Hematopoiesis, University of Tokyo, Tokyo, Japan.

In this study, we demonstrate the application of the Affymetrix GeneChip Mapping 500K arrays for an integrated analysis of genotype, loss of heterozygosity (LOH), and copy number using DNA derived from formalin-fixed, paraffin-embedded (FFPE) tissues. FFPE material tends to yield degraded DNA and is thus sub-optimal for use in many downstream applications. The Mapping 500K arrays can be used for genotype and copy number analysis of >500K SNPs, employing a technology that includes PCR amplification of SNPs on fragment sizes from 100bp to 1143bp. We found that a pre-qualifying PCR test adequately predicted the performance of FFPE DNA on the arrays. Average call rates for the FFPE samples were reduced compared to nonFFPE samples, but a closer examination of SNP by SNP performance revealed that genotyping success was dependent on amplicon size and therefore easily predicted and corrected for. Average concordance rates between FFPE and fresh frozen samples from the same tumor surpassed >98% on the smaller fragment sizes, despite some genetic differences due to tumor heterogeneity. Importantly, FFPE and fresh frozen tumor samples provided the same copy number and LOH profiles, indicating the feasibility of a complete analysis of FFPE-derived samples using this platform. In conclusion, we have shown that the Mapping 500K Array can be applied to FFPE-derived samples for genotype, copy number, and LOH analysis, thereby potentially allowing thousands of archival samples to be studied using this integrated system.

Congenital Diaphragmatic Hernia associated with Duplication of 11q23-qter. *M. Klaassens[1,2], D.A. Scott[3], B. Lee[3,4], D. Tibboel[2], A. de Klein[1]* 1) Clinical Genetics, Erasmus MC, Rotterdam, the Netherlands; 2) Pediatric Surgery, Erasmus MC, Rotterdam, the Netherlands; 3) Molecular and Human Genetics, Baylor College of Medicine, Houston (TX), USA; 4) Howard Hughes Medical Institute, Chevy Chase (MD), USA.

Little is known about the etiology of Congenital Diaphragmatic Hernia (CDH), a relatively common birth defect with a significant mortality, but there is increasing evidence for a strong genetic contribution. Both numerical and structural chromosomal abnormalities have been described in patients with CDH. Partial trisomy 11q and partial trisomy 22 associated with the common t(11;22) has been reported in several cases of CDH. It has been assumed that the diaphragmatic defect seen in these individuals was due primarily to duplication of material from chromosome 22q11. Here we describe a family with a t(11;12) in which one of two brothers with partial trisomy 11q has a left sided posterolateral CDH. This is the second case of CDH in partial trisomy 11q due to an unbalanced translocation other than t(11;22). Using array-based comparative genomic hybridization and fluorescent in situ hybridization we mapped the breakpoints in both brothers and their mother who is a balanced translocation carrier. Our results suggest that duplication of one or more genes on an ~19 Mb region of 11q23.3-qter predispose for the development of a diaphragmatic hernia. These effects may be the primary cause of CDH in individuals with a t(11;22) or may be additive to effects from the duplication of chromosome 22 material. We also conclude that the partial trisomy 11q syndrome has a variable phenotype and that CDH should be added to the spectrum of anomalies that can be present in this syndrome.

A male with a small duplication at 17p11.2 (Smith-Magenis region) characterized by FISH and microarray CGH.

J. Jung[1], *J. Xu*[2] 1) Medical Genetics Program of Southwestern Ontario; 2) Cytogenetics, London Health Sciences Centre and University of Western Ontario, Canada.

Our patient presented with an early history of moderately severe developmental delays, behavioral difficulties, failure to thrive and recurrent respiratory tract infections. He exhibited mild dysmorphic features which included bilateral epicanthal folds, periorbital fullness, anteverted nares, smooth philtrum, relatively thin upper lip, a high arched palate and mild fifth finger clinodactly. Initial chromosomal analysis and Fragile-X studies were reportedly normal. Later features noted included hypernasality of speech and a prominent nose. At 20 years of age he had a weight of 112 pounds (5th percentile), height 64 inches (<3rd percentile) and head circumference 53.5 cm (5th percentile). He had relatively large hands measuring 19.5 cm (97th percentile). Radio-ulner synostosis was associated with limited range of movement. His ears measured 6.3 cm (50th-75th percentile). He remains developmentally delayed but has good verbal skills coupled with a friendly and outgoing personality. General physical health is good. A repeat chromosomal G-banding analysis at 600 band level revealed a small interstitial duplication at 17p11.2. Metaphase FISH using a probe for Smith-Magenis syndrome (SMS, Vysis) region confirmed this duplication. Microarray CGH analysis (Signature Genomics Laboratories, LLC) of 969 clones for 304 loci on 41 chromosome arms identified a single copy gain for 3 BAC clones (RP11-524F11, RP11-1149K20, RP11-958E14) covering the RAI1 gene at 17p11.2. This duplication is further confirmed by interphase FISH using RP11-1149K20. This duplication is the reciprocal recombination product of the deletion found in SMS. This is a de novo rearrangement as the parents have a normal karyotypes. More cases with cytogenomic characterizations (e.g. microarray) are needed for the molecular karyotype/phenotype correlation.

Congenitally adducted thumbs and cognitive impairment in a mother and her two sons. *S. Nikkel* Dept Genetics, CHEO, Ottawa, ON, Canada.

A unique family is reported consisting of a mother and her two sons who have the same clinical features, with an otherwise negative family history. All three have mental retardation. The upper limbs are quite unique. The thumbs congenitally were in a fixed adducted position. All three have had surgery to obtain some release. There appears to be both bone and soft tissue malformation. There is limited supination and pronation at the wrists. The eldest son has camptodactyly of the fourth and fifth fingers of the right hand. Their voices are unusual in that they have a high-pitched quality. They have similar facial features with synophrys and pinched nasal tip, however these features are seen in other family members who do not have the limb differences and are cognitively normal. Growth is unremarkable. Karyotype and subtelomere analysis was normal. Neuroimaging was likewise unremarkable. Adducted thumbs are seen in a number of syndromes where there is arthrogryposis, spasticity and/or intracranial anomalies. This family does not appear to fit into any of these groupings. It is suspected that the mother has a new dominant mutation that she has passed on to her two children. An X-linked condition is also possible, although the mother is as severely as affected as her boys.

A new mechanism for genomic rearrangements causing genomic disorders. *J.A. Lee*[1], *J.R. Lupski*[1,2,3] 1) Dept. Molecular & Human Gen, Baylor College of Medicine, Houston, TX; 2) Dept. Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Genomic disorders are a group of human genetic diseases caused by DNA rearrangements that result in the gain, loss, or disruption of a gene or genes for which dosage is critical. These disorders are characterized by similar genomic features in the rearrangement-susceptible regions, but represent a wide spectrum of unrelated clinical entities. Thus far, the prevailing mechanism for rearrangements causing genomic disorders is non-allelic homologous recombination (NAHR) between region-specific low-copy repeats (LCRs) for recurrent events that have breakpoints which cluster and for some non-recurrent alterations; NAHR can use closely-related repetitive (eg. *Alu*) sequences as recombination substrates. Non-homologous end joining (NHEJ) has also been implicated as a recombination mechanism for numerous non-recurrent rearrangements. In the context of the genomic disorder Pelizaeus-Merzbacher disease (PMD), an X-linked recessive dysmyelinating disorder caused most frequently by non-recurrent duplication including the dosage-sensitive *PLP1* gene, but also by deletion and point mutations, our data suggest an alternative mechanism involving errors of replication as opposed to recombination. We have analyzed breakpoint junctional sequences in PMD patients with different-sized (~200 kb - 7 Mb) genomic duplications and deletions, and found evidence for sequence at the breakpoint coming from different genomic locations. The most parsimonious explanation involves a stalled DNA replication fork that switches strand templates and reinitiates DNA synthesis at a nearby but distinct genomic location. Our model of replication Fork Stalling and Template Switching (FoSTeS) may help to explain some of the more complex duplication and deletion rearrangements associated with PMD that have been reported in the literature, and potentially other non-recurrent complex rearrangements as well.

Evaluation of Sequencing Analysis Software for Complex Disease Studies. *C. Liu* Dept Psychiatry, Knapp Res Ctr, Univ Chicago, Chicago, IL.

In the study of complex disease genetics, resequencing may be required for the discovery of polymorphic markers, and it is especially needed for study of rare variants. A multiple-rare-variants common disease model normally requires resequencing of hundreds of case and control individuals. In order to identify all the rare variants and to obtain genotype data of all the subjects for statistical analyses, sequencing analysis software must be adapted to this larger size samples and data output needs. We propose that the key needs for the sequencing analysis software in rare variants model studies are: 1) use of annotated reference sequences; 2) low false negative and false positive calls; 3) informative SNP and genotype reports that are ready for statistical analysis; 4) friendly interface for manual review of SNPs and genotypes; 5) correlation of identified variants with SNPs in dbSNP; 6) functional annotation of discovered variants; 7) speed and capacity to handle large amount of sequencing data; 8) Database to manage sequence data and analysis results. Using sequencing data from a 2 Kb region in 360 individuals, we evaluated the major current resequencing analysis software packages including: Mutation Surveyor 2.2 from SoftGenetics, Sequencher 4.6 from GeneCodes, SeqScape 2.5 from Appliedbiosystems, SeqMan 7.0 from DNASTAR, NovoSNP, SNPDetector, and Phred/Phrap/Polyphred/consed suite. Key parameters were compared among the software. Phred/phrap score-based Unix/Linux academic-free software outperforms commercial software in many aspects. However, the Unix environment might be a significant hurdle for many desktop computer users. By and large, all the existing software requires further development to work more efficiently for a complex disease rare variant project. For example, Polyphred cannot use annotation information from reference sequences while SeqScape is good at using annotation input. Function of checking of variants against dbSNP data is not available. High false positive rate seems to be a more serious problem than a false negative rate in our evaluation. We propose that future software development needs to address the eight needs listed above.

G protein-coupled receptor GPR143 mutation causes X-linked recessive inheritance congenital idiopathic nystagmus. *J.Y. Liu[1], X. Ren[1], X. Yang[2], T. Guo[2], Q. Yao[1], L. Li[3], L. Wang[4], X. Dai[1], Z. Cai[1], Z. Tang[1], M. Liu[1], Q.K. Wang[1,3]* 1) Human Genome Research Ctr, Huazhong Univ Sci & Tech, Wuhan, Hubei,China; 2) Development of Proof-Testing, Renmin Hospital of Tanghe, Tanghe, Henan, China; 3) Department of Molecular Cardiology, Lerner Research Institute, and Center for Cardiovascular Genetics, The Cleveland Clinic Foundation, Cleveland, OH, USA; 4) Eye Center, Peking University, Beijing, China.

Abstract: Objectives:Congenital idiopathic nystagmus (CIN) is characterized by involuntary, rhythmical, repeated oscillations of one or both eyes without other diseases. No specific gene has been identified for CIN. We studied a five-generation Chinese family with nystagmus as the sole phenotype to map and identify a disease-causing gene for CIN. Methods: Linkage analysis was used to identify the chromosomal location of the disease gene and direct DNA sequence analysis was used for mutation detection. Results: The family showed X-linked recessive inheritance. Using the family, a new genetic locus for CIN was mapped to an approximately 10.6 Mb region flanked by DXS996 and DXS7593 on Xp22 with a peak multipoint LOD score of 8.89. Analysis of 21 candidate genes in the region revealed a novel S89F mutation in the second transmembrane domain of GPR143, a G protein-coupled receptor. All male patients in the family carried the mutation, and the female carriers were heterozygous for the mutation. The S89F mutation was not identified in 200 normal controls. Interpretation: Our results identify a new genetic locus for congenital idiopathic nystagmus on chromosome Xp22 and indicate that mutations of GPR143 can be a cause of disease in families with nystagmus as the sole neurological manifestation. Key Words: GPR143 mutation; congenital idiopathic nystagmus; X-linked recessive inheritance.

A female patient with Aicardi syndrome and Duplication of Williams Syndrome Critical region(7q11.23). *P. Jayakar[1], J. Teppenberg[2], I. Gadi[2], M. Duchowny[1], J. Aicardi[3]* 1) Miami Childrens Hospital,Miami, FL; 2) Laboratory Corporation of America,Research Triangle Park, NC; 3) University College of London,London.

Aicardi syndrome (AS) is an X- linked dominant condition characterized by infantile spasms, callosal agenesis and chorioretinal 'lacunae'.The outcome of AS is severe, with a high mortality,considerable morbidity and usually a poor developmental outcome.A locus at Xp22.3 has been suggested but not confirmed.We present a 15 month-old non dysmorphic female who started having infantile spasms at age 3months. She is severely delayed, microcephalic and visually inattentive. EEG was consistent with infantile spasms. MRI brain showed closed lip schizencephaly on the left,operculum polymicrogyria on the right and agenesis of corpus callosum. Ophthalmology evaluation showed numerous round retinal lacunae consistent with Aicardi syndrome.Chromosomal analyses and metabolic newborn screen were normal.Comparative Genomic hybridization (CGH) performed, using a 434 BAC constitutional Spectral Genomics array, revealed a gain of DNA in 9contiguous BACs (clone RP5-1177A1,RP5-1127A24,RP11-622P13,RP11-17A14,RP4-439N19,CTB-51J22,CTB-52H6,CTA-27oD13,RP4-665P5) corresponding to a duplication of proximal 7q-arr cgh 7q11.23(RP5-1177A1-----> RP4-665P5)x3.The BAC duplication was confirmed by conventional FISH using a Williams syndrome critical region probe (WSCR,Vysis Inc.) for ELN, LIMK at 7q11.23.The FISH result showed 2 contiguous signals in the metaphase analysis and 3 signals on interphase analysis.Parental chromosomes were normal.The reported clinical phenotype of duplication of 7q11.23 is severe expressive speech delay and minor facial dysmorphic features. To our knowledge this is the first case of Aicardi syndrome phenotype associated with duplication of WSCR(7q11.23) genes. Additionally, the schizencephaly and polymicrogyria are atypical for either syndrome.CGH is a powerful molecular cytogenetic diagnostic tool, which may help define new genomic mechanisms of disease.With the molecular heterogeneity of AS we propose that all patients with atypical AS phenotype should undergo genetic evaluation and CGH testing.

Genetic Variations in the TORC2 Gene Are Not Associated with Type 2 Diabetes in Japanese. *P. Keshavarz, H. Inoue, M. Itakura* Division of genetic information, Institute for Genome research, The University of Tokushima, Tokushima, Japan.

Type 2 diabetes (T2D) often exhibits fasting hyperglycemia due to elevated hepatic gluconeogenesis. The transducer of regulated cAMP responsive element-binding protein 2 (TORC2; MIM 608972) plays a central role in transcriptional regulation of genes encoding gluconeogenic enzymes such as phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G6Pase). Interestingly, the human TORC2 gene is located on chromosome 1q21, an important candidate locus for T2D. We therefore hypothesized that genetic variation(s) in the TORC2 gene might affect the risk of developing T2D. To test this, we first screened all the TORC2 coding exons for single nucleotide polymorphisms (SNP) in 32 Japanese T2D patients. We identified seven SNPs, including one common (Met147Val) and three rare (Arg379Cys, Ala423Gly and Arg482Trp) non-synonymous SNPs, and a SNP in the 3' untranslated region. In addition, we selected an additional seven validated SNPs within and near the gene. Subsequently, these SNPs were genotyped in a large Japanese population comprising 911 unrelated patients with T2D and 876 control subjects. Single-locus tests of association between either SNP allele frequencies or SNP genotype frequencies and case-control status revealed no significant associations. The linkage disequilibrium (LD) analysis revealed a LD block (Lewontin's coefficient $|D'|>0.99$), covering the entire TORC2 gene region and spanning >22 kb in full length. Three common haplotypes were identified, accounting for >99% of chromosomes, and there were no statistically significant association between these haplotypes and T2D. These findings suggest that the SNPs in the TORC2 gene are unlikely to have major effects on susceptibility to T2D in Japanese.

Meiotic segregation and location of chromosome breakpoints in rare Robertsonian translocations: sperm studies and molecular cytogenetic studies in 7 cases of rare rearrangements. *K. Moradkhani[1, 2], J. Puechberty[2], S. Bhatt[1], G. Lefort[2], P. Sarda[2], S. Hamamah[3], F. Pellestor[1, 3]* 1) Cytogenetics Human Gametes, Inst Human Genetics, CNRS UPR 1142, Montpellier, France; 2) Department of Cytogenetics, CHU Arnaud de Villeneuve, Montpellier, France; 3) Department of Reproductive Biology B, CHU Arnaud de Villeneuve, Montpellier, France.

The mechanisms underlying the occurrence and the meiotic behaviour of rare Robertsonian translocations are poorly understood. To better elucidate the formation and the transmission of these rare chromosomal rearrangements, we have studied the sperm segregations and the breakpoint locations of 7 rare Robertsonian translocations. FISH analyses using LSP and WCP probes for chromosomes 13, 14, 15, 22, were performed on spermatozoa from the translocation carriers. The location of breakpoints was performed on chromosome preparations from the 7 patients. Different sets of centromeric-specific DNA probes were used to accurately identify breakpoint locations in acrocentric chromosomes. In all translocations, a high incidence of alternate segregation producing normal or balanced sperm was observed (78.5% to 93.2%) Significant variations in rates of imbalances resulting from the adjacent segregation mode were also noted (6.7% to 21.4%). Identification and comparison of breakpoints in the 7 translocations revealed a high degree of variability in location of breakpoints. The majority of breakpoints were located in the proximal short arms of the chromosome involved. This study shows that rare Robertsonian translocations display also a high predominance of alternate meiotic segregation over adjacent mode. However, significant variations in rates of imbalances exist in sperm, which could reflect variations in the formation and the meiotic behaviour of rare Robertsonian translocations. The high diversity of breakpoint locations in rare translocations might result in discernible variations in the production of unbalanced gametes. This could also be one of the keys to the variable alterations of spermatogenesis observed in Robertsonian translocation carriers. This study was supported by a reseach project PHRC (N7732) from the C.H.U. of Montpellier.

Generation of novel mouse models for Down syndrome using a human artificial chromosome (HAC) vector system. *J. Kudoh[1], K. Miyamoto[1], N. Suzuki[2], K. Sakai[1], S. Asakawa[1], M. Ikeno[2], T. Okazaki[2], N. Shimizu[1]* 1) Dept. Mol. Biol., Keio Univ. Sch. Med., Shinjuku-ku, Tokyo, Japan; 2) Inst. Compr. Med. Sci., Fujita Health Univ., Toyoake, Aichi, Japan.

Down syndrome (DS), or trisomy 21, is caused by the inheritance of three instead of two copies of human chromosome 21 (HC21). Individuals with DS show characteristic faces, mental retardation, congenital heart defect, increasing risk of leukemia in postnatal periods and early onset type of Alzheimer disease in adulthood. It is difficult to identify critical gene(s) for each phenotype because the number of partial trisomy 21 is limited and the phenotype is highly variable even with full trisomy 21. Therefore mouse models have been used to study phenotype-genotype correlations in DS. HC21 is homologous to three different mouse chromosomes (MMU): The 28 Mb region of HC21 is homologous to MMU16 (23.2 Mb), 1.6 Mb to MMU17 (1.1 Mb), and 3 Mb to MMU10 (2.3 Mb). The best studied mouse model Ts65Dn with partial trisomy MMU16 shows deficits in learning and memory, and display a variety of phenotypes that are seen in DS. However, the heart defect characteristic of DS has not been observed in Ts65Dn mice. So, we focus on genes in regions homologous to MMU17 and MMU10 to generate novel mouse models for DS. BAC clones containing the entire target gene(s) were selected and transferred into mouse embryonic stem (ES) cells using a human artificial chromosome (HAC) as a vector. Using these HAC containing ES cells, we are now producing mice harboring a HAC that carries human chromosome 21 gene(s). These novel mouse model will be useful to identify a gene(s) responsible for a phenotype(s) of DS and analyze gene-dosage effects at the levels of transcriptome, proteome and metabolome.

Array-based comparative genomic hybridization identifies high frequency of cryptic chromosomal rearrangements in patients with syndromic autism spectrum disorders. *ML. Jacquemont[1], S. Leclerq[1], D. Sanlaville[1], R. Redon[2], V. Malan[1], O. Raoul[1], V. Cormier-Daire[1], S. Lyonnet[1], J. Amiel[1], M. Le Merrer[1], D. Héron[3], MC. de Blois[1], M. Prieur[1], M. Vekemans[1], NP. Carter[2], A. Munnich[1], L. Colleaux[1], A. Philippe[1]* 1) Inserm U 781 & Departement de Genetique, Hopital Necker-Enfants Malades, Paris, France; 2) The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge CB10 1SA, UK; 3) Département de Génétique, Hôpital de la Pitié-Salpétrière, Paris, France.

Autism Spectrum Disorders (ASD) refer to a broader group of neurobiological conditions, Pervasive Developmental Disorders (PDD). They are characterized by a symptomatic triad associating qualitative alteration in social interactions, defect in communication abilities and repetitive and stereotyped interests and activities. Prevalence of ASD ranges from 1 to 3/1000 individuals. Despite several arguments for a strong genetic contribution, molecular basis of a majority of cases remain unexplained. About 5% of autistic patients have a chromosome abnormality visible with cytogenetic methods. The most frequent are 15q11-q13 duplication, 2q37 and 22q13.3 deletions. Many other chromosomal imbalances have been described. However most of them remain undetectable using routine karyotype analysis, thus impeding diagnosis and genetic counselling. We investigated 59 patients presenting with syndromic ASD using a DNA microarray constructed from large insert clones spaced at approximately 1 Mb intervals across the genome. Sixteen clinically relevant rearrangements were identified in 15 patients (25.4 %): 8 deletions and 7 duplications. Altered segments ranged in size from 200kb to 16 Mb (1 to 19 clones). No recurrent abnormality was identified. These results clearly demonstrate that array-CGH should be considered as an essential aspect of the genetic analysis of patients with syndromic ASD. Moreover, besides their importance for diagnosis and genetic counselling, they may allow the delineation of new contiguous gene syndromes associated with ASD. Finally, the detailed molecular analysis of the rearranged regions may open the way for the identification of new autistic spectrum disorders genes.

Providers knowledge of genetics: A survey of 5,915 individuals and families with genetic conditions. *E.K. Harvey*[1], *C.E. Fogel*[2], *K.D. Christensen*[3], *S.F. Terry*[3], *J.D. McInerney*[1] 1) NCHPEG, Lutherville, MD; 2) Gallaudet University, Washington, DC; 3) Genetic Alliance, Washington, DC.

Individuals affected by genetic conditions are increasingly seeking genetics-related information from their primary care providers rather than a geneticist. **Objective:** To analyze individuals and families experiences as patients of a variety non-genetics-trained healthcare providers. **Design:** Staff at the Genetic Alliance (GA) and National Coalition for Health Professional Education in Genetics worked with a University of Maryland graduate student in genetic counseling to design a web-based survey for patients and families with genetic conditions. We recruited study participants from genetic advocacy organizations that are members of the GA. A total of 5,915 respondents completed the survey between December 2004 and August 2005. **Outcome Measures:** Respondents assessments of their providers knowledge of the genetic condition in the respondents family; respondents self-assessed knowledge of genetics; respondents sources of genetics information; and factors contributing to positive and negative experiences with providers. **Results:** The distribution of poor knowledge scores assigned by respondents to 25 provider types was: minimum 16% (hematologist/oncologist), maximum 62% (emergency physician), median 31.2%, average 31.7%. The most frequently consulted provider type, family practice/primary care, received a poor knowledge score from 39% of respondents. Sixty-four percent of total respondents reported receiving no genetics-education materials from their providers. Respondents who saw a genetics specialist rated their own knowledge of the relevant genetics significantly higher than those who did not. Most respondents lacked confidence in their providers knowledge of the genetics related to the conditions in the respondents families, and most reported receiving no genetics-education materials from their providers. **Conclusion:** Educational institutions and professional societies should consider increasing and improving educational offerings in genetics to meet the needs of the increasing number of patients who require genetics-related services.

OST3 mutation in non-syndromic mental retardation expands the spectrum of Congenital Disorders of Glycosylation? *F. Molinari[1], S. Romano[1], W. Morelle[2], P. de Lonlay[1], A. Munnich[1], L. Colleaux[1]* 1) INSERM U781, Hopital Necker-Enfants Malades, Paris, France; 2) Unité Mixte de Recherche CNRS/USTL 8576, Université des Sciences et Technologies de Lille 1, Lille, France.

Congenital disorders of glycosylation (CDG) is a group of inherited disorders that affect glycoprotein biosynthesis. Eighteen different CDG types have been described so far and they are characterized by a central nervous system dysfunction and multi-organ involvment. Group I CDG results in the failure of assembly or transfer of the N-glycan chain while group II CDG is defined as defects in the processing of the protein-bound glycan. Recent studies have underlined the extreme clinical variability of CDG syndromes. Here, we report on a non syndromic mental retardation (MR) in two sibs born to first cousin French parents. Homozygosity mapping in the two mentally retarded sibs and the two healthy children led to the identification of a unique homozygous region of 8 Mb on 8p23.1-p22. This interval encompasses the gene *TUSC3/OST3* (*Ost3 S.cerevisae* homologue) encoding a protein involved in the oligosaccharyltransferase complex which catalyses the transfer of an oligosaccharide chain on nascent proteins, the key step of the N-Glycosylation. Sequencing the *OST3* gene identified a one base-pair insertion in exon 6, 787_788insC. The mutation co-segregated with the disease and resulted in a premature stop codon 37 codons downstream of the coding sequence (N263fsX300). Extensive work-up (Caryotype analysis, liver function, clotting factors, brain MRI, EEG) was unremarkable with normal isoelectric focusing and Western blotting assay of serum N-glycoproteins. Recent studies of glycoprotein fucosylation and polysialic acid (PSA) modification of neuronal cell adhesion molecules have shown the critical role of glycoproteins in synaptic plasticity (in particular on their glycan structures). However, our results provide the first demonstration that a defect in N-Glycosylation can result in non syndromic MR providing therefore new insights in the understanding of the pathophysiological bases of MR.

