Background: Chromosome 11q has not only been found to contain mutations responsible for the several Mendelian disorders of the skeleton, but it has also been linked to bone mineral density (BMD) variation in several genome-wide linkage studies. Furthermore, quantitative trait loci (QTL) affecting BMD in inbred mice and baboons have been mapped to a region syntenic to human chromosome 11q. The aim of the present study is to determine whether there is a QTL for BMD variation on chromosome 11q in the Chinese population. Methods: Nineteen microsatellite markers were genotyped for a 75 c region on 11q13-25 in 306 Chinese families with 1459 subjects. BMD (g/cm2) was measured by DXA. Linkage analyses were performed using the variance component linkage analysis method implemented in Merlin software. Results: For women, a maximum LOD score of 1.62 was achieved at 90.8 cM on 11q21 near the marker D11S4175 for femoral neck BMD; LOD scores greater than 1.0 were observed on 11q13 for trochanter BMD. For men, a maximum LOD score of 1.57 was achieved at 135.8 cM on 11q24 near the marker D11S4126 for total hip BMD. Conclusion: we have not only replicated the previous linkage finding on chromosome 11q but also identified two sex-specific QTL that contribute to BMD variation in Chinese women and men.

***KRAS, BRAF, MAP2K1/2* and *MAPK1/3* mutation analysis in cardio-facio-cutaneous (CFC) syndrome: genotype and phenotype correlation.** *Y. Narumi[1], Y. Aoki[1], T. Niihori[1], G. Neri[2], H. Cavé[3], A. Verloes[3], C. Nava[3], M.I. Kavamura[4], N. Okamoto[5], K. Kurosawa[6], H. Ohashi[7], R.C.M Hennekam[8], L. Wilson[8], G. Gillessen-Kaesbach[9], D. Wieczorek[9], P. Lapunzina[10], S. Kure[1], Y. Matsubara[1]* 1) Dept Med Genet, Tohoku Univ Sch Med, Sendai, Japan; 2) Istituto di Genetica Medica, Rome, Italy; 3) Hôpital Robert Debré, Paris, France; 4) Federal Univ of San Paulo, San Paulo, Brazil; 5) Osaka Med Ctr & Res Inst for Maternal & Child Health, Osaka; 6) Kanagawa Childrens Med Ctr, Yokohama; 7) Saitama Childrens Med Ctr, Saitama, Japan; 8) Inst of Child Health, London, UK; 9) Univ Essen, Essen, Germany; 10) Hosp Univ La Paz, Madrid, Spain.

Cardio-facio-cutaneous (CFC) syndrome is characterized by a distinctive facial appearance, cardiac defects, ectodermal abnormalities and mental retardation. Clinically, it overlaps with both Noonan syndrome and Costello syndrome, which are caused by mutations in two molecules of the RAS pathway (*PTPN11* and *HRAS* respectively). Recently, we discovered germline mutations in *KRAS* and *BRAF* in 19 of 43 patients with CFC syndrome, suggesting that dysregulation of the RAS/RAF/MEK/ERK pathway is a molecular basis for CFC syndrome. We here analyzed *KRAS* and *BRAF* in new 13 CFC patients and identified five *BRAF* mutations in eight patients. To characterize the further pathogenesis of CFC syndrome, we analyzed downstream molecules of *BRAF*, *MAP2K* (MEK) 1/2 and *MAPK3/1* (ERK1/2), in 29 patients without *KRAS* or *BRAF* mutations. We identified two mutations of *MAP2K1* in four patients and four new *MAP2K2* mutations in four patients. In total, mutations were identified in 35 of 56 (63 %) CFC patients (3 in *KRAS*, 24 in *BRAF* and 8 in *MAP2K1/2*). There was no significant difference in 81 clinical manifestations and calculated CFC indices among 3 patients with *KRAS*, 16 patients with *BRAF* and 6 patients with *MAP2K1/2* mutations. Relative macrocephaly, sparse curly hair, mental retardation and delayed speech were present in 90 % of mutation-positive patients. No mutations were identified in *MAPK3/1*. Further molecular analysis of RAS pathway will be necessary to identify new genes responsible for mutation-negative CFC patients.

Rod monochromacy: A genetic heterogeneity in the Tunisian population. *F. OUECHTATI[1], A. MERDASSI[2], K. DEROUICHE[2], L. LARGUECH[2], L. EL MATRI[2], S. ABDELHAK[1]* 1) Unit of Research Molecular Investigation of Genetic Orphan Diseases, Pasteur Institute of Tunis, Tunis, Tunisia; 2) Unit of Research Oculogenetics, Institute of Ophthalmology Hedi Rais, Tunis, Tunisia.

The complete achromatopsia named also rod monochromacy is a rare, congenital hereditary stationary disorder of retina featuring complete inability to discriminate between colours, diminished visual acuity in daylight, photophobia, horizontal pendular nystagmus which appear from the fifth month after the birth. . Its prevalence has been estimated at about 1 in 30,000 to 50,000. Achromatopsia is genetically heterogeneous with variable expressivity. The complete form is recessively inherited. The three achromatopsia genes are *CNGA3*, *CNGB3* which respectively encode for and subunits of the cGMP gated cation channel in cone cells and *GNAT2* which encodes the subunit of cone transducin. The transducin and the cGMP gated cation channel are important for the amplification and the transmission of visual signal from cones to the cortical regions. We report here a genetic analysis of a large consanguineous Tunisian family with nine individuals presenting with complete achromatopsia. Genetic linkage to *CNGA3* gene was investigated. For this purpose microsatellite markers overlapping this gene D2S2311 and D2S2175 were selected. Genotyping and linkage analysis excluded linkage to *CNGA3* gene. A previous study has shown that a sporadic Tunisian case with rod monochromacy shared the P372S mutation in *CNGA3* gene with a German patient. This result underlines the rich genetic background related to Tunisian population history which is characterized by a genetic heterogeneity as it has been reported in the Italian population for the same dyschromatopsia.

Validation and implementation of a panel of SNPs for large-scale zygosity testing and population genetics. *U. Hannelius[1], C.M. Lindgren[1,2], C. Lagerberg[3], V-V. Mäkelä[2], A. Lindstedt[2], L. Gherman[3], G. Tybring[3], J. Kere[1,2]* 1) Department Biosciences and Nutrition, Karolinska Institute, Huddinge, Sweden; 2) Clinical Research Centre, Karolinska University Hospital, Stockholm, Sweden; 3) Department of Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm, Sweden.

Background: Genetic fingerprinting is widely used in forensic sciences, paternity testing and in zygosity testing. Unambiguous identification of samples based on their DNA profiles strengthens the specificity and validity of genetic research.

Aim: To validate a panel of 50 SNP:s that can be used for large-scale zygosity testing as well for population genetic research on a range of different templates.

Results: We selected an initial panel of 50 highly polymorphic (MAF >20% in HapMap CEU population, phase I data) SNP:s including the AMELXY assay with a criterion of no inter-marker LD. 15 CEPH trios and 36 unrelated Coriell samples using DNA and whole genome amplified (Repli-G) DNA as template were genotyped in duplicates. Three SNP:s failed the initial validation. When considering all genotyped samples as well as HapMap data the global genotype concordance was 99.7% (SD 0.7%). Further, we genotyped 100 twin pairs and identified two pairs with wrongly assigned zygosity. The global success rate considering all genotyped samples was 98.4% (SD 1.4%). Preliminary findings show that DNA of lower quality yields lower success rates while the genotype concordance remains unaffected. The random match probability for full siblings being IBS=2 at all loci was 1.58e-10.

Conclusions: Compared to STR typing, the high multiplexing level and rapid analysis makes SNP typing a significantly more efficient and cost-effective way of large-scale DNA-profiling. We have started work on determining the genetic structure in the Swedish population using the validated SNP panel and a set of 2136 samples representative of the Swedish population.

Molecular Genetics of Primary-Angle Closure Glaucoma in a Chinese familyMolecular Genetics of Primary-Angle Closure Glaucoma in a Chinese family. *hui. li, xiao.hua dai, jin.yu liu, mu.gen liu, qing. wang* Center for Human Genome Resear, Huazhong University of Science and Technology, Wuhan, Hubei, China.

Purpose: Juvenile and late-onset primary open-angle glaucoma (POAG) has been associated with myocilin (MYOC) gene and CYP1B1 gene (2p21), with a predominantly autosomal dominant or recessive mode of inheritance respectively. Although there are some similarities in the phenotype of POAG and in particular primary angle-closure glaucoma (PACG), little is known about the role of MYOC and CYP1B1 in the causation of PACG. In this research, we therefore investigated the role of MYOC and CYP1B1 gene in PACG by screening the genes in a Chinese family with autosomal dominant. Methods: Complete ophthalmic examination and genomic DNA were obtained from a Chinese pedigree with 5 family members, in which 3 were confirmed PACG patients. Five polymorphic microsatellite markers, d10S547, d10S1653, d1S218, d2S367 and d2S2259, closely linked to the three know glaucoma genes optn, myoc and cyp1b1 were selected from the ABI PRISM Linkage Mapping Set MD10 panel for linkage analysis. The Chinese pedigree was screened for sequence alterations in the MYOC and CYP1B1 genes by polymerase chain reaction and automated sequencing. Two hundred unrelated individuals without glaucoma were studied as control subjects. Results: In our pedigree we have present three patients whose genomes harbor both MYOC and CYP1B1 sequence variants. These included the Arg46Stop mutation in MYOC gene and CG (L432V) polymorphism in CYP1B1 gene, which have been reported in individuals with POAG. However, both sequence alterations identified have not been identified in same control Chinese individuals. Conclusions: These observations suggest a possible role of MYOC and CYP1B1 in PACG, which probably do not cause glaucoma by inactivating either of normal MYOC and CYP1B1 function , but rather via digenic interaction and/or yet unidentified locus linked to the disease.

Identification of a novel locus for mitochondrial DNA depletion. *J. Mollet[1], J.P. Jais[2], E. Sarzi[1], D. Chretien[1], A. Munnich[1], A. Rotig[1]* 1) INSERM U781, Hosp Necker, Paris, France; 2) Service de Biostatistique et dInformatique Médicale. Hôpital Necker-Enfants Malades.

Mitochondrial DNA depletion syndrome (MDS) is a clinically and genetically heterogeneous condition characterized by reduction in mtDNA copy number responsible for multiple oxidative phosphorylation (OXPHOS) enzyme deficiency. In our series of more than 50 patients with severe mtDNA depletion, the disease-causing mutation has been identified in only 36% of the patients. We identified a large consanguineous family from North-Africa with multiple respiratory chain deficiency associated with mtDNA depletion. The four patients presented neonatal hypotonia, growth retardation and/or liver enlargement. Metabolic investigations revealed hyperlactatemia and highly elevated levels of urinary thymidine and uracil but these features were not consistently found in all patients. Biochemical analyses of skeletal muscle revealed OXPHOS deficiency in ¾ patients. A genome wide scan was performed using the GeneChip Human Mapping 10K 2.0 Array (Affymetrix) but did not revealed any region of homozygosity common to the four affected children. Nevertheless, a more careful examination of clinical, biological and enzymological data suggested the occurrence of two diseases in this family. Based on this hypothesis, we were able to identify a first region of homozygosity on chromosome 1 encompassing the DPYD gene encoding the dihydropyrimidine dehydrogenase. Mutations of DPYD were found in the three patients with high level of urinary thymidine and uracil. A second region common to the three patients with OXPHOS deficiency was found on chromosome 21 with a maximum multipoint lod-score of 3.597. Candidate genes are now under investigation. This work will hopefully lead to identification of a novel nuclear gene responsible for mtDNA depletion.

Mutational analysis of SCN2A gene in Italian families with Benign Familial Neonatal-Infantile Seizures (BFNIS).

E. Mannarino[1, 3], F. Annesi[1], E.V. De Marco[1], S. Carrideo[1], F.E. Rocca[1], G. Provenzano[1], P. Tarantino[1], I.C. Cirò Candiano[1], D. Civitelli[1], G. Tortorella[3], A. Gambardella[1, 2], G. Annesi[1] 1) National Research Council , Institute of Neurological sciences , Mangone (CS), Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 3) Division of Infantile Neuropsychiatry Department of Medical and Surgical Pediatrics, University Hospital of Messina, Italy.

Benign autosomal dominant epilepsy syndromes of the first year of life include two main syndromes: benign familial neonatal seizures in which seizures start around day 3 and it is usually caused by defects in potassium channel genes KCNQ2 and KCNQ3, and benign familial infantile seizures which begins around 6 months of age but no genes have been so far identified. Recently, molecular studies have separated an intermediate variant of BFNIS, in which seizure onset varies from 2 days to 3.5 months and it is caused by mutations in the voltage-gated sodium channel alpha2 subunit (SCN2A) gene on chromosome 2. In this study, we wished to screen 2 families with BFNIS from southern Italy for mutations in SCN2A gene. Both families originated from southern Italy. The first family contained 3 affected individuals over four generations, in whom seizures always started around two months of age. In the second family with 4 affected individuals over four generations seizures started around day 17. Response to antiepileptic drugs and the outcome were good in both families. After informed consent, DNA was analyzed for mutations in the coding regions of SCN2A (28 exons) by PCR and sequencing. One proband from each family was screened. We have not found any mutation in the examined exons of the SCN2A gene. Mutations in SCN2A gene were reported in families with BFNIS of Italian, Canadian, Australian and American origin. Nonetheless, also in the original report some BFNIS families did not carry any mutations in SCN2A. Our data provide further evidence for genetic heterogeneity associated with BFNIS. It might be possible, however, that these families have SCN2A mutations in a nontranslated sequence. Supported by FIRB-MIUR anno 2001 RBNEO1XP4.