Peters' Plus syndrome is a congenital disorder of glycosylation caused by mutations in *B3GALTL*. *S.A.J. Lesnik Oberstein[1], M. Kriek[1], S.J. White[1], M.E. Kalf[1], K. Szuhai[2], J.T. den Dunnen[1], M.H. Breuning[1], R.C.M. Hennekam[3,4]* 1) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Department of Molecular Cell Biology, Leiden University Medical Center, Leiden, The Netherlands; 3) Clinical and Molecular Genetics Unit, Institute of Child Health, London, United Kingdom; 4) Department of Pediatrics, Academic Medical Center, Amsterdam, The Netherlands.

The purpose of this study was to identify the genetic basis of Peters Plus syndrome, an autosomal recessive disorder characterized by anterior eye chamber defects, a disproportionate short stature, developmental delay, characteristic craniofacial features and cleft lip/palate.

To detect potential micro-rearrangements affecting the disease locus, we performed genome-wide 1 Mb resolution array-CGH (comparative genomic hybridization) on DNA of patients clinically diagnosed with Peters Plus syndrome. In two brothers, adjacent BAC clones were found to be present in a single copy, representing an approximately 1.5 Mb interstitial deletion on chromosome 13 (q12.3q13.1), spanning six genes. As none was an obvious candidate gene, we sequenced all exons and flanking sequences of these genes in one of the affected brothers. A point mutation (c.1020+1G>A) was detected in the beta 1,3-galactosyltransferase-like gene (HGNC symbol *B3GALTL*), within the donor splice site of exon 8. We subsequently performed targeted sequencing analysis for the presence of the c.1020+1G>A mutation in an additional 18 Peters Plus patients from 15 families and detected a homozygous c.1020+1G>A mutation in 16 of 18 patients. In the remaining two patients (siblings), a single c.1020+1G>A mutation was present. Upon sequencing the remainder of the gene we detected a second point mutation in intron 5 (c.437+5G>A). The deleterious effect of both mutations on normal splicing was confirmed by reverse-transcriptase PCR (RT-PCR) on patient material.

Peters Plus syndrome is hereby shown to be a monogenic disorder of glycosylation caused by mutations in *B3GALTL*.

Confirmation of Protective Haplotypes Spanning the CFH Gene in Age-related Macular Degeneration. *J.L. Haines[1], K. Spencer[1], L.M. Olson[1], M.A. Hauser[2], S. Schmidt[2], W.K. Scott[2], P. Gallins[2], N. Schnetz-Boutaud[1], A. Agarwal[3], E.A. Postel[4], M.A. Pericak-Vance[2]* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Human Genetics and Department of Medicine, Duke University Medical Center, Durham, NC; 3) Vanderbilt Eye Institute, Vanderbilt University Medical Center, Nashville, TN; 4) Duke University Eye Center and Department of Ophthalmology, Duke University Medical Center, Durham, NC.

Age-related macular degeneration is a devastating disorder, which may result in legal blindness and adversely affects the quality of life for the nearly 2 million Americans suffering from the advanced forms of the disease. In addition to the well-known risk imparted by carrying the Y402H variant in the complement factor H (CFH) gene on chromosome 1, recent evidence for the existence of protective haplotypes spanning CFH has been reported (Hageman et al. 2005, Okamoto et al. 2006). Age-adjusted score statistics provided support for two of these protective haplotypes in our large dataset of 584 sporadic cases and 248 controls ($p<0.01$ and $p=0.069$). We also observed protective effects of these haplotypes in a completely independent family-based dataset with 127 multiplex families($p=0.021$ and $p=0.018$). Most interestingly, we found a marginally significant interaction between one of the protective haplotypes and ever/never smoking status, adding to the growing body of evidence that smoking is an important environmental covariate for AMD, which needs to be considered in genetic studies.

Co-chaperones of the glucocorticoid receptor and depression during pregnancy. *E.R. Katz[1,2], T.C. Deveau[2], D.J. Newport[2], Z.N. Stowe[2], J.F. Cubells[1,2], E.B. Binder[2]* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Psychiatry and Behavioral Sciences, Emory University, Atlanta, GA.

Depression during pregnancy is a major womens health concern. Pregnancy induces dramatic changes in the function of the hypothalamic-pituitary-adrenal axis, leading to elevated maternal cortisol levels. Several mechanisms may limit the activity of cortisol during pregnancy, one of them being increased glucocorticoid receptor (GR)-resistance, which is observed in approximately 80% of pregnant women. The absence of this adaptive response to increasing levels of cortisol may lead to a hypercortisolemic state, which may contribute to depression during pregnancy. One potential mechanism altering GR sensitivity in pregnancy is changes in the expression profile of GR co-chaperones, which have been shown to regulate GR signaling. To test the hypothesis that co-chaperone proteins are regulated throughout the peripartum period and that altered regulation of these proteins may contribute to depression, we investigated the peripheral-blood monocyte expression profiles of 12 co-chaperones of the GR in 8 women at 6 time points (pre-conception, 12, 24 and 36 weeks gestation and 4 and 12 weeks postpartum) and 8 depressed and 8 non-depressed women at 24 weeks gestation. During gestation, we observed a significant up-regulation of FKBP5 and NCOA1 expression, while FKBP4 and STUB1 were significantly down-regulated. Additionally, a significant up-regulation of GR expression itself was observed. The GR and its co-chaperone transcripts normalized by 12 weeks postpartum compared to preconception levels, except for PPIA, which exhibited significant up-regulation at both 4 and 12 weeks postpartum. Expression levels of FKBP5 and BAG1 were negatively correlated with depression scores at 24 weeks gestation. These data suggest that in peripartum depression, a mal-adaptive regulation of chaperone expression could oppose the pregnancy associated GR-resistance. The down-regulation of FKBP5 and BAG1 in women with peripartum depression would lead to less GR resistance, increasing the biologic activity of cortisol which may contribute to depression in pregnancy.

Making Policy for Our Children: The Advisory Committee on Heritable Disorders in Newborns and Children.

R.R. Howell[1], M. Lloyd-Puryear[2] 1) Department of Pediatrics, Miller School of Medicine, University of Miami, Miami, FL; 2) Maternal and Child Health Bureau, Health Resources and Services Administration.

The **Advisory Committee on Heritable Disorders and Genetic Diseases in Newborns and Children** was created by Congress to advise and guide the Secretary of the federal Department of Health and Human Services regarding the most appropriate application of childhood and universal newborn screening tests, technologies, policies, guidelines and programs for effectively reducing morbidity and mortality in newborns and children having or at risk for heritable disorders. This Committee began its work in 2003 and provides technical information to the Secretary HHS in order that the Secretary might develop policies and priorities to enhance the ability of State and local health agencies to provide for newborn and child screening, counseling and health services. The Committee also provides advice on a specific grant program delineated in its authorizing legislation. Coordination and operational services are provided by the Associate Administrator, MCHB, HRSA, with direction and guidance from the Assistant Secretary for Health.

The 15 members of the Committee are appointed by the Secretary and provide special expertise in the field of heritable disorders or in providing screening, counseling, testing or specialty services for newborns and children at risk for heritable disorders. The Committee also includes members of the public having special expertise about or concern with heritable disorders.

The early meetings of the Committee focused on the American College of Medical Genetics report which recommends an expanded and uniform newborn screening panel. The Committee accepted this report and unanimously recommended the report to the Secretary for his consideration and action. Currently the Committee is finalizing its process for nominating, evaluating and recommending screening tests for newborns and children for specific genetic disorders.

This presentation will outline that recommendation process and its implications for screening newborns and children. We will also address other relevant Committee activities.

Interaction of Hermansky Pudlak Proteins Within Biogenesis of Lysosome-related Organelle Complex-2. *P.K. Held, W. Westbroek, M. Ayub, H. Dorward, A. Helip-Wooley, M. Huizing, W.A. Gahl* MGB, SHBG, NHGRI/NIH, Bethesda, MD.

Hermansky Pudlak syndrome (HPS) is a rare, genetically heterogeneous autosomal recessive disease characterized by oculocutaneous albinism, prolonged bleeding, and occasional colitis or pulmonary fibrosis. The proteins encoded by HPS genes play a role in the biogenesis of lysosome-related organelles, but their precise biological functions remain elusive. Different HPS proteins interact with each other in BLOCs, i.e., Biogenesis of Lysosome-related Organelle Complexes. Specifically, human HPS3, HPS5, and HPS6 proteins interact in BLOC-2, but the mode of interaction has not been identified. It has been suggested that HPS5 and HPS6 directly interact, while HPS5 and HPS3 engage in an indirect interaction. In previous studies, we unsuccessfully attempted to confirm the direct interaction of human HPS5 and HPS6 by yeast two-hybrid screening; we speculate that yeast lack the machinery necessary for posttranslational modifications to enable interaction of the human proteins. Consequently, we employed a mammalian interaction system. Using the MAPPIT (MAmmalian Protein-Protein Interaction Trap) system, we demonstrated a strong, direct interaction between the HPS6 protein and the longer of two splice forms of HPS5. Immunoprecipitation studies in cultured human embryonic kidney cells confirmed the direct interaction of HPS6 with the long form of HPS5, which has a putative WD40 domain at its N-terminal site. This domain is interrupted in the short form of HPS5, and it may function as the platform for a protein-protein interaction with HPS6 and, perhaps, other proteins. Validating the mode of interaction between HPS proteins is critical to understanding how the BLOCs are formed and whether additional proteins exist within the different complexes. There are many patients who are clinically, but not genetically, diagnosed with HPS, suggesting that additional interacting proteins exist within the known BLOCs. We plan to use the MAPPIT system to identify these additional HPS proteins, with a goal of identifying the basic defect in HPS patients who do not have subtypes 1-8.

Natural history of aging in Cornelia de Lange syndrome. *A.D. Kline[1], P. Sponseller[2], C. Pichard[2], M. Grados[3], D. Tuchman[4], H. Levy[5], A. Kimball[1], N. Blagowidow[1]* 1) Harvey Institute Human Genetics, Greater Baltimore Medical Center, Baltimore, MD; 2) Department of Orthopaedics, Johns Hopkins University School of Medicine; 3) Department of Psychiatry, Johns Hopkins University School of Medicine; 4) Pediatric Gastroenterology, Sinai Hospital of Baltimore; 5) Department of Internal Medicine, Johns Hopkins University School of Medicine.

Findings of 44 patients with Cornelia de Lange syndrome (CdLS), seen in a multidisciplinary clinic for adolescents and adults, have allowed the following observations about the natural history. The patients ranged from 13 to 37 years, with 48% older than 17 years, and demonstrated a sex ratio of 1:1. Although most patients remain small, 15% develop obesity with age, most commonly in the truncal region. Gastroesophageal reflux persists or worsens, and there are early long-term sequelae, including development of Barrett esophagus in the teens and 20s. Over 35% have chronic sinusitis, of whom one-third have nasal polyps. Blepharitis improves with age, and both cataracts and detached retina have been noted. Osteopenia and osteoporosis have been observed, with occasional fractures. One third have leg length discrepancy. Low levels of vitamin D, estrogen and testosterone have been measured. Most females have delayed menarche and irregular menses, but normal gynecologic exams and pap smears. Although the phenotype is somewhat variable, a distinct pattern of facial changes with aging is evident. Premature gray hair is frequent; two patients have had cutis verticis gyrata. Behavioral issues and specific psychiatric diagnoses, including self-injury, anxiety, attention deficit disorder, autistic features, depression and obsessive-compulsive behavior, may arise or worsen with aging. These findings present evidence for accelerated aging in CdLS. Of the 45% who underwent mutation analysis, only a third demonstrated a detectable mutation in NIPBL or SMC1L1, and no genotype-phenotype correlations have been able to be made. Specific clinical management for adults with CdLS can be recommended.

Initial Analysis of Linkage Disequilibrium in the Mexican Mestizo Population. *A. Hidalgo-Miranda, I. Silva-Zolezzi, J. Estrada, E. Barrientos, S. March, L. del Bosque-Plata, O. Perez-Gonzalez, E. Balam-Ortiz, A. Contreras, A. Inchaustegui, C. Davila, L. Orozco, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Mexico develops a national platform in genomic medicine to improve health of the Mexican population. A key component of this effort is the production of a haplotype map to improve the design of association studies for common diseases. The Mexican population has a unique genetic origin, more than 80% of the population is considered Mestizo, resulting from the admixture of any of 62 ethnic groups with the Spaniards in the last 500 years. We collected 1,200 blood samples from distant states of Mexico. From these, we analyzed 104 samples from Sonora (n=20), Yucatan (n=17), Guerrero (n=21), Zacatecas (n=19), Veracruz (n=18) and Guanajuato (n=9) using the 100K Affymetrix SNP array. Our goal was to determine minor allele frequency (MAF) distribution and estimate linkage disequilibrium (LD) decay with genomic distance, measured as the fraction of markers with highly correlated alleles using r^2 and D' (r^2>0.8, D'>0.8) in the Mexican population. We compared our results with the Affymetrix 100K SNP array data from the International HapMap Project. We included samples with a SNP call rate 95% using the Dynamic Model (DM) algorithm. Additional analysis with the Bayesian Robust Linear Model with Mahalanobis distance classifier (BRLMM) increased our SNP call rate to 97% Allele frequency distribution in these samples showed a similar pattern to that of other populations when MAF 15% In contrast, the percentage of markers in the 0-5% bin is among the lowest when compared to a similar analysis performed by Bonnen et al, 2006 on the European, Asian, African and Kosrean populations. Our results show similar LD decay as compared to the non-African populations included in the International HapMap Project. MAF distribution in this sample suggests a higher genetic heterogeneity in Mexican Mestizos compared to other populations. To increase the resolution of this analysis, 100 samples from each of these states are being analyzed using the Affymetrix 500K SNP array.

Values in conflict: U.S. public attitudes on embryonic stem cell research. *K.L. Hudson, D.J. Kaufman, R. Faden, J. Scott* Genetics & Public Policy Center, Berman Bioethics Institute, Johns Hopkins Univ, Washington, DC.

Purpose: The policy debate surrounding embryonic stem cell (ESC) research has been animated and divided by many moral issues. To assess the publics attitudes about ESC research, related moral issues, and the effect of using either the term *somatic cell nuclear transfer (SCNT)* or *cloning*, we surveyed 2,122 Americans.

Results: A majority of the sample (67%), which cut across most demographic groups, approved of ESC research using embryos remaining after IVF. A majority (59%) supported a federal policy for ESC research more permissive than the current policy while 22% favored retention of the current U.S. policy and 16% would ban ESC research. Attitudes towards ESC research were not explained solely by views on the moral status of embryos. For example, fully one third of those giving a week-old embryo in a Petri dish maximum moral status nonetheless approved of ESC research and supported relaxing federal ESC research policy. Similarly, 17% of those affording the embryo no/low moral status disapproved of ESC research.

The sample was divided and half were asked questions about *SCNT* and the other half about *cloning*. Both terms were defined identically. When the process of creating embryos for ESC research was called *cloning*, 29% approved of its use, while 46% approved when *SCNT* was used ($p<0.0001$). Approval for using *SCNT* to make a child was twice as high as approval for using *cloning* (24% vs. 10%, $p=0.004$).

Conclusion: Wide support for ESC research in the US cuts across political, religious and socioeconomic lines. Unlike the polarized views expressed in the policy debate, for many Americans, opinions on ESC do not mirror their attitudes about the moral status of the human embryo. Even though defined identically, use of the term SCNT or cloning resulted in vastly different stated opinions. SCNT was associated with much higher levels of support for both ESC research and reproductive purposes.

Counseling Implications in Familial 3q29 Microdeletion Syndrome. *S. Jamal[1], XL. Huang[1], HFL. Mark[1,2], JM. Milunsky[1,3,4]* 1) Center for Human Genetics, Boston University School of Medicine; 2) Dept. of Pathology, BUSM; 3) Dept. of Pediatrics, BUSM; 4) Dept. of Genetics and Genomics, BUSM.

3q29 microdeletion syndrome [MIM 609425] is a newly identified condition that was first described in 2001 in a 2 month old with moderate mental retardation, facial dysmorphism, horseshoe kidney, and hypospadias. Six other patients have been identified as having this syndrome with all determinable cases being reported as isolated/*de novo*. We present the first known familial case of two siblings with 3q29 microdeletion syndrome. The proband, aged 4 years 10 months, presented with mild mental retardation, significant speech delay, and atypical behaviors. Her growth parameters are between the 25-50th %ile. She is noted to have dysmorphic features including: a long and narrow face, broad nasal bridge, upslanting palpebral fissures, deep philtrum, micrognathia, pectus excavatum, and ligamentous laxity. She also has a right ear pit, posteriorly rotated small ears, history of recurrent otitis media, and bilateral conductive hearing loss. Renal ultrasound was normal. The probands brother, aged 2 years, presented with global developmental delay, significant speech delay, and possible autistic spectrum disorder. His growth parameters are at the 50th %ile. He is noted to have dysmorphic features including: a long and narrow face, broad nasal bridge, long philtrum, carp-shaped mouth, micrognathia, and pes planus. He also has a left ear tag, borderline low set ears, and possible bilateral conductive hearing loss. High resolution chromosome and subtelomere FISH analysis on blood samples of both sibs revealed a deletion of 3q29: 46,XX,del(3)(q29).ish(pcp3q-,wcp3+) and 46,XY,del(3)(q29).ish(pcp3q-,wcp3+), respectively. Maternal high resolution chromosome and subtelomere FISH analysis were normal. A paternal blood sample was not available for analysis. We describe the first known case of familial 3q29 microdeletion syndrome. Describing these two affected siblings will further elucidate the clinical phenotype and significance associated with 3q29 microdeletion syndrome and have significant implications for genetic counseling.

Implications for Clinical Management in Incomplete WAGR(O) Syndrome with an Atypical 11p13 Deletion. *XL. Huang[1], S. Jamal[1], HFL. Mark[1,2], TA. Maher[1], JM. Milunsky[1,3,4]* 1) Center for Human Genetics, Boston University School of Medicine; 2) Dept. of Pathology, BUSM; 3) Dept. of Pediatrics, BUSM; 4) Dept. of Genetics and Genomics, BUSM.

WAGR syndrome is a rare, yet well described contiguous gene disorder typically characterized by Wilms tumor, Aniridia, Genitourinary abnormalities, and Mental Retardation [MIM 194072]. A diagnosis requires the presence of aniridia and at least one other major acronymous criterion in conjunction with a constitutional chromosomal deletion at 11p13, the location of the PAX6 and WT1 genes. Deficiencies in the PAX6 gene result in ocular, central nervous system, and pancreatic abnormalities. Abnormalities in the WT1 gene result in an increased risk for Wilms tumor, nephropathy, and genitourinary abnormalities. We present a 19 year old female with multiple ocular abnormalities including: bilateral aniridia, corneal opacities, optic nerve hypoplasia, microcornea, ptosis, and a history of strabismus and nystagmus, as well as microcephaly, bilateral SNHL, short stature, patent ductus arteriosus repair, marked obesity, dextroscoliosis, mental retardation, and behavioral problems. Several urinalyses and renal ultrasounds were normal. High resolution chromosomal analysis revealed a deletion between 11p11.2-12 or 11p13-14. BAC-FISH analysis revealed an interstitial chromosomal deletion: 46,XX,del(11)(p13p14.3). This 9.8Mb deletion encompasses *at least* the PAX6 gene promoter and distal genes. The WT1 gene, although typically deleted in patients with WAGR syndrome, was present in our patient. Consequently, these findings are compatible with the absence of genitourinary abnormalities and no evidence for an increased risk of developing Wilms tumor in our patient. We present a patient with an atypical 11p13 deletion with clinical features consistent with WAGR(O) syndrome. Elucidating the particular region of 11p that is absent in patients with WAGR(O) syndrome has significant clinical implications since individuals with the WT1 gene present do not require Wilms tumor surveillance. This patient provides further elucidation of WAGR(O) syndrome and the value of FISH determination of the genotype.

Association Analysis of vitamin D binding protein (DBP) Gene Polymorphisms with Variations of Obesity Related Traits in Caucasian Nuclear Families. *H. Jiang[1,3*], D.H. Xiong[2,3*], Y.F. Guo[1], F. Yang[1,3], Y. Chen[1,3], F. Zhang[3,4], H.W. Deng[1,3,4], *The first two authors contributed equally to this work.* 1) Laboratory of Molecular and Statistical Genetics, Hunan Normal University, Changsha, Hunan, P R China; 2) Departments of Orthopedic Surgery and Basic Medical Sciences, University of Missouri - Kansas City, Kansas City, MO,USA; 3) Osteoporosis Research Center and Department of Biomedical Sciences, Creighton University, Omaha, NE, USA; 4) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, P R China.

Vitamin D binding protein (DBP) gene is well known for its function on glucose and vitamin D metabolism in human populations. Previous studies suggested that the in vivo DBP level may play a role in the etiology of obesity. However, few studies explored the contribution of DBP gene to the variance of obesity phenotypes. In the present study, we investigate the relationship of DBP polymorphisms and obesity in Caucasian nuclear families. We genotyped fourteen SNPs (Single Nucleotide Polymorphisms) located in and around the DBP gene in 1873 Caucasian subjects from 405 nuclear families. Three obesity-related quantitative phenotypes were investigated, including body mass index (BMI), fat mass and percentage of fat mass (PFM). Single SNPs and haplotypes (three blocks) were tested by family based association using the FBAT software. SNP2 (rs17467825) and its corresponding haplotype GAA (frequency 0.270) in block1 showed strongest associations with PFM (P=0.0011 and 0.0023, respectively). In multivariate test significant association was also observed for SNP2 with fat_mass & BMI & PFM (P=0.0098). Subsequent sex-stratified analyses demonstrated nominal association for SNP2 and haplotype GAA with PFM in the female subgroup. Polymorphisms of DBP gene were significantly association with human PFM, especially in female, suggesting the importance of DBP gene in the pathogenesis of human obesity.

Dysregulation of sodium channel 4 subunit by expanded polyglutamine. *F. Oyama, H. Miyazaki, K. Okamura, Y. Machida, M. Kurosawa, T. Sakurai, N. Nukina* Lab Structural Neuropathology, RIKEN Brain Science Inst, Saitama, Japan.

Sodium channel 4 (4) is an auxiliary subunit of the voltage gated-sodium channels. We have identified 4 as an EST that was significantly downregulated in the striatum of HD model mice and found that reduction in 4 started at a presymptomatic stage of the HD model mice. In contrast, spinal cord neurons, which generate only negligible levels of expanded polyQ aggregates, maintained normal levels of 4 expression even at the symptomatic stage. Expanded polyQ with NLS expression suppressed the promoter activity of 4 gene in PC12 cells. Forskolin, an activator of the cAMP/PKA pathway, did not affect 4 promoter activity, indicating that 4 is not cAMP-responsive gene. These findings strongly suggest that sodium channel 4 subunit is a novel molecule, which is an upstream non-cAMP-responsive gene in HD pathogenesis.

PharmGKB - Accentuating the Knowledge in the Knowledge Bases. *T. Klein, C. Thorn, T. Boussard, M. Carrillo, J. Hebert, A. Hodge, M. Woon, J. Gallerani, M. Gong, W. Gor, D. Holbert, M. Kiuchi, F. Liu, A. MacBride, T.C. Truong, T. Zhou, R. Altman* Dept Genetics, Stanford Univ, Stanford, CA 94305-5120.

The mission of the Pharmacogenetics and Pharmacogenomics Knowledge Base (PharmGKB; http://www.pharmgkb.org) is to catalyze pharmacogenetic and pharmacogenomic research. The PharmGKB collects, organizes, and disseminates data and knowledge about pharmacogenetics and pharmacogenomics. It is focused on supporting hypothesis generation.

In order to deliver optimal health care, scientists must understand the mechanisms of human drug response. The relevant literature is extensive, but does not efficiently support hypothesis generation, particularly when considering large data sets. Scientists therefore require data resources that 1) provide links to successful experimental approaches, 2) provide a starting point for studying analogous systems, 3) set standards of evidence in the field, 4) allow data to be pooled for increased power, and 5) store public data and knowledge in an archival manner. The PharmGKB is designed to provide these resources.

The PharmGKB team has created an infrastructure composed of data, curated knowledge, software, and hardware. The PharmGKB is expected to attract important public data sets relating to the variation in drug response, as it becomes the major repository for pathways of drug action and metabolism. We are helping to define standards for phenotype data exchange. Because PharmGKB maintains data associated with single individuals, it must protect the confidentiality and privacy of study subjects.

The PharmGKB is part of the NIH/NIGMS Pharmacogenetics Research Network (U01GM61374).

.

Assessment of allele-specific gene silencing by siRNA duplexes and short hairpin RNAs with wild and mutant-type reporter alleles. *Y. Ohnishi[1,2], M. Yoshida[2], Y. Tamura[2], K. Tokunaga[1], H. Kimura[2], H. Hohjoh[2]* 1) Dept Human Genetics, Univ Tokyo, Tokyo, Japan; 2) National Institute of Neurosience, NCNP, Tokyo, Japan.

Allele-specific gene silencing by RNA interference (RNAi) is therapeutically useful for specifically suppressing the expression of alleles associated with disease. To realize such allele-specific RNAi (ASP-RNAi), the design and assessment of small interfering RNA (siRNA) duplexes conferring ASP-RNAi is vital, but is also difficult. We have developed an easy evaluation system, which depends on heterozygous reporter plasmids encoding the *Photinus* and *Renilla luciferase* genes, for siRNA duplexes conferring ASP-RNAi. The system could allow assessment, if designed siRNA duplexes have the potential for specifically inhibiting the expression of target alleles without suppressing the expression of other alleles. Using the system with the *Swedish APP* variant related to familial Alzheimers disease as a model, we examined effects of various synthetic siRNA duplexes and also of their structural modifications on ASP-RNAi. Based on the results, we further constructed shRNA expression vectors for a long lasting ASP-RNAi. The results, however, indicated that the effect of shRNA on ASP-RNAi was different from those of synthetic siRNA duplexes; this may be caused by possibly mixed siRNA duplexes derived from shRNA by various Dicer digestion. To improve ASP-RNAi with shRNA, we introduced base substitutions in siRNA sequences so that the resultant siRNAs could strongly discriminate mutant allele from wild type one. From a series of screening of siRNAs carrying various substitutions by using the system described above, we found competent siRNA duplexes conferring a strong ASP-RNAi. Based on the observations, construction of new shRNA expression vectors is now in progress. In this meeting, we would like to discuss base substitutions in siRNA sequence, by which ASP-RNAi could be enhanced, and the system with reporter alleles to assess ASP-RNAi.

Regulation of a sense/antisense transcript within TAF1/DYT3 that contains a sequence change (C>T) exclusively found in patients with X-linked dystonia-parkinsonism. *U. Müller, T. Herzfeld, J.A. Kress, D. Nolte* Institute of Human Genetics, Justus-Liebig University, Giessen, Germany.

X-linked dystonia parkinsonism (XDP) is associated with disease-specific sequence changes (DSCs) within TAF1/DYT3. TAF1/DYT3 encodes multiple transcripts including four major variants (var.1-var.4) relevant to XDP (Nolte et al., 2003). Var.1 and var.2 include exons of TAF1 (TATA-box binding protein-associated factor 1) in addition to exons not previously recognized as parts of the TAF1 gene (referred to as exons 1-5). Var. 3 and var.4 are encoded by exons 2-4 and exons 3-4, respectively. Exon 4 is utilized by all four major transcript variants and includes a C>T exchange (DSC3) in patients exclusively. We performed functional analyses of exons 2-4 encoding transcript variant 3. In silico analysis of the 5'region of exon 2 revealed several sites for human transcription factors including Sp1, HIF-1, MEF-2, Ikaros, and c-Ets-2. We cloned fragments upstream of exon 2 of various sizes (1644bp, 639bp, 253bp, 137bp) in pGL3/luciferase. Expression studies in U87 and NT2/D1 cells demonstrated that the two larger but not the smaller fragments activated luciferase and thus contain the functional promoter (referred to as 5'var.3 promoter). Coexpression of Ikaros isoform 2 in cells containing either the 1644bp or the 639bp fragment resulted in promoter suppression. Additional functional analyses including HIF-1 and MEF-2c did not affect promoter activity. The 3'end of exon 4 contains a LTR promoter with strong activity in antisense direction. This promoter is a member of the HERV9 family and is included in a 521 bp fragment that is functional in the luciferase assay. We are currently exploring whether the LTR promoter regulates other promoters of the TAF1/DYT3 transcript system, such as the 5' var.3 promoter, and whether DSC3 affects this potential regulation. Nolte D, Niemann S, Müller U: Specific sequence changes in multiple transcript system DYT3 are associated with X-linked dystonia parkinsonism. Proc. Natl. Acad. Sci (USA) 100: 10347-10352 (2003).

ENCODE Multiple Species Sequencing Data elucidate the early history of Mammals and allow the detection of evolutionary characteristics in Hominoid lineage. *S. Nikolaev[1], J. Montoya-Borgos[2], E.H. Margulies[3], NISC Comparative Sequencing Program[3,4], J. Rougemont[5], B. Nyffeler[5], S.E. Antonarakis[1]* 1) Genetic Medicine and Development, University of Geneva, Switzerland; 2) Animal Biology, University of Geneva. Switzerland; 3) Genome Technology Branch, National Human Genome Research Institute, NIH, Bethesda, 20892, USA; 4) NIH Intramural Sequencing Center, National Human Genome Research Institute, NIH, Bethesda, 20892, USA; 5) Vital-It team, Swiss Institute of Bioinformatics, Lausanne. Switzerland.

Understanding the early evolution of placental mammals remains the last challenging issue in mammalian phylogeny. Here we address this question by using the sequence data of the ENCODE consortium which include orthologous regions of genomes in 18 species belonging to all main mammalian lineages. Phylogenetic reconstructions based on an unprecedented amount of Coding Sequences (CDS) taken from 218 genes resulted in a highly supported tree placing the root of Eutheria between Afrotheria and Exafroplacentalia (Boreoutheria and Xenarthra). This topology was validated by the phylogenetic analysis of a new class of genomic phylogenetic markers, conserved non-coding sequences (CNC). Applying the Shimodaira-Hasegawa test on the CDS dataset resulted in the rejection of the Atlantogenata theory (Xenarthra grouping with Afrotheria), while this test rejected the second alternative scenario, the Epitheria theory (Xenarthra at the base), when performed on the CNC dataset. Thus the two datasets contain complementary phylogenetic signal, and only taken together settle the debate about the position of the eutherian root. Using phylogenetic reconstructions based on CNCs, non-synonymous (dN) and silent (dS) substitutions from CDS, we show that, within mammals, primates display a slowdown of evolutionary rates in all three genomic features. Hominids and particularly humans show the most severe slowdown, which is consistent with the longer generation time. Despite the observed general slowdown, hominoids and particularly humans have undergone a relaxation of purifying selection acting on constrained elements, which is consistent with the smaller effective population size found in these lineages.

Malignant Hyperthermia Susceptibility: Diagnostic procedure and novel RYR1 mutations. *S. Levano, M. Singer, S. Treves, A. Urwyler, Th. Girard* Departments of Anesthesia and Research, University Hospital, Basel, Switzerland.

Malignant hyperthermia (MH) is a dominantly inherited pharmacogenetic disorder of skeletal muscle whose diagnosis is established by the in-vitro contracture test (IVCT). This method is invasive, not applicable to young children, handicapped and elderly persons leading many researchers to refine and develop new diagnostic procedures. Since the introduction of new EMHG guidelines in 2001 implementing genetic testing in those families where causative mutations in the ryanodine receptor type 1 (RYR1) have been confirmed, we have found that 40 % of the Swiss MH families harbour 8 of 23 causative RYR1 mutations. More importantly, in Switzerland, in 2001 more patients were diagnosed MH susceptible (MHS) by molecular genetic methods than the IVCT (29 vs 14, respectively): the V2168M RYR1 mutation was the most frequent causative mutation and has been found in 16 Swiss families. Since in humans MH is a heterogenetic disease, there is a need to find new RYR1 causative mutations in order to include them in a genetic based-MH diagnostic assay. In the present report we screened the whole RYR1 cDNA in 36 samples and describe the genotype and phenotype correlation of 4 novel potentially causative mutations. The nucleotide substitutions alter the encoded amino acids that are highly conserved throughout evolution as well as in the different human RYR isoforms. We found good concordance between the segregation of the novel mutations among three generations and the MH phenotypes based on the IVCT. The R2336H RYR1 substitution was detected in 9 out of 36 families in 26 out of 30 individuals who were diagnosed as MHS. The other 4 MHS individuals were excluded from this analysis because of no direct inheritance. The D2730G, E2404K and D544Y RYR1 substitutions were each found in single families and all 25 MHS subjects who were diagnosed as MHS by the IVCT, were mutation carriers. All 83 MH normal (MHN) individuals in the 12 families were not carriers for these novel mutations and the mutations were not found in 100 control samples. The functional effect of these four novel mutations is currently under investigation.

Association between the severity of angiographic coronary artery disease and paraoxonase-1 promoter gene polymorphismT(-107)C in Iranian population. *E. Javadi[1,2], A. Jalilian[2], M. Doosti[2], P. Amiri[1], B. Shariati[3]* 1) Shariati hospital, EMRC(Endocrine and Metabolism Research Center), Tehan, Tehran, Iran; 2) Department of Medical Biochemistry,school of medicine of Tehran university,Tehran ,Iran; 3) Department of community medicine,school of medicine,Tehran university of medical science,Tehran,Iran.

Increased plasma low-density lipoprotein-cholestrol(LDL-C)levels are associated with enhanced LDL oxidation that represents and additional risk for coronary artery disease(CAD).Paraoxonase-1(PON1)is an enzyme associated with the high-density lipoprotein(HDL)particle.It catalyses the hydrolysis of organophosphates and protects LDL from oxidative modification in vitro by hydrolyzing lipid peroxides,suggestive of a role for PON1 in the development of CAD.The present study tested the hypothesis that PON1 promoter plymorphismT(-107)C could be a risk factor for CAD in Iranian patients.Paraoxonase promoter genotypes were determined in 300 consecutive subjects(>40 years old)who underwent coronary angiography(150 subjects with 50% stenosis served as cases[CAD+]and 150 subjects with <20% stenosis served as controls[CAD-].Paraoxonae promoter genotypes were determined by PCR and BSTU1 restriction enzyme digestion .CAD+ subjects did not show any significant difference in the distribution of PON1 promoter genotypes as compared to CAD- subjects(p=.075)However the analysis of PON1 promoter genotypes distribution showed an higher percentage of (-107)TT among CAD+ compared with CAD-(P=.027).After controlling for other risk factors,the T(-107)C polymorphism had correlation with age(p=.027).After controlling for other risk factors,the T(-107)C polymorphism had correlation with age(p=.012),but did not show any correlation with other risk factors such as BMI,gender,smoking,diabetes,level of HDL-C,LDL-C,TG and TC.These data suggest that the TT genotype may represent a genetic risk factor for coronary artery disease in Iranian population.

Decreased expression of Hsp27 associated with cell toxicity in a cellular model of Machado-Joseph Disease. *M. Hsieh[1, 2], W.H. Chang[1], F.C. Wen[1]* 1) Dept Life Sci, Tunghai Univ, Taichung Taiwan, Taiwan; 2) Life Science Research Center, Tunghai Univ, Taichung, Taiwan.

Machado-Joseph disease (MJD) is an autosomal dominant spinocerebellar degeneration caused by the expansion of a polyglutamine tract within the gene product, ataxin-3. We have previously shown that increased oxidative stress and decreased expression of Hsp27 may be contributory factors for the pathogenesis of Machado-Joseph disease. In this study, we utilized neuroblastoma SK-N-SH cells stably transfected with full-length MJD with 78 polyglutamine repeats to further investigate the mechanism resulting in decreased expression of Hsp27 and how endogenous expression of Hsp27 influences neuronal cell survival. Results from semi-quantitative RT-PCR and 35S-methionine pulse-chase labeling revealed that decreased expression of Hsp27 in mutant MJD cells is due to defects in protein synthesis. These findings provide the first evidence that mutant ataxin-3 may be involved in deregulation of protein synthesis. In addition, in contrast to Hsp70, we demonstrated that Hsp27 degradation in SK-N-SH cells does not go through proteasome degradation pathway. Furthermore, t-butyl hydroperoxide was used to assess the tolerance of different passages of cells expressing mutant ataxin-3. Our results indicated that earlier passages of mutant cells were less tolerant to exogenous oxidative stress, which may be due to the decreased endogenous Hsp27. Consistently, we showed that over-expression of Hsp27 desensitizes SK-N-SH-MJD78 cells to poly-Q toxicity. These results support a model that full-length mutant ataxin-3 expression does significantly impair cells ability to respond to stresses, which may be partly due to decreased expression of Hsp27 together with increased cell toxicity in cells expressing mutant ataxin-3.

Further support for *KIAA0319* as a susceptibility gene for developmental dyslexia. *D. Harold[1], S. Paracchini[2], T. Scerri[2], M. Dennis[2,3], N. Cope[1], G. Hill[1], V. Moskvina[1], J. Walter[2], A.J. Richardson[2], M.J. Owen[1], J.F. Stein[2], E.D. Green[3], M.C. ODonovan[1], J. Williams[1], A.P. Monaco[2]* 1) Cardiff University, UK; 2) University of Oxford, UK; 3) National Human Genome Research Institute, Bethesda, MD.

The DYX2 locus on chromosome 6p22 is the most replicated region of linkage to developmental dyslexia (DD). Two candidate genes within this region have been implicated in the disorder: *KIAA0319* and *DCDC2*. Five variants within *DCDC2* have shown association with DD in a US and a German sample. We genotyped these variants in two independent UK samples from Cardiff and Oxford. Although nominally significant associations were detected between three *DCDC2* SNPs and reading traits in the Oxford sample, no association with DD was observed for any *DCDC2* variant in the Cardiff sample.

Having previously found evidence that variation in *KIAA0319* confers susceptibility to DD, we sought to refine this association by genotyping 36 additional SNPs in the gene. Ten SNPs, predominantly clustered around the first exon, showed the most significant association with DD in one or both UK samples, including rs3212236 in the 5flanking region ($P = 0.00003$) and rs761100 in intron 1 ($P = 0.0004$). The location of this association may indicate the presence of susceptibility variants influencing gene regulation.

The KIAA0319 and DCDC2 proteins share functional similarities: both appear to play a role in neuronal migration, a mechanism that has been implicated in the development of DD. We tested for epistatic interactions between variants in the two genes and observed a significant interaction between rs793862 in *DCDC2* and rs761100 in *KIAA0319* ($P = 0.007$).

Thus our data provide further support for *KIAA0319* as a DD susceptibility gene in the UK population. The evidence implicating *DCDC2* is inconsistent, but it may contribute to DD susceptibility through epistatic interactions with *KIAA0319*.

A Novel CFTR Mutation in a Korean Infant with Cystic Fibrosis. *J.H. Lee, G-H. Kim, J.M. Ko, H-W. Yoo*
Pediatrics, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

Cystic fibrosis (CF) is the most common lethal autosomal recessive disease in Caucasians, but rare in Asians. The mutations of cystic fibrosis transmembrane conductance regulator (CFTR) gene are responsible for CF. Up to date, 3 cases of CF have been reported and only one of them diagnosed based on the genotype of the CFTR gene. We encountered a 4-month-old Korean Infant with CF and his diagnosis was confirmed by CFTR gene mutation analysis. The patient was born to health parents of non-consanguineous marriage. The patient underwent surgical operation, due to meconium ileus at birth. He had chronic respiratory symptom, failure to thrive, fatty liver with hepatomegaly, and cholestasis. The mutations of the CFTR gene were identified in the patient and his parents. The patient was a compound heterozygote with a nonsense mutation of c.263T>G, resulting in an amino acid change of p.Leu88X in exon 3. It was previously described in a Korean patient with CF. The other is a novel mutation; c.2089-2090insA mutation (p.Arg697Lysfsx33) in exon 14. The mutation c.263T>G was inherited from his father, and the c.2089-2090insA mutation from his mother. His parents were apparently healthy carriers. We report a novel CFTR mutation in a Korean infant with CF.

Expression profile pathology of Alzheimer disease model mice is enhanced by low omega-3 polyunsaturated fatty acid diet: synapse is the intersection of the disease and diet. *T. Morihara[1], B. Teter[2], S. Ball[2], G.P. Lim[2], F. Calon[2], L. Zhao[2], F. Yang[2], M. Takeda[2], S.A. Frautschy[2], G.M. Cole[2]* 1) Psychiatry, Osaka University Graduate School of Medicine, Suita, Osaka, Japan; 2) Neurology, University of California Los Angeles, North Hills, CA.

Background: Alzheimer Disease (AD) is a complex disease, which is affected by environmental factors. Diet including 3 polyunsaturated fatty acid is the one of the important environmental factors that were shown to impact on AD by epidemiological studies. We used AD model animals (APP transgenic mice), which allow to control environmental factors. Four gropes, APP Tg mice with standard chow, with low 3 chow and non Tg mice with standard chow, with low 3 chow were analyzed. We previously reported that the amyloid pathology which is the central pathology of AD was enhanced by low 3 diet in APP Tg mice (*J Neurosci* 2005 25:3032, *Neuron* 2004 43:633).

Results: To address the underlying interaction between these two complex factors, AD and diet, microarray analysis were performed. The number of genes affected by diet was 117 in APP Tg mice, which was 17 times more than in Tg-. The number of genes affected by APP Tg on the animals with standard diet was 305. In the animals with low 3 diet, 604 genes were affected by APP Tg. These observations suggested that low 3 diet and APP transgene enhance their expression profiles change each other. To reveal what kinds of genes were commonly changed by diet and APP transgene, GO annotation analysis were performed using EASE. 74 genes which were commonly changed by diet and APP transgene were compared to the genes generally affected by diet (117 genes) or APP transgene (604 genes). The enriched GO annotations in the commonly changed 74 genes were transmission of nerve impulse and synaptic transmission.

Conclusion: The two complex factors APP transgene (AD causative mutation) and low 3 diet enhance their expression profile each other. Synapse was identified as the intersection of the two factors.

A Fourth Phenotype for Autosomal Dominant Hypercholesterolemia. *A. Marques[1], M. Abifadel[1], J. Bonneau[1], K. Ougerram[2], Y. Zair[2], M. Devillers[1], D. Erlich[1], M. Krempf[2], C. Junien[1], A. Munnich[1], J-P. Rabès[1], C. Boileau[1], M. Varret[1]* 1) INSERM U781, Hôpital Necker-Enfants Malades, Paris, France; 2) INSERM UR539, Hôtel-Dieu, Nantes, France.

Autosomal Dominant Hypercholesterolemia (ADH), characterized by isolated elevation of LDL-cholesterol, is associated with high risk of premature cardiovascular disease. Three genes have already been implicated : LDLR (low density lipoprotein receptor), APOB (apolipoprotein B-100) and PCSK9 (proprotein convertase subtilysin kexin-like 9). We now report a large French ADH family in which involvement of these three genes was excluded and named the pathology HCHOLA4 in accordance with the official nomenclature. Our aim is to identify the new disease gene and to define the associated pathophysiology. A whole-genome scan, using 232 polymorphic microsatellite markers, located the HCHOLA4 gene at 16q22.1 in a 5.31 cM interval. Functional candidate genes in the critical interval were tested by sequencing but no causal mutation was detected. In vivo kinetics of apolipoprotein B-100-containing lipoproteins, conducted in 2 affected members, mainly showed a decrease in LDL catabolism like as observed in LDLR mutation carriers. Q-PCR analysis of LDLR expression in EBV-transformed lymphoblasts, cultured in standard and cholesterol-deprived mediums, showed that cells of two affected subjects do not reply to cholesterol deprivation by activating LDLR expression contrary to controls in whom the expression rate increases 2-fold. This lack of reply to cholesterol deprivation has also been described in LDLR mutation carriers. These results suggest that this novel form of ADH is due to an alteration, direct or not, in LDL receptor endocytosis or intracellular traffic. Furthermore, we performed two-dimensional electrophoresis for cytosolic and membrane proteins from lymphoblasts and fibroblasts and observed different profiles for affected subjects when compared to non-affected relatives. Mass spectrometry for twenty of the more significatively different proteins is in process. We expect to identify one or more proteins for wich the coding gene is localized in the 16q22.1 interval of interest.

Investigation of Candidate Genes for Attention-Deficit/Hyperactivity Disorder in the Chromosome 5p12-q11 Region. *N. Laurin[1], A. Ickowicz[2], T. Pathare[2], M. Malone[2], R. Tannock[2], R. Schachar[2], J.L. Kennedy[3], C.L. Barr[1,2]* 1) Cell & Molecular Division, Toronto Western Research Institute, Toronto, ON, Canada; 2) Brain and Behaviour Programme, The Hospital for Sick Children,; 3) Centre for Addiction and Mental Health, Department of Psychiatry, University of Toronto, Toronto,ON, Canada.

Attention-deficit/hyperactivity disorder (ADHD) is a highly heritable childhood-onset disorders characterized by age-inappropriate levels of inattention, hyperactivity and impulsivity. Three independent genome scans aimed at uncovering major risk genes for ADHD have been performed using affected sib pairs. Region 5p12-q11 was the only region presenting evidence of linkage in all screens. The aim of this research was to investigate candidate genes located in this region for their involvement in ADHD in our sample of families from Toronto. Four genes were selected according to their role in brain functions, their interaction with systems known to be important in ADHD, their expression pattern and/or results from animal studies. These are the genes for glial-derived neurotropic factor (GDNF), islet-1 (ISL-1), the hyperpolarization activated cyclic nucleotide-gated potassium channel-1 (HCN1) and a glial glutamate transporter (SLC1A3) previously implicated in ADHD. A total of 15 SNPs across these genes were genotyped and analyzed using the transmission disequilibrium test (TDT). The study sample consisted of 258 nuclear families ascertained through a proband with ADHD (311 affected children). Analysis of individual markers did not yield significant association for any of the markers. Moreover, no bias was revealed for any of the haplotypes observed for each gene. Finally, when analyzed in relation to dimensional symptom scores of inattention and hyperactivity/impulsivity, no strong association was demonstrated for individual markers or haplotypes. Our results do not support major involvement of ISL-1, GDNF or HCN1 in ADHD in our sample of families. In addition, we did not replicate previous finding implicating SLC1A3 in ADHD. Further genetic studies for susceptibility candidates in this region are necessary in order to identify a causal gene.

Genetic variation in myosin IXB is associated with ulcerative colitis. *K.A. Hunt[1], A.A. van Bodegraven[2], C.R. Curley[3], A.J. Monsuur[4], R.J. Playford[1], C.G. Mathew[5], C. Wijmenga[4], J.D. Rioux[3], D.A. van Heel[1], M.J. Daly[3]* 1) Institute of Cell and Molecular Science, QMUL, London, UK; 2) VU University Medical Centre, Amsterdam, The Netherlands; 3) The Broad Institute, Cambridge, MA; 4) University Medical Center Utrecht, The Netherlands; 5) King's College London School of Medicine, London, UK.

Background: Common variations in the 3 region of myosin IXB (MYO9B) have recently been associated with celiac disease (Monsuur, Nat Genet 2005). The mechanism by which these variations lead to increased susceptibility in celiac disease is unclear. MYO9B is known to be an atypical motor protein with a Rho-GTPase domain, is expressed in leucocytes and intestinal epithelial cells, and is involved in cytoskeletal modification and tight junction assembly.

Aims: We hypothesised that MYO9B variants might also promote susceptibility to other intestinal inflammatory diseases, including Crohns disease and ulcerative colitis.

Methods: 8 tag SNPs for the 3 MYO9B region were studied in three independently collected and genotyped inflammatory bowel disease case-control cohorts of Northern European descent, comprising in total 2717 cases (1197 Crohns disease, 1520 ulcerative colitis) and 4440 controls.

Results: Common variation in MYO9B was found to be significantly associated with inflammatory bowel disease in all cohorts examined (most associated SNP rs1545620, meta-analysis P = 1.9 x 10-6, OR=1.2), with the same alleles showing association as reported for celiac disease.

Conclusions: Interestingly, rs1545620 causes an amino acid change (Ala1011Ser) in the third calmodulin binding IQ domain of MYO9B. Unlike previous variants (in other genes) predisposing to inflammatory bowel disease, the association at MYO9B is considerably stronger with ulcerative colitis, although weaker association with Crohns disease is also observed. These data imply shared causal mechanisms underlying intestinal inflammatory diseases, and potentially other auto-immune diseases.

Clinical and molecular investigation of a patient with atypical Noonan syndrome. *A-M. Nystrom[1], G. Annerén[1], B. Stromberg[2], M-L. Bondeson[1]* 1) Department of Genetics and Pathology, Uppsala University, Rudbeck Laboratory, Uppsala, Sweden; 2) Women's and Children's Health, Uppsala University, Uppsala, Sweden.

The autosomal dominant disorder Noonan syndrome (NS) is characterised by heart defects, facial dysmorphism and short stature. Gain-of-function mutations of the gene *PTPN11* on 12q24 have been identified in around 50% of the NS patients and recently, missense mutations in *KRAS* on 12p12.1, have also been found to cause NS. Clinical overlap between NS and Neurofibromatosis type 1 (NF1) is well known. NF1 is characterised by cutaneous neurofibromas, cafe'-au-lait spots, Lisch nodules and freckling of axillary and inguinal regions and is caused by haploinsufficiency of the *NF1* gene, mapped to 17q11.2. Here, we report the clinical and molecular investigation of a patient with an atypical and severe form of NS. Besides the classical NS phenotype, the proband suffer from mild mental retardation, a type I Arnold Chiari malformation, scoliosis, malrotation of the intestines and of the genito-urinary tract, right-sided hydronephrosis and café-au-lait spots. The probands sister and father presented with café-au-lait spots (CALS) but with no other clinical manifestations of NS. Mutation analysis of the *PTPN11* gene revealed a recurrent *de novo* mutation, 853 T>C; F285L in the proband that was absent in the father and the sister. The result thus suggests that the CALS and NS in this family are caused by distinct genetic entities. Linkage analysis and direct sequencing of the *NF1* gene revealed a variant, 5425 C>T; R1809C in the proband. The variant which co-segregated with the CALS in the family was absent in 150 control chromosomes. Both *PTPN11* and *NF1* operate in the same pathway suggesting that the alterations identified in the *PTPN11* and *NF1* genes in our NS patient could explain her severe and atypical symptoms.

An Extra Structurally Abnormal Chromosome derived from a t(17;22)pat without phenotypic consequences. *C. Morales-Peydro[1,2], E. Margarit[1], I. Madrigal[1], A. Soler[1], A. Sánchez[1]* 1) Servei Bioquímica i Genètica , Hospital Clínic , Barcelona, Spain; 2) Fundació Clínic, Hospital Clínic, Barcelona.