A variant in CDKN2a is associated with physical function in older people. *A. Murray[1], T.M. Frayling[1], A.J. Hurst[1], L.W. Harries[1], H. Song[2], K.T. Khaw[2], R. Luben[2], P.G. Surtees[2], S. Bandinelli[3], A.M. Corsi[4], L. Ferrucci[5], J.M. Guralnik[5], R.B. Wallace[6], A.T. Hattersley[1], P.D. Pharoah[2], D. Melzer[1]* 1) Peninsula Medical School, University of Exeter, Exeter, Devon, United Kingdom; 2) University of Cambridge, UK; 3) Italian National Research Council on Aging, Florence, Italy; 4) University of Florence, Italy; 5) National Institute on Aging, Maryland, USA; 6) University of Iowa, USA.

Aging is thought to be affected by a small number of biochemical pathways and recent evidence suggests that cell cycle arrest contributes, when senescence and cell loss exceeds cell regeneration. However, whether cellular senescence is a causal factor of age-related damage has been controversial, especially in humans. Cyclin-dependent kinases (CDKs) are involved in regulating the cell cycle and are in turn regulated by the CDKN family of inhibitors. Thus the CDKN genes are candidates for human aging.

Physical functioning is known to be highly heritable in old age and may be a better marker of the aging phenoptype than longevity. We used an initial study of 926 women aged 65 to 80yrs from the Norfolk site of the EPIC study and tested 25 tag SNPs in 5 CDKN genes. Physical functioning was measured by SF36 questionnaire. The rare allele of the rs2811712 SNP in CDKN2a ($p16^{ink4a}$) was associated with reduced limitation on the SF36 scale; odds ratio 1.38 (95%CI 1.06-1.79, p=0.015). The same allele of rs2811712 was associated with reduced physical limitation, measured by reported and performance tests, in 4 additional studies: two independent sets of respondents from the EPIC study (1916 individuals), 730 subjects from the Italian InChianti aging study and 419 subjects from the Iowa site of the Established Populations for Epidemiologic Studies in the Elderly (EPESE). The overall odds ratio was 1.31(95%CI 1.15-1.50), and was highly significant (p =7.4x10-5).

These data provide evidence for CDKN2a having a role in human age-related functioning, which may be mediated by influencing cell senescence.

Screening for the modifier gene(s) involved in phenotypic variation and malignant degeneration of neurofibromatosis type 1. *H.J. Kim, Y.R. Park, H.J. Jung, S.J. Park, S.Y. Jeong* Dept Medical Genetics, School of Medicine, Ajou University , Suwon, Korea.

Neurofibromatosis type 1 (NF1) is one of the most common inherited autosomal dominant disorders, with an estimated incidence of 1 per 3,500 births. NF1 is caused by mutations in the *NF1* gene which consists of 57 exons and encodes a GTPase activating protein (GAP), neurofibromin. NF1 is notable for its extreme phenotypic variability both within and between families and for a gradual malignant degeneration of normal and/or benign tumor cells within an individual. In addition to multiple allelism of the *NF1* locus, the influence of modifying gene(s) and the impact of stochastic events have been suggested as causes of this variability. However, there has been no clear evidence to explain the phenotypic variations among patients with an identical mutation. Korean NF1 patients also show a wide range of phenotypic variations. We screened 27 unrelated Korean NF1 patients for mutations and identified 25 distinct NF1 mutations. Mutation study revealed a wide spectrum of *NF1* mutations in Korean patients. A genotype-phenotype correlation analysis suggests that there is no clear relationship between specific *NF1* mutations and clinical features of the disease. For whole gene expression comparison among normal fibroblast, benign and malignant tumor cells, we used ACP (annealing controlled primer) based PCR method, GeneFishing DEG (differentially expressed gene) Screening, which substantially improves the specificity and sensitivity of PCR and eliminates the false positives and poor reproducibility of previous DEG discovery methods such as cDNA microarray. In this study, we performed DEG screening using RNAs from NF1 patient with 120 sets of ACP. We found total 64 DEGs that include 37 DEGs showing up-regulation and 27 DEGs showing down-regulation in malignant cells. We have cloned and sequenced 20 DEGs and 44 DEGs remain to be identified. A further functional analysis for the candidate DEGs may lead to identification of the key modifier gene(s). This study will contribute to a better understanding the phenotypic variability and the mechanism of the malignant degeneration of NF1.

Down-regulation of the Dopamine Receptor D2 (Drd2) in mice lacking Ataxin 1. *A. MATILLA-DUEÑAS[1], A. HUNT[1], M. HUBANK[1], J. HOLTON[2], T. REVESZ[2], A. PASTORE[3], R. GOOLD[1]* 1) Institute of Child Health, University College London, London, United Kingdom; 2) Institute of Neurology, University College London, London, United Kingdom; 3) National Institute for Medical Research, London, United Kingdom.

Ataxin 1 (Atxn1) is a protein of unknown function associated with spinocerebellar ataxia type 1 (SCA1) in humans, a neurodegenerative disease characterized by loss of balance and motor coordination (ataxia) due to progressive cerebellar dysfunction. The disease symptoms in SCA1 are caused by an expanded polyglutamine within Atxn1, which causes neurotoxicity in humans, mice, and flies by unclear gain-of-function mechanisms. Lack of Atxn1 in mice causes cerebellar motor deficits in the absence of neurodegeneration or apparent neuropathological abnormalities. To investigate the molecular mechanisms underlying cerebellar dysfunction in Atxn1-null mice, we generated their cerebellar gene expression profiles using oligonucleotide microarrays. We have identifed several genes implicated in the retinoid/thyroid hormone receptors signaling pathways dysregulated in Atxn1-null mice, including the dopamine receptor D2, the dopamine transporter, the retinol binding protein 1, and the thyroid hormone transporter transthyretin. Drd2 protein levels are severely decreased in the cerebellum and other brain regions in Atxn1-null mice. We provide evidence for transcriptional regulation by Atxn1 targeting the Drd2 promoter and we demonstrate that Atxn1 physically interacts and functions synergistically with transcription factor Sp1 to trans-activate Drd2 expression. The interaction and transcriptional effects are mediated by the AXH domain within Atxn1 and are abrogated by the expanded polyglutamine in mutant Atxn1. Our study provides evidence implicating ataxin 1 in the regulation of Sp1-dependent transcription and identifies molecular targets that could underlie the neurobehavioural deficits in Atxn1-null mice. Identifying the molecular pathways regulated by Atxn1 mediating cerebellar function can provide insights into the molecular mechanisms underlying cerebellar neurodegeneration in SCA1 and establish effective therapeutic strategies.

Genetic and acquired factors for ossification of the posterior longitudinal ligament of the spines in Japan; a case-control study. *G. Kobashi[1], K. Ohta[1], A. Hata[2], M. Washio[3], K. Okamoto[4], Japan OPLL Epidemiological Study Group*
1) RadGenomics Research Group, Research Center for Charged Particle Therapy, National Institute of Radiological Science, Chiba, Japan; 2) Department of Public Health, Chiba University Graduate School of Medicine, Chiba, Japan; 3) Department of Community Health and Clinical Epidemiology, St. Marys College, Kurume, Japan; 4) Department of public Health, Aichi Prefectural college of Nursing and Health, Nagoya, Japan.

To elucidate risk factors of genetic variants and acquired factors such as lifestyles for ossification of the posterior longitudinal ligament of the spines (OPLL) in Japan, a case-control study was carried out. A self-administered questionnaire was obtained from 63 patients with OPLL in collaborate hospitals and age, sex and domicile-matched controls, 126 from hospital patients without OPLL and 126 from health check up in a town. Genotypes of vitamin-D receptor gene (*VDR*) F*ok*I genotype, lipoprotein lipase gene (*LPL*) H*ind*III genotype, and nucleotide pyrophosphatase gene (*NPPS*) IVS15-14TC were identified by use of PCR-RFLP methods. Frequency of *VDR* F*ok*I F allele was higher in OPLL (0.66) than in hospital controls (0.54) and population controls (0.56)(p0.05), while no significant differences were found in distributions of *LPL* H*ind*III genotypes and *NPPS* IVS15-14TC genotypes between cases and controls. An univariate analysis of the data from the questionnaire survey revealed high body mass after middle age, history of diabetes, history of hypertension, lack of body pliableness or stocky body shape, and some characters in Type A tendency were significantly associated with OPLL. A tree-based analysis to clarify confoundings among them revealed *VDR* F*ok*I F allele was associated with history of diabetes, suggesting that *VDR* F*ok*I F allele was the third factor of the association between OPLL and diabetes. *VDR* F allele was suggested to be associated with OPLL as well as diabetes. Further case-control studies in OPLL using candidate genes of hypertension are needed to elucidate the pathogenesis in OPLL and establish an effective intervention program for OPLL.

DNA array profiling of genes involved in differentiation of stem cell to spinal cord precursor cell in mouse. *H. Jeong, J.I. Ahn, H.J. Jeong* Molecular Pharmacology, NITR/KFDA, Seoul, Korea.

Stem cell is one of most promising therapeutic tools for neurodegenerative diseases such as Parkinsons and Alzheimer and so on. Stem cell therapy still has lots of obstacles to overcome to become a reliable therapeutic option. The biggest hurdle confronted is how to regulate correctly the pluripotency of stem cell to get intended cell type like motor neurons in this presented study. In this study, we isolated neural stem cells from E11.5 mouse spinal cord and differentiated them to motor neuron by using well known compounds like retinoic acid and BMP-2. The functionality of obtained cell was confirmed by a co-culture system of motor neuron and skeletal myotubes. To identify related genes in differentiation of stem cell to motor neuron, DNA microarray was employed to find genes whose expression level was significantly changed along the differentiation at day 2, 4 and 8. We isolated 1066 genes which had shown at least 2-fold expression at more than one day out of 23666 genes. These isolates included and some unexpected genes transcription factors (Nkx6.2, four and a half LIM domains, basic helix-loop-helix domain containing class B etc.) in addition to motoneuron-related genes such as ChPT1, PLD2, Nkx6-2 and NDE2. In this study, we identified groups of genes involved in differentiation of stem cell into motoneuron including genes with no known previous functions in stem cell differentiation, like Tbx20 and Lmo2 so on. Further investigation on these genes may shed light on the understanding of stem cell into spinal cord precursor cell that can facilitate studies of the mechanisms underlying induction and differentiation of stem cell to motoneuron.

Identification of prosencephalon-specific enhancer of SALL1: Comparative genomic approach using chick embryonic system. *K. Izumi[1], M. Aramaki[1], M. Uchikawa[2], H. Kondoh[2], Y. Naito[1], R. Kosaki[3], T. Takahashi[1], K. Kosaki[1]* 1) Department of Pediatrics, Keio University, Tokyo, Japan; 2) Graduate School of Frontier Biosciences, Osaka University, Suita, Japan; 3) Department of Clinical Genetics and Molecular Medicine, National Center for Child Health and Development, Tokyo, Japan.

Comparative genomics is a promising approach for disclosing regulatory elements that govern the unique spatio-temporal gene expression patterns of morphogenetic genes. Conserved non-coding genomic sequences have been considered as candidate regulatory elements. We performed a systematic survey for conserved non-coding elements (CNEs) belonging to the SALL1 gene, the causative gene of Townes-Brocks syndrome [TBS]. A comparison of the genomic sequences of humans and avians revealed 5 CNEs in the vicinity of the SALL1 gene. Genomic fragments corresponding to each CNE were inserted into reporter cassettes consisting of GFP cDNA and a minimal promoter. After CNE insertion, the construct was transfected using in vivo electroporation. If the CNE conferred enhancer activity at a specific location in the embryo, a GFP signal was detected in vivo. Among the 5 CNEs that were examined, one 623 bp-long CNE (CNE3) exhibited tissue-specific enhancer activity. At the neurula stage, the GFP was visualized in the prosencephalon. Histological analyses revealed that the GFP signal was present only on the ventral side of the prosencephalon. At the pharyngula stage, the GFP signal was confined within the anterior neural ridge, which represents the morphogenetic center regulating the patterning of the anterior neural plate. The GFP signal distribution in the forebrain recapitulated the SALL1 expression pattern previously demonstrated using in situ hybridization. This report identified, for the first time, an enhancer element of SALL1. Documentation of enhancer activity in the forebrain corresponds to the clinical observation that some patients with TBS have central nervous system dysfunctions. A comparative genomic approach, when combined with a chick embryo electroporation system, represents an effective method for identifying developmental regulatory elements.

Genome-wide association study of human narcolepsy using 500,000 SNPs. *T. Miyagawa[1], M. Kawashima[2], N. Nishida[1], J. Ohashi[1], R. Kimura[1], A. Fujimoto[1], M. Honda[3], Y. Honda[4], K. Tokunaga[1]* 1) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 2) Department of Sleep Disorder Research, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 3) Tokyo Institute of Psychiatry, Tokyo, Japan; 4) Sleep Disorder Clinic of Seiwa Hospital, Tokyo, Japan.

Human narcolepsy is a sleep disorder that is associated with multiple genetic and environmental factors. Narcolepsy affects 0.02-0.06% of the general population in the United State and Europe whereas 0.16-0.18% in Japan. A genetic factor strongly associated with the disorder has been found in the human leukocyte antigen (HLA) region: the HLA DRB1*1501-DQB1*0602 haplotype. However, it is suggested that narcolepsy susceptibility gene(s) other than HLA also exist because HLA DRB1*1501-DQB1*0602 haplotype carriers are about 12% in the Japanese general population, and the HLA alone cannot statistically explain all genetic factors. Therefore, to identify unknown narcolepsy susceptibility gene(s), we performed a genome-wide association study instead of a candidate gene approach. We genotyped about 500,000 SNPs in 110 narcoleptic patients and 191 healthy controls (Affymetrix GeneChip Human Mapping 500K Array Set) and performed case-control association analyses. The subjects investigated in this study were all Japanese living in the Tokyo area. We identified about 1,000 SNPs that were associated with human narcolepsy at significant p values of lower than 10^{-3}. Since it is possible to include a lot of false positive SNPs in this result, we are going to increase the sample sizes and perform a replication study. We also plan to compare the results in the present study with those in the genome-wide association study using about 23,000 microsatellite markers (Kawashima et al. Am. J. Hum. Genet. 2006).

Functional association of an intron variant of CXCR3 with the risk of asthma. *Y. Kim, J.W. Choi, M.Y. Hwang, H.S. Cheong, H.D. Shin, C.S. Park, B. Oh* Center for Genome Science, KNIH, Seoul, Korea.

Complex trait-diseases such as asthma have been known caused by accumulative effects of multiple genes that individually exert quantitative portions of the genetic influence. Genes known implicated in pathogenesis of the diseases could be possible candidates as the disease risk factors. Asthma is known as a respiratory disease characterized by airway hyper-responsiveness, increased numbers of lung mast cells, elevated mucous production, and pulmonary inflammation with prominent infiltration of lymphocytes and eosinophils. The chemokines and their cognate receptors play primary roles in chemotaxis mediating trafficking of leukocytes to the site of inflammation. By using a candidate gene approach, we have previously shown that single nucleotide polymorphism in the intron of CXCR3 (c. 12+234G>A) was statistically associated with the risk of asthma (OR=0.73 (0.58-0.93), P=0.009). To determine if this association may be attributable to alteration of the CXCR3 gene expression by the genetic variation in the intron region, we employed two-way approaches in this study: a reporter gene expression assay and quantitative analysis of the allele-specific expression level. Results from the reporter gene expression assay showed that Jurkat or HEK293 cells transfected with the reporter construct carrying the promoter and intron regions with minor allele of the variant expressed lower level of the reporter gene, relative to the cells with the constructs bearing either the promoter, intron, or both of the promoter and the intron with common allele of the variant. Quantification of transcription level revealed that the CXCR3 transcripts was lower in transformed lymphocytes from the minor allele-carrying individuals than ones from the common-allele carrier, which was consistent with the result from the reporter gene assay. These data, together with the previous data from the case-control study, suggested that the CXCR3 intron variant was functionally associated with the risk of asthma by affecting the expression level of the gene.

A confoundings of candidate single nucleotide polmorphisms for pregnancy-induced hypertention in Japan. *K. Ohta[1], G. Kobashi[1], H. Yamada[2], A. Hata[3], H. Minakami[2], S. Fujimoto[4], K. Kondo[5], Hokkaido PIH Epidemiological Study Group* 1) RadGenomics Research Group, Research Center for Charged Particle Therapy, National Institute of Radiological Sciences, Chiba, Japan; 2) Department of Obstetrics and Gynecology, Hokkaido University Graduate School of Medicine, Sapporo, Japan; 3) Department of Public Health, Chiba University Graduate School of Medicine, Chiba, Japan; 4) Tenshi Hospital, Sapporo, Japan; 5) The University of the Air, Chiba, Japan.

To clarify the context of the gene-gene interrelationship in the manifestation of PIH, we analyzed Met235Thr variant of the angiotensinogen gene (*AGT*) and Glu298Asp variant of the endothelial nitric oxide synthase gene (*NOS3*) in terms of 4G/5G variant of the plasminogen activator inhibitor gene (*PAI-1*). One hundred forty-five Japanese patients with PIH were matched with 357 Japanese normal pregnant controls according to age and parity. Genotypings of variants of *AGT*, *NOS3* and *PAI-1* were carried out using PCR-RFLP methods after extraction of genomic DNA from 1.0 ml of whole blood samples. In the subgroup of 4G/4G of *PAI-1*, the frequency of T235 of *AGT* was higher in PIH (0.78) than in controls (0.56) (p0.017), while in the subgroup of 4G/5G+5G/5G of *PAI-1*, no significant differences were found in the frequency of T235 of *AGT* between PIH (0.71) and controls (0.6). On the other hand, in the subgroup of 4G/4G of *PAI-1*, no significant differences were found in distributions of the frequency of GA+AA of *NOS3* between PIH (0.18) and controls (0.1), but in the subgroup of 4G/5G+5G/5G of *PAI-1*, the frequency of GA+AA of *NOS3* was higher in PIH (0.3) than in controls (0.15) (p0.017). Women carrying T235 of *AGT* had an elevated risk for PIH because the local AGT expression is elevated in developing spiral arteries in women carrying this allele. On the other hand, Asp298 of *NOS3* is associated with the reduction of NO in PIH. The present result suggests that coagulative tendency by 4G/4G of *PAI-1* may play a role in pathogenesis of PIH in the subgroup possessing TT of *AGT*.

Long-term expression and clinical improvement of Mucopolysaccharidosis I in dogs and cats from neonatal, intravenous, retroviral vector gene therapy. *M. Haskins[1], A. Traas[1], P. Wang[1], B. Wang[2], X. Ma[2], P. O'Donnell[1], R. Herati[2], B. Wang[2], K. Cullen[1], U. Proiuck[1], T. O'Malley[1], M. Sleeper[1], G. Aguirre[1], K. Ponder[2]* 1) Sch Vet Med, Univ Pennsylvania, Philadelphia, PA; 2) Sch Med, Washington University, St. Louis, MO.

Mucopolysaccharidosis I (MPS I) is a lysosomal storage disease due to deficient activity of alpha-L-iduronidase (IDUA). The MPS I cat has a 3 base-pair deletion and the MPS I dog a premature stop codon. We treated 9 MPS I cats and 7 MPS I dogs at 2-5 days of age intravenously with 0.5 to 10.1 X 10E9 transducing units/kg of a retroviral vector (RV) expressing canine IDUA from the human 1-antitrypsin promoter. **MPS I cats:** Seven treated cats had serum activity 30-fold normal (286416 U/ml) and 245-fold normal (23552763 U/ml) at 1 month (low and high RV dose, respectively). However, all cats lost expression by 3 months from a CTL response to the canine IDUA protein. Two additional MPS I kittens were treated with the immunosuppressive agent CTLA4-Ig for 2 weeks at the time of high dose RV therapy and have maintained 20- & 25-fold normal serum IDUA activity for more than a year. Liver biopsies at 4 months had IDUA activity 4- & 5.7-fold normal (90 & 123 U/mg protein). Glycosaminoglycans (GAG) were reduced to 3.9 & 6.0 ugm/mg protein (untreated 36.614.9, N=4; normal=1.20.9, N=4). Clinically, the two CTLA4-Ig/RV cats had improvements in facial dysmorphia, corneal clouding, stature, posture, and mobility. **MPS I dogs:** The treated dogs had a mean 23-fold normal serum IDUA activity (22-749 nmol/ml/hr). The 3 oldest dogs at more than 1 year of age have stable activity at 1.3-, 2.1-, and 41-fold normal. In liver biopsies, IDUA activity was 5-fold normal (133163 U/mg protein). GAG was reduced to 2.31.3 ugm/mg protein (untreated=264, N=3; normal=1.30.7, N=3). Clinically, the MPS I dogs had improvements in facial dysmorphia, corneal clouding, and mitral valve lesions. No treated dog had signs of cervical cord compression. **Conclusion:** These data show that neonatal, intravenous, RV gene therapy was successful in producing high, stable serum IDUA levels in MPS I cats and dogs, improving clinical disease.

Genetic teesting of nonketotic hyperglycinemia: Detection of genomic deletion within *GLDC* by multiplex ligation-dependent probe amplification. *S. Kure[1], J. Kanno[1], T. Hutchin[2], F. Kamada[1], A. Narisawa[1], Y. Aoki[1], Y. Matsubara[1]* 1) Dept Medical Genetics, Tohoku Univ Sch Medicine, Sendai, Japan; 2) Department of Clinical Chemistry, Birmingham Childrens Hospital, United Kingdom.

Nonketotic hyperglycinemia (NKH) is an inborn error of metabolism characterized by accumulation of glycine in body fluids and various neurological symptoms. NKH is caused by deficiency of the glycine cleavage multi-enzyme system with three specific components encoded by *GLDC*, *AMT*, and *GCSH*. The majority of patients are deficient of enzymatic activity of glycine decarboxylase, which is encoded by *GLDC*. Our recent study has suggested that there are a considerable number of *GLDC* mutations, which are not identified by the standard exon-sequencing method (Kure et al., Hum Mutat 2006;27:343-52). We have developed a screening system for *GLDC*, deletions by multiplex ligation-dependent probe amplification (MLPA). Two distinct cohorts of patients with typical NKH were screened by this MLPA method: the first cohort consisted of 45 families with no identified *AMT*, or *GCSH*. mutations and the second cohort was comprised of 20 patients from the UK. *GLDC*, deletions were identified in 16 of 90 alleles (18%) in the first cohort and 9 of 40 alleles (22.5%) in the second cohort. Fourteen different types of deletions of various lengths were identified, including one allele where all 25 exons were missing. We determined flanking sequences of interstitial deletions in five patients, and *Alu*-mediated recombination was identified in 3 of the 5 patients. These results suggest that *GLDC* deletions are a significant cause of NKH and that MLPA analysis is a valuable first-line screening for NKH genetic testing.

Investigation of the inducible nitric oxide synthase gene (NOS2A) polymorphisms in multiple sclerosis. *I. Manna[1], P. Valentino[2], A. La Russa[1], F. Condino[1], R. Nisticò[2], A. Clodomiro[2], M. Canino[2], R. Cittadella[1], A. Quattrone[1,2]* 1) Institute of Neurological Sciences (ISN) -CNR, Mangone, Cosenza, Italy; 2) Institute of Neurology, University Magna Græcia, Catanzaro, Italy.

Multiple sclerosis (MS) is a chronic inflammatory disease of the central nervous system (CNS), characterised by demyelinisation, gliosis and various degrees of axonal damage. Nitric oxide (NO) is a biological signaling and effector molecule and is especially important during inflammation. Inducible nitric oxide synthase (iNOS) is one of the three enzymes responsible for generating NO, and it is up-regulated in the CNS of animals with experimental allergic encephalomyelitis (EAE) and in patients with MS. The gene encoding iNOS, NOS2A, is located on chromosome 17q11.2-12, a region identified in genome wide screens as suggestive for linkage and association with MS. This study investigated the contribution of two functionally polymorphisms located in the promoter region of the NOS2A gene to susceptibility to MS. A group of patients with clinically definite MS (n = 115) were genotyped for a multiallelic pentanucleotide (CCTTT)n tandem repeat and a bi-allelic tetranucleotide AAAT/AAAAT repeat, and compared to group of healthy controls (n = 238). For the case-control study, patients and controls were genotyped for these polymorphisms using a PCR methods that involved the primer sense labelled with the fluorescent dye 6-fam. To determine the different alleles the PCR products were resolved on an ABI 377 automated DNA sequencer and analyzed using Genescan 3.1. For statistical analysis we collected (CCTTT)n alleles in two categories according to the number of repeats : Short alleles (S<10 repeats) and Long alleles (L>10 repeats). The differences among groups distribution were assessed using chi square test or exact test based on Monte Carlo method for sparse data. To assess differences in clinical features among subject with different genotype, one-way analysis of variance or Kruskal-Wallis test was used. No significant differences in allele or genotype frequencies for the NOS2A polymorphisms between MS patients and controls were observed ($p>0.05$), also when the stratified analysis for gender was performed. Lack of association was also observed when the data were stratified for specific clinical variables (age at examination, age at onset, disease duration and EDSS) ($p>0.05$). Statistical analysis demonstrates lack of association between the NOS2A promoter polymorphisms and MS and hence the gene does not appear to play a genetically significant role in MS pathology.

Aneuploidy risk evaluation according to the degree of analyte deviation in combined I. trimester screening. *M. Macek[1], M. Simandlova[1], S. Vilimova[1], R. Vlk[1], H. Cuckle[2], I. Spalova[1], A. Lashkevich[1], B. Cardova[1], M. Turnovec[1], J. Diblik[1], M. Havlovicova[1], M. Macek Jr.[1]* 1) Charles University Prague and University Hospital Motol, Prague, Czech Republic; 2) Leeds Screening Centre, University of Leeds, United Kingdom.

The aim of this study was to asess the efficacy of combined I. trimester screening by PAPP-A and free hCG, nuchal translucency measurements, LifeCycle/Elipse software, by the degree and number of marker deviations from 1.6-1.9 MoMs. 1415 I. trimester sera examinations were confirmed by cytogenetics. Aneuploidy risk categories (cat.) I.-IV. were defined according to marker number and degree of deviation, presuming the lowest aneuploidy risk in cat. I. and highest in cat. IV. Cat. I. (1.6-1.9 MoM) was detected in 46.2%, II. (0.5-0.6 and 1.9-2.0 MoM) in 11.7%, III. in 31.6% (only one marker >2.0 or <0.5), IV. in 10.7% (3-4 markers <0.5 and/or >2.0) of cases. In cat. I. only structural aberrations were detected in 2/688 (0.29%); in cat. II. only heterochromosomal aneuploidies (47,XXY; 46,XX/45,X) were found in 2/163 (1.23%); in cat. III. autosomal and heterochromosomal aneuploidies, including FRAXA syndrome, were detected in 6/468 (1.28%). Cat. IV. provided the highest 10/96 (10.4%) efficacy (+21,+13, triploidy, mosaics 45,X/46,XX and 47,XYY), compared to cat. I.-II. (p=0.00001). Combination of all markers in cat. III.-IV. assured 100% detection of all types of autosomal aneuploidies, whereas only number/degree of analyte deviations, 100% of heterochromosomal aneuploidies in categories II.-IV. Aneuploidy risk is also related to number/degree of marker deviations that increase detection rate of combined I. trimester screening: cat. I. without aneuploidy, cat. II. only with heterochromosomal aneuploidies, in cat. III. heterochromosomal and autosomal aneuploidies, with highest aneuploidy detection rate in cat. IV. Such screening strategy enables individualization of prenatal care and diagnosis. Genetic counseling is recommended in cat. II.-IV., prenatal diagnosis in III.-IV. according to results of clinical and ultrasound examinations and contingent screening in woman within cat. III.-IV. Supported by VZFNM MZO00064203.