We report on a healthy 35 year-old male referred for genetic counselling because of familial antecedents of mental retardation (paternal uncle). G-banded chromosome analysis on peripheral blood revealed the presence of an Extra Structurally Abnormal Chromosome (ESAC) in all analysed cells. Cytogenetic evaluation of his parents and brother was performed; the karyotype of his mother and his brother were normal while the karyotype of the father was 46,XY,t(17;22)(p13.3;q12). The der(22) chromosome of the father was cytogenetically identical to the ESAC identified in the patient. Unfortunately, the mentally retarded uncle had died at the age of 55 years due to cerebral vascular disease without chromosomal study. Additional analyses were performed to confirm the origin of the ESAC. Fluorescence in Situ Hibridation (FISH) showed the presence of 3 signals of TUPLE-1 probe (22q11), one of them hybridising on the marker. Multiplex Ligation-dependent Probe Amplification (MLPA) analysis, carried out using commercial subtelomeric MLPA kits (MCR-Holland), detected subtelomeric trisomy of 17p and 22p. These results confirmed the origin of the marker as a derivative chromosome 22, consequence of an abnormal segregation of the paternal t(17;22). The triplication of the 22q11 region is compatible with the Cat Eye syndrome, a chromosome anomaly that presents high variability in its clinical expression, including unaffected individuals. However, the most surprising finding was the lack of phenotypic repercussion of the 17p subtelomeric trisomy. In order to discard the existence of a normal cell line, due to the lost of the ESAC during post-zygotic development, a cytogenetic analysis of cultured epithelial cells exfoliated from the urinary tract has been performed. Exhaustive examination tests (abdominal ultrasound scan, cranial magnetic resonance and ophthalmologic and cardiac exploration) have been recommended to discard undetected anomalies. In the present case, providing genetic counselling is difficult due to the unpredictable clinical consequences of the ESAC in the next generation.

The Ghosal disease gene maps to chromosome 7q33. *B. Isidor[1], N. Dagoneau[1], C. Huber[1], D. Genevieve[1], B. Bader-Meunier[2], S. Blanche[3], C. Picard[3], M.C. De Vernejoul[4], A. Munnich[1], M. Le Merrer[1], V. Cormier-Daire[1]* 1) Dept of Genetics and INSERM U781, Necker Hospital, Paris, France; 2) Dept of Pediatrics, Kremlin Bicetre Hospital, France; 3) Dept of Pediatric Hematology, Necker Hospital, Paris, France; 4) Rhumatology, Lariboisiere Hospital, Paris, France.

Increased bone density disorders are a heterogenous group of conditions resulting from an imbalance between bone resorption and bone formation. The international classification of bone disorders has divided these conditions into two groups 1)those with no modification of bone shape and 2)those with metaphyseal and/or diaphyseal involvement. Among this last group, Ghosal disease also called hematodiaphyseal dysplasia(GHDD, OMIM 231095) is a rare autosomal recessive disorder first described in 1988 by Ghosal in five patients and further delineated in 1993 by Gumruck in two siblings. GHDD is characterized by diaphyseal dysplasia with some metaphyseal involvement in association with aregenerative corticosensitive anemia. The main differential diagnosis is Camurati-Engelmann disease (OMIM 131300), an autosomal dominant disorder due to TGF mutations, differing from GHDD by the absence of anemia and the presence of a marfanoid habitus, with muscular weakness and pain. We have had the opportunity to collect the DNA samples of two inbred families originating from Algeria and Tunisia and including five affected individuals ranging in age from 18 months to 34 years. All of them fulfilled the diagnostic criteria for GHDD. The presenting symptom in all the children (3/5) was pallor related to anemia while in one of the adults, anemia was detected by the systematic blood count. Using an homozygosity mapping strategy, we found linkage of the disease locus to chromosome 7q33(Zmax=4.21 at =0 at locus D7S2513) in a 3.4Mb interval defined by loci D7S2560 and AC 091742-GT. This region encompasses 34 genes and six of them were regarded as candidate genes based on their putative function i.e. ATP6V0A4, RAB19B, HIPK2, MLD1,BRAF, PTN. All these genes were excluded by direct sequencing. We hope that ongoing studies will help to solve the pathogenesis of corticosensitive anemia and diaphyseal dysplasia.

A second family with COG7 deficiency reveals a consistent phenotype including microcephaly, adducted thumbs, growth retardation, VSD and episodes of hyperthermia. *E. Morava[1], R. Zeevaert[2], E. Korsch[3], D.J. Lefeber[4], K. Huijben[4], S. Wopereis[4], G. Matthijs[2], R. Wevers[4]* 1) Department of Pediatrics, University Medical Center Nijmegen, Nijmegen, The Netherlands; 2) Department of Human Genetics, University of Leuven, Belgium; 3) Pediatric Hospital Amsterdamerstrasse, Köln, Germany; 4) Laboratory of Pediatrics and Neurology, University Medical Center Nijmegen, Nijmegen, The Netherlands.

Here we describe the clinical and biochemical characteristics of two additional patients diagnosed with Congenital Disorder of Glycosylation type II due to a defect in COG7; one of the 8 subunits of the Conserved Oligomeric Golgi complex. The patients presented with growth retardation, progressive, severe microcephaly, hypotonia, adducted thumbs, feeding problems by gastrointestinal pseudoobstruction, failure to thrive, cardiac anomalies, wrinkled skin and episodes of extreme hyperthermia. A combined disorder in the biosynthesis of N- and O- linked glycosylation with hyposialylation was detected. Western blot analysis showed a severe reduction in the COG5 and COG7 subunits of the Conserved Oligomeric Golgi complex. A homozygous, intronic splice site mutation (c.169+4A>C) of the COG7 gene was identified. The children presented with a similar phenotype as those previously described with the same mutation, except for the lack of skeletal anomalies and only a mild liver involvement in our patients. We suggest performing protein glycosylation studies and western blot for the different COG subunits followed by sequence analysis in children with progressive microcephaly, growth retardation, hypotonia, adducted thumbs and cardiac defects, especially in association with skin anomalies or episodes of hyperthermia.

Androgen insensitivity syndrome: several novel mutations in the androgen receptor gene associated with sex determination. *O.T. Mueller[1,2], H. Mason-Suares[3], R. Hitchcock[1], A. Root[2]* 1) Molecular Genetics Section, All Childrens Hospital, St. Petersburg, FL; 2) Pediatrics Department, University of South Florida, St. Petersburg, FL; 3) Eckerd College, St. Petersburg, FL.

Androgen Insensitivity Syndrome (AIS) is caused by loss-of-function mutations in the androgen receptor gene (AR). Mutations in AR result in variable clinically phenotypes from that of a clinically normal female with a blind vaginal pouch (complete AIS, CAIS), to an incompletely virilized male with ambiguous genitalia (partial AIS, PAIS), to sub-virilized males often with sub-fertility and gynecomastia (mild AIS, MAIS). In this report, we present mutation analysis of AR in seventy individuals with a 46,XY karyotype in whom the diagnosis of AIS was suspected. Pathogenic mutations in AR were identified in 19 patients, 10 of which have not been previously reported. Mutations detected included 12 amino acid substitution (missense) mutations, two chain termination (nonsense) mutations, three small deletions or insertions causinga reading frameshift and premature termination, one in-frame codon deletion, and one base change that created a novel cryptic donor splice site resulting in exon skipping. Two mutations including one nonsense and one missense were detected as mosaics with the normal sequence in the peripheral white blood cells analyzed. These cases of mosaicism have an ambiguous phenotype suggesting that somatic mutation may be a significant cause of phenotypic variability in partial AIS. Missense mutations were evaluated using online SIFT and PolyPhen assessment tools which use phylogenetic conservation of amino acid changes to predict structural and functional effects. In 8 of the 12 missense mutations, both tools supported a pathogenic effect. However, in the remaining four cases these tools were either not in agreement, or conflicted with the phenotype, and were not useful for interpretative purposes.

A powerful method for testing haplotype-disease association in genomewide studies. *B.E. Huang[1], C.I. Amos[2], D.Y. Lin[1]* 1) Department of Biostatistics, Univ North Carolina, Chapel Hill, NC; 2) Department of Epidemiology, MD Anderson Cancer Center, Houston, TX.

The analysis of genomewide association studies requires methods that are both computationally feasible and statistically powerful. Given the large-scale collection of single nucleotide polymorphisms (SNPs), one cannot afford to ignore the information contained in their interrelationships. In particular, utilizing haplotypes rather than individual SNPs and accounting for correlations in adjustment for multiple testing can lead to increased power. We have developed a statistically powerful and numerically efficient method for detecting haplotype-disease association in genomewide studies by sliding windows of SNPs over the genome. This method consists of an efficient algorithm to calculate a proper likelihood-ratio statistic for any given window of SNPs, along with an accurate and efficient Monte Carlo procedure to adjust for multiple testing. Simulation studies based on the HapMap data showed that the proposed method performs well in realistic situations. We applied the new method to a case-control study of 2,300 SNPs on chromosome 18 to test for association with rheumatoid arthritis. Several loci were identified as having possible effects on the disease, none of which would have been detected with existing methods.

Whole genome microarray analysis of gene expression in an imprinting center deletion mouse model of Prader-Willi syndrome. *N. Kibiryeva[1], D.C. Bittel[1], R.A. White[1], D.J. Driscoll[2], M.G. Butler[1]* 1) Children's Mercy Hospital and University of Missouri-Kansas City, Kansas City, MO; 2) University of Florida, Gainesville, FL.

Prader-Willi syndrome (PWS) is due to loss of paternally expressed genes in the 15q11-q13 region which directly or indirectly causes dysregulation that controls neurodevelopment and function. Little is known about the global effects on gene expression that might result. To further characterize genetic alterations we used whole genome microarrays to analyze gene expression in brain tissue from a PWS mouse model (on the C57BL/6J strain) resulting from a paternally derived imprinting center deletion (PWS IC deletion). Of more than 45,000 probes examined, 59% were detectable and 69 had a significant change in expression of at least 1.5 fold with a false discovery rate of 5% in brain of PWS IC deletion mice relative to normal littermates less than 24 hours old. The known paternally expressed genes from the PWS critical region had detection signals below the threshold in the PWS IC deletion mice but were clearly detectable in control littermates. Three previously unstudied transcripts, AK013560, BB314814 and BB182944, located in the mouse PWS critical region, chromosome 7B, were expressed only from the paternal allele and apparently under regulatory control of the imprinting center. The three genes with the highest expression relative to control littermates were pro-opiomelanocortin (*Pomc*, an obesity related gene) and two transcripts of unknown function. Upregulation of the *Pomc* gene has been reported previously in brain tissue from PWS deletion mice (TgPWS) and may contribute to their failure to survive. In addition, *Mc5r* gene (involved in eating behavior and obesity) was also upregulated in our PWS IC deletion mice relative to control littermates. Several of these genes were studied by quantitative RT-PCR which confirmed their expression status. In addition, a small cluster of genes on mouse chromosome 18B3 was reported to be upregulated by haploinsufficiency of the 7B region in TgPWS deletion mice. However, we did not find evidence of changed expression of these genes in our PWS IC mouse model.

Zoom-in CGH arrays for the characterization of variable breakpoint contiguous gene syndromes. *J.J. Johnston, R.L. Walker, S. Davis, P.S. Meltzer, L.G. Biesecker* NHGRI/NIH, Bethesda, MD.

Contiguous gene syndromes cause pathology via haploinsufficiency for adjacent genes. Some contiguous gene syndromes have stereotypical breakpoints, but others have variable breakpoints. In the latter, the extent of the deletions may be correlated with severity. The Greig cephalopolysyndactyly contiguous gene syndrome (GCPS-CGS) is a multiple malformation syndrome caused by haploinsufficiency of *GLI3* and adjacent genes. As well, non-CGS GCPS can be caused by deletions or duplications within *GLI3*. Although FISH can identify large deletion mutations in patients with GCPS or GCPS-CGS, it is not practical for identification of small intragenic deletions or insertions and it is difficult to accurately characterize the extent of the large deletions using this technique. We have designed a custom CGH array that allows identification of deletions and duplications at kilobase resolution in the vicinity of *GLI3*. The array averages one probe every 730 basepairs for a total of ~14,000 probes over 10 Mb. We have analyzed 16 individuals with known or suspected deletions/duplications. In 15/16 individuals (14 deletions and one duplication) the array confirmed the prior results. In the remaining patient, the normal array CGH result was correct and the prior assessment was a false positive qPCR. We conclude that high-density CGH array analysis is more sensitive than FISH analysis for deletion detection and provides clinically useful results on the extent of the deletion. We suggest that high-density array CGH analysis should replace FISH analysis for assessment of deletions and duplications in patients with contiguous gene syndromes caused by variable deletions.

Educational and Outreach Programs for Genomic Medicine in Mexico. *S. March, A. Lopez, J. Bedolla, C. Davila, V. Castellanos, A. Hidalgo-Miranda, I. Silva-Zolezzi, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Mexico develops a national platform in genomic medicine. For this, the Mexican Congress created the National Institute of Genomic Medicine (INMEGEN) that develops scientific research in genomic medicine and has developed different educational programs for a wide range of groups, including graduate students and postdoctoral trainees, medical students, elementary and secondary school kids, as well as the general public. As a part of its graduate programs INMEGEN developed the first courses in genomics for Latin America: Introduction to genomic medicine, Genomic applications in medical pediatrics and Genomic applications in internal medicine. In these courses students develop research proposals using genomic tools to conduct research on a national health problem. In 2006 we initiated life broadcast to universities in 60% of the states of Mexico. We broadcast in real time academic lectures to audiences in Mexico, Central and South America, and Spain. In addition, we have developed and distributed over a dozen educational materials in Spanish related to genomic medicine. We produced a three comic series aimed to target population ages 11-14 yrs. The purpose of this effort is to offer basic education about the human genome, genomic applications to health care, as well as the ethical and legal implications of genomic medicine. These educational programs include a web-based component (www.inmegen.gob.mx) that offers information and services, including materials from our graduate courses, over 20 in-house publications, 100 video-lectures and several brochures. During 2005, our web portal received over 1.9 million visits and more than 1.3 million documents were downloaded from over 38 countries, mostly from Latin America. This electronic resource has turned into a major educational tool in genomic medicine for the Spanish-speaking world. In summary, Mexico develops a strong educational and outreach strategy as a key component of its national platform in genomic medicine. We predict that a knowledgeable society will be a major asset to successfully develop genomic medicine.

Using disease information in tagSNP selection for disease association mapping. *N. Liu* Dept of Biostatistics, Univ of Alabama at Birmingham, Birmingham, AL.

Selection of subsets of single nucleotide polymorphisms (SNPs) is important and challenging for genome wide association studies. Using such tagSNPs not only reduces cost in genotyping, but also increases efficiency and power in statistical analysis since redundant SNPs have been removed and the number of tests could be greatly reduced. In recent years tagSNP selection has drawn much attention and many methods have been proposed to effectively select these tagSNPs using various criteria. However, existing tagSNP selection methods do not take disease information into consideration and may result in inefficient selection of SNPs for the purpose of gene-disease association mapping. We propose a method for tagSNP selection that can take into account disease status in case-control studies. We first break down large marker sets into many disjoint pieces, and then use a tree-based method to search for tagSNPs. We evaluate the method using both simulated data and real data. The results show that the tagSNPs chosen using the proposed method have more power in certain situations.

Craniofacial And Growth Plate Abnormalities in a Mouse Model of Trichorhinophalangeal Syndrome Type I. *D. Napierala[1], K. Sam[1], R. Morello[1], Q. Zheng[1], T. Bertin[1], R. Shivdasani[3], B. Lee[1,2]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Howard Hughes Medical Institute; 3) Dana-Farber Cancer Institute and Harvard Medical School, Boston, MA.

To elucidate molecular mechanisms leading to Trichorhinophalangeal syndrome (TRPS) we studied Trps1 mutant mice with a deletion of the GATA-type DNA-binding domain of the Trps1 transcription factor (Trps1GT mice). Heterozygous Trps1GT mice phenocopy human TRPS type I. TRPS is a dominantly inherited craniofacial and skeletal dysplasia characterized by short stature, hip abnormalities, cone-shaped epiphyses, and premature closure of growth plates reflecting defects in endochondral ossification. Moreover, TRPS patients have distinctive craniofacial features, some possibly attributable to defects of soft tissue, but the bulbous nose and micrognathia point to skeletal abnormalities. To quantify craniofacial changes in the Trps1GT mice we applied laser 3D surface scanning. This morphometric analysis revealed reduced size of mandible, and possibly also maxilla in the heterozygous Trps1GT mice. Consistent with a gene-dosage effect, the craniofacial abnormalities are more severe in homozygous Trps1GT mice. To elucidate the role of Trps1 in endochondral ossification we analyzed long bones of homozygous Trps1GT mice. Analysis of embryos across developmental stages revealed delayed onset of chondrocyte hypertrophy and slower progression of pre- and hypertrophic chondrocytes into terminal stage. Additionally, the Trps1 null mice demonstrated abnormal mineralization of the growth plate chondrocytes and perichondrium. Both mineralization and chondrocyte maturation are regulated by the Runx2 transcription factor, therefore we tested the potential interaction of Trps1 and Runx2 in vitro. Co-transfection experiments demonstrated that Trps1 represses Runx2-mediated transactivation of the reporter gene. Moreover, Trps1 forms complexes with binding sites of GATA transcription factors in the Runx2 promoter only in cells that do not express endogenous Runx2. Our data indicate that Trps1 regulates chondrocyte hypertrophy and mineralization and it could do so partially through repression of Runx2.

A genomewide search finds major susceptibility loci for nicotine dependence on chromosome 10 in African-Americans. *M.D. Li[1], T.J. Payne[2], J.Z. Ma[1], X.-Y. Lou[1], D. Zhang[1], R.T. Dupont[3], K.M. Crews[2], G. Somes[4], N.J. Williams[4], R.C. Elston[5]* 1) Psychiatric Medicine, University of Virginia, Charlottesville, VA; 2) ACT Center for Tobacco Treatment, Education & Research, University of Mississippi Medical Center, Jackson, MS; 3) Department of Criminology and Criminal Justice, University of Memphis, Memphis, TN; 4) Departments of Preventive Medicine and Dental Hygiene, University of Tennessee Health Science Center, Memphis, TN; 5) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Although several linkage studies on nicotine dependence (ND) have been conducted, all samples to date are primarily of European origin. In this study, we conducted a genomewide scan in 1261 individuals representing 402 nuclear families of African-American (AA) origin. We examined 401 microsatellite markers for ND, which was assessed by smoking quantity (SQ), the Heaviness of Smoking Index (HSI), and the Fagerström Test for ND (FTND). After performing linkage analyses using various methods implemented in the GeneHunter and S.A.G.E. programs, we found a region near marker D10S1432 on chromosome 10q22 between D10S1208 and D10S2470 that showed a significant linkage to Indexed SQ with a maximum LOD score of 4.17 at 92 cM, and suggestive linkage to HSI, SQ, and log-transformed SQ. Additionally, we identified three regions on chromosomes 9q31 at marker D9S1825 at 136 cM, 11p11 between markers D11S1993 and D11S1344, and 13q13 between markers D13S325 and D13S788 that met the criteria for suggestive linkage to at least one ND measure. Other locations on chromosomes 15p11, 17q25, and 18q12, exhibited some evidence of linkage (LOD >1.44). Some of these regions have been linked to smoking behavior at nominally significant levels in other studies, providing independent replication of the regions for ND in different cohorts. In summary, we found significant linkage on chromosome 10q22 and suggestive linkage on chromosomes 9, 11, and 13 for major genetic determinants of ND in an AA sample. Further analysis of these positive regions by fine mapping and/or association analysis is warranted.

Association of TNF -308 GA polymorphism and cancer risk. *K. Kohut[1], T. Kirchhoff[1], N. Ishill[2], A. Zelenetz[3], J. Lee[1], K. Lafaro[1], K. Offit[1, 3]* 1) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Department of Epidemiology and Biostatistics, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Lymphoma Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY.

BACKGROUND: In a recent study, the International Lymphoma Epidemiology Consortium analyzed 12 single nucleotide polymorphisms (SNPs) in 9 genes involved in immune and inflammatory processes, using 3586 cases of non-Hodgkin lymphoma and 4018 controls, from 8 centers in Europe, Canada, and U.S. The TNF -308 GA polymorphism was associated with increased risk of non-Hodgkin lymphoma, particularly diffuse large B-cell lymphoma. METHODS: To investigate whether geographically distinct cohorts resulted in biases due to population stratification, we compared population frequencies of the TNF -308 GA polymorphism in prior studies. We also analyzed 601 lymphoma, 780 breast cancer, 577 prostate cancer and 374 colon cancer cases along with 1039 unaffected controls in an Ashkenazi Jewish population, considered to be genetically homogeneous. TaqMan assay on ABI 7900 HT Sequence Detector and Sequence Detection Software 2.0 (Applied Biosystems) was used. Analysis included 2 or Fishers exact tests and unconditional logistic regression. RESULTS: Frequencies differed among geographically disparate cohorts. While there was no excess of A/A + G/A in diffuse large B-cell lymphomas in Ashkenazim (p=0.55), there was a trend for an excess of A/A genotypes (p=0.07). This finding supports association with this subtype of lymphoma, as observed by Rothman *et al*. A significant association of the TNF -308 GA allele with cancer risk was observed by performing simulations on data from prior studies. CONCLUSIONS: The G/A genotype was associated with prostate cancer risk (p=0.01), (OR 1.7 95%CI 1.04-2.8 (1 variant allele) and 3.6, 95% CI 0.4-34.6 (2 variant alleles), trend p=0.02). These findings are consistent with a prior observation of an increased risk in Korean prostate cancer cases heterozygous for G/A. We found no associations between G/A or A/A genotypes and risk of colon or breast cancer.*et al*.

Genetic and clinical epidemiology of pediatric idiopathic epilepsy in Newfoundland and Labrador. *K. Mahoney, S. Moore, D. Buckley, M. Alam, S. Penney, P. Parfrey* Memorial University of Newfoundland, St. John's, NL, Canada.

Epilepsy is a common neurological disorder with an incidence of 40 to 80 per 100 000. Approximately 40-60% of all cases of epilepsy are idiopathic. Most cases of idiopathic epilepsy follow complex inheritance patterns.
The objective of this study is to describe the incidence and genetic epidemiology of idiopathic epilepsy (IE) in Newfoundland.
All childhood cases of IE from 1997 to 2006 have been identified from the pediatric neurology clinic at the Janeway Hospital, the only childrens hospital in the province. Informed consent, family history, and medical information was obtained from parents of probands who are followed up in the clinic.
The incidence of IE for the population of children living on the Avalon region of the province from 1999 to 2003 was 80 per 100 000. This represents 56 newly diagnosed cases in a population of 13 779. This rate is approximately two to three fold greater than most populations of children in other developed regions.
121 individuals (116 families) are being followed up in the pediatric neurology clinic and are eligible to enter the study. 97 families were contacted and 86 agreed to participate. 72 of these families have provided family history data. To date, DNA samples have been obtained from 19 families.
At least 6 pedigrees are compatible with autosomal dominant inheritance with three or more affected individuals in three generations within three degrees of relation to the proband. 43 pedigrees have 3 or more affected individuals beyond three degrees of relation to the proband and thus are compatible with autosomal recessive or polygenic inheritance. In the remaining 23 pedigrees, the proband is the only known affected individual.
Further molecular studies are being undertaken in one family in which the pedigree is strongly supportive of autosomal dominant inheritance.
The incidence of epilepsy is high in Newfoundland and the genetic contribution to the etiology of epilepsy is also high.

Mass Spectrometric Identification of Proteins in Patients with Platelet Storage Pool Deficiencies. *D.M. Maynard[1], H.F.G. Heijnen[2], M.K. Horne[3], J.G. White[4], H.D. Edwards[1], L.C. Riney[1], A. Helip-Wooley[1], W.A. Gahl[1]* 1) SHBG, MGB, NHGRI, NIH, Bethesda, MD; 2) Dept. of Hematology and Cell Biology, Univ. Medical Center, Utrecht, The Netherlands; 3) Hematology Service of the Dept. of Laboratory Medicine, W.G. Magnuson Clinical Center, NIH, Bethesda, MD; 4) Univ. of Minnesota, Depts. of Laboratory Medicine and Pathology and Pediatrics, Minneapolis, MN.

Platelets contain three types of secretory organelles, i.e., alpha granules, delta granules and lysosomes. These organelles have specific molecular compositions, genetic diseases, ultrastructural morphology, kinetics of exocytosis, and secretory responses to different stimuli. A deficiency in granule-bound substances in platelets causes a group of congenital bleeding disorders known as storage pool deficiencies (SPDs). For some disorders, such as Hermansky-Pudlak syndrome (HPS), most of the genetic bases have been determined. For others, such as -SPD (Gray Platelet syndrome), only the clinical and histological states have been defined. In order to understand the molecular bases for such genetic disorders, we are using proteomics and mass spectrometry combined with biochemical verification to identify causative gene products and potential interacting partners. After platelet disruption, sub-cellular organelles were separated using sucrose gradient ultracentrifugation. Granule fractions were confirmed by electron microscopy and Western blotting using antibodies to granule-specific proteins. Protein fractions were separated by 1-D SDS-PAGE. Proteins bands were excised, digested in-gel with trypsin, and resulting peptides were analyzed by 1D-LC-MS/MS. Raw files were submitted to the NIH Mascot cluster using Mascot Daemon and were searched against the SwissProt-Trembl database. DBParser was used for data processing and report generation. Preliminary mass spectrometry data from control samples confirms the presence of alpha granule-specific proteins in the fraction identified by Western blotting and EM. Further experiments are underway to analyze other granule fractions and to investigate samples from patients with a variety of storage pool deficiencies.

Triplication of 4q32.1q32.1: A new syndrome with minimal clinial findings and Hirschprung disease? *M.J.M.Trip Nowaczyk[1], J.C. Wang[1], I. Teshima[2]* 1) Dept of Pathology and Molecular Medicine, McMaster Univ., Hamilton, Canada; 2) Dept of Pediatric Lab Medicine, Hospital for Sick Children Dept of Pediatrics, Univ. of Toronto, Toronto, Canada.