SNP association study of esophageal squamous cell carcinoma in a high-risk population from China. *D. Ng[1], N. Hu[1], X.Y. Han[2], C. Giffen[3], Z.Z. Tang[2], A.M. Goldstein[1], M.P. Lee[4], P.R. Taylor[1]* 1) Genetic Epidemiology Branch, DCEG, NCI, NIH, DHHS, Bethesda, MD; 2) Shanxi Cancer Hospital, Taiyuan, Shanxi, PR China; 3) Information Management Services, Inc., Silver Spring, MD; 4) Laboratory of Population Genetics, CCR, NCI, NIH, DHHS, Bethesda, MD.

Esophageal squamous cell carcinoma (ESCC) incidence and mortality rates in north-central China are the highest in the world; rates in this region exceed the average Chinese rate by 10-fold and the US Caucasian rate by 100-fold. Geographic variation of ESCC rates in China suggests that environmental and/or lifestyle factors are major contributors to the etiology of esophageal cancer. In high-risk regions such as Shanxi Province, there is a strong tendency towards familial aggregation suggesting an etiologic role for genetic susceptibility and/or gene-environment interactions. To identify susceptibility genes that predispose to ESCC, we completed a pilot case-control whole genome SNP association study using the Affymetrix 10K SNP array in 50 ESCC patients and 50 matched controls from Shanxi Province. Using the generalized linear model (GLM) with adjustments for potential confounders and multiple comparisons, we identified 37 SNPs associated with disease assuming a recessive mode of inheritance, 48 SNPs assuming a dominant mode and 53 SNPs in a continuous mode. When the 37 SNPs identified from the GLM recessive mode were used in a principal component analysis, the first principal component correctly predicted 46 of 50 cases and 47 of 50 controls. To correct for 10,264 separate analyses, we used a Bonferroni-adjusted significance level of $P < 4.87187 \times 10\text{-}6$ to select combined SNPs identified from the GLMs of all three modes of transmission. Thirty-eight SNPs were identified that met the Bonferroni-adjusted significance level and were located in or near genes. To further validate these SNPs for genetic susceptibility/risk assessment, we performed a second study in which 300 new ESCC cases and their matched controls were genotyped using a multiplex oligonucleotide ligation assay to examine the 38 SNPs identified from the pilot case-control study.

Mutations in each of three Ribonuclease H2 subunits cause Aicardi Goutières Syndrome and mimic congenital viral brain infection. *A.P. Jackson[1], A. Leitch[1], B.E. Hayward[2], A. Garner[1], R. Parmar[2], E. Griffith[1], M. Ali[2], P. Lebon[3], D.T. Bonthron[2], C. Ponting[4], Y.J. Crow[2], The AGS consortium* 1) Medical Genetics, MRC Human Genetics Unit, Edinburgh, United Kingdom; 2) Leeds Institute of Molecular Medicine, University of Leeds, St Jamess University Hospital, Leeds, LS9 7TF, UK; 3) Service de Virologie, Hôpital Cochin, St Vincent de Paul, 82 Avenue Denfert Rochereau, 75674, Paris, France; 4) MRC Functional Genetics Unit, Department of Human Anatomy & Genetics, University of Oxford, South Parks Road, Oxford, OX1 3QX, UK.

Aicardi Goutières Syndrome (AGS) is an autosomal recessive neurological disorder whose clinical and immunological features parallel those of congenital viral infection. Using a combination of positional cloning, homology prediction and functional studies, we determine the human counterparts of the S.cerevisiae RNase H2 enzyme complex and identify pathogenic mutations in all three protein subunits, AGS2 (RNASEH2B, FLJ11712), AGS3 (RNASEH2C, AYP1) and AGS4 (RNASEH2A). Additionally, we show that these mutations may lead to reduced enzymatic function. Our findings thus demonstrate a role for this ribonuclease in human neurological disease, and suggest an unanticipated relationship between Ribonuclease H2 and immune response, which warrants further investigation.

A locus for familial skewed X chromosome inactivation maps to chromosome Xq25 in a family with a female manifesting Lowes syndrome. *M.A. Melis[1], M. Addis[1], C. Meloni[1], A. Cao[2], R. Congiu[1], S. Santaniello[1], M. Loi[3], F. Emma[4], O. Zuffardi[5, 6], R. Ciccone[5], G. Sole[2], M. Cau[1]* 1) Scienze Biomediche e Biotecnol, University of Cagliari, Cagliari, Italy; 2) Istituto di Neurogenetica e Neurofarmacologia, CNR, Selargius (CA) Italy; 3) Servizio di Neuropsichiatria. Azienda Ospedaliera G. Brotzu, Cagliari, Italy;; 4) Department of Nephrology and dialysis, Bambino Gesù, Children's Research Hospital, Rome, Italy; 5) Genetica Medica Università di Pavia, Italy; 6) IRCSS Policlinico San Matteo, Pavia, Italy.

In mammals X linked gene products can be dosage compensed between males and females by inactivation of one of the two X chromosomes in the developing female embryos. X Inactivation choice is usually random in embryo mammals , however several mechanisms can influence the choice determining skewed X inactivation. As consequence, females heterozygous for X linked recessive disease can manifest the full phenotype. Herein, we report a family with extremely skewed X inactivation that produced the full phenotype of Lowe's syndrome, a recessive X linked disease, in a female. The X chromosome inactivation studies detected an extremely skewed inactivation pattern with a ratio of 100:0 in the proband as well as in 5 out of seven unaffected female relatives in 4 generations. The OCRL1 de novo mutation, resides in the active paternally inherited X chromosome. The analysis of the minimal XIST promoter did not show DNA sequenze variation. Array-CGH revealed a normal profile of all chromosomes including the X. X chromosome haplotype analysis localized the familial skewed X inactivation locus to chromosome Xq25 with a maximum multipoint LOD score of 2.11 between markers DXS8059 and DXS8057. The description of this case adds Lowe's syndrome to the list of X-linked disorders which may manifest the full phenotype in females because of the skewed X-inactivation. Furthermore our study indicates that the skewed X inactivation in this family depends most likely on the inheritance of a dominant X-linked trait controlling X chromosome choice in X inactivation or cell proliferation.

Cytoplasmic aggregates and proteolytic cleavage of the 1A calcium channel in Spinocerebellar ataxia type 6. *T. Ishiguro, K. Ishikawa, T. Amino, T. Tsunemi, H. Mizusawa* Dept Neurology, Tokyo Medical & Dental Univ, Tokyo, Japan.

Spinocerebellar ataxia type 6(SCA6)is dominantly inherited ataxia clinically characterized by pure cerebeller symptoms, and pathologically characterized by nearly selective and progressive death of Purkinje cells. The causative mutation is the expansion of (CAG) repeat coding polyglutamine in the carboxyl terminal of the alpha1A voltage-dependent calcium channel. In this study, we show that a 75kD 1A carboxyl (C-) terminal fragment is cleaved from the full length calcium channel protein in western blots when 1A subunits containing either of 13 polyglutamine (Q13), 28 polyglutamine (Q28), or 165 polyglutamine (Q165) tracts were transiently expressed in PC12 cells. On immunohistochemistry using polyclonal antibody against the channel protein, C-terminal fragment was present both in the perinucler space and cytoplasm in cultured PC12 cells. On the other hand, the N-terminal part of the 1A was not always co-localized with C-terminal fragment. These cytoplasmic aggregates were morphologically similar to the 1C2 positive small granular aggregates seen in Purkinje cells of SCA6 patients brains. The present study may indicate that a certain proteolytic cleavage of the channel protein is underlying in the formation of calcium channel aggregates.

The TBX1 gene in the 22q11.2 deletion and duplication syndromes: a susceptibility factor for mental retardation.

D. Heine-Suner[1], L. Torres-Juan[1], J. Rosell[1], M. Morla[3], F. Garcia-Algas[2], M. de la Fuente[2], M. Juan[4], A. Tubau[4], M. Bernues[1], A. Perez-Granero[1], N. Govea[1], X. Busquets[3] 1) Secció de Genetica, Hosp Univ Son Dureta, Andrea Doria 55, Palma de Mallorca 07014, Balearic Islands, Spain; 2) Servei de Pediatría, Hosp Univ Son Dureta, Andrea Doria 55, Palma de Mallorca 07014, Balearic Islands, Spain; 3) Unitat de Investigació, Hosp Univ Son Dureta, Andrea Doria 55, Palma de Mallorca 07014, Balearic Islands, Spain; 4) Servei de Obstetricia i Ginecologia, Hospital Son Llatzer, Carretera de Manacor, km4, 07198 Palma de Mallorca, Balearic Islands, Spain.

A mutational screen for TBX1 mutations was performed on 38 non-deleted patients that had clinical features compatible with the 22q11.2 deletion syndrome. Two rare variants were identified. The first is a de novo missense mutation in a patient with Tetralogy of Fallot, immunodeficiency and slight developmental delays. This mutation is localized in exon 9C and possibly affects a conserved amino acid within a transactivation domain. The second mutation is within the 5UTR region. This change affects two brothers with isolated congenital heart disease. Modelling studies show that this change affects the 5UT mRNA secondary structure. In addition, in vitro translation experiments showed this change to double the protein doses. Recently, patients referred for fragile-X were found to be carriers of duplications in the 22q11.2 region. Because the 5UT nucleotide change is functionally equivalent to a duplication of the TBX1 gene we screened 200 patients referred for fragile-X determination and detected 3 carriers of this change not detected in 400 healthy controls. However, affected carriers had all a normal carrier parent, which shows that the presence of the 5UT change is not sufficient to cause congenital heart disease or mental retardation. In conclusion, we report a new de novo mutation in the TBX1 gene responsible for cardiac defects as the main feature, and show that a rare variant affects TBX1 doses. Furthermore, we find that the change that increases the doses of TBX1 is a susceptibility factor to suffer features of the 22q11.2 duplication syndrome.

Analysis of BBS protein expression in an in vivo model organ system. *H. May-Simera[1], D. Jagger[2], A. Forge[2], P.L. Beales[1]* 1) Molecular Medicine Unit, UCL Inst Child Health, London, United Kingdom; 2) Centre for Auditory Research, UCL Ear Institute, London, United Kingdom.

Bardet-Biedl syndrome is a rare heterogeneous condition, characterized by obesity, polydactyly, renal abnormalities, retinal dystrophy and cognitive impairment. To date 11 genes have been identified (*BBS1-11*). Given that mutations in any of the BBS genes result in clinically indistinguishable phenotypes, it is likely that BBS proteins participate in common cellular processes. Several BBS genes have been associated with ciliary function and cognate proteins have been localized to the centrosome and basal body of ciliated cells. Previous analysis of BBS protein expression has predominantly centered on in vitro cell culture systems. Given the limited extrapolation of cell lines to live organisms we have focused attention on whole organ systems, in particular the mammalian cochlea. The developmental organization of sensory hair cells is under control of the kinocilium (a primary cilium) and its basal body and furthermore, the cochlear supporting cells are uniquely rich in microtubules. Our prior studies have identified that three Bbs mouse mutants (*Bbs1*, *4* and *6*) have hair cell defects likely associated with perturbation of planar cell polarity. However, the extent of these defects is unlikely to entirely explain the profound deafness exhibited by null mice. Therefore, we have further investigated the involvement of Bbs proteins in the auditory sensory epithelium. Within the organ of Corti, as expected, we observed a ubiquitous expression of Bbs6 within basal bodies. By contrast, in epithelial support cells there was strong but specific cytoskeletal expression of Bbs4 and Bbs2 in a distinct temporal pattern. These data suggest that some but not all Bbs proteins are tightly associated with microtubule function. We believe the inner ear presents an ideal organ structure for studying the developmental role of Bbs proteins. Owing to their microtubular enrichment, these support cells will be particularly useful to examine the involvement of low abundance cytoskeletal proteins.

The Norwegian Mother and Child Cohort Study (MoBa): a prospective cohort for genetic and epidemiological research. *R. Lyle[1], L.M. Irgens[1, 2], K. Haug[2], W. Nystad[1], R. Skaerven[1, 2], C. Stoltenberg[1], P. Magnus[1], The MoBa Study Group* 1) Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway; 2) Medical Birth Registry of Norway, Locus of Registry Based Epidemiology, Department of Public Health and Primary Health Care, University of Bergen.

The Norwegian Mother and Child Cohort Study (MoBa) is a large-scale prospective pregnancy cohort for genetic epidemiological research. The objective is to collect data on exposures and health outcomes to critically test etiological hypotheses by estimating the association between exposures, genetic factors, and disease. The target population is all pregnant women in Norway, recruiting 100 000 pregnancies in 1999-2008. As of April 2006, ~70,000 pregnancies have been included. The participation rate is 42.7%, and the father participates in 82.9% of these cases. Four main types of variable are included in MoBa: 1. Questionnaire variables (~7000 questions in 6 questionnaries) 2. Data from biological samples (DNA, plasma, urine, RNA) 3. Derived variables from research groups 4. Exposure and outcome data acquired by record linkage with the birth, cancer, prescription, cause of death and vaccination registries. MoBa is unique in having recruited fathers, and routinely extracting DNA from mother, father and child. There are thus 10 000s of trios available for genetic research. MoBa allows researchers to have valid measures of both genes and the environment in the same study. An additional strength of MoBa is that trios allow great flexibility in study design and the types of research questions that can tackled. For example, the case-parent design, which opens the possibility of detecting effects of maternal genes, fetal genes and their interaction. Details of MoBa can be obtained online (www.fhi.no/morogbarn). The MoBa protocol is available (www.fhi.no/dav/14DFADA9F4.pdf) and includes information on consent, data collection and questionnaires. A set of guidelines for researchers applying for access to data and samples has been established and researchers are encouraged to use this unique resource. We will present the organisation of MoBa, including the biobank, details of ongoing research projects, and access procedures.

Beta adrenergic receptor (ADRB2) SNP and lung function in preschool children. *J. Hankinson[1], L. Lowe[2], S. John[1], A. Custovic[2], A. Woodcock[2], W. Ollier[1], A. Simpson[2]* 1) CIGMR, University of Manchester, United Kingdom; 2) North West Lung Centre.