We present three brothers and their mother with triplication of 4q. They present with minimal facial anomalies resembling velocardiofacial syndrome or myotonic dystrophy. The oldest boy has hydrocephalus (HCP), right sided ptosis, the middle one has Hirschprung disease (HD) and the third has HD, HCP and bilateral talipes equinovarus. The three sons share with their mother the following facial features: long midface, myopathic face, wide nasal bridge, short nose, short palpebral fissures, and low set, small and squared off ears. All four have mild developmental delay. Cytogenetic analysis showed an abnormal chromosome 4 in the four patients. At 850-band resolution the segments between 4q31.3 and 4q32 were duplicated. FISH analysis of metaphase and interphase cells with labeled BAC probes showed three signals for clone RP11-192D11 (located within 4q32.1) on the rearranged chromosome. Only one signal for the other probes located within 4q31.3, 4q32.2, 4q32.3, and 4q33 was observed suggesting that the band 4q32.1 was triplicated. Thus, the karyotypes for the boys were 46,XY,dup(4)(q31.?3q3?2)mat.ish trp(4)(q32.1q32.1)(RP11-192D11+++). There are no previous reports of 4q triplication; there are more than 65 reports of duplications 4q, of which 23 can be classified as pure. Our patients closely resemble the three patients with dup 4q31.1q32.3 reported by Goodman et al. [1997] suggesting a phenotype associated with multiple doses of this band. Four previously reported patients with 4q duplications had HD: two with duplication resulting from t(4;14)(q31.3;p11.2) who had a very mild phenotype similar to our patients; one with complex rearrangement involving monosomy 1pter; and one with monosomy 9qter. The last two patients had multiple congenital anomalies and mental retardation, likely as a result of the associated monosomies. It is possible that a gene or genes at 4q32.1 may be involved in pathogenesis of HD. It also appears that multiple doses of band 4q32.1 are relatively well-tolerated.

Association of genetic variations in the *G-CSF* gene with lung function decline and cross-sectional levels in smoking induced COPD. *J. He[1], K. Shumansky[1], J.E. Connett[2], N.R. Anthonisen[3], P.D. Paré[1], A.J. Sandford[1]* 1) James Hogg iCAPTURE Ctr, Univ British Columbia, Vancouver, BC, Canada; 2) Division of Biostatistics, School of Public Health, University of Minnesota, Minneapolis, Minnesota, USA; 3) Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada.

Background: Granulocyte colony-stimulating factor (G-CSF) or CSF3 is an important survival and proliferation factor for neutrophils. Neutrophils release proteinases that break down connective tissue in the lung parenchyma and contribute to emphysema and decline of lung function. Recently, it was shown that a single nucleotide polymorphism (SNP) was associated with peripheral blood granulocyte count among workers exposed to benzene. Objective: To determine whether SNPs and haplotypes of *CSF3* are associated with change or level of lung function in smoking induced COPD. Methods: Three SNPs of *CSF3* were studied in 587 non-Hispanic whites who had the fastest (n = 281) or the slowest (n = 306) decline of lung function selected from among continuous smokers followed for 5 years in the NHLBI Lung Health Study (LHS). These SNPs were also studied in 1074 non-Hispanic whites with the lowest (n = 536) or the highest (n = 538) baseline lung function at the beginning of the LHS. Results: The *CSF3* -1719C/T was associated with baseline lung function in an additive model, odds ratio (OR) = 0.73, 95% confidence interval (CI) = 0.56 to 0.95, P = 0.018 after adjustment for confounding factors and was still significant after adjustment for multiple comparisons. There was also a significant association of *CSF3* haplotype with baseline FEV_1 levels (globe test p = 0.004 and 0.027 before and after adjustment for confounding factors, respectively). Conclusion: Genetic variations in *CSF3* were associated with lung function in COPD patients. Supported by the NHLBI Lung Health Study and the Canadian Institutes of Health Research.

A potential therapy for inherited neuropathy: Oral curcumin mitigates the clinical and neuropathologic phenotype of the *Trembler-J* mouse. *M. Khajavi, K. Shiga, W. Wiszniewski, J. Yan, G.J. Snipes, J.R. Lupski* Dept of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

There have been tremendous advances in our understanding of the molecular genetic bases of inherited peripheral neuropathies during the last decade and a half. This has revolutionized diagnostics, enabling accurate and secure diagnosis, precise recurrent risk estimates, prenatal diagnosis and better management of patients. However, there has been a complete failure to translate these findings in molecular based therapeutics. The molecular cause of Charcot-Marie-Tooth disease type 1 (CMT1) in the majority of patients is a duplication of a 1.4 Mb region on the short arm of chromosome 17 containing the dosage sensitive peripheral myelin protein 22 gene (*PMP22*). Alteration in *PMP22* gene expression can have profound effects on the development and maintenance of peripheral nerves. Consequently, the regulation of *PMP22* gene expression has been the focus of one therapeutic strategy for CMT1 (Sereda et al., 2003; Passage et al., 2004). These therapeutic approaches show promise in animal studies, but they are not feasible for other genetic causes of CMT because such molecular strategies only apply to *PMP22* over-expression. Here, we demonstrate that oral administration of curcumin, a dietary supplement, partially mitigates the severe neuropathy phenotype of the *Trembler-J* mouse model in a dose dependent manner. Many myelin gene mutants (e.g. *MPZ* and *PMP22*) cause severe disease (Dejerine-Sottas neuropathy, DSN; congenital hypomyelinating neuropathy, CHN) apparently by protein accumulation within the ER, causing Schwann cell apoptosis, and subsequently peripheral neuropathy. Administering curcumin significantly decreases the percentage of apoptotic Schwann cells and results in increased number and size of myelinated axons in sciatic nerves leading to improved motor performance. Our findings indicate that oral curcumin supplementation is apparently sufficient to relieve the toxic effect of mutant aggregation induced apoptosis and improves the neuropathologic phenotype in mice suggesting a potential therapeutic role in selected forms of inherited peripheral neuropathy.

Mitochondrial haplogroups are associated with asthma and total serum IgE levels. *B.J. Klanderman[1,2], S. Mazza[1], J.C. Celedon[1,2,3], S.T. Weiss[1,2], B.A. Raby[1,2,3]* 1) Channing Laboratory, Department of Medicine, Brigham & Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Division of Pulmonary and Critical Care Medicine, Beth Israel Deaconess Medical Center, Boston, MA.

Maternal history of asthma and/or atopy is a major risk factor for the subsequent development of asthma and allergy in childhood. Although mitochondrial mutations have been implicated in several maternally inherited monogenic disorders, no studies of mitochondrial polymorphisms and asthma have been reported. We evaluated whether common mitochondrial haplogroups are associated with asthma and total serum IgE levels. 8 common mitochondrial single nucleotide polymorphisms (mtSNP) were genotyped in two cohorts of European ancestry: 512 adult women with incident asthma and 517 matching controls participating in the Nurses' Health Study (NHS) and 654 children ages 5-12 years with mild to moderate asthma participating in the Childhood Asthma Management Program (CAMP). Genotyping was performed using TaqMan probe hybridization assays. 93 random NHS samples were run in duplicate for all assays and demonstrated 100% concordance. In the CAMP Study, genotype data from probands mothers was also 100% concordant across all assays. Completion rates in both cohorts were > 95% for all markers. mtSNP 9055 was seen at higher frequency in NHS asthma cases (frequency 11.1%) than controls (8.0%, p = 0.02). Association analysis using haplo.score identified two haplogroups associated with asthma: one haplogroup at a frequency of 3.83% among cases compared to 1.27% among controls (p=0.0002) and another at a frequency of 9.97% among cases and 11.3% among controls (p=0.04). The CAMP Study is a case-only (family-based) cohort, thus precluding evaluation of mitochondrial SNP associations with asthma status. However, quantitative analysis of mitochondrial haplogroups identified two haplogroups of 11.0% and 1.87% frequency that were associated with log-transformed total serum IgE levels, an important intermediate phenotype in asthma and atopy (p=0.006 and 0.01, respectively). These data suggest that common mitochondrial haplogroups influence asthma diathesis.

NAT2 and NER genetic variants and susceptibility to sporadic prostate cancer in African Americans. *S.E. Hooker[1], C. Bonilla[1], C.A. Ahaghotu[2], R.A. Kittles[1]* 1) Human Cancer Genetics, Ohio State University, Columbus, OH; 2) Division of Urology, Howard University Hospital, Washington, DC.

Prostate cancer is a common malignancy that disproportionately affects African American men. The large ethnic differences in prostate cancer risk are unlikely to be completely explained by environmental factors such as diet and lifestyle. Instead environmental exposures may modulate prostate cancer risk in combination with genetic variation in genes responsible for chemical and dietary carcinogen metabolism and DNA damage repair. We report on single nucleotide polymorphisms in six genes involved in carcinogen metabolism and DNA repair in 254 African American prostate cancer cases and 301 healthy controls from Washington, DC. Genotyping was performed using MassARRAY for fourteen SNPs within the NAT2, ERCC1, XPF/ERCC4, XPG/ERCC5, and CSB/ERCC6 genes. Structured association analyses were performed using individual ancestry estimates to control for admixture stratification. Smoking status, BMI and age were included as covariates in the analyses. We found that individuals homozygous for an XPG/ERCC5 -72C/T promoter polymorphism had significant reduction in risk for prostate cancer (OR= 0.12; 95%CI=0.03-0.48). A haplotype trend regression test also revealed a protective effect for the haplotype bearing the T allele (P=0.003). In silico analyses suggest a functional implication for the promoter variant since it deletes a GCF transcriptional factor binding site responsible for the down-regulation of transcription. The protective effect of the promoter SNP on risk for Pca was independent of smoking. In contrast, none of the SNPs typed for NAT2, ERCC1, ERCC4 and ERCC6 showed significant association with risk. Additionally, tests for genotype interactions were not significant. We note that there may be other factors, such as dietary exposures which may modulate prostate cancer risk in combination with genetic variation within the NAT2 and NER genes. Our results, in combination with previous independent observations of LOH for ERCC5 in prostate tumors, provide further evidence of a role for XPG/ERCC5 in the etiology of prostate cancer.

Intravenous immune globulin treatment for Hereditary Inclusion Body Myopathy: A pilot study. *I. Manoli[1], S. Sparks[1], G. Rakocevic[2], G. Joe[3], J. Shrader[3], B. Sonies[3], C. Ciccone[1], D. Krasnewich[1], M. Huizing[1], M. Dalakas[2], W.A. Gahl[1]* 1) MGB, NHGRI, NIH, Bethesda, MD; 2) NINDS, NIH, Bethesda, MD; 3) RMD, NIH, Bethesda, MD.

Hereditary Inclusion Body Myopathy (HIBM) is an autosomal recessive, adult onset, non-inflammatory neuromuscular disorder with no effective treatment. The causative gene, GNE, codes for UDP-N-acetylglucosamine 2-epimerase/N-acetylmannosamine kinase, which catalyzes the first two reactions in the synthesis of sialic acid. Reduced sialylation of muscle glycoproteins, such as -dystroglycan and neural cell adhesion molecule (NCAM), is observed in HIBM. In this pilot study we treated 4 HIBM patients with intravenous immune globulin (IVIG), as a means of providing high quantities of sialic acid, considering that IgG contains 8mol of sialic acid/g. IVIG was infused as a loading dose of 1g/kg on two consecutive days followed by 3 doses of 400mg/kg at weekly intervals. The primary outcome was muscle strength assessed by Quantitative Muscle Testing; secondary parameters included a 6-minute walk test, grip and tongue strength, swallowing function, and the Human Activity Profile questionnaire. Muscle biopsies were obtained before and after IVIG. Mild improvements in the strength of certain muscle groups were recorded. Function of the right and left quadriceps improved by 13-154% and 8-48%, respectively, in 3 patients. Similarly, shoulder abduction improved by 24-79% on the right and 13-184% on the left in 3 patients. Esophageal motility and lingual strength improved in the 2 patients with abnormal barium swallows. Minimal to modest qualitative improvements in daily activities were experienced in 3 patients. No unexpected side effects occurred. Mild headaches and vomiting after loading with IVIG subsided within 48h. Muscle immunohistochemistry and western blot analyses for -dystroglycan, NCAM and PSA-NCAM did not demonstrate any appreciable changes. The absence of inflammation in HIBM muscle suggests that the noted mild benefits were not related to the anti-inflammatory or immunomodulatory effects of IVIG. The uses of IVIG and other sources of sialic acid are being explored as treatment options for HIBM.

Sequence analysis of small SMN1 mutations in SMA compound heterozygotes. *D.C. Mihal, S.J. Bridgeman, R.E. Pyatt, T.W. Prior* Pathology, The Ohio State University, Columbus, OH.

While 95% of clinically diagnosed Spinal Muscular Atrophy (SMA) patients have homozygous deletions of the SMN1 gene, the remainder are presumably compound heterozygotes with one deleted SMN1 allele and a small mutation in the other. The molecular identification of the later is complicated by the presence of the pseudogene SMN2, but can be critical in determining a complete genetic diagnosis. We therefore examined the detection of compound heterozygotes in individuals clinically diagnosed with SMA. Validation of SMN1 sequence detection was performed using ABI dye terminator sequence technology on a series of carriers with defined SMN2 copy numbers ranging from 0 to 5. Peak intensity ratios were created by examining the major and minor alleles and adjacent bases at two of the five single base changes that distinguish SMN1 from SMN2. The results indicated that SMN1 alleles at both positions were consistently detectable despite increasing SMN2 copy numbers. Using this approach, mutations in seven compound heterozygotes samples previously defined by the cloning and sequencing of SMN1 were confirmed by direct genomic sequencing. We then examined ten presumptive compound heterozygotes all meeting the following criteria: clinically diagnosed with SMA, SMN1 homozygous deletion negative, and possessing a single SMN1 gene copy by dosage analysis. These samples were then screened by sequence analysis for small mutations in SMN1 reported in the human gene mutation database. We identified mutations in three individuals consisting of a single base insertion in exon 2a, Y130C in exon 3, and an 11 base duplication in exon 6. Despite rigid criteria to define compound heterozygotes for sequence analysis, mutations were only identified in 30% of the individuals screened. The remaining 70% are ambiguous as they may possess unidentified mutations in regulatory or other relevant non-coding regions of SMN1, or may be carriers with a neuromuscular disease that symptomatically resembles SMA. Clearly, careful clinical discrimination is essential to assess the likelihood of these possibilities within this substantial portion of presumptive compound heterozygotes.

Enhanced linkage maps from family-based genetics studies. *C. He[1], X. Kong[1], S. Buyske[1], D.E. Weeks[2], T.C. Matise[1]* 1) Rutgers Univ, Piscataway, NJ; 2) University of Pittsburgh, PA.

Meiotic linkage maps are the foundation of linkage mapping for disease genes. Existing genome-wide linkage maps were built using only small collections of pedigrees, and so they have wide confidence intervals. The 95% CI for a 10cM map distance in Marshfield maps is from about 4 to 19cM. Incorrect marker order and map distances can lead to incorrect or imprecise results from linkage analyses, so there is a clear need for more accurate genetic maps for disease mapping studies. We have collected a very large sample of genotype data from disease-mapping studies genotyped by Mammalian Genotyping Service (MGS) in Marshfield. Our current sample includes genotypes for more than 18,000 individuals from over 4,500 pedigrees for markers on the Marshfield screening sets 8-11. These sets have average map resolutions of 8-10 cM. Our data collection has a total of 6.81 million genotypes and several ethnic groups are represented. We have cleaned numerous pedigree structure and genotyping errors, as well as verified the marker orders. We have used this dataset to a) test for population-specific distribution of recombination; and b) re-estimate the distances (including confidence intervals) on these screening set maps, both sex-averaged and sex-specific. The maps from Caucasian, Chinese, Hispanic samples are in quite good agreement with each other. We only found one map interval on chromosome 8p with significant difference between Caucasian and Chinese. Some comparisons between different Caucasian sub-populations have also been performed and no significant difference was found. The maps from the African-American sample have some significant differences with those from other populations. However this may be due to an apparently higher rate of genotyping errors present in this particular study. Our analyses result in screening set maps with improved accuracy, which can in turn be used to improve the accuracy of disease-mapping studies. The total map length of our enhanced maps is about 7% longer than Marshfield maps. Taking advantage of our large sample size, the 95% CI for a 10 cM map interval is only about 2cM long.

Detection of atypical duplications in 22q11.2 around the DiGeorge/Velocardiofacial region by array-based comparative genomic hybridization(Array CGH). *Z. Ou[1], X. Lu[1], H. Yonath[1], E. Roeder[2], V. Enciso[2], A.C. Chinault[1], A.L. Beaudet[1], S.W. Cheung[1], A. Patel[1]* 1) Dept. of Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept. of Pediatrics, UTHSCSA, San Antonio, TX.

The chromosome 22q11.2 region is susceptible to rearrangement, mediated by low copy repeats (LCRs). Three genomic disorders are caused by deletion or duplication in this region, DGS/VCF syndrome is the most common genomic disorder often associated with microdeletion on chromosome 22q11.2 region, resulting from non-allelic homologous recombination (NAHR) between LCR22 substrates, whereas cat-eye syndrome and duplication 22 syndrome are associated with tetrasomy, and segmental trisomy, respectively. We developed chromosomal microarray analysis (CMA) and designed the CMA to detect all rearrangements causing known genomic disorders including the DGS/VCFS region. The clones in the DGS/VCFS region have been selected to flank LCR22s. Seven patients with DGS/VCFS region duplications have been identified to date of which four were inherited from one of their parents. Three cases with an interstitial duplications map between the proximal LCR22-3b and the distal LCR22-5, span ~2Mb,and partially overlaps with DGS/VCFS typical 3Mb deletion region. In one case the duplication mapped between LCR22-3a and LCR22-3b and in another duplication between LCR22-3a and LCR22-4, both of which are also located within DGS/VCFS typical 3Mb deletion region. In two cases the duplication mapped between LCR22-4 and LCR22-5, which is outside the typical 3 Mb DGS/VCF associated deletion region. The breakpoints for none of these seven cases localize to LCR22-2 which are involved in the typical DGS/VCFS deletions. In 4 cases, the breakpoints map at LCR-3b which is not involved in the typical DGS/VCFS rearrangements. Our data further document the utility of clinical implementation of high resolution genome analysis using CMA. Such rearrangements are not observed by current clinical testing. Furthermore, we show that the genomic architecture within the DGS/VCFS genomic region appears to be recombination prone and subject to genomic instability causing multiple types of chromosome rearrangements in the DGS/VCFS region.

Evaluation of the clinical utility of a Family History Tool. *S.M. O'Neill[1], W.S. Rubinstein[1], L..S. Acheson[2], M.T. Ruffin[3], Family Healthware Evaluation Collaboration* 1) Evanston Northwestern Healthcare, Evanston, IL; 2) Case Western Reserve University, Cleveland,OH; 3) University of Michigan, Ann Arbor, MI.

The Family Healthware Tool (FHT) is a web-based program created by the Centers for Disease Control and Prevention(CDC)that collects family history of 6 common diseases, Coronary heart disease(CHD), Stroke(CVA), Diabetes(DM), and Colon(CC), Breast(BC) and Ovarian(OC)cancers. In addition to eliciting disease type and age of onset for first and second degree relatives, the program gathers information about an individuals behavioral risk factors and current screening practices. A risk assessment is performed for each of the diseases using complex algorithms[1] which generate tailored risk and preventive health messages for the user. The CDC selected 3 sites to evaluate the clinical utility of this new public health tool in over 6000 healthy participants between the ages of 35 and 65 ascertained through primary care practices. This randomized controlled trial examines the effect of the tool on risk perceptions, disease related attitudes and beliefs, and change in health behaviors. Case subjects complete a pretest and the FHT and changes are evaluated through a 6 month posttest. Controls will not complete the FHT until after their 6 mo. posttest. At the ENH site, 300 control subjects and 537 case subjects have enrolled. The average age of case subjects is 53 and most are Caucasian (90%) females (76%). Most cases (86%) chose to complete the tool online without assistance and the average completion time was 14.6 minutes. Overall, 453/537 (84.4%) have a strong(S) or moderate(M) family-history based risk for at least one of these diseases; CHD[S 36%, M 26%], CVA[S 16%, M 35%], DM[S 11%, M 28%],CC[S 1.5%, M 11%], BC[S 10%, M 15%], OC [S 4%, M 6%]. Use of the FHT algorithms suggests a substantial burden of family-history based risk in the adult primary care population, particularly for heart disease and stroke. Implementing the automated FHT as a standard part of clinical practice may identify subpopulations who would benefit most from targeted prevention strategies.

Autism outcome extremes: biological but not social factors predict recovery. *M.K. Morgan, J.H. Miles, T.N. Takahashi* Med Gen Div, Univ of MO Hosp, Columbia, MO.

Autistic children exhibit a wide range of outcomes; a small portion recover to become independent adults, whereas others show minimal to no recovery. This study examines the extremes of the outcome curve: 7 in a recovered group (REG) vs 12 with poor outcomes (POG). Both groups were diagnosed with autistic disorder between the ages of 2 & 3 yrs. Selection criteria for POG included no functional language, high dependence, and 9 yr old. REG selection criteria were functionally verbal, attends regular classes, and independent functioning for age. Those with syndromes were excluded. Comparison of the groups revealed no differences in ethnicity, pre/perinatal or teratogenic problems. Family factors generally assumed to improve outcomes were all better in POG: high SES was over represented in POG (72.7 vs 50.0%) & low SES was less (9.1% vs 50.0%). More POG parents were married & probands were more apt to live with both parents (66.7% vs 42.9%). Though not significantly different, POG mothers reported less depression. The primary differences between the recovered & poor outcome groups were in biological measures. All dysmorphic probands were in POG (16.7%); no REG were dysmorphic. All seizure patients were in POG (8.3%). POG children were less apt to be normocephalic (33.3% vs 71.4%); 58.3% POG children were macrocephalic; 8.3% microcephalic. POG children had more regressive onsets (41.7% vs 28.6%). POG were mostly male (92%) and REG mostly female (57%). Pedigrees were analyzed to see if additive inherited tendencies impacted recovery. There were no differences in family loading for alcoholism, cognitive, language, or behavior disorders including ADHD or seizures. REG probands had a greater family history of autism (57.1 vs 16.7%) & more affected sibs (37.5% vs 14.3%). These results indicate there are fundamental biological & presumably genetic differences between autism that remediates and that which does not. Outcome appears to be an intrinsic component of the phenotype. Family & social factors did not associate with recovery. Analyses of educational and behavioral therapies are underway.

Autism probands with a mildly affected parent: a case-control study. *D.G. Ingram, T.N. Takahashi, J.H. Miles* Med Gen Div, Univ MO Hosp, Columbia, MO.

Identifying autistic traits in parents of autism probands may decrease sample heterogeneity, increase power for research analyses and allow us to study parent-of-origin effects. Twenty-seven autism probands were identified as having a parent with prominent autistic traits (study group, SG), compared with 252 probands not having an affected parent (comparison group, CG). Within the affected parents, 58% exhibited social deficits, 42% communication deficits, and 27% repetitive stereotyped behaviors. Groups did not differ in age, race, height, weight, head circumference, CARS score, dysmorphology, syndrome diagnosis, sex ratio, sib recurrence rate, abnormal EEG or MRI, or onset with regression. A greater proportion of SG families had high socioeconomic status (P=0.037). In terms of outcome measures, SG probands had higher IQ/DQs (P=0.009), a higher proportion of IQ/DQs > 70 (P=0.015), and a higher proportion of conversational language (P=0.016). Language and IQ/DQ scores were used to create an outcome classification of excellent, good, and poor. SG probands had more excellent outcomes (P=0.002) and less poor outcomes (P=0.006); outcome measure results did not change when probands < 8 years old were excluded from analysis. In addition to the parent with autistic traits, SG families had a higher prevalence of language disorders (P=0.045) and depression (P=0.050), but a lower prevalence of cognitive disorders (P=0.036). Comparing probands within the SG with an affected mother (M) vs. father (F) revealed trends towards parent-of-origin effects for excellent outcome (M=100% vs. F=41%, P=0.199) and conversational language (M=100% vs. F=54%, P=0.247). Overall, SG probands tended to have better outcomes, increased family history of neuropsychiatric disorders, and displayed evidence of parent-of-origin effects with better outcomes if the mother was affected. We speculate that parents autistic traits are a marker for specific genes that convey risk for autism, and that this genetic liability may work via epigenetic mechanisms.

X-Linked Creatine Transporter Deficiency Presenting as a Mitochondrial Disorder. *K. Limbo[1], C. Parker[1], J. Vockley[2], T. Wood[3], M. Friez[3], O.A. Abdul-Rahman[1]* 1) Department of Pediatrics, University of Mississippi Medical Center, Jackson, MS; 2) Department of Pediatrics, Childrens Hospital of Pittsburgh, University of Pittsburgh School of Medicine, Pittsburgh, PA; 3) Greenwood Genetics Center, Greenwood, SC.

Creatine transporter deficiency is an X-linked disorder characterized by developmental delay with severe language impairment, seizures, and hypotonia. Reduction in creatine uptake results in elevated urine creatine and CSF creatine deficiency. Mutations in the sodium-dependent creatine transporter (SLC6A8) are causative. We report a patient who was initially suspected of having a mitochondrial disorder, but was later found to have a creatine transporter defect. The patient is a 10 year-old Caucasian male born at term gestation with an uncomplicated prenatal course. By age 2, he had significant developmental delay and truncal hyptonia. An EEG showed epileptiform discharges, but no overt seizure activity was recognized. MRI of the brain was normal. Metabolic testing was performed and detected elevations of blood lactate, alanine, glycine, and C2- and C4-aclycarnitine. Urine organic acid analysis identified ethylmalonic acid and TCA cycle intermediates. Suspicion of a mitochondrial disorder prompted a muscle biopsy. Respiratory chain analysis, carnitine levels, CPT assay, coenzyme Q levels, and mitochondrial DNA testing of muscle were all normal. Blood mitochondrial DNA analysis was also normal. However, repeat serum chemistries demonstrated persistently low creatinine levels. Urine guandinoacetate was normal. However, urine creatine was significantly elevated. DNA analysis of SLC6A8 demonstrated a complex rearrangement which is still undergoing further characterization. Creatine uptake studies are currently pending. Review of the literature identified a second patient with a creatine transporter defect who initially presented with elevations of ethylmalonic acid, 3-methylglutaconic acid, and TCA cycle intermediates. Based on these two patients, we recommend testing for disorders of creatine metabolism in patients with a suspected mitochondrial disorder when no specific defect can be identified.