Rationale: Specific airway resistance (sRaw), is a sensitive and reproducible measure of lung function in young children - higher sRaw indicating poorer lung function. Albuterol is an ADRB2 agonist and is the most common treatment used for wheezing illness. We investigated the relationship between a SNP in ADRB2 and pre and post albuterol sRaw at age 5 years in the setting of a population based birth cohort study. Methods: Lung function at age 5 years was assessed using plethysmographic measurement of sRaw at baseline and after bronchodilator [bd] (400 mcg albuterol). Results were also expressed as change in sRaw after bd as % of baseline sRaw (% change), and change in absolute value of sRaw after bd (absolute change). Wheeze in the last 12 months was assessed by parental questionnaire. Children were genotyped (n=636) for a SNP in the ADRB2 gene (rs1042713, Arg16Gly). Results were analysed using regression.Results: The SNP was in Hardy Weinberg equilibrium with a minor allele (Arg) frequency of 36.6%. Of the 636 children, 136 had wheezed in the previous 12 months. Wheezing children had poorer lung function at baseline (kPa/s, GM [95% CI] 1.26 [1.21-1.31] vs. 1.14 [1.13-1.16], $p<0.001$). Although both groups showed a significant improvement in lung function after bd ($p<0.001$) lung function was still poorer in wheezing children (kPa/s, GM [95% CI] 1.02 [0.99-1.05] vs. 0.97 [0.96-0.98], $p=0.001$).There was no difference in baseline or post bd lung function by genotype group ($p>0.2$). Amongst wheezing children however, minor allele homozygotes (Arg/Arg) showed a much smaller % change in sRaw post bd than the heterozygotes and common allele homozygotes (% change GM [95% CI] 1.99 [-11.55-15.52] vs. 18.38 [15.51-21.25], $p=0.003$) Similar results were seen when absolute change was considered ($p=0.014$). There was no difference in response to bd by genotype group amongst non-wheezing children ($p>0.4$) Conclusions: Amongst wheezing children, those homozygous for the minor allele showed a significantly smaller response to albuterol than wheezing children in the other genotype groups.

Accounting for genotyping errors in tagging SNP selection. *W. Liu[1], T. Yang[2], W. Zhao[1], G.A. Chase[1]* 1) Dept. of Health Evaluation Sciences, Penn State College of Medicine; 2) College of Information Sciences and Technology, Penn State University Park.

Many tagging SNP selection algorithms have been developed to optimally select the minimal informative subset of SNPs. One limitation of the existing algorithms is that they assume the reported genotypes are error free. However, genotyping errors are often unavoidable in practice. Many tagging SNP selection methods depend heavily on the estimated haplotype frequencies. Recent studies have demonstrated that even slight genotyping errors can lead to serious consequences with regard to haplotype reconstruction and frequency estimation. Here we present a tagging SNP selection method that allows for genotyping errors. Our method is a modification of the pair-wise r^2 tagging SNP selection algorithm proposed by Carlson et al. We replaced the standard EM algorithm in Carlsons method with an EM that accounts for genotyping errors in an attempt to obtain better estimates of the haplotype frequencies and r^2 measure. Through simulation studies, we compared the performance of our modified algorithm with that of the original algorithm. We found that the number of tags selected by both methods increased with increasing genotyping errors though our method led to smaller increase. We also studied the power of haplotype and single marker association tests using the selected tagging SNPs. We found that the power of haplotype association tests decreased dramatically with increasing genotyping errors. The power of single marker tests also decreased, but not at much as the decrease in haplotype tests. The power reduction in tests using tags selected from both methods was similar. Our method led to slightly higher power in haplotype tests, while Carlsons method led to higher power in single marker tests. When restricting the mean number of tags selected to be close to the baseline number, we still found reduction in power of the tests using the selected tags in the presence of genotyping errors. The power of all the tests resulted from our method was similar to that resulted from Carlsons method. These findings have implications for optimal selection of tagging SNPs in disease gene mapping.

Monozygotic twins of Smith-Magenis syndrome. *R. Kosaki[1], T. Okuyama[1], T. Tanaka[1], O. Migita[1], K. Kosaki[2]* 1) Clinical Genetics , National Childrens Medical Center, Tokyo, Japan; 2) Dept.of Pediatrics ,Keio Univ.School of Medicine,Tokyo.

Smith Magenis syndrome (SMS) is caused by an interstitial deletion of chromosome 17p11.2 involving the RAI1gene. Characteristic features include, broad squared face, midface hypoplasia, mild upslanting palpebral fissures, prognathism, upper lip eversion , short stature moderate mental retardation, sleep disturbance and behavior problems such as self injury . Among more than 150 SMS cases reported to date, all the cases have been sporadic except for a family in which the unaffected mothers were mosaic for 17p11.2 deletion. Sib pairs or twin pairs have not been reported. We here document first monozygotic twins of SMS. The male twins were born to a 26-year-old Japanese G2P1-3 woman with no previous medical problems. There was no consanguinity, or family history of mental retardation. The twins were delivered at 37 weeks of gestation. The placentation was diamniotic and monochorionic. At birth, the weight of twin A was 1812g, length 42.5cm, and head circumference 31.1cm. Apgar score was 5-7. The birth weight of twin B was 2564g, length 46cm, and head circumference 32cm. Postnatal courses of the twins were comparable. At the age of 3 years, the twins were referred to the genetic department because of developmental delay and self-injuring activities such as skin picking and nail yanking. Dysmorphic features, which were all concordant between the twins. At 5 years of age, the twin developed sleep disturbances. Karyotyping revealed deletion of (17)(p11.2p11.2). Identical twins have been reported in several multiple congenital anomaly syndromes such as Alagille syndrome and 22q11.2 deletion. Discordance in severity between the twin pairs in those reoprt pointed towards significant role of chance-like variation in the pathogenetic action of the mutated genes. In contrast, the SMS twins demonstrated a strikingly similar developmental and behavior patterns. The observation does not necessary indicate, but suggests a relatively large contribution of the genetic factors on the evolution of the SMS phenotype.

Genetic basis of autistic spectrum disorders: twin study of routinely-screened sample. *T. Nishiyama[1], S. Sumi[2], H. Taniai[3]* 1) Dept of Biological Information, Nagoya City Univ, Nagoya, Japan; 2) Nagoya Western Rehabilitation Center for Children with Disabilities, Nagoya, Japan; 3) Nagoya Child Welfare Center, Nagoya, Japan.

Background: A few twin study of autistic spectrum disorders suggested that these disorders were predominantly genetically determined, although only a small portion of them used statistically sound methods (Bailey et al.,1995).**Objective:** We examined the genetic structure of autistic spectrum disorders in an sample routinely screened in Nagoya city, Japan.**Methods:**A twin sample was ascertained through the annual routine screening for all cases with childhood autistic spectrum disorders, based on the criteria of pervasive developmental disorder (PDD) of *DSM-IV*. To examine the extent to which PDD fit specific models of genetic and environmental causation, these data were subjected to structural equation modeling by using the Mx software (Neale and Cardon, 1992). To correct for ascertainment bias we carried out a bivariate analysis of the final diagnosis, using categorical raw data option of Mx. The first statistical model tested incorporated the effects of three parameters: additive genetic (A), shared environmental (C), and non-shared environmental (E) factors. Successive models in which one or more of these variables were dropped from the full model were tested to examine the extent to which each model fit the observed data.**Results:** Fifteen pairs (7 monozygotic;MZ and 8 dizygotic;DZ) of twins were found for the study period of about two years. The concordance for PDD by pairs was 100% in the MZ and 25% in the DZ pairs. The structural equation modelling revealed that the AE model was best fitting(Akaikes Information Criteria; AIC, -1.110) among the models tested (AIC, 0.0 in the ACE model, 15.9 in the CE model, and 123.4 in the E model). The heritability estimate of the most favored model were 1.00 (95% confidence interval,0.99 to 1.00). **Conclusions:** It was confirmed that a broader phenotype such as PDD is likely under a high degree of additive genetic control, although our biased sampling may attribute to the present extreme findings.

185delAG in a Sri Lankan family with no Ashkenazi ancestry. *W. Meschino, H. Dorman, J. Furnival, J. Guo, J. Honeyford, D. Kennedy, M. Shama, J. Steer, K. Chun, D. Allingham-Hawkins* Genetics Program, North York General Hosp, Toronto, ON, Canada.

A 42 year old Sri Lankan woman presented to the familial breast/ovarian cancer clinic for counselling due to a history of invasive ductal carcinoma at age 37 followed by endometrial cancer at age 41. Family history revealed that her mother had developed breast cancer at age 37 and died of cancer at age 42. There were no other known cases of breast or ovarian cancer in the family. Screening of the BRCA1 and BRCA2 genes was performed using the protein truncation test plus direct sequencing of exons 2 and 5 of BRCA1. The common Ashkenazi Jewish (AJ) mutation, 185delAG, was found in exon 2 of BRCA1. A repeat analysis on a fresh specimen confirmed the finding. 185delAG is considered a "founder" mutation in the AJ population with a carrier frequency of ~1%. Carriers of 185delAG have a lifetime breast cancer risk of approximately 60%. Outside of the AJ population, however, this mutation is relatively rare. It has been observed in a group of non-Jewish Americans of Spanish descent from the San Luis Valley in Colorado as well as occasionally in other individual families with no known Jewish ancestry. This is the first report, to our knowledge, of 185delAG being identified in a Sri Lankan family. Haplotype analysis is pending to determine if the mutation is residing on the same haplotype as the common Ashkenazi mutation, another previously identified haplotype or one not previously described.

This family also presented an unusual counselling challenge in that when the younger, unaffected sister of our patient presented for counselling and predictive testing, she requested that the test results be given not to her but to her older brother, who attended the counselling session with her, as he is the paternal figure in the family. The counsellor was assured that the woman herself would return for full counselling but only after her brother had received her results and gently conveyed them to her. This is an example of the importance of flexibility and sensitivity to cultural traditions while delivering genetic services.

First reported case of CML in a patient treated with hydroxyurea for sickle cell disease (SCD). *A.S. Kulharya, A. Kutlar, K. Natarajan* Pathology, Medical College of Georgia, Augusta, GA.

Hydroxyurea (HU) is an effective treatment for controlling painful symptoms of SCD. Its effectiveness stems from its ability to be myelosuppressive, induce HbF, and modify red cell-endothelial cell interactions. No overt toxicity was observed in a study of 101 children with SCD treated with HU. There have been 4 reported cases of malignancy in SCD patients on HU therapy; 2 of these were found to be unrelated to the treatment. None of theses cases were of CML. We present the case of a 29 year old black male with SCD diagnosed with chronic phase CML. He has been treated with HU since 1997. His disease course has been remarkable for two thrombotic cerebrovascular accidents (CVA), both before the age of eight and an ICH in Nov 2004. His only other SCD related event has been gallstones requiring a cholecystectomy at age 18. He has been relatively free of vaso-occlusive episodes with no other symptoms. He has been on a chronic exchange transfusion regimen for his history of CVA. He developed transfusional iron overload initially treated with Desferoxamine and later with ICL670 (Exjade) in the context of a clinical trial. He has been occasionally non compliant with iron chelation and HU therapy. He first presented in Oct 2005 with an elevated WBC count which subsequently decreased. In Jan of 2006, his WBC count was in excess of 100,000 with an abnormal differential. Platelet count and Hb were essentially unchanged from baseline. He underwent a bone marrow aspirate and biopsy for flow cytometry, histopathology, and cytogenetic analysis. A peripheral blood analysis by FISH with a dual color dual fusion probe suggested the presence of an atypical abnormal clone with BCR/ABL fusion. However, routine cytogenetic analysis of bone marrow demonstrated a typical Ph chromosome in all the cells analyzed. The patient was started on imatinib mesylate at a dose of 400mg a day and has done well since then. The diagnosis of CML in this patient is unusual considering that HU is commonly used in the treatment of chronic myeloid disorders to stabilize the blood cell count.

***Slc25a19* is a mouse mitochondrial transporter necessary for viability, neural tube closure, erythropoiesis, and maintenance of mitochondrial thiamine pyrophosphate pools.** *M.J. Lindhurst[1], G. Fiermonte[2], S. Song[3], E. Struys[4], F. De Leonardis[2], A. Chen[1], A. Castegna[2], N. Verhoeven[4], C.K. Mathews[3], F. Palmieri[2], L.G. Biesecker[1]* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Department of Pharmaco-Biology, Laboratory of Biochemistry and Molecular Biology, University of Bari, Bari, Italy; 3) Department of Biochemistry and Biophysics Oregon State University, Corvallis, OR; 4) Department of Clinical Chemistry, VU University Medical Center, Amsterdam, The Netherlands.

A missense mutation in *SLC25A19* causes Amish lethal microcephaly (MCPHA), which is characterized by severe microcephaly, brain malformations, -ketoglutaric aciduria and premature death. Previous data suggested that SLC25A19, also called DNC, was a mitochondrial deoxyribonucleotide transporter. We generated a knockout mouse model of *Slc25a19*. These animals had 100% prenatal lethality by E12. Affected embryos at E10.5 have a neural tube closure defect with ruffling of the neural fold ridges, a yolk sac erythropoietic failure and elevated -ketoglutarate in the amniotic fluid. We found that these animals have normal mitochondrial ribo- and deoxyribonucleoside triphosphate levels, suggesting that transport of these molecules is not the primary role of SLC25A19. We identified thiamine pyrophosphate (ThPP) transport as a candidate function of SLC25A19 through homology searching and confirmed it using transport assays of the recombinant reconstituted protein. The mitochondria of *Slc25a19*$^{-/-}$ and MCPHA cells have undetectable and markedly reduced ThPP content, respectively. The reduction of ThPP levels causes dysfunction of the -ketoglutarate dehydrogenase complex, which explains the high levels of this organic acid in MCPHA. In addition, pyruvate dehydrogenase activity is also decreased suggesting that transport of this cofactor into the mitochondria is important for central nervous system development and supports the hypothesis that the developing brain has a higher need for oxidative metabolism than other organs.

Pooled whole genome association genome scanning: validation using 100k Centurion and 500k Mendel Affymetrix microarray sets. *Q.R. Liu, T. Drgon, C. Johnson, D. Walther, G.R. Uhl* Molecular Neurobiology Branch, NIDA/NIH, Baltimore, MD.

Association genome scanning is of increasing interest for identifying chromosomal regions, genes and gene variants that contribute to vulnerability to complex disorders. Pooling strategies can efficiently perform allele typing, preserve confidentiality and reduce costs. We have helped to pioneer microarray-based pooled association genome scanning using 1.5K and 10K Affymetrix SNP arrays (Uhl et. al., 2001, AJHG; Liu et. al., 2005 PNAS). We now describe validation of pooled genotyping using early access versions of Affymetrix 100K and 500 K arrays and report the variation that we have obtained in comparing results of pooled with those of individually-determined genotypes. We obtained hybridization intensity data from perfect-match cells from these arrays and performed background subtraction, normalization, and arctangent transformations of A vs B allele hybridization intensity ratios. We compared values obtained from different pools of DNAs and compared them with expected allele ratios, the fraction of A and B alleles obtained from individually genotyping the individuals whose DNAs were used at 1:1; 1:5 and 1:15 ratios in these validating pools. Data from 150,000 informative SNPs was used yielded correlations between pooled and individually-determined genotypes of r2 = 0.95. This value rises to 0.99 if the 10% of the most poorly performing SNPs are removed. These values, and other validating results, appear to be at least as favorable as alternative approaches that use RAS values (Kirov et. al., 2006, BMC Genomics). They provide correlations that improve upon those reported using hybridization with long PCR amplimers and large-format wafer arrays (Hinds et. al., 2004, Hum Genomics). Adjacent presentations illustrate use of this approach in elucidating chromosomal regions and genes that contain alleles which appear to influence vulnerability to addictions. (Support: NIH-IRP, NIDA, DHHS).

Newborn screening for cystic fibrosis in the Czech Republic: results from a pilot study. *A. Holubova[1], F. Votava[2], V. Skalicka[3], V. Vavrova[3], D. Zemkova[3], P. Kracmar[2], M. Libik[1], J. Camajova[1], T. Piskackova[1], M. Macek[1]* 1) Charles University Prague, CF Center University Hospital Motol, Prague, Czech Republic; 2) Department of Pediatrics, University Hospital K. Vinohrady, Prague, Czech Republic; 3) Department of Pediatrics, University Hospital Motol, Prague, Czech Republic.

According to epidemiologic / genetic studies the incidence of CF in our country is 1:2700 newborns. Thus, given the current birthrate ~35 new cases of CF should annually be detected. However, registry data demonstrated that 1/3 of CF patients remains clinically undiagnosed and that the age at diagnosis has markedly increased (prior to 1998 median: 0.58; between 1999-2005: 1.2 years). Therefore, in II/2006 we started two tier (IRT/DNA) pilot CF neonatal screening project (NSCF) comprising Bohemian regions, representing ~2/3 of our population. Altogether 45,453 newborns were examined during the initial 9 month period. In 545 cases (1.2%), who had IRT concentration above the continuously adjusted cut off level, we examined the most common CFTR mutations. The diagnosis of CF was established in 5 newborns (2x F508del/F508del; 2x F508del/G551D; 1x F508del/R117H-7T - mild CF) and these children were subsequently referred to CF Centres. Furthermore, we detected 42 newborns with 1 CFTR allele (35x F508del, 2x CFTRdele2.3/21kb/, 2x N1303K, 1x G551D, 1x I507del and 1x I148T). Until now 27 follow up sweat tests (ST) were performed (26x 30mmol/L, 1x 30-40mmol/L). IRT recall was carried out in 14 children with IRT 200ng/mL and with a non-detectable CFTR allele - 11 children had negative IRT recall and 1 child was positive (ST negative). From these results the incidence of CF can preliminarily be adjusted to 1:9090 newborns. However, these results can be skewed due to lower number of newborns tested, effect of prenatal diagnosis and/or false negativity of NSCF. Supported by IGA MZCR 8236-3, VZFNM MZO00064203(6112).

Fine mapping of a linkage region on chromosome 17q13 reveals GABARAP and DLG4 are associated with vulnerability to nicotine dependence in European-Americans. *X.-Y. Lou[1], J.Z. Ma[1], J. Beuten[1], D. Sun[1], T.J. Payne[2], M.D. Li[1]* 1) Department of Psychiatric Medicine, University of Virginia, Charlottesville, VA; 2) ACT Center for Tobacco Treatment, Education & Research, University of Mississippi Medical Center, Jackson, MS.

A two-stage association study was conducted for a genomic region on chromosome 17q13-13.2 that was reported by us to harbor susceptibility gene(s) for nicotine dependence (ND). We first used ten SNPs in six genes within the region to determine which SNP/gene is associated with ND, which was assessed by smoking quantity (SQ), the Heaviness of Smoking Index (HSI) and the Fagerström Test for ND (FTND), in a total of 2037 subjects from 602 nuclear families of either African-American (AA) or European-American (EA) origin. Individual SNP analysis revealed that SNPs rs17710 and rs222843 in the GABARAP exhibited significant association with at least one age- and gender-adjusted ND measure in the EA sample and rs222843 still remained significant with adjusted FTND after correction for multiple testing (P = 0.009 under both dominant and recessive models). Although no SNP in the DLG4 was found to be significantly associated with ND, we found a G-G haplotype with a frequency of 14.2% formed by SNPs rs2242449 and rs507506 that showed significant inverse association with three ND measures (P = 0.003, 0.015 and 0.024, for SQ, HSI and FTND, respectively). We also found an A-A haplotype at a frequency of 8.8% formed by SNPs rs17710 and rs222843 in the GABARAP, that showed significant association with three ND measures (P = 0.006, 0.019 and 0.024, for SQ, HSI and FTND, respectively). To confirm these findings with a better coverage of the genes of interest, we conducted second stage association analysis by genotyping four more SNPs for GABARAP and nine for DLG4 on the same sample. Our second stage of association analysis results supported our finding of significant association of the two genes with ND. No significant association was detected in the AA sample. In summary, our two-stage association analysis results indicate that the GABARAP and DLG4 genes are involved in the etiology of ND in EA smokers.

Knock-in mouse model of Usher type IC. *J. Lentz[1], F. Pan[1], S. Ng[1], P. Deininger[2], B. Keats[1]* 1) Dept Genetics, Louisiana State Univ HSC, New Orleans, LA; 2) Dept Epidemiology, Tulane Univ Health Sciences Center, New Orleans, LA.

Usher syndrome type I is characterized by deafness at birth, vestibular dysfunction and progressive retinitis pigmentosa beginning in early adolescence. A cryptic splice site mutation (216GA) in exon 3 of the *USH1C* gene on chromosome 11p, which encodes a PDZ-domain protein, harmonin, was found in Acadian Usher type IC families in south Louisiana. *In vitro* analysis using constructs containing the mutant 216A and subsequent analysis of patient cells lines revealed a 35 base deletion. In order to analyze the impact of this frame-shift mutation, we created a knock-in mouse model containing the human 216GA mutation. A targeting construct was made containing 5 and 3 homology arms, each 4kb in length, and a 650 base pair fragment containing exons 3 and 4 from human *USH1C* cloned from an Acadian patient homozygous for the 216A mutation. 129SvEvTac embryonic stem cells were electroporated with the targeting construct, and after 10 days of neomycin (neo) selection, clones were screened by PCR and Southern blot analysis for homologous recombination. Two clones positive for targeted insertion were microinjected into C57BL/6 blastocystes and transplanted into pseudo-pregnant females. Chimeras were bred with cre-deletors for simultaneous deletion of the neo gene and germline transmission of the 216A allele. Four subsequent generations of offspring have now been genotyped. All homozygous *Ush1c*216A (216AA) mice are hyperactive, display circling and head tossing behavior, and do not display a Preyer reflex at 21-25 days old. They are similar in size and weight to their heterozygous and wild type litter mates, and both male and female homozygous *Ush1c*216A mice are fertile. Heterozygous mice show no behavioral phenotype. RT-PCR analysis of the cochlea and retina from 216AA mice shows the same 35 base pair deletion characteristic of Usher IC patients. Assessment of hearing and vision defects, as well as gene and protein expression are in progress.

Met80Ile polymorphism of the APOBEC1 gene, relating to plasma HDL cholesterol level, is a risk and modifies age-at-onset of male Alzheimer disease. *K. Kamino[1], R. Kimura[1], M. Yamamoto[1], A. Nuripa[1], T. Tanaka[1], T. Kudo[1], H. Akatsu[2], K. Kosaka[2], H. Yamagata[3], T. Miki[4], K. Urakami[5], Y. Wakutani[6], K. Wada[6], K. Nakashima[6], H. Kawakami[7], R.C.P. Go[8], R. Perry[8], T.D. Bird[9], G.D. Schellenberg[10], M. Takeda[1]* 1) Post-Genomics & Diseases, Osaka University Gradate School of Medicine, Suita, Osaka, Japan; 2) Choju Medical Institute, Fukushimura Hospital, Toyohashi, Aichi, Japan; 3) Preventive Medicine, Ehime University Graduate School of Medicine, Toon, Ehime, Japan; 4) Geriatric medicine, Ehime University Graduate School of Medicine, Toon, Ehime, Japan; 5) Biological Regulation, School of Health Science, Faculty of Medicine, Tottori University, Yonago, Tottori, Japan; 6) Neurology, Institute of Neurological Sciences, Faculty of Medicine, Tottori University, Yonago, Tottori, Japan; 7) Clinical Neuroscience and Therapeutics, Hiroshima University Graduate School of Biomedical Sciences, Hiroshima, Japan; 8) Epidemiology, University of Alabama at Birmingham, Birmingham, AL; 9) Neurology, University of Washington, Seattle, WA; 10) Neurology, Pharmacology, University of Washington, Seattle, WA.

Apolipoprotein B mRNA-editing enzyme (APOBEC1) gene encodes catalytic enzyme, editing APOB-100 into APOB-48 mRNA by cytidine deamination. Since the APOBEC1 gene is located in a risk locus of Alzheimer disease (AD) at 12p, the Met80Ile polymorphism (rs2302515) in catalytic domain was subjected to case-control studies composed of 958 AD and 1361 controls in three ethnic backgrounds. Meta-analysis supported that the Ile/Ile genotype is a risk for male AD (O.R. = 1.51, 95%C.I. = 1.09-2.12), and also relates to earlier age-at-onset ($p<0.01$). On the other hand, the Ile/Ile genotype was gradually increased after 70 years old in population-based controls, and related with higher plasma HDL cholesterol level ($p<0.05$). Our results indicates that the Ile/Ile genotype of the APOBEC1 gene is a novel risk factor and modifies age-at-onset of AD, and plasma cholesterol profile related to the genotype suggests the etiological difference between AD and atherosclerosis.

Axonal swellings and impaired axonal transport in a mouse model of spastic paraplegia linked to spastin mutation. *A. Tarrade[1, 6], C. Fassier[1, 6], S. Courageot[1], D. Charvin[1], E. Mouisel[1], J. Vitte[1], A. Thorel[2], N. Fonknechten[3], N. Roblot[1], D. Seilhean[4], A. Diérich[5], J.J. Hauw[4], J. Melki[1]* 1) Molecular Neurogenetics Laboratory, INSERM U798, University of Evry, 91057 Evry, France; 2) Centre des materiaux, Evry; 3) Genoscope, Evry, France; 4) Laboratoire de Neuropathologie, Groupe Hospitalier Pitié-Salpétrière, Paris, France; 5) IGBMC, Illkirch, France; 6) Equal contribution.

Hereditary spastic paraplegia (HSP) is a neurological disorder characterized by axonal degeneration of corticospinal tracts. The most prevalent form of autosomal dominant HSP is linked to spastin (Sp) mutations. Homologous recombination in murine ES cells has been used to create a deletion of Sp exons 5 to 7 leading to a premature stop codon and the lack of the AAA domain. Examination of spinal cord revealed focal axonal swellings in descending and ascending tracts of mutant but not control mice. Electron microscopic analysis of the axonal swellings has shown an accumulation of organelles and cytoskeletal components suggesting an impairment of axonal transport in vivo. The frequency of axonal swellings was increasing with age in agreement with late and slowly progressive motor defect of mutant mice. Primary cultures of cortical motor neurons derived from embryos showed a localization of spastin in both the cell body and neurites. Mutant cortical neurons have normal viability and neurite outgrowth but develop focal swellings in the distal part of neurites. Our data strongly suggest for the first time that spastin, a protein involved in microtubule severing, is essential to maintain neurite integrity and axonal transport in vivo. Further investigations in our cellular model will help in clarifying the molecular pathway linking spastin, microtubule severing and axonal transport. In spite of the evidence for their involvement in distinct processes, mutations of paraplegin, PLP, KIF5A or spastin (this study) are leading to similar axonal degeneration and transport defect. The availability of a cellular model of spastic paraplegia should help in finding components able to stabilize or rescue neurite defects.

Truncation of the *Kcnq1ot1* non-coding RNA uncovers dual mechanisms of imprinting for *Cdkn1c*. *M.J. Higgins[1], G.V. Fitzpatrick[1], E.M. Pugacheva[2], Z. Abdullaev[2], V.V. Lobanenkov[2], J.Y. Shin[1]* 1) Department of Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY; 2) Molecular Pathology Section, Laboratory of Immunopathology, National Institute of Allergy and Infectious Diseases, NIH, Rockville MD 20852.