Association of -308A Allele of Tumor Necrosis Factor Gene (TNF?) with Asthma in Mexican Pediatric Patients.

S. Jiménez-Morales[1,2], F. Cuevas[3], Y. Saldaña[1], J. Ramírez[1], L. Orozco[1] 1) Laboratory of Research, National Institute of Genomic Medicine, Mexico D.F, Mex; 2) PhD Experimental Biology Program, Autonomous Metropolitan University; 3) Pneumology and Torax Surgery Department, National Institute of Pediatric.

Asthma is one of the most important respiratory diseases in development countries. Genetic variations in the nucleotide sequence of genes with an important role in the antiinflamatory, inmunoregulatory response, have been associated to asthma in several populations. However, deep divergence in the distribution of some single base polymorphisms (SNPs) is noted en Caucasian, African-American, Asian and Hispanic-Latino ethnic groups. The aim of this study was to know whether IL4R?, TNF? and IL10 polymorphisms are associated with asthma in Mexican pediatric patients. We performed a case-control study in 82 Mexican patients with clinical diagnosis of asthma and 248 individuals without allergy and asthma history as controls. We genotyped 6 SNPs (IL4R?: Ser503Pro, Arg576Gln and TNF?: -308G/A, -238G/A, IL10: -1082G/A, -582C/A) using 5'exonuclease assay (TaqMan) for allelic discrimination. Polymorphisms in IL4R? and IL10 did not show association with asthma. However, the TNF? -308A polymorphisms was more frequent in asthma patients when they were compared with controls (P=0.04, OR=2.25; 95% CI= 0.97-4.83). Our preliminary results suggest that polymorphism in TNF? gene could play and important role in the susceptibility to development asthma. More studies are underway to confirm these results.

Loss of biallelic expression of 15q11-13 GABA-A receptor subunit genes in Rett syndrome and autism. *A. Hogart, R.P. Nagarajan, D.H. Yasui, K.A. Patzel, J.M. LaSalle* Medical Microbiology & Immunology and Rowe Program in Human Genetics, University of California Davis School of Medicine, Davis, CA.

Human chromosome 15q11-13 is a complex locus containing imprinted genes as well as a cluster of three GABA-A receptor subunit genes, *GABRB3*, *GABRA5*, and *GABRG3*. The GABR genes have relevance to Prader-Willi and Angelman patients with heterozygous 15q11-13 deletions and autism patients with maternal 15q11-13 duplications. GABRB3 protein expression is also reduced in Rett syndrome (RTT), caused by mutations in *MECP2* on Xq28. Although *Gabrb3* is biallelically expressed in mouse brain, the imprinting status of GABR genes in humans has not been conclusively determined. Therefore, we analyzed allelic expression of the 15q11-13 GABR genes in post-mortem human brain using SNPs within the coding region of each gene. Equal biallelic expression of at least one GABR gene was observed for 21 controls, demonstrating that these genes are not imprinted in human brain. Interestingly, 4/12 autism and 1/3 RTT samples expressed only one allele for one or more GABR gene, suggesting a variable loss of normal biallelic expression. To determine if allelic expression correlated with overall transcript levels, quantitative RT-PCR was performed. As a group, samples with loss of biallelic expression did not have significantly lower expression of *GABRB3* than those with biallelic expression, however, both autism and RTT samples had lower *GABRB3* transcript levels compared to controls. Since MeCP2 has been shown to positively regulate *GABRB3*, further studies were conducted to elucidate a role for MeCP2 in allelic expression. Chromatin immunoprecipitation and bisulfite sequencing demonstrated binding of MeCP2 to methylated intronic sequences in *GABRB3* and *GABRG3* without evidence for allele-specific methylation. Developmentally regulated homologous 15q11-13 pairing in neurons has been previously described to be dependent on MeCP2. Autism and RTT patients deficient for MeCP2 expression exhibit disrupted 15q11-13 pairing, suggesting that MeCP2 and *trans* interactions are necessary for normal gene expression of the 15q11-13 GABR cluster.

Proteomic profiling of hippocampal synaptoneurosomes in the mouse model of fragile X syndrome. *M. Nakamoto[1], D. Cheng[1], J. Peng[1], U. Narayanan[1], R. Alisch[1], H. Yi[2], S.T. Warren[1]* 1) Human Genetics; 2) Imaging Facility; Emory Univ, Atlanta, GA.

Fragile X syndrome (FXS) is a common form of inherited mental retardation and is caused by loss of FMRP. FMRP, an mRNA-binding protein, can suppress translation of target transcripts and the absence of FMRP results in excess translation of target mRNAs. Synaptic plasticity requires local protein synthesis of preexisting messages and in the absence of FMRP, electrophysiological measures of plasticity, such as mGluR5-induced long term depression (LTD) are exaggerated, consistent with the over translation of LTD-required protein(s). Indeed, mGluR5-induced LTD, which is sensitive to protein synthesis inhibitors in wildtype (wt) mice, is insensitive to the same inhibitors in *Fmr1* knockout (ko) mice. This suggests that in ko mice there are preexisting and constitutively expressed proteins that are normally translated locally in response to synaptic stimulation. We sought to identify such proteins in hippocampal synaptoneurosomes (SNs) from wt and ko mice utilizing a high throughput liquid chromatograph coupled with highly sensitive tandem mass spectrometer (LC-MS/MS). We compared mGluR5-stimulated wt SNs with unstimulated wt SNs to identify proteins normally induced by synaptic stimulation and compared unstimulated ko SNs with unstimulated wt SNs to identify proteins constitutively over expressed in the ko mice. We identified 7 proteins whose abundance was increased at least 2-fold in wt SNs upon stimulation and were at least 2-fold constitutively overexpressed in unstimulated ko SNs. The highest level of constitutive overexpression in ko SNs (8-fold) was eukaryotic elongation factor 1A protein (eEF1A), which showed a 2.4-fold increase in wt SNs upon mGluR5 stimulation. These results were verified by western blotting. Since eEF1A mRNA is a known FMRP ligand located in dendrites, our data suggest translational regulation of eEF1A by FMRP is lost in its absence. Moreover, overexpression of eEF1A may be responsible for the global increase of protein synthesis reported in ko mouse brain. These data provide further mechanistic insight into FMRP function and the consequence of its loss.

Primary Care Screening for Hereditary Cancers. *M. Kramer[1], J. Rispoli[1], T. Pollin[1], N. Khanna[2], S. DeLany[1]* 1) Genetic Counseling; University of Maryland, School of Medicine, Baltimore, MD; 2) Family Medicine; University of Maryland, Baltimore, MD.

Limitations in screening for hereditary cancer in primary care settings have been identified by several studies. In order to increase screening ability, physicians stated that they would like further education on screening patients for hereditary cancer. A study was conducted at the University of Maryland School of Medicine to determine what aspects of screening need improvement and what educational approaches would be preferred. 48 primary care physicians completed a questionnaire that asked about their practice and confidence in screening for hereditary cancers. They were also asked to assess cancer risk from four family history vignettes. Only 8% of physicians screened all patients regularly. A majority (88%) of physicians screened patients by asking about a presence or absence of a family history of cancer. Only 42% of respondents obtained a three-generation family history. Participants cited lack of time as the greatest barrier to hereditary cancer screening. No respondent correctly estimated risk as low, moderate or high, in more than 3 of 4 scenarios. Participants had the most difficulty assessing risk for low and moderate risk patients, resulting in overestimation of risk for inheriting a predisposition gene for cancer. Physicians (87%) stated that they would like more education on screening for hereditary cancer and that they would attend yearly lectures. Physicians indicated that they would particularly appreciate more information on cancer susceptibility tests and identifying high-risk patients. Only half of participants knew about local genetics services. These data indicate a need for further education of primary care physicians regarding both screening techniques and availability of resources and point toward some of the preferred means of providing this education.

Identification of PML-RARA rearrangement by RT-PCR and sequencing in an acute promyelocytic leukemia without t(15;17) on G-banding and FISH. *J. Han[1], K.E. Kim[1], K.H. Kim[1], J.S. Kim[2], J.I. Park[3]* 1) Department of Laboratory Medicine, Dong-A-University College of Medicine, Busan, Korea; 2) Department of Internal Medicine, Dong-A-University College of Medicine, Busan, Korea; 3) Department of Biochemistry, Dong-A-University College of Medicine, Busan, Korea.

t(15;17)(q22;q12) is seen in 70-90% of APL cases, leading to the formation of two reciprocal fusion genes, PML-RARA on the der(15) and RARA-PML on the der(17) chromosomes. A number of different variant translocations have been characterized in the remaining cases of APL. There are also APL patients with cytogenetically normal chromosomes 15 and 17. Combining molecular techniques such as RT-PCR, FISH, or sequencing has been a useful tool in identifying those abnormalities. FISH using a commercially available dual color, dual fusion probe could detect almost all PML-RARA fusions including variant and cryptic forms. We report a unique case of de novo APL with a cryptic PML-RARA rearrangement. This patient had a karyotype of 47,XX,+8 and no additional chromosomal abnormalities. Metaphase FISH of the patient did not show PML-RARA fusion signals. However, PML-RARA chimeric transcripts could be identified by RT-PCR and cDNA sequencing. A diagnosis of APL was made and she was treated with combination chemotherapy including idarubicin and all trans retinoic acid (ATRA). The chemotherapy was well tolerated and a complete hematologic remission was achieved four weeks later. Evidences of PML-RARA fusion gene could not be detected any longer and cytogenetic studies showed a normal karyotype. The newer FISH method is significantly superior to the previous FISH probes, accurately detecting cryptic, variants or complex translocations involving chromosomes 15 and 17. However, depending on the size of the insertion, the target could be so small that it does not hybridize with the probe or even hybridization itself might not generate a fluorescent signal large enough to be visualized by FISH. To resolve the presence or absence of a masked PML-RARA fusion, it may be necessary to further evaluate by using of other molecular testing.

Frequency of Thiopurine Methyltransferase alleles in Mexican population. *A. Inchaustegui, O.A. Perez-Gonzalez, L. Castellanos-Tapia, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

6-Mercaptopurine (6-MP), 6-thioguanine, and azathioprine are thiopurine drugs used in the treatment of patients with leukemia, autoimmune diseases and transplant recipients. Thiopurine methyltransferase (TPMT) catalyzes an S-methylation reaction in the metabolism of these agents. The activity of the TPMT enzyme is affected by the presence of polymorphisms in the *TPMT* gene. Polymorphisms in this gene have been documented in 2-10% of different populations around the world. The Mexican population has a unique genetic origin, more than 80% of the population is considered Mestizo, resulting from the admixture of any of 62 ethnic groups with Spaniards in the last 500 years. To establish the allelic and genotypic frequencies of functional polymorphisms (238G>C and 719A>G) in the Mexican population, we analyzed samples from 994 healthy Mestizo volunteers, 54.6% men and 45.4% women, from six states in separate areas of Mexico using allelic discrimination based on TaqMan technology (AB). Analysis of 238G>C (*TPMT*2*) showed 100% of the ancestral alleles. In contrast, analysis of 719A>G (*TPMT*3C*) showed an allele frequency of 5.2% for G with genotype frequencies of 9.6% for heterozygous (AG) and 0.4% for homozygous (GG) individuals. Results were confirmed by direct sequencing 11% of the samples. The presence of 719G allele is predictive of phenotype; individuals heterozygous 719A>G have intermediate enzyme activity, and subjects homozygous for this allele are TPMT deficient. Patients heterozygous in 719A>G are at intermediate risk of dose-limiting toxicity (Black AJ, et al. 2001. *Ann Intern Med* 129:716). These initial results will contribute to establish a screening program to detect those Mexican Mestizo patients with increased sensitivity to these drugs in order to adjust dose levels and decrease severe adverse effects. In addition, reduction in the amounts of 6-MP administered to these patients will result is a significant reduction of treatment cost. This initial analysis is part of the national platform of genomic medicine that Mexico develops for its population.

Midwives and genetics in Australia: current practice, anticipated needs. *S.A. Metcalfe[1,2], M. Bishop[1,2], Y. Bylstra[1], C. Gaff[3,4]* 1) Genetics Education and Health Research , MCRI, Melbourne, Australia; 2) Dept Paediatrics, The University of Melbourne, Australia; 3) Genetic Health Services Victoria, Australia; 4) Institute of Medical Genetics, Cardiff University, Cardiff, UK.

In Australia, the model of midwifery healthcare appears to lie somewhere between that of the USA and the UK. Midwives are an essential component of prenatal and postnatal care of women, yet their role in genetics in Australia has not been described, recognised or supported. Using both qualitative and quantitative approaches we investigated how genetics is incorporated into current and expected roles of midwives. Focus groups (9) were conducted with midwives (n=50) and 11 interviews with organisational managers and educators from the state of Victoria. Also, 2 focus groups were held with prenatal and neonatal genetic experts (n=10). Midwives discussed their experiences in dealing with genetic issues, while managers and experts were asked about their opinions on midwives practice, and what they expect their role to entail. Transcripts of discussions were analysed and major themes identified. Both managers and midwives recognised that midwives care primarily for normal or low risk pregnant women. Experts supported autonomy for discussing prenatal and neonatal screening tests, whilst managers saw midwives essentially as resource/information providers. Midwives reported their role in regards to genetics includes information provider, counsellor, and support person. Perceived boundaries with other health professionals was also discussed. Genetics seems to impact on the midwife role through the whole continuum of pregnancy, being defined mostly by organisational practice and population demographics, rather than personal experience or knowledge. Data from the qualitative part of the study was used to inform the development of a survey which has subsequently been validated. Items in the survey include areas of current practice, knowledge, skills, attitudes and requirements for education. The survey has been sent to 850 midwives, data is being collected and will be presented. Together the study will inform educational needs and policy regarding midwife practice of genetics.

Holoprosencephaly: Clinical and genetic study about 350 patients (1996-2006). *S. Odent[1], L. Pasquier[1], C. Dubourg[2], C. Bendavid[2], C. Henry[3], S. Jaillard[3], M.R. Durou[2], I. Gicquel[2], V. David[2]* 1) Genetique Medicale, Hopital SUD, Rennes Cedex2, France; 2) CNRS UMR6061, Groupe Genetique humaine, Universite Rennes1, 35 043 Rennes cedex, France; 3) Laboratoire de Cytogénétique, CHU de Rennes, Hopital Pontchaillou, France.

Holoprosencephaly (HPE) is the most common brain malformation resulting from incomplete cleavage of the prosencephalon (1 out of 16.000 live births; 1 out of 250 conceptuses). HPE is associated with a wide spectrum of craniofacial malformations ranging from lethal forms (alobar HPE with cyclopia) to less severe forms such as lobar HPE and normal face. The etiology is very heterogeneous involving environnemental factors, chromosomal abnormalities and at least 7 genes. Since 1996, our team has started to work on the wide clinical and genetic variability of holoprosencephaly. Patient samples (fetuses or children with normal karyotype) and clinical data (from HPE to microforms) were collected from medical teams in France and Europe. Systematic mutation analysis and genomic rearrangements of the five main genes (SHH, ZIC2, SIX3, TGIF, GLI2) were performed. About 19%sequence changes were identified among 350 DNA samples The familial cases confirmed an extreme clinical variability. Then, microrearrangements were detected by QMPSF, MLPA and CGH array (particularly in fetuses) improving the rate of molecular defects to a total of 30%;. Several patients samples within 2 microdeletions and/or duplications were identified supporting multiple-hit hypothesis involving others genetics and/or environnemental factors. We performed molecular prenatal diagnosis four times with fetal US scan and cerebral MRI screening. At last, we show involvement of cerebral malformations as Aprosencephaly/Atelencephaly linked to SIX3 mutations and cerebellar hypoplasia to SHH gene. Pan-hypopituitarism and cleft lip/palate were associated with GLI2. This work has improved molecular diagnosis rate in Holoprosencephaly and therefore the genetic counseling.

Expression profiling of retinoblastoma and meibomian cell carcinoma using cDNA microarray. *A. Kumar[1], S.K. Dorairaj[2], R. Prakash[2], C.P. Venkatesh[2], S. Chakraborty[1]* 1) MRDG, Indian Inst Science, Bangalore, India; 2) Minto Ophthalmic Hospital, Bangalore, India.

Development and progression of tumors is a multistep process dictated by expression of many genes. DNA microarray could facilitate identification of genes involved in tumor development by hybridizing cDNA samples from normal and tumor tissues on cDNA microarrays. Although it is well known that the loss-of-function of retinoblastoma protein causes retinoblastoma, it is not known as to how many other genes are involved in development and progression of retinoblastoma. Besides, the most common treatment available till date to treat retinoblastoma is enucleation of the affected eye(s). Therefore, finding targets for therapeutic intervention for retinoblastoma using microarray technique will be of paramount importance. Nothing is known about the genes involved in development and progression of meibomian cell carcinoma. The purpose of this study was to fill this gap using cDNA microarray technology. We have ascertained a total of 11 retinoblastoma (Rb) and five meibomian cell carcinoma (MCC) samples. We have also ascertained normal retina samples from eye globes which were discarded after removing cornea for corneal transplantation from individuals who donated their eyes. We have also collected normal eyelids from individuals who went through eyelid reconstruction surgery for a variety of reasons. We have isolated total RNAs from all of the retinoblastoma, meibomian cell carcinoma, normal retina and normal eyelid samples. We have analyzed three retinoblastoma samples using three 19K human microarray slides (University Health Network, Toronto). A comparison of the hybridization data showed up-regulation of 1,002 and down-regulation of 480 genes. Using semi-quantitative PCR, we have validated six genes so far. We have also carried out microarray analysis for two MCC tumors using human 8K microarray slides. Seventy genes were upregulated and 405 genes were downregulated. We have validated five genes so far in a panel of five MCC samples. The results will be presented and discussed. (Funding from ICMR, New Delhi is gratefully acknowledged).

A Novel mutation in the VDR gene in an Iranian patient with vitamin D-dependent Rickets type II. *V. Hadavi[1], N. Almadani[1], W. Wuyts[2], M.H. Kariminejad[1], H. Najmabadi[1]* 1) Kariminejad-Najmabadi Pathology & Genetics Center, Tehran, Iran; 2) Department of Medical Genetics, University and University Hospital of Antwerp, Antwerp, Belgium.

The vitamin D receptor (VDR), is the mediator of all genomic actions of vitamin D3 and it's analogs. Mutations in VDR results in target organ resistance to 1alpha,25-dihydroxy vitamin D [1,25(OH)2D3], the active form of vitamin D, and cause hereditary 1,25-dihydroxyvitamin D resistant rickets (HVDRR). This disease also called vitamin D-dependent rickets type II and is transmitted in an autosomal recessive mode. We report on a 5 years old girl affected with type II vitamin D-dependent Rickets, who appeared normal at birth but developed the clinical and biochemical features of calciferol deficiency with hypocalcaemia and rickets in the first year of life. She suffered from total alopecia and metaphyseal dysplasia in both hip joints and in pelvic. She was hospitalized at the age of four due to Diabetes Mellitus. Sequence analysis of all coding exons of VDR gene was performed and revealed a single homozygous point mutation in exon 7 causing a premature termination codon, Tyr295X. The Tyr295X mutation causes a truncation of the VDR protein, thereby deleting a large portion of the steroid hormone-binding domain (amino acids 295-424).

Triplication of the 1p36.3 Region in Two Siblings with Seizure Disorder. *S.-H.L. Kang[1], D. del Gaudio[1], P.A. Eng[1], M.L. Cooper[1], A. Scheffer[2], S. Vacha[2], C.A. Bacino[1], S.W. Cheung[1], T. Sahoo[1]* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Agilent Laboratories, Palo Alto, CA.

Duplications involving the terminal short arm of chromosome 1 are extremely rare. Deletions of 1p36 are one of the most common human microdeletion syndromes and have been extensively characterized. Genotype-phenotype correlations across the 10 Mb region frequently involved in the deletion syndrome suggests that there are multiple dosage-sensitive genes within this region. Constitutional duplications involving chromosome 1p described in the literature have been identified to be interstitial in nature involving variable segments, both in size and location, and consequently with variable phenotypic manifestations. To our knowledge, no cases of triplication of 1p36, and potentially familial in origin, have ever been reported. We describe two female siblings presenting with seizures, abnormal EEG and global developmental delay (at around 2 years of age) associated with regression in early childhood. Physical examination revealed no dysmorphic features. Array-CGH revealed a gain of greater than two copies of ~2.2 Mb including the telomeric region of the short arm of chromosome 1 (1p36.3). High-resolution G-banded chromosome and fluorescence in situ hybridization analyses were concordant with direct/tandem triplication of the terminal 1p36.3 segment. Additional studies including quantitative PCR for multiple amplicons across the putative segmental gain confirmed the presence of two additional copies of the 1p36 segment and provided a more precise estimate of the size and boundary of the rearrangement. The resulting gain includes increase in copy number of a number of genes that might be responsible for the phenotype. Interestingly, the potassium channel beta-subunit gene (*KCNAB2*) located approximately 6 Mb proximal to the 1p telomere, that has been implicated in the seizure disorder observed in some patients with deletions in 1p36, is not contained within the rearranged segment.

Detecting Epistatic Needles in Genome-Wide Haystacks. *J.H. Moore, B.C. White* Computational Genetics Laboratory, Department of Genetics, Dartmouth Medical School, Lebanon, NH.

The detection of epistasis is an important priority in the genetic analysis of complex human diseases. The most challenging epistatic effects to model are those that do not exhibit statistically significant marginal effects. Identifying these types of nonlinear interactions in the context of genome-wide association studies is considered a *needle in a haystack* problem. Given this complexity, it is unrealistic to expect that stochastic search algorithms will do any better than a simple random search. Our goal was to test this null hypothesis and then develop and evaluate a stochastic search algorithm that is capable of finding epistatic needles with the assistance of expert knowledge. We first developed a genetic programming (GP) approach to picking SNPs for epistasis evaluation using multifactor dimensionality reduction (MDR). This new GP-MDR approach was evaluated using simulated epistatic interactions of varying heritability (0.01, 0.025, 0.05, 0.1, 0.2, 0.3, 0.4) and minor allele frequency (0.2, 0.4) that were embedded in genome-wide datasets with varying numbers of SNPs (1000, 10000, 100000) and varying sample sizes (200, 400, 800, 1600, 3200, 6400). We found no evidence to suggest that GP-MDR performed better than random search on these simulated genome-wide datasets. Next, we modified GP-MDR to select SNP combinations for virtual recombination, mutation, and reproduction by the GP based on prior information about the quality of each SNP as assessed during a pre-processing analysis by the ReliefF filter algorithm. We found that the expert knowledge provided by ReliefF about which SNPs might be interacting significantly improved the ability of GP-MDR to identify epistatic SNPs in the absence of marginal effects over that of a simple random search. An important advantage of this approach is that any form of expert knowledge could be used to guide the stochastic search algorithm. For example, information about biochemical pathways, protein-protein interactions, Gene Ontology (GO), or even evidence from the literature could be used in addition to statistical measures such as ReliefF. (Funded by NIH R01s LM009012 and AI59694, PI-Moore).

Comprehensive analysis for large deletions in TSC1 and TSC2 in TSC patients: frequency, utility and reliability of MLPA, and genotype-phenotype correlations. *P. Kozlowski[1], P.S. Roberts[1], S. Dabora[1], D. Franz[2], J. Bissler[2], H. Northrup[3], K-S. Au[3], S. Jozwiak[4], D.J. Kwiatkowski[1]* 1) Dept Medicine, Brigham & Women's Hosp, Boston, MA; 2) U. Cincinnati, OH; 3) UT Houston, TX; 4) Children's Hospital, Warsaw, Poland.

Tuberous sclerosis is an autosomal dominant disorder caused by mutations in either of two genes, TSC1 and TSC2. Point mutations and small indels account for about 75% of mutations in unselected patients. Large deletion and insertion mutations are known to occur in TSC1 and TSC2, but their frequency is uncertain. We examined 269 TSC DNA samples (216 small-mutation-negative and 53 unscreened) for large deletion/duplication mutations using both commercial (MRC-Holland) and our own TSC1 and TSC2 MLPA probe sets. These combined probe sets permit interrogation of all TSC1/2 exons, as well as 15-50kb of flanking sequence. Large deletion mutations in TSC1 and TSC2 were identified in 50 (19%) of 269 TSC patients, of which 46 were in TSC2, and 4 were in TSC1. Only 12 deletions were intragenic in TSC2, and one in TSC1, so that 37 (74%) deletions extended beyond the 5, 3 or both ends of TSC1 or TSC2. Mutations were identified in 22% of small-mutation-negative and 6% of unscreened samples. Only 1 of the 50 (2%) samples showed evidence of duplication. Six of 49 (12%) deletions were mosaic, affecting ~30-60% of cells. All mosaic, single exon, and intragenic deletions were confirmed by LRPCR. In addition, all deletions were concordant between the two sets of probes for each gene. Genotype/phenotype analysis showed that 18 of 22 patients with TSC2 deletions extending 3 into the PKD1 gene had early onset polycystic kidney disease; further analysis continues. Break-points of intragenic deletions were randomly distributed along the TSC2 sequence. Our own 20-plex probe sets gave more robust performance than the 40-plex probe sets from MRC Holland. In conclusion, this comprehensive analysis indicates that large deletions in TSC1 and TSC2 account for about 0.5% and 6% of mutations seen in TSC patients, respectively, and that MLPA is a highly sensitive and accurate method for their detection.

Epigenetic differences in monozygotic Rett syndrome twin with different severity. *T. Kubota[1], Y. Chunshu[1], K. Endoh[1], M. Sohtome[1], M. Sasaki[2]* 1) Dept. Epigenetic Medicine, Univ. of Yamanashi, Yamanashi, Japan; 2) Dept. Child Neurology, National Center of Neurology and Psychiatry, Tokyo, Japan.