A cluster of imprinted genes in 11p15.5 are involved in the cancer-predisposition condition Beckwith-Wiedemann syndrome (BWS) and in some sporadic tumors. This genomic region consists of two independently regulated subdomains; the telomeric region, includes the maternally expressed *H19* gene and the paternally expressed *IGF2* gene and is regulated by a CTCF-dependent chromatin insulator, while the centromeric subdomain contains 8 imprinted genes regulated by the KvDMR1 imprinting control region (ICR). Loss of methylation at KvDMR1, a frequent epimutation in BWS, is associated with silencing of the *CDKN1C* tumor suppressor gene and is the probable cause of the disease. Previous studies suggest that KvDMR1 regulates imprinted expression by functioning as a chromatin insulator or silencer, or by acting as the promoter for the non-coding *Kcnq1ot1* RNA. Using cell culture-based reporter assays, we show that the enhancer-blocking element and the *Kcnq1ot1* promoter are completely separable. Furthermore, EMSA and chromatin immunoprecipitation demonstrate the presence of two binding sites for the CTCF. To test whether the non-coding RNA has a function in imprinting, we inserted a poly(A) cassette downstream of the *Kcnq1ot1* promoter to truncate the transcript. Following paternal transmission of this mutation, all genes under the control of KvDMR1 lose imprinting in the placenta. In contrast, while most of these genes exhibit widespread loss of imprinting in the embryo, *Cdkn1c* retains maternal-specific expression in some fetal tissues despite global loss of paternal methylation at its promoter. These results indicate that, while most imprinted genes in this domain are regulated exclusively by the noncoding *Kcnq1ot1* RNA, in some cell types *Cdkn1c* is silenced by an RNA-independent mechanism, perhaps by a CTCF modulated chromatin insulator. Thus KvDMR1 is the first ICR shown to repress the same gene by two distinct mechanisms.

Expression analysis of microRNAs during eye development in mouse. *M. Karali, V. Marigo, S. Banfi* Telethon Institute for Genetics and Medicine, Naples, Italy.

microRNAs (miRNAs) are a class of small (21-25 nucleotide), endogenous RNAs that negatively regulate gene expression by binding to target sites in the 3 UTR of messenger RNAs. Although they have been found to regulate developmental and physiological processes in several organs and tissues, their role in the eye transcriptome is completely unknown. We decided to perform detailed expression analysis for fourteen miRNAs that have been previously found to be expressed in the developing eye in non-mammalian vertebrates (zebrafish). We determined their spatiotemporal localization in the murine eye during development by RNA in situ hybridization (ISH) using LNA (locked-nucleic-acid)-modified DNA oligonucleotide probes. We analysed their expression at embryonic stages E10.5 (by whole-mount ISH) and E16.5 and on postnatal eyes at P0, P8 and adult. The analysed miRNAs are expressed in the eye with diverse and only partially overlapping patterns, which may reflect their role in the differentiation of retina precursors, establishment of cell-fate and, ultimately, development of the stratified adult retina and other ocular structures. To begin understanding the molecular mechanisms underlying the regulation of miRNA expression, we also analysed the genomic location of the miRNA primary transcripts. The analysis revealed that most eye-expressed miRNAs overlap with or are in the near vicinity of uncharacterized transcripts derived predominantly from eye cDNA libraries. Expression analysis by RNA ISH in adult murine eye showed that some of these transcripts share very similar cellular distribution with their corresponding miRNAs, suggesting that miRNAs may share common expression regulatory elements with their host genes. The precise determination of the expression patterns of these miRNAs will be instrumental for a better understanding of the mechanisms controlling gene expression in the eye both in physiological and in pathological conditions.

Bronchoscope-Guided, Targeted Lobar Aersolization of HDAd into the Lungs of Baboons: Exceedingly High Pulmonary Transduction Throughout the Entire Lung with Negligible Toxicity. *P. Ng[1], P. Hiatt[2], R. McConnell[2], D. Palmer[1], Y. Zuo[1], D. Dimmock[1], M. Finegold[3], A. Beaudet[1], N. Brunetti-Pierri[1]* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Pulmonary Pediatrics, Baylor Col Medicine, Houston, TX; 3) Dept Pathology, Baylor Col Medicine, Houston, TX.

Uniform delivery of gene therapy vectors to all lung lobes will be important for CF gene therapy. This important objective has not been achieved in large animals. Therefore, we have developed an approach to specifically deliver vector into each of the lung lobes; an intracorporeal nebulizing catheter is inserted into a bronchoscope to permit visual targeted aerosolization of vector specifically into each lung lobe. Using this approach, 2 ml of 0.1% LPC containing $1x10^{12}$ vp of HDAd-K18LacZ was sequentially aerosolized into each lung lobe of a baboon. Halfway through the procedure a slight, transient and fluctuating decrease in O_2 saturation of no more than 2% was noted that did not warrant supplemental O_2. The procedure was otherwise uneventful and well tolerated with quick recovery. No changes in chest X-rays taken at 6 h, 24 h and at necropsy 72 h post-vector were observed compared to baseline. At necropsy, the lungs were stained with X-gal to reveal extensive transduction of the epithelium in the large and small airways in all lung lobes. Substantial transduction was exclusively restricted to the airway epithelial cells and submucosal glands, the target cells for CF gene therapy. Assessment of the proximal major bronchi from each lung lobe revealed that ~20% of the airway epithelial cells were transduced in the LUL, 90% were transduced in the LML, LLL, RUL, RML and RLL, and ~80% were transduced in the AC. Approximately 70% of the epithelial cells in the tracheal sections examined were transduced. These unprecedented results demonstrate that exceedingly high levels of transduction of the airway epithelial cells and submucosal glands throughout all lung lobes in a large animal can be achieved with negligible toxicity and should pave the way towards successful clinical CF gene therapy.

Novel technical approaches to prenatal diagnosis of genetics disorders. *D. Louesdon[1], C. Bernabe[1], E. Feyereisen[2], R. Frydman[2], A. Benachi[3], A. Yamgnane[3], Y. Dumez[3], A. Munnich[1], J. Steffann[1], J.P. Bonnefont[1]* 1) Department of Genetics, INSERM unit U781, Hopital Necker,Paris, France; 2) Obstetrics and Reproductive medicine unit, Hopital A. Béclère, Clamart, France; 3) Obstetrics unit, Hopital Necker, Paris, France.

The development of early, non invasive, simple, and low-cost procedures for PND is an important challenge for medical genetics. Amniocentesis and chorionic villous sampling, currently the methods of choice, are implemented late during the gestation (10-14 weeks), carry a fetus loss risk (0.5-1.0 %), and remain costly. Optional techniques based on the isolation of fetal DNA or fetal cells from maternal blood or transcervical sampling have not proven to be suitable for a routine implementation so far. Thanks to the presence of trophoblastic fetal cells in the endocervical canal of pregnant women at as soon as 5 weeks of gestation, we developed two approaches based on analysis of nucleated elements from transcervical cell samples, retrieved by endocervical lavage (16 women) or by cytobrush (19 women) at various terms of gestation. Presumptive fetal cells (syncitiotrophoblastic/ cytotrophoblastic cells) were isolated, based on their morphological characteristics, using an inverted microscope. Single cell DNAs were subjected to whole genome amplification, and subsequently haplotyped along with parental DNAs, using multiplex polymorphic markers. 60 presumptive fetal cells from 19 women (8-11 weeks of gestation) were retrieved by cytobrush. half of the DNAs failed to appropriately amplify. Only 2 of the remaining ones were shown to be fetal in origin, indicating that this approach is currently not suitable for a routine application. 99 presumptive fetal cells from 16 women (6-11 weeks of gestation) were retrieved by endocervical lavage. Prior to 8 weeks of gestation, 38 of the 66 cells were shown to be fetal (8/9 women). After 8 weeks of gestation, 24 of the 33 cells were shown to be fetal (4/7 women). This approach enabled us to carry out 3 successful early PND for various disorders (6-8 weeks of gestation). We are currently testing feasibility of fetal cells isolation by either approach at earlier terms of gestation.

Chromosome map reveals stage-specific gene signatures and identifies genetic hotspots during murine embryonic gonad development. *T.L. Lee[1], D. Alba[1], V. Baxendale[1], O.M. Rennert[1], W.Y. Chan[1, 2]* 1) Laboratory of Clinical Genomics, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD; 2) Departments of Pediatrics and Biochemistry & Molecular Biology, Georgetown University School of Medicine, Washington D.C.

Despite the identification of key genes like Sry to be integral during embryonic gonad development, the chromosomal activity and stage classification in the genomic context is still poorly understood. To understand the genetic events of gonad development, we performed Serial Analysis of Gene Expression (SAGE) to profile the transcriptome in male embryonic gonads at E10.5, E11.5, E12.5, E13.5, E15.5 and E17.5 with an average of 152K coverage. Instead of resorting to static descriptive analysis, we developed algorithms to assign the SAGE tags to the corresponding chromosomal position based on the Unigene assignments and displayed in chromosome graphic format using the completed mouse genome information. Chromosomal hotspots with significant changes at any time point will be highlighted based on co-localization of gene expression. This is useful for determining the importance of specific chromosomal region at particular time point and the potential consequences due to chromosome duplication or deletion. Furthermore, the biological implication of significant chromosomal clusters will be extracted and further analyzed by linking to different mutation and functional annotation databases. Altogether, we have identified more than 70,000 genes in the six gonad libraries, far beyond the Affymetrix microarray coverage. Importantly, we observed a prominently increase in global genomic activity from E10.5 to E17.5, and identified important chromosomal regions related to the developmental processes and validated by established mouse models with developmental disorders. Taken together, the representation of male gonad SAGE data in transcription maps format is a new way of visualizing transcriptome data and allows rapid identification of chromosomal segments important in male embryonic gonad development. These candidate regions represent possible treatment targets and as markers in early diagnosis for male developmental disorders.

Expansion of ALFRED, the ALlele FREquency Database. *K.K. Kidd[1], H. Rajeevan[1], K.-H. Cheung[1,2], R. Gadagkar[2], S. Stein[1], U. Soundararajan[1], J.R. Kidd[1], A.J. Pakstis[1], P.L. Miller[2]* 1) Department of Genetics; 2) Center for Medical Informatics; Yale University School of Medicine, New Haven, CT 06520-8005 USA.

ALFRED (http://Alfred.med.yale.edu) is an actively curated database designed to make allele frequency data on anthropologically defined human population samples readily available to the scientific community. It currently (June 1, 2006) has data on 1,688 polymorphisms and 498 populations with a total of 50,296 frequency tables (one population typed for one site). The database is updated on a daily basis. Over the past year the types and quantity of data have increased considerably and the unique collection of allele frequencies in ALFRED has been integrated into the broader set of genetic databases by links *from* PharmGKB and dbSNP *to* ALFRED. Among various searching option enhancements is the ability to display gene/locus information in chromosomal order in addition to alphabetical order.

The number of allele frequency tables has almost doubled in the past year. Currently, the frequencies for hundreds of genetic markers typed by Marshfield on many populations are being loaded into ALFRED. Genotype data is now also stored in ALFRED. Genotype tables for only 47 polymorphic sites typed on 40 populations have been entered so far but more are being added as quickly as possible. ALFRED description pages can now be accessed from dbSNP by direct URL links from rs# definition/description pages. When ALFRED has frequency data for a polymorphism with an rs#, the frequency section of the dbSNP page indicates Additional frequency data available with an active link to the site page in ALFRED. From that page frequency data can be displayed in several different formats and/or downloaded as text or in XML format. Similar links also exist from PharmGKB to the relevant ALFRED locus page and site page. As new data are added to ALFRED, those links are updated. The newest display option in ALFRED provides pie charts displayed on a global map. The GIS format has been upgraded and allows selection of populations by geographic region as well as the display of frequencies. ALFRED is supported by US NSF BC0096588.

Significant associations between MTHFR gene polymorphism and obesity traits were found in a large family sample. *X.G. Liu[1,2], L.J. Zhao[3], D.H. Xiong[3], R.R. Recker[3], H.W. Deng[1,2,3]* 1) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xian, Shaanxi, 710049, China; 2) Department of Orthopedic Surgery and Basic Medical Sciences, School of Medicine, University of Missouri- Kansas City, Kansas City, Missouri, 64108-2792, USA; 3) Osteoporosis Research Center and Department of Biomedical Sciences, Creighton University, Omaha, Nebraska, 68131, USA.

Background: It is well established that Methylene tetrahydrofolate reductase (MTHFR) palys an important role in bone metabolism. Studies indicated that MTHFR indirectly correlated with obesity. This study was to test the hypothesis that MTHFR is associated with obesity traits.

Materials and Methods: 1,873 US Caucasians with European origin in 405 nuclear families were recruited. Fat mass, lean mass, and percentage fat mass (PFM) were measured with dual x-ray absorptiometry (DXA). Body mass index (BMI) was calculated from weight to height square. Five selected single nucleotide polymorphisms (SNPs) around the MTHFR gene were genotyped. family-based association test (FBAT) and QTDT (quantitative transmission disequilibrium test) were performed to test the association between the MTHFR gene and the four obesity-related phenotypes.

Results: In within-family-association analysis implemented in QTDT, significant association were found between rs17037390 (located at intron4 of MTHFR gene) and fat mass (P=0.0075), lean mass (P=0.0122), BMI (P=0.0132) and PFM (P=0.0136). These associations were all confirmed in the FBAT analysis by P-value of 0.0051, 0.0123, 0.0068, and 0.011362, respectively. After correcting for the overly conservative Bonferroni correction, the associations remained significant between rs17037390 and fat mass (P=0.0257), BMI (P=0.0345) in FBAT test, and between rs17037390 and fat mass (P=0.0375) in QTDT analysis.

Conclusion: The MTHFR gene is associated with obesity.

X-chromosome inactivation patterns in multiple sclerosis: a twin study. *B.M. Herrera[1, 2], K.M.E. Morrison[1, 2], S.V. Ramagopalan[1, 2], M.R. Lincoln[1, 2], S. Orton[1, 2], M.J. Chao[1, 2], M.Z. Cader[1, 2], G.C. Ebers[1, 2]* 1) Wellcome Trust Centre for Human Genetics, Oxfordshire, United Kingdom, OX3 7BN; 2) Department of Clinical Neurology, University of Oxford, United Kingdom, OX2 6HG.