Rett syndrome (RTT) is an X-linked dominant disease caused by *MeCP2* mutations. MeCP2 is bound to the promoters of genes and controls their expression, suggesting that pathogenesis of RTT is mis-regulation of genes in the brain. Here we performed genetic and epigenetic analyses on monozygotic RTT twins with different severity. The twin sisters were 3.5 y.o. The older sister (OS) showed typical RTT features, such as epilepsy and hand wringing, by 2 y.o., whereas the younger sister (YS) was an atypical RTT, who had almost normal linguistic development by 2 y.o., but lost words thereafter. DNA polymorphisms at 6 microsatellite markers on various chromosomes were identical, indicating that twins were monozygotic. Both twin showed one base deletion in *MeCP2* [c.806delG (p.Gly269ArgfsX288)]. X-chromosome inactivation (XCI) patterns, obtained by methylation-specific PCR assay, were similar between twins in either lymphocytes (OS49:51, YS47:53), or hairs originated from the same embryonal origin (ectoderm) as CNS (OS40:60, YS51:49). Monozygotic twins with RTT did not show any apparent differences in genetic (mutation) and epigenetic (XCI pattern) factors. It has recently reported that DNA-methylation patterns become gradually different after birth between individuals. Thus, we are now investigating methylation at the MeCP2-target genomic sites, whether the sites are less methylated in severe OS than in milder YS, because less methylation can deteriorate the function of the preserved nearly half amount of normal MeCP2 in RTT.

De Novo Balancd Complex Chromosome Rearrangement (CCR) - 46, XY, t(8;10),t(8;12) associated with Autism Spectrum Disorder (ASD)- Cytogenetic, FISH and Microarray analysis. *D.S. Krishnamurthy[1], M. Susan[1], M. Naveed[1], S.K. Murthy[2], K. Sperling[3]* 1) Cytogenetics and Moleclar Cytogenetics, Canadian Specialist Hospital,DUBAI, UAE; 2) Cytogenetics Unit,Genetics Dept Al Wasl Hospital, DOHMS, DUBAI, UAE; 3) Institut fur Humangenetik University of Berlin, Berlin,Germany.

Autism Spectrum Disorder (ASD) is a rare behavioral phenotype defined by a qualitative impairment in reciprocal social interaction, impairment in communication and imaginative activity. About 1.7 % to 4.8 % of individuals with ASD have chromosome abnormalities, including unbalanced translocations, inversions, rings, and interstitial deletions and duplications. Balanced or unbalanced Complex chromosome rearrangements (BCCR/CCR) are rare structural abnormalities involving at least three chromosomes and three or more break-points. We report a 8-5-year-old boy with delayed speech and ASD associated with a BCCR involving chromosomes 8, 10 and 12. His Karyotype showed - 46,XY, der(8),t(8;12)(q22;q22), der(10), t(8;10)(q22;q25), del(12)(q22->qter). Teleomere FISH confirmed the the translocation brekpoints at terminal regions (8q;10q;12q).The family history was non-informative suggesting a possible de novo rearrangement. The karyotype in both the parents are normal. Fragile X (FMR1-gene)test was negative [30+1-1 repEats- normal range 6-49 repeats (2)]. FISH analysis for PWS (SNPRN LSI 15q11-q13) showed normal result. CGH analysis confirmed normal karyotype (rev ish XY). Microarray analysis confirmed no deletion or duplication of chromosomes 8,10 and 12.Balanced Complex de novo rearrangement may lead to disruption of genes at the breakpoints, position effect or cryptic imbalances in the genome. However, little is known about possible imbalances at the junction points. This case suggests that aberrations at 8q22, 10q25, and/or 12q22 may result in pervasive developmental disorder,associated with mild cognitive delay. The etiology and pathogeneis of ASD in balanced complex chromosome rearrangement, confirmed by array-CGH will be discussed.

Splicing analysis cassette vector system showed that either a polypyrimidine-tract or an exonic splicing enhancer is essential for correct splicing of dystrphin exon19. *Y. Habara[1], M. Doshita[2], Y. Yokono[2], M. Yagi[1], Y. Takeshima[1], M. Matsuo[1]* 1) Department of Pediatrics, Kobe University Graduate School of Medicine, Japan; 2) Kobe Pharmaceutical University, Japan.

Splicing signal is located not only at exon-intron boundary but also at deep into exons and introns in human genes. For this reason, it is sometime difficult and also confusing to find a responsible mutation of genetic disorder. We developed a vector assay system to examine mRNA splicing patterns in order to identify sequence elements essential for correct splicing. The vector expresses a reporter minigene under CMV promoter, containing two exons and adjacent intron which have a multiple cloning site (MCS) in the center. To analyze splicing patterns, a part of the target gene from patients, control or artificially mutated genes are ligated into the MCS of this vector. After making reporter fusion minigenes, plasmids are transfected into culture cells to express the minigenes. Then, cells are harvested and splicing patterns are analyzed by RT-PCR. We analyzed which element is essential for correct splicing of dystrophin exon19 by using this cassette vector system. Dystrophin exon19 was spliced as an exonic splicing enhancer (ESE) dependent manner; the exon19 was included to mature-mRNA when it had an ESE, and the exon19 was skipped when the ESE was eliminated from exon19 sequence. First, we confirmed that whether this ESE dependent manner is recapitulated in HeLa cells with this vector. Then we changed the polypyrimidine tract (Py-tract) sequences located upstream of exon19 to examine the relationship between ESE and Py-tract. It revealed that the ESE is not essential for correct exon usage when the activity of Py-tract is strong (10 nucleotides of U-stretch). On the other hand, when the exon has a full length ESE, 6 of 10 nucleotides alteration from pyrimidine to purine in Py-tract is not affected for its splicing pattern. It is suggested that either the good Py-tract or the fully active ESE is essential for correct splicing of dystrophin exon19. Also, it showed that this cassette vector system enable us to analyze splicing pattern by a single cloning and transfection steps.

The p53 codon 72 polymorphism is associated with primary open angle glaucoma in the Japanese population. *F. Mabuchi[1], S. Tang[2], K. Kashiwagi[1], Z. Yamagata[2], H. Iijima[1], S. Tsukahara[1]* 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Yamanashi, Japan.

Objective: Previous studies looking at the association of the p53 gene polymorphism and primary open angle glaucoma (POAG) revealed conflicting results. Additionally, there have been no studies in the Japanese population. We thus assessed whether genetic polymorphism of p53 was associated with POAG in the Japanese population.

Methods: Genomic DNA was examined in a cohort of 102 Japanese patients with POAG and 67 control subjects. The average age was 61.6 15.2 years (mean SD) for the POAG patients, and 66.1 9.4 years for the control subjects. The p53 genotype (a G to C substitution at codon 72 which changes an arginine to a proline residue) was determined using pyrosequencing analysis, and compared between POAG patients and control subjects.

Results: There was a significant difference in the genotype frequencies between the POAG and control groups (P = 0.0039 Chi-square test), and the frequency of the C allele was significantly higher in the POAG patients compared to the control subjects (36.8% vs. 24.6%, P = 0.023 Fisher exact test).

Conclusion: The p53 codon 72 polymorphism is associated with POAG and may be a maker for POAG in the Japanese population. Further studies in the other ethnic populations should be performed to elucidate the relationship between the p53 gene and POAG.

Identification of a genetic locus for Donnai-Barrow syndrome. *S. Kantarci[1], P.K. Donahoe[1], R.S. Hill[2], L. Al-Gazali[3], D. Lacombe[4], N. Chassaing[4,5], E. Bieth[5], G. Black[6], D. Donnai[6], C. Walsh[2], B.R. Pober[1,2]* 1) Massachusetts General Hospital,HMS, Boston, MA; 2) Children's Hospital,HMS, Boston MA; 3) FMHS, UAE University, Al Ain United Arab Emirates; 4) Hôpital Purpan, Toulouse France; 5) CHU Pellegrin, Bordeaux, France; 6) Marys Hospital, Manchester, UK.

Background: Donnai-Barrow syndrome (DBS)is a rare autosomal recessive [OMIM#222448] genetic disorder involving congenital diaphragmatic hernia (CDH), exomphalos, absent corpus callosum, hypertelorism, myopia, and sensorineural deafness. As part of our ongoing studies to uncover genes associated with CDH, we performed locus mapping on DBS. Methods: We recruited four DBS patients, with prior normal chromosome studies, from two distinct branches of a highly inbred family from the UAE. Array-based comparative genomic hybridization (aCGH) (Spectral Chip 2600) was performed on two patients. We applied the Affymetrix 10K SNP genotyping chip to identify areas of shared homozygosity among the affecteds; homozygous regions were confirmed using microsatellite analysis. Additionally, we obtained DNA from two previously reported multiplex DBS families from France on which we performed microsatellite analysis. We also recently recruited three DBS families, members of the original DBS kindreds, reported from the UK. Sequence analysis of candidate genes has been carried out in one affected member from each family (by SeqWright). Results:o In the UAE kindreds, aCGH results were normal. 10K SNP chip revealed several regions of shared homozygosity in the four patients, with a promising 10 cM homozygous block on chr.2. Microsatellite analysis narrowed the region to ~18 Mb on 2q23.3-q31.1. The highest single point LOD score was 3.2619. o Microsatellite markers on 2q23.3-q31.1 showed different haplotypes between affected and unaffected sibs in the French families. o Haplotype analyses of the UK families are underway. o Sequencing of 45 gene candidates in the chromosome 2 critical region has been completed for 10 genes. Conclusions: We identified a genetic locus in 2q23.3-q31.1 for DBS. Identification of the genetic basis of this monogenic CDH syndrome is likely to reveal a locus contributing to the more common polygenic form of CDH.

Gene Diversity at hypervariable polymorphic loci in African populations and its impact on estimating admixture components in admixed African populations of the American continent. *H. Lee, W. Niu, R. Chakraborty* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

Gene diversity within Africa is the highest compared to other continents. As a consequence, there are criticisms of estimating admixture components in African populations using a single specific population from Africa as the source of their African gene pool. Using allele frequency data on 13 short tandem repeat (STR) loci used in DNA forensics, we examined the extent of gene differentiation at these loci between populations of the African continent, and the impact of the choice of ancestral African source population on admixture estimates in some admixed African populations of the continental USA. Allele frequency data were collected on eight sub-Saharan African populations from Kenya, Equatorial Guinea, Mozambique, Angola, and Rwanda. Admixed African populations included general US Blacks, Brazilian Blacks, and the three Caribbean populations (Trinidad, Jamaica, and Bahama). The gene diversity estimate within Africa (i.e., proportion of genetic variation due to between population differences) was 0.63%, which is almost 3-fold higher than that of the European populations published before. Dendrogram analyses also revealed this greater diversity within the African continent, although in terms of clusters, the admixed African populations clustered with the African populations. In terms of admixture estimates, however, the choice of specific African populations as the source of the ancestral gene pool did not change the admixture components appreciably. For example, for the US Blacks the proportion of African genes in their gene pool ranged between 78 to 89%, depending upon the choice of specific African populations. Of the three Caribbean populations, Trinidad showed comparatively smaller contributions (57 to 69%) of African gene pool. Our results indicate that even though between-population diversity within Africa is larger than that in European continent, this diversity is trivially smaller than the genetic difference between Africans and Europeans. Therefore, when estimating admixture proportons, choice of different indigenous African population make little difference.

Comparative Mouse Genomics Centers Consortium (CMGCC): Improved understanding of the biological significance of environmentally-responsive human polymorphisms. *K.A. McAllister, F.L. Tyson, E. Maull, G. Collman, CMGCC Steering Committee* Susceptibility and Population Health Branch, Division of Extramural Research and Training, NIEHS, NIH, Research Triangle Park, NC.

The National Institute of Environmental Health Sciences (NIEHS) Comparative Mouse Genomics Centers Consortium (CMGCC) was established with the goal of developing knockout and transgenic mouse models that harbor human single nucleotide polymorphisms (SNPs) and/or mutations in DNA repair and cell cycle control genes that could alter sensitivity to environmental agents. These models will be used to enhance our understanding of the biological significance of human DNA polymorphisms and their role in combination with environmental stressors resulting in disease outcomes including multiple cancers, aging-related diseases (including Werners Syndrome), diabetes, and obesity. This multidisciplinary Consortium is comprised of University Centers in Harvard Medical School, University of Texas, MD Anderson Cancer Center, University of Cincinnati Medical School, University of Texas Health Sciences Center at San Antonio, Buck Institute CMGC, and the University of Washington. The CMGCC has developed over 70 mouse models in various stages of validation. Validated mouse models and resources developed by the CMGCC are available to the scientific community and can be accessed at the CMGCC website, http://www.niehs.nih.gov/cmgcc. The CMGCC has also developed the Federated Mouse Database which includes in silico bioinformatics and comparative mouse phenotype assessment tools, as well as mouse model dissemination or repository data. Unique contributions of CMGCC include the utilization and comparison of different approaches to humanizing polymorphisms in mouse models, the development of high-throughput phenotyping technologies, and the use of short-term challenges of the mouse models to environmental agents. Of particular interest is a humanized mouse line with a p53 codon 72 polymorphism modulating the risk of developing several environmentally-influenced cancers and an XRCC1 mouse model with potential increased sensitivity to colon cancer when environmentally challenged.

Incorporating single locus tests into haplotype cladistic analysis in case control studies. *J. LIU*[1,2], *J. ZHANG*[1,2], *C.J. PAPASIAN*[1], *H. DENG*[1,2,3,4] 1) BASIC MEDICAL SCIENCE, UNIVERSITY OF MISSOURI, 2411 HOLMES STREET, KANSAS City, MO. 64108; 2) Department ORTHOPEDIC SURGERY,UNIVERSITY OF MISSOURI, 2411 HOLMES STREET, KANSAS City, MO. 64108; 3) LABORATORY OF MOLECULAR AND STATISTICAL GENETICS, COLLEGE OF LIFE SCIENCES, HUNAN NORMAL UNIVERSITY, CHANGSHA, HUNAN 410081, P. R. CHINA; 4) THE KEY LABORATORY OF BIOMEDICAL INFORMATION ENGINEERING OF MINISTRY OF EDUCATION AND INSTITUTE OF MOLECULAR GENETICS, SCHOOL OF LIFE SCIENCE AND TECHNOLOGY, XI'AN JIAOTONG UNIVERSITY, XI'AN 710049, P.R.CHINA.

In case control studies, genetic associations for complex diseases may be probed either with single-locus tests or with haplotype-based tests. Although different views have been expressed on the relative merits and preferences for the two test strategies, haplotype-based analyses are generally believed to be more powerful for detecting genes with modest etiological effects and may be useful for detecting rare causal variants. However, the main drawback of haplotype-based association tests is the large number of distinct haplotypes, which increases the degrees of freedom (df) for corresponding test statistics, thus reducing the statistical power. To enhance the efficiency and power of haplotype analyses, we propose a haplotype clustering analysis that is based on the haplotype cladistic analyses developed by Durrant et al. for decreasing the df. In our method, we use P values obtained in individual SNP locus association tests as a measure of weight. The weight will be used in computation of similarity measures, which are used in construction of distance metric between pairs of haplotypes. To assess our proposed new method, we perform computer simulation studies to compare the performance of 1) conventional haplotype-based approach, 2) cladistic analysis method (CLADHC) by Durrant et al., and 3) our weighted cladistic analysis method, under different scenarios. The results demonstrated increased statistical power and Positive Predictive Value (PPV) by using our weighted cladistic analysis method, when compared with the CLADHC method and the conventional haplotype-based approach. Therefore, our new approach has practical significance in the general field of human genetics.

Investigations of a candidate region for dyslexia on chromosome 7q32. *H. Matsson[1], H. Anthoni[1], M. Zucchelli[1], J. Schumacher[2], G. Schulte-Körne[3], I.R. Koenig[4], J. Nopola-Hemmi[5], H. Lyytinen[6], M.M. Nöthen[7], J. Kere[1,8], M. Peyrard-Janvid[1]* 1) Biosciences and nutrition, Karolinska Institutet, Huddinge, Sweden; 2) Institute of Human Genetics, University of Bonn, Germany; 3) Dept of Child and Adolescent Psychiatry and Psychotherapy, University of Marburg, Germany; 4) Institute of Medical Biometry and Statistics, University of Lübeck, Germany; 5) Dept of Pediatrics, Jorvi Hospital, Finland; 6) Dept of Psychology and Child Research Center, University of Jyväskylä, Finland; 7) Dept of Genomics, Life & Brain Center, University of Bonn, Germany; 8) Dept of Medical Genetics, Biomedicum, University of Helsinki, Finland.

Dyslexia is the most common childhood learning disorder and may have a significant impact on social development. The specific reading and spelling deficits are manifested in spite of normal intelligence, senses, education and social environment. Dyslexia shows genetic heterogeneity, and at least eight loci (DYX1-8) contributing to dyslexia phenotypes have been mapped and up till now, four candidate genes have been described. It is important to identify novel loci and investigate the functional significance of the genetic variation in dyslexia. Our previous genome scan suggested linkage of dyslexia to a region on chromosome 7q32 with a non-parametric linkage score of 2.8 in 11 Finnish families. The *FOXP2* gene, implicated in a severe speech and language disorder, is located within the linkage peak but no exonic mutations or SNPs were revealed in dyslexic family members in a previous screening. In order to identify the causal variant within the region, we performed a more detailed linkage analysis using 14 additional polymorphic microsatellite markers spanning the 7q32 region. The analysis of marker genotypes allowed an increased resolution of the linkage peak and the linked region was restricted to approximately 9 cM. We are extending the investigation by genotyping microsatellite markers on 251 German families with a total of 429 individuals with dyslexia. Analyses of the chromosome 7 region in this large independent sample set may refine further a locus for dyslexia and support further candidate gene analysis.

Iminoglycinuria: Molecular findings. *R. Kleta[1], T. Coskun[2], B. Tinloy[1], H.I. Aydin[2], M. Gunay-Aygun[1], H. Stanescu[1], I. Bernardini[1], W.A. Gahl[1]* 1) SHBG, MGB, NHGRI, NIH, Bethesda, MD, USA; 2) Department of Pediatrics, Division of Pediatric Nutrition & Metabolism, Hacettepe University Faculty of Medicine, Ankara, Turkey.

Disorders such as cystinuria (basic aminoaciduria) and Hartnup disorder (neutral aminoaciduria) have been instrumental in identifying the genes responsible for renal tubular transport of amino acids at the plasma membrane level. For iminoglycinuria, candidate genes like SLC6A20 and SLC36A1 have been proposed to be causative. This is because heterologous expression studies have shown that their gene products mediate uptake of proline and glycine, two of the amino acids improperly handled by the proximal tubules of individuals with iminoglycinuria. We identified two patients with iminoglycinuria by serum and urine amino acid analyses showing typically elevated fractional excretions of glycine, proline and hydroxyproline only. Sequencing of all coding exons (including the splice sites) of SLC6A20 and SLC36A1 showed no disease-causing mutations. Based on homology, expression, and function, another member of the SLC36 family, SLC36A2, was selected as a candidate gene for iminoglycinuria. Sequencing of all coding exons of SLC36A2 also revealed no disease-causing mutations. We conclude that amino acid transport genes other than the proposed candidates might be responsible for iminoglycinuria. We are pursuing patients and active collaborations to elucidate the basic genetic defect in iminoglycinuria.

Is disease severity in alkaptonuria modified by a common SNP in the organic anion transporter MRP4 / ABCC4?

M.A. Kayser[1], P. Suwannarat[1], W. Introne[1], H.A. Austin[2], M. Tuchman[1], B. Tinloy[1], C. Klein[1], K. OBrien[1], I. Bernardini[1], W.A. Gahl[1], R. Kleta[1] 1) SHBG, MGB, NHGRI, NIH, MD, USA; 2) NIDDK, NIH.

Alkaptonuria is a rare metabolic disorder of tyrosine catabolism in which the organic compound homogentisic acid (HGA) binds to connective tissue and causes darkened cartilage (ochronosis), joint destruction, and cardiac valve deterioration. In our investigation of more than 90 alkaptonuria patients, we previously identified 4 women with an ochronotic phenotype but normal HGA excretion. All had been treated with the tetracycline derivative minocycline. Tetracyclines are secreted into the urine by proximal tubular organic anion transporters. These transporters recognize a variety of drugs, xenobiotics, and organic acids, including p-aminohippurate (PAH). We had sequenced all coding exons of OAT1, OAT3, OAT4, and MRP4, in 2 of our 4 pseudo-ochronotic patients. Both exhibited a homozygous intronic acceptor splice site mutation, IVS2-5T>C, in MRP4. PAH clearance was abnormally low in the one patient we studied, demonstrating the deleterious effect of this mutation on organic anion transport. We generated a restriction site in MRP4 to screen for IVS2-5T>C. In 136 alleles from patients with alkaptonuria, we found the expected frequency of wildtype (70%) and minor (30%) alleles. We propose that this common MRP4 SNP, IVS2-5T>C, can potentially modulate the clinical severity of alkaptonuria, since HGA secretion depends upon an intact organic anion transporter. To pursue this, we measured plasma HGA levels in our alkaptonuria patients and correlated them with the presence of the MRP4 SNP. Our preliminary data support a potential influence of this SNP on plasma HGA levels. Our findings point toward a gene product that modifies the severity of alkaptonuria and could have a major impact on the clinical course of other organic acidurias, in which documented variability among affected siblings currently has no explanation.

Pitfalls in Homozygosity Mapping - Revisited. *G. Landoure[1], H. Stanescu[2], M.A. Knight[1], A.A. Taye[1], M. Arcos-Burgos[2], D. Pineda[2], W.A. Gahl[2], K.H. Fischbeck[1], R. Kleta[2]* 1) Neurogenetics Branch, NINDS, NIH, Bethesda, MD, USA; 2) MGB, NHGRI, NIH.

Myasthenia gravis is usually a sporadic condition, but approximately 4% of patients have a positive family history. We studied an Italian-American kindred in which the parents are first cousins; 5 of 10 siblings had autoimmune myasthenia. Affected family members had positive anti-acetylcholine receptor antibodies and other manifestations of autoimmune disease. The age of onset ranged from 50 to 79 years. The horizontal inheritance pattern and consanguinity suggested an autosomal recessive model, so we assessed linkage in the context of shared homozygosity. A genome-wide scan was performed using polymorphic markers spaced at 2 cM intervals. We probed 7 members of the family, i.e., 4 affected children, 2 unaffected children and one child with a less well defined phenotype. Using the Lander-Kruglyak multipoint linkage algorithm that includes homozygosity mapping (implemented in the Homoz) and considering affected individuals only, we found significant linkage with a LOD score of 3.28 for a region of shared homozygosity on chromosome 13. Taking unaffected individuals into account reduced the LOD score for this locus to 1.57. Haplotype reconstruction (using the SIMWALK software package) showed homozygosity in both affected and unaffected family members. A parametric multipoint analysis of the same data, without taking into account homozygosity (GENEHUNTER software), revealed a negative LOD score for this region. Instead, a single locus with a LOD score of 2.18 was detected on chromosome 2. Haplotype reconstruction of affected and unaffected individuals was consistent with this localization and was compatible with compound heterozygosity in affected individuals. In summary, even though homozygosity by descent appears more likely for recessive disorders in inbred families, the possibility of having two different disease-carrying alleles has to be considered. Our family with several affected children from a consanguineous marriage illustrates this principle.

Gitelman syndrome and sclerochoroidal calcifications: The critical importance of renal regulation in calcium homeostasis. *K. O'Brien[1], E. Tsilou[2], M. Lynch[1], C. Stuart[1], A. Jeong[1], R. Kleta[1], W.A. Gahl[1]* 1) SHBG, MGB, NHGRI, NIH, Bethesda, MD, USA; 2) Ophthalmic Genetics and Visual Function Branch, NEI, NIH.

Calcium homeostasis is critical for many intracellular functions. Hypocalcemia as well as hypercalcemia can present with acute life-threatening complications. Ionized and total calcium levels are tightly regulated within the vascular compartment. Gitelman syndrome is caused by mutations in the electroneutral sodium-chloride transporter gene SLC12A3 in the distal convoluted tubule of the kidney. In general, patients present with the unique combination of hypocalciuria and normocalcemia. Gitelman syndrome patients are often diagnosed accidently in late childhood or their twenties with hypokalemia, hypomagnesemia and metabolic alkalosis. More severe and distinct forms of renal tubular salt losing with neonatal or infantile presentations comprise Bartter syndromes. Here we present clinical, molecular and ophthalmological findings in a 60-year-old patient with Gitelman syndrome and her unaffected 62-year-old sister. The patient was compound heterozygous for two missense mutations in SLC12A3 and showed typical hypocalciuria. She had impressive peripheral sclerochoroidal calcifications without significant visual impairment. The blood compartments calcium homeostasis is maintained by well-defined mechanisms that involve vitamin D, parathyroid hormone, calcitonin, and the kidney. Our findings point to the possibility that chronic, long-term calcium overload, as occurs in Gitelman syndrome due to diminished renal excretion, can lead to ectopic precipitation of calcium in areas such as the retina. Enhancing urinary calcium excretion in patients with Gitelman syndrome might warrant consideration.

Ordered Stratification to Reduce Obesity Heterogeneity in Linkage Analyses of Type 2 Diabetes Quantitative Traits. *A.K. Manning[1], J. Dupuis[1], C. Lui[4], C. Fox[3], L.A. Cupples[1], J. Meigs[2]* 1) Biostatistics Department, Boston University, Boston, MA; 2) General Medicine Division and Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 3) The NHLBIs Framingham Heart Study and the Division of Endocrinology, Diabetes, and Hypertension, Brigham and Womens Hospital, Harvard Medical School, Boston, MA; 4) Department of Neurology, Boston University School of Medicine, Boston, MA.

Background: Heterogeneity in adiposity complicates detection of genomic loci predisposing to type 2 diabetes. Obesity may unmask diabetes susceptibility genes, or may produce non-genetic phenocopies. Methods: We conducted an ordered subsets linkage analysis (OSA) to diabetes-related traits (including fasting insulin and 28-year time averaged fasting plasma glucose (tFPG)) in 330 families of the Framingham Offspring Study. Subsets were constructed by adding one family at a time in increasing (lean family to obese) or decreasing (obese to lean) order, with the OSA LOD reported as the maximum LOD score observed in any of the subsets. Permutation p-values derived from 1000 random family orderings tested the hypothesis that ordering by obesity gave stronger linkage than random ordering. Results: On chromosome 1, with families ordered by increasing family mean waist circumference (WC), linkage to tFPG at 256 cM increased from 2.5 to 3.6 (p=0.02; 260 families with mean 100.1 cm). On chromosome 19, with families ordered by decreasing WC, linkage at 67 cM increased from 2.4 to 4.2 (p=0.03; 131 families with mean 96.0 cm). On chromosome 3, with families ordered by decreasing WC variance, linkage to fasting insulin at 79 cM increased from 2.9 to 4.8 (p=0.008; 186 families with SD 8.9 cm). Conclusion: At some genomic loci, obesity obscures linkage to diabetes-related traits. On chromosomes 3 and 19, where more obese families showed the strongest linkage to diabetes, diabetes-susceptibility genes may be unmasked by excess adiposity. These and chromosome 1 appear likely to harbor obesity-interacting diabetes susceptibility genes. Obesity effects should be considered in diabetes whole-genome association studies.

Telomere Shortening in T Lymphocyte Metaphases and Interphases and Individual Chromosomes 21 and 1, from Older Individuals with Down Syndrome and Dementia. *E.C. Jenkins[1], M.T. Velinov[1], L. Ye[1], H. Gu[1], D. Pang[1,2], D.A. Devenny[1], W.B. Zigman[1], N. Schupf[1,2], W.P. Silverman[1,3]* 1) NYS Institute for Basic Research in Devel. Disabil., Staten Island; 2) Taub Institute for Research on Alzheimer Disease Aging Brain, Columbia Univ, NY; 3) Kennedy-Krieger Institute, Johns Hopkins Univ, Baltimore, MD.

We have previously shown that telomeres, chromosome ends consisting of highly conserved TTAGGG repeats, are shortened in individuals with Down syndrome (metaphases and interphases from short-term whole blood cultures) when they have dementia. Using quantitative telomere protein nucleic acid FISH analysis, we have now extended our observations to a second sample. Subjects were ascertained through the NYS Developmental Disability Service System, and classified as demented if they developed progressive memory loss, disorientation, and functional decline over a period of at least one year. An additional study of a female with Down syndrome and clinical presentation similar to mild cognitive impairment (see ASHG 2005, #761) also showed reduced telomere size, thus confirming our initial study and further strengthening our hypothesis that telomere shortening is a candidate biomarker of dementia status. Also, we have compared light intensities within telomeres of chromosomes 21 (selected because of its triplication) and 1 (selected because of its size difference with 21) within 20 cells from three matched pairs of individuals (based on age and sex). Results indicated that chromosome 21 ($ps<0.008$, 0.0001, and 0.0001) and 1 ($ps<0.002$, 0.0002, and 0.006) telomere light intensities were significantly reduced in individuals with dementia. We also have examined p and q arms separately and found evidence that there may be some type of sentinel effect for specific chromosome arms in some individuals. (Note: Sentinel was used in MBC Online 2004;15(8):3709-18, to explore the possibility that just one or two sentinel telomeres may be responsible for replicative senescence induction.) (This work was supported in part by NYS OMRDD, Alzh. Assoc. grants IIRG-99-1598, IIRG-96-077; by NIH grants PO1 HD35897, RO1 HD37425, RO1 AG014673, and RO1 AG14771.).

A case of renal hypouricemia with nephrotic syndrome and acute renal failure. *K. Ichida[1], Y. Takeda[2], A. Abe[2], K. Hanaoka[1], S. Nakanishi[2], M. Umezu[2], M. Fukagawa[2], T. Hosoya[1]* 1) Div. of Kidney and Hypertension, Jikei Univ Sch Medicine, Tokyo, Japan; 2) Div. of Nephrology and Dialysis Center, Kobe University School of Medicine, Kobe, Japan.

Renal hypouricemia is an inherited and heterogeneous disorder characterized by increased uric acid clearance. Uric acid is reabsorbed via URAT1 on the apical membrane in the proximal tubules, and mutations in SLC22A12 encoding URAT1 cause renal hypouricemia. About ten percentages of the affected patients have exercise-induced acute renal failure as complication. Here, we present a renal hypouricemic case with nephrotic syndrome and acute renal failure. A 64-years-old Japanese female, having non-steroidal anti-inflammatory drug (NSAID) for lumbago, admitted with symptoms of edema and oliguria. Clinical examination showed autoantibody negative nephrotic syndrome and acute renal failure without hyperuricemia. After steroid pulse therapy for nephrotic syndrome and hemodialysis for acute renal failure, the renal function recovered to a normal range in a few weeks. Renal biopsy on the fiftieth hospital day demonstrated a minor glomerular abnormality with slight tubular inflammation. After the recovery of renal function, hypouricemia due to increase of uric acid clearance indicated that the patient was affected with renal hypouricemia. We identified homozygous G774A mutation in SLC22A12 of the patient. As the mechanism of acute renal failure accompanied by renal hypouricemia, renal reperfusion injury due to vasoconstriction has been proposed resulting from an exercise-induced increase in oxygen free radicals and a lack of urate, free radical scavengers. In this case, nephrotic syndrome and the usage of NSAID instead of exercise were suggested to decrease the renal flow leading to acute renal failure. This is the first report of renal hypouricemia with acute renal failure related with nephrotic syndrome and NSAID.

Lack of genotypic effect of polymorphism in C-Reactive protein gene on serum CRP level in a Japanese rheumatoid arthritis cohort. *K. Ikari, S. Momohara, E. Inoue, M. Hara, T. Tomatsu, H. Yamanaka, Y. Kawaguchi, N. Kamatani* Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

Rheumatoid arthritis (RA) is a chronic systemic inflammatory disease of unknown cause, with a prevalence rate of approximately 1%. C-reactive protein (CRP) is present during inflammation and is one of the main measures for disease activity of RA. CRP has an advantage over erythrocyte sedimentation rate (ESR), a traditional marker for inflammation because it is independent of physical properties such as age, sex, pregnancy, the size/shape of red blood cells or plasma composition. However, polymorphisms in CRP genes are reported to be associated with serum CRP level in recent studies. Supposing this association is true, using CRP to monitor treatment without any information on the genotype may mislead physicians on the best course of care. Therefore, we aimed to determine whether this CRP polymorphism is associated with serum CRP level in Japanese RA patients.

The study was a part of a Japanese RA cohort project that included over 4000 Japanese RA patients (IORRA: Institute of Rheumatology RA cohort). DNA samples were available from 1284 patients, of whom, 1128 were randomly selected for this study. Genotyping of the CRP polymorphism (rs1205) was performed using the TaqMan fluorogenic 5' nuclease assay. Disease Activity Score 28 (DAS28) was used to assess disease activity of RA since it was independent of CRP. A cross-sectional analysis using the DAS28 and serum CRP data in April 2003 in the cohort study was performed on 1021 patients (patients with missing data for DAS28 or CRP were excluded). Differences in serum CRP level and DAS28 among CRP genotypes were analyzed by regression analysis. There were no significant differences among CRP genotypes for serum CRP level or DAS28. The mean CRP level was 1.17, 1.22, and 1.21 for homozygote of a major allele, heterozygote, and homozygote of a minor allele, respectively while the mean DAS28 score was 3.49, 3.66, and 3.54, respectively. We conclude that CRP gene is not associated with serum level of CRP in Japanese RA patients; CRP can be used to measure disease activity of RA without testing the genotype.

Tagging single-nucleotide polymorphisms in excision repair cross-complementing group 1 (*ERCC1*) and risk of primary lung cancer in a Chinese population. *H. Ma[1], L. Xu[2], J. Yuan[3], M. Shao[4], Z. Hu[1], F. Wang[3], Y. Wang[4], W. Yuan[2], J. Qian[4], Y. Wang[2], G. Jing[1], X. Huo[1], F. Chen[1], Y.Y. Shugart[5], L. Jin[2, 4], Q. Wei[6], T. Wu[3], H. Shen[1], W. Huang[2], D. Lu[4]* 1) Department of Epidemiology and Biostatistics, Cancer Research Center of Nanjing Medical University, Nanjing, China; 2) Department of Genetics, Chinese National Human Genome Center at Shanghai, Shanghai, China; 3) Institute of Occupational Medicine, School of Public Health, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China; 4) State Key Laboratory of Genetic Engineering, School of Life Sciences, Fudan University, Shanghai, China; 5) Epidemiology Department, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA; 6) Department of Epidemiology, The University of Texas M. D. Anderson Cancer Center, Houston, TX, USA.

Excision repair cross-complementing group 1 (ERCC1) is one of the core enzymes in the NER pathway, and polymorphisms in *ERCC1* may lead to altered DRC and therefore confer inherited predisposition to cancer risk. To test the hypothesis that common variants in *ERCC1* may be associated with lung cancer risk, we performed genotyping analyses for seven selected SNPs in *ERCC1* using TaqMan assay in a case-control study of 1010 patients with incident lung cancer and 1011 cancer-free controls in a Chinese population. We found that the variant genotypes of the rs3212948 C allele were associated with significantly decreased risk of lung cancer. Similarly a significant protective effect was also evident for the variant genotypes of rs1007616 C/T. Stratified analysis revealed that the protective effects of these two SNPs were both more evident among young subjects and subjects without family history of cancer. Consistently, when assessing each unique haplotype compared to the most common haplotype TAGCACG with the EM algorithm in *Haplo.stats*, the risk of lung cancer was significantly decreased among people who carry the haplotype TCCCATT with the variant rs3212948C and rs1007616T alleles. These findings indicate that *ERCC1* polymorphisms may contribute to the etiology of lung cancer.

East Asian-specific natural selection at the leukocyte immunoglobulin-like receptor A3 (*LILRA3*) locus. *K. Hirayasu[1,2], J. Ohashi[1], H. Tanaka[2], K. Kashiwase[2], M. Takanashi[2], M. Satake[2], K. Tokunaga[1], T. Yabe[2]* 1) Human Genetics, University of Tokyo, Tokyo, Japan; 2) Tokyo Metropolitan Red Cross Blood Center, Tokyo, Japan.

[Purpose] Leukocyte immunoglobulin-like receptors (LILR) are a family of activating and inhibitory receptors expressed on cells of the myeloid and lymphoid lineages. The *LILR* family is comprised of 11 functional genes encoded on chromosome 19. On the basis of the structural feature, LILR is divided into activating (LILRA1, -A2, -A4, -A5, -A6), inhibitory (LILRB1, -B2, -B3, -B4, -B5), and soluble (LILRA3) forms. Only the *LILRA3* gene exhibits a presence or absence variation due to a 6.7-kb deletion, which removes a leader peptide and all of the Ig-like domains of the gene. We previously reported that the allele frequency of the *LILRA3* deletion is extremely high (71%) in Japanese. In this study, we examined the geographic distribution of the *LILRA3* deletion in East Asians, and assessed the evolutionary significance of the *LILRA3* deletion, using the HapMap database.

[Methods] The *LILRA3* genotypes were determined by the PCR-SSP typing method in East Asians (Chinese-Korean, Man, Mongolian, and Buryat), and HapMap population samples (JPT, CHB, CEU, and YRI). F_{ST} values were calculated for all the polymorphic SNPs on chromosome 19 in the HapMap database.

[Results] High allele frequencies of the *LILRA3* deletion in East Asians (Chinese-Korean 84%, Man 79%, Mongolian 56%, and Buryat 76%) were observed, in contrast to the frequency reported for African (6%), Caucasian (26%), and South Asian (10%). The comparison of F_{ST} value for the *LILRA3* deletion with those for SNPs on chromosome 19 revealed that East Asians (JPT and CHB) and the others (CEU and YRI) were significantly differentiated for the *LILRA3* deletion polymorphism.

[Conclusion] Our results suggest that natural selection has acted to increase the allele frequency of the *LILRA3* deletion in East Asians, and lead us to speculate that susceptibility to some kind of disease such as infectious disease prevalent in East Asians might be a selective pressure at this locus.

TBX5 Gene Expression is Regulated Through Two Nkx2.5 Binding Elements. *G. Liguo, Q. Guangrong, X. Na, S. Kailai* Medical Genetics, China Medical University, Shenyang, Liaoning, China.

TBX5 gene is expressed in the developing heart, limb bud, lung and trachea at an early stage. TBX5 expression is precisely controlled in the developing heart and limbs in human and mice. Haploinsufficiency or overexpression of TBX5 gene causes heart abnormity. TBX5 interacts with other two cardiac transcription factors-NKX2.5 and GATA4, playing a central role during early cardiac development. But the regulation mechanism and pathway are unknown. Studies suggested that inter-regulation mechanisms maybe exist among the 3 transcription factors. As a marker of cardiac precursor cell differentiation, Nkx2.5 belongs to Homeobox gene family and plays a key role during cardiac development of fruit, mouse and human. Nkx2.5 regulates many downstream genes expression during heart formation. There is interaction between NKX2.5 and TBX5 transcription factors, but it is still not clear whether there exist upstream or downstream regulation between the two transcription factors. Our primary studies suggest that besides of interaction, NKX2.5 gene maybe locate upstream of TBX5 gene and regulate TBX5 gene expression during the regulative network involved in cardiac development. Using P-Match software, we predicted two possible Nkx2.5 binding elements at -139~-142 and -312~ -315 in 600bp sequence up to TBX5 gene transcription start site. The nucleotide sequences of special oligonucleotides and mutation probes were designed; Nuclear extracts were prepared from myocardium of mouse. Two Nkx2.5 binding elements were identified by electrophoretic mobility shift assay(EMSA). TBX5 promoter sequence of human and Nkx2.5 cDNA of mouse were cloned, respectively. Then we constructed luciferase report vector pGL3-TBX5 and eukaryotic expression vector pcDNA3.0-Nkx2.5. By transfecting different plasmids into COS7 cell line, the roles of Nkx2.5 proein to TBX5 gene was observed. The cell transfection results clearly demonstrate that 650bp up to transcription start site of TBX5 gene are able to drive luciferase reporter expression. The luciferase activity of COS7 cells increase significantly when co-transfection pcDNA-Nkx2.5 constructs.

Genome-wide microarray CGH analysis in patients with Aicardi syndrome. *T. Mizuguchi[1, 2], M. Kato[3], N. Matsumoto[1, 2]* 1) Department of Human Genetics, Yokohama City University , Yokohama , Japan; 2) Solution-Oriented Research for Science and Technology (SORST), JST, Kawaguchi, Japan; 3) Department of Pediatrics, Yamagata University School of Medicine, Yamagata, Japan.

Aicardi syndrome (AiS) is characterized by a clinical triad of callosal agenesis, infantile spasms and chorioretinal lacunae. AiS are generally found only in females. Importantly chromosomal abnormalities involving Xp22.3 were reported in some patients with AiS-like phenotype. These suggested that AiS may be an X-linked dominant disorder with hemizygous male lethality. Genetic analysis using familial cases is impossible due to severe outcomes of affected females, thus underlying causes of AiS remain unknown. We investigated eight AiS individuals by microarray comparative genomic hybridization analysis (array-CGH) containing 4234 FISHed BAC clones with a 0.75 Mb resolution across the entire genome. The aim of this study is to detect submicroscopic chromosomal abnormalities harboring a candidate locus/gene(s). We found a total of 28 chromosomal imbalances (gains or losses) among the patients by microarray CGH. Each patient possessed four to 12 copy number changes. Twenty of the changes were supposed to be copy number variants according to the public database of genomic variants, but eight were novel, including one on X chromosome. These changes are currently under investigation.

A link between hyperammonemia, potassium and water homeostasis and interastrocyte signaling. *U. Lichter-Konecki[1, 2], J.M. Mangin[1], V. Gallo[1]* 1) Center for Neuroscience Research, CRI,; 2) Division of Genetics & Metabolism, Children's National Medical Center, Washington, DC.

Acute hyperammonemia (HA) causes cerebral edema and severe brain damage in children with urea cycle disorders (UCDs) and in patients with liver failure. Chronic HA is associated with developmental delay and mental retardation in children with UCDs and with neuropsychiatric disturbances in patients with chronic liver dysfunction. The pathophysiology of the encephalopathy associated with these disorders has not yet been elucidated. Often treatment cannot prevent severe brain injury and neurological sequela. One of the cellular effects described in hyperammonemic encephalopathy (HAE) is astrocyte swelling. The swelling is considered to be causally related to the brain edema of acute HA.We studied the changes in metabolic and signal transduction pathways in acutely isolated astrocytes and brain tissue of mice with urea cycle disorders using microarray analysis. By crossing GFAP-EGFP transgenic mice with *Otc*^{spf} mice, we created a mouse with a urea cycle disorder, which also expresses EGFP in astrocytes, allowing for their purification by FACS. Expression analysis of FACS-purified astrocytes and cortex indicated changes in the expression of genes which mediate inter-astrocyte signaling and potassium and water homeostasis. These include the Connexin-43, the potassium channel subunit Kir4.1 and 5.1, and the water channel Aquaporin 4 genes. These findings indicate that proteins which facilitate potassium and water homeostasis and inter-astrocyte signaling might be potential targets for developing new therapies for HAE.

This work was supported by NIH-Mental Retardation and Developmental Disabilities Research Center Grant P30HD40677, by an Avery Research Scholar Award and a Research Advisory Council Award of the Childrens Research Institute.

Dynamic developmental changes of DNA methylation in the *Snrf-Snrpn* locus. *T. Kishino[1], K. Miyazaki[1], C. Mapendano[2], N. Niikawa[2], T. Ohta[3]* 1) Ctr. for Frontier Life Scie., Nagasaki Univ., Nagasaki; 2) Dept. of Hum. Genet., Grad. Sch. of Biomed. Scie., Nagasaki Univ., Nagasaki; 3) Inst. of Personalized Health Scie., Health Scie. Univ. of Hokkaido, Hokkaido.

The mouse *Snurf-Snrpn* locus has several multiple alternative transcripts, called *IC transcripts*, which initiate in exons (Un) that are distributed in a 500-kb region upstream of *Snurf-Snrpn* and share *Snurf-Snrpn* exons except exon 1 at the downstream region. Both of *Snurf-Snrpn* and *IC transcripts* are expressed highly in the brain exclusively from the paternal allele. We recently reported that *IC transcripts* were expressed only in the brain and ovary, especially in neurons and oocytes, whereas *Snurf-Snrpn* is known to be ubiquitously expressed in all tissues. The promoter region of *Snurf-Snrpn* has allele-specific differentially methylated region 1 (DMR1) established in gametogenesis and stably maintained during cell differentiation. Thus, the differential methylation at the DMR1 is supposed to be a parental mark for the imprinting domain. However, the mechanism of spatial and temporal expression of *Snurf-Snrpn* and *IC transcripts* is unknown. To investigate the epigenetic determinant of their spatiotemporal expressions, we analyzed the developmental changes of DNA methylation in U1 exon, and two DNase hypersensitivity sites (DHS) in DMR1; DHS1 in *Snrpn* 5 promoter and DHS2 in *Snrpn* intron 1. The bisulfite sequencing assay revealed that DHS1 was gametically methylated in oocyte, as has been reported before, however DHS2 was unmethylated during gametogenesis and became biallelically methylated during development in somatic tissues except in the brain. In U1 exon, both alleles were methylated in gamete and somatic tissues except in the brain. Interestingly, in the brain, the paternal DHS2 allele escaped methylation and paternal U1 allele was partially unmethylated especially in neurons. Recently DHS2 was reported to act as an enhancer of the *SNRPN* promoter and two upstream promoters U1A and U1B in human. Our results suggest that methylation status in U1 exon and DHS2 in DMR1 might be associated with spatiotemporal transcriptions in the mouse *Snurf-Snrpn* locus.

High density BAC clone mapping and visualizing genomic organization of satellite DNA by BAC fiber-FISH. *Y.C. Li[1], Y.M. Cheng[2], P.C. Hsu[1,2], T.S. Li[2], C.C. Lin[2]* 1) Dept Biomedical Sci, Chung Shan Medical Univ, Taichung, Taiwan; 2) Dept.Medical Research, China Medical University and Hospital.

The Indian muntjac (*Muntiacus muntjac vaginalis*) with 6 chromosomes in female and 7 in male is an ideal species for study chromosome rearrangement, comparative genomic, karyotype and genome evolution. A bacterial artificial chromosome (BAC) library of this species will be an invaluable resource not only for comparative sequence analysis, but also for the understanding of mechanisms involving centric fusion, telomere-mediated translocation, centromere inactivation, and genomic organization and alterations. We therefore have constructed a BAC library of male Indian muntjac. In total 164,736 individual BAC clones have been obtained. The average size of the inserts was estimated at 80 kilobases by analyzing almost 620 randomly chosen clones using *Not*I digestion followed by Pulsed Field Gel Electrophoresis (PFGE). Assuming that the Indian muntjac genome contains $2.6X10^9$ bp, the total library constructed corresponds to 5X genome coverage. The chromosomal location of over 700 BAC clones was each mapped to the Indian muntjac metaphase chromosomes by fluorescence in situ hybridization (FISH), thus providing a high density FISH BAC clone map of the species never been achieved. We have also investigated the genomic organization of several cervid centromeric satellite DNAs isolated from our laboratory using BAC fiber-FISH technology and some results of the study are presented in this communication. The genomic organization of these centromeric satellite DNAs should shed light on their structural aspect. Furthermore, the centromeric BAC clones mapped will also provide an excellent resource for the isolation of new centromeric satellite DNA sequences and their role in centromere function that can be evaluated by an artificial-chromosome assay. This could lead to the construction of function artificial mammalian chromosomes with gene therapy potential. This study was supported by grants from the National Health Research Institute (NHRI-EX94-9207SI) and from the National Science Council (NSC94-2320-B040-042).

Maternal uniparental disomy of the telomeric end of chromosome 16 is responsible for a malonic aciduria. *S. Malvagia[1], L. Papi[2], A. Morrone[1], MA. Donati[1], F. Ciani[1], E. Pasquini[1], H.R. Scholte[3], M. Genuardi[2], E. Zammarchi[1]*

Malonic aciduria is a rare autosomal recessive disorder caused by a deficient activity of Malonyl-CoA decarboxylase. The human MLYCD gene encoding this enzyme has been mapped on chromosome 16q24.3. It is organized in five exons and 14 mutations have been reported so far. We report on a patient with arm and leg tremors since birth, who then developed tachypnea, pallor, and feeding refusal. On admission he was tachypnoic, hypotonic and soporous with a heart rate of 140/min. Metabolic investigations showed hypoglycaemia, mild hyperammonemia, grossly decreased total and free carnitine. Urine organic acid analysis revealed high a excretion of malonic acid consistent with malonyl-CoA decarboxylase deficiency, confirmed by reduced activity in cultured fibroblasts. High doses of carnitine and a diet low in lipids led to a reduction in malonic acid excretion. The child's clinical conditions markedly improved: growth was normal, and the cardiomyopathy was almost normalized. When he was 4 months old, he suddenly and unexpectedly died. No autopsy was performed. Molecular analysis of the MLYCD gene performed on the probands genomic DNA identified a homozygous c.655-659delACTG de novo small deletion. The same mutation was present in his mother, but not in his father. Paternity was confirmed by microsatellite analysis. We then investigated 14 markers of chromosome 16 in order to test the hypothesis of maternal uniparental disomy (UPD). Segmental maternal UPD was detected. Maternal isodisomy of 16q24 led to homozygosity for the mutant allele causing the patients disease. Since UPD can dramatically reduce the risk of recurrence, we would like to stress the importance of analysing parental DNA in the presence of homozygosity for genetic counseling.

Possible role of the *TNFRSF4* gene in the pathogenesis of womens essential hypertension. *Y. Mashimo[1], Y. Suzuki[1], K. Hatori[1], Y. Tabara[2], T. Miki[3], K. Tokunaga[4], A. Hata[1]* 1) Department of Public Health, Chiba University Graduate School of Medicine, Chiba, Japan; 2) Department of Medical Genomics, Ehime University School of Medicine, Ehime, Japan; 3) Department of Geriatric Medicine, Ehime University School of Medicine, Ehime, Japan; 4) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan.

Essential hypertension is a complex disorder that results from the interaction of a number of susceptibility genes and environmental factors. We have conducted screening of 121 candidate genes to identify responsible genes for hypertension. A part of candidate genes were chosen due to renal expression changes by long term salt loading detected by microarray experiment in mice. After several rounds of screening by case-control study using Japanese samples, SNPs of the *TNFRSF4 (tumor necrosis factor receptor, superfamily, member 4)* gene showed a significant association in female. We performed a detailed and duplicated association study and functional analysis of the gene. SNPs identification and linkage disequilibrium (LD) analysis of the entire gene have revealed that this gene is in one LD block and four tag SNPs in the 5 flanking region sufficiently consist major haplotypes. A four-SNP haplotype association study with 261 cases and 270 controls showed a significant result. In the hypertensives, the frequency of the C-C-A-A haplotype was significantly low (p0.05) and that of the C-T-G-A was slightly high (p=0.26) when compared with the controls. To confirm the association, another set of Japanese female samples (388 hypertensives and 584 normotensives) was analyzed. A significantly higher frequency of C-C-A-A and significantly lower C-T-G-A were observed in the cases than in the controls. On the other hand, the difference was not observed in male samples (299 hypertensives and 303 normotensives). Lower promoter activity of C-T-G-A haplotype determined by luciferase assay suggested the functional significance of this haplotype. Results of replicated association and functional analysis indicate an involvement of the *TNFRSF4* gene in the pathogenesis of female essential hypertension.

Identification of two sex-specific quantitative trait loci in chromosome 11q for hip bone mineral density in Chinese. *Q.Y. Huang[1], M.Y.M. Ng[1], C.L. Cheung[1], V. Chan[1], P.C. Sham[2], A.W.C. Kung[1]* 1) Department of medicine, The University of Hong Kong, Hong Kong; 2) Genome Research Center,The University of Hong Kong, Hong Kong.