Multiple Sclerosis (MS), like many other autoimmune diseases has a higher prevalence among females (female: male ratio of ~2.4:1). There is clear evidence of a maternal parent-of-origin effect which remains unexplained. X-linked transmission of susceptibility has been previously proposed; however linkage and association studies have provided some inconclusive support for a susceptibility locus for MS on the X-chromosome. In order to compensate for gene dosage, female embryos undergo a random process of X-chromosome inactivation (XCI). The inactivation is stable and transmitted to the progeny cells. Studies have shown skewed XCI to be a possible operating factor in autoimmune diseases. In this study we investigate the role of skewed XCI patterns in MS. We used a cohort of 188 concordant and discordant twin pairs from the CCPGSMS (95 MZ and 93 DZ) to investigate XCI patterns; we analyzed the androgen receptor (AR) locus using a fluorescent HpaII/polymerase chain reaction assay. The lack of success from high density linkage and association studies in the search for susceptibility genes to MS, suggests that it is time to move away from the Mendelian paradigm and take into account secondary inheritance mechanisms which have so far been overlooked in studies of complex disease. Similarly to other studies, our results indicate that skewed XCI mosaicism may play a role in the pathogenesis of multiple sclerosis.

Extreme phenotypic variations within a family with SALL1 mutations: Isolated preaxial polydactyly to Goldenhar syndrome-like phenotype. *K. Kosaki[1], R. Kosaki[2], H. Samejima[1], C. Torii[1], R. Fujimaru[3], H. Yamada[4], K. Iijima[2]* 1) Keio Univ, Dept Pediatr, Tokyo, Japan; 2) Natl Ctr Child Health & Development,Tokyo, Japan; 3) Osaka City Kita Hosp, Dept Pediatr, Osaka, Japan; 4) Osaka City General Hospital, Dept Pediatr, Osaka, Japan.

Townes-Brocks syndome (TBS) is a genetic disorder caused by mutations in SALL1 whereas Goldenhar syndrome (GS), which phenotypically resembles TBS, is considered to be a non-genetic disorder caused by a vascular accident in the embryonic stapedial artery. We report extreme phenotypic variations within a family with SALL1 mutations; the elder sister presented with a TBS-like phenotype including external ear anomalies, preaxial polydactyly, and anteriorly placed anus, whereas the younger sister presented with a GS-like syndrome phenotype including atretic ear canals, mandibular hypoplasia, and right preaxial polydactyly as well as epibulbar dermoid. The mother had triphalangeal thumbs but was otherwise structurally normal and the father was asymptomatic. Analysis of the SALL1 gene revealed that both daughters were heterozygous for non-sense mutation L419X within the first zinc finger domain. In addition, both daughters were heterozygous for a missense substitution P270L. The P270 residue is highly conserved among various vertebrate species and the P270L substitution was not present among 100 control individuals. The mother was heterozygous for L419X and the father was heterozygous for P270L. Hence, the daughters were compound heterozygotes for L419X and P270L. Obviously, heterozygosity for the P270L does not, in itself, have any detrimental effect because the father was devoid of any features attributable to the SALL1 mutation. However, the P270L may be functionally relevant in that the P270 residue is highly conserved and may have contributed to the severity of the phenotype in the daughters who had concurrent L419X mutation. To our knowledge, the younger daughter is the first patient with a SALL1 mutation to exhibit classic GS-like phenotype with epibulbar dermoid. The observation lends further support to the concept that GS is an etiologically heterogeneous disorder that may have a genetic basis in some cases.

Experience with the uptake of preimplanatation genetic diagnosis (PGD) for the purpose of family balancing. *S.L. McAdoo, R.R. Sharp, L. McCullough, S.A. Carson, P. Amato, J.E. Buster, J.A. Hamilton, F.Z. Bischoff, P.L. Cisneros, J.L. Simpson* Baylor College of Medicine, Houston, TX.

INTRODUCTION: Couples having one or more children of a given sex may desire a child of the opposite sex for purposes of family balancing. The publics opinions on gender preferences and selection have been surveyed often, but data have not been elicited from couples actually willing to pursue the laborious and costly methods (IVF with PGD) to do so. The objective of this study was to characterize couples willing to consider undergoing PGD for family balancing. METHODS: Press releases were disseminated through multiple media outlets. Those responding underwent a telephone screen to determine eligibility. Exclusion criteria included couples without prior children, couples medically ineligible for IVF, and couples who require assisted reproductive methods to achieve pregnancy. At that time, limited demographic information was collected and a short overview of the study and necessary technology provided. RESULTS: A total of 158 couples were screened. Of these, 24 (15%) did not meet eligibility, 64 (41%) failed to return our follow-up phone calls or could not be re-contacted, 19 (12%) declined (typically due to cost). There remained 51 couples (32%) with full expectations of proceeding to the interview stage. Subjects consisted of 58% Caucasian, 12% Hispanic, and 4% each of Middle Eastern, African-American, or Asian, and 18% of mixed ethnicity. Approximately two-thirds were from Texas. The group was religiously diverse: Protestant 38%, Catholic 29%, no religion 16%, Jewish 4%, other 13%. Mean ages were 36 years (male) and 33 years (female). Eighty-four percent had at least 2 prior children of one sex, and 16% had only one child. Twenty-eight (56%) desired a boy. It is of note that out of the initial group of 51, only 18 actually came for the scheduled visit. CONCLUSION: Family balancing and gender selection elicit wide-spread public interest, but few couples seem committed to proceeding once informed of procedure details, financial costs, and physical demands of PGD. Open access to PGD for family balancing is unlikely to generate huge demands in the U.S.

Novel mutations in four patients with pyruvate carboxylase deficiency. *S. MONNOT[1, 2], V. SERRE[1], B. CHADEFAUX-VEKEMANS[3], S. ROMANO[4], P. DE LONLAY[4], J. AUPETIT[3], V. PAQUIS[2], A. MUNNICH[1], J.P. BONNEFONT[1]* 1) Medical Genetics, INSERM unit U781, Hopital Necker, Paris,; 2) Medical Genetics, Hopital Archet 2, Nice,; 3) Metabolic Biochemistry, Hopital Necker, Paris,; 4) Pediatrics, Hopital Necker, Paris, France.

Isolated pyruvate carboxylase (PC) deficiency (Biotin-unresponsive) is a rare metabolic disorder inherited in an autosomal recessive way. Three phenotypes have been described, based on seriousness of the clinical presentation. Only 6 mutations of the PC gene have been reported so far. We screened the PC gene in four unrelated families with PC deficiency. Three Caucasian patients presented with the French form of the disease,of whom two died in the first week of life, and the third one at 7 months. Another patient, born to consanguineous parents from Saudi Arabia, currently 2 years old, suffered mental retardation and recurrent lactic acidosis episodes (American form). PC enzymatic activity was undetectable in all patient fibroblasts. Direct sequencing of the 23 exons of the PC gene on genomic DNA identified 6 novel variants, namely, heterozygous c.911AG (exon 7, p.Tyr304Cys) and IVS7-1GT for patient 1, homozygous c.467GA (exon 3, p.Arg156Gln) for patient 2, heterozygous c.1748GT (exon 12, p.Arg583Leu), and c.2876dupT (exon 17) for patient 3, and heterozygous c.3392_3400del9nt (exon 20) for patient 4. Scanning of one hundred control chromosomes failed to detect any of the missense mutations. cDNA sequencing showed that the splice mutation and the duplication resulted in RNA decay, while the remaining mutations had no apparent effect on the mRNA. At the protein level, *i)* missense mutations were located in highly conserved amino-acid domains of the protein, *ii)* we took advantage of the similarities of the PC with the biotin carboxylase subunit of *Aquifex aeolicus* PC and the *Propionibacterium shermanii* transcarboxylase to model the putative impacts of these mutations on protein conformation. Taking into account available molecular data, it appears that truncating mutations are predominantly found in the French phenotype, while missense mutations are more frequently associated with the American form of the disease.

Localization of chronic obstructive pulmonary disease susceptibility genes on chromosome 2q. *C.P. Hersh, R. Lazarus, B.J. Klanderman, B.A. Raby, A.A. Litonjua, D.L. DeMeo, J. J. Reilly, S.T. Weiss, E.K. Silverman* Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Rationale: In the Boston Early-Onset Chronic Obstructive Pulmonary Disease (COPD) Study families, significant evidence for linkage of COPD-related traits has been demonstrated on chromosome 2q. To date, only one potential COPD susceptibility gene in the region has been identified (SERPINE2).

Methods: In the first phase, we genotyped 1402 SNPs across the 20 Mb linked region in 309 cases with severe COPD from the National Emphysema Treatment Trial and 330 control smokers without airflow obstruction. In the second phase, we genotyped 914 SNPs in significant regions from phase 1 in the same cases and controls. To follow-up significant results from phase 2, 122 SNPs were genotyped in 949 individuals from 127 families in the Boston Early-Onset COPD Study.

Results: Based on single SNP and haplotype association analysis of phase 1, we focused on 50 regions for phase 2. After phase 2 genotyping, the evidence for association increased in 11 of these regions. In one of the 11 regions, spanning 300kb, 9 SNPs in two genes, XRCC5 (X-ray repair complementing defective repair in Chinese hamster cells 5; ATP-dependent DNA helicase II) and PECR (peroxisomal trans-2-enoyl-CoA reductase), showed replicated associations in the family-based study.

Conclusions: Dense fine mapping of chromosome 2q has identified two genes with replicated association for COPD-related traits. In order to validate and generalize these results, studies in additional populations are ongoing.

Support: NIH grants HL080242, HL71393, HL075478; ALA Career Investigator Award; Alpha-1 Foundation.

The PTPN22 gene and type 1 diabetes in children. *YJ. Lee[1, 2, 5], CY. Huang[1], SG. Shu[3], FS. Lo[4], CL. Lin[2], CK. Chen[2], ZC. Wang[2], HF. Liu[2], CC. Chu[2], M. Lin[2], FY. Huang[1,5]* 1) Dept Pediatrics; 2) Dept Medical Res, Mackay Memorial Hosp, Tamshui, Taipei; 3) Dept Pediatrics, Taichung Veterans General Hospital, Taichung; 4) Div Endocrinology, Dept Medicine, Chang Gung Children's Hospital, Taoyuan; 5) Dept Pediatrics, Taipei Medical University, Taipei; Taiwan.

dbSNP rs2476601, a functional SNP (C/T) in the PTPN22 gene, is associated with type 1 diabetes (**T1D**) and other autoimmune diseases in both Caucasians and Sardinians. However, this SNP is not present in Japanese but a SNP in the promoter region (rs2488457) of the gene was found to be associated with T1D in Japanese and Koreans. Thus, it is worthwhile to investigate the PTPN22 gene in other ethnicity. **Subjects** The patients were 374 unrelated children (178 boys, 196 girls) with T1D. Their age of diagnosis was 7.3 3.9 (0.3 - 16.2) years. The controls were 303 hospital personnel and individuals having a routine health examination or minor surgery. None had a history of autoimmune disease. All individuals were Chinese living in Taiwan. The individuals studied gave informed consent and the study was approved by the Institutional Review Board. **Methods** The genotype of dbSNP rs2476601 was C/C in all 30 of the patients and 29 of the controls using both RFLP and sequencing from both directions. Thus, this SNP did not exist in Chinese investigated. Then 4 SNPs including rs2488457 (promoter), rs1217419 (IVS2), rs2797415 (IVS15) and rs1217412 (Exon 21), scattering in the PTPN22 gene were genotyped using RFLP or TagMan (ABI) method. GAD-Ab and IA2-Ab were measured in most patients. Those with positive autoantibodies were considered to have type 1A diabetes **(T1AD)**. **Results** There were no significant difference in the frequencies of genotype, allele and phenotype in the 4 SNPs between T1D patients and controls. Similar findings were also noted between patients with T1AD and controls except for a marginally significant difference was detected in T phenotype of SNP rs1217412 between patients with T1AD and controls [187 (67.3%) vs 181 (59.7%), OR 1.39, 95% CI 0.99-1.95, p=0.06.] **Conclusions** The PTPN22 gene might not be associated with T1D in Chinese children. Genotyping rs1217412 and other SNPs in a larger dataset is necessary.

TLR4 and cardiovascular and metabolic phenotypes in myocardial infarction survivors. *F. Nyberg[1,2], T. Illig[3], M. Kolz[3], T. Bellander[1,4], F. Forastiere[5], K. Katsouyanni[6], J. Pekkanen[7], J. Sunyer[8], A. Peters[3], AIRGENE Study Group* 1) Institute of Environmental Medicine, Karolinska Institute, Stockholm, Sweden; 2) Medical Sci/Epidemiology, AstraZeneca R&D Molndal, Molndal, Sweden; 3) Institute of Epidemiologie, GSF-Forschungszentrum, Neuherberg, Germany; 4) Department of Occupational and Environmental Health, Stockholm County Council, Stockholm, Sweden; 5) Local Health Authority RME, Department of Epidemiology ASL, Rome, Italy; 6) Department of Hygiene and Epidemiology, University of Athens, Athens, Greece; 7) Department of Environmental Health, National Public Health Institute (KTL), Kuopio, Finland; 8) Institut Municipal d'Investigació Médica. (IMIM), Barcelona, Spain.

Background: TLR4 has been suggested as a candidate gene for cardiovascular disease and metabolic phenotypes (coronary heart disease, acute coronary syndrome, myocardial infarction (MI), hyperlipidemia-induced atherosclerosis etc) and may modify the treatment effect of statins. Since TLR4 has many functions and affects many pathways it is of interest for understanding disease mechanisms to explore how TLR4 associates with different cardiovascular and metabolic phenotypes in MI survivors

Methods: We recruited 1003 MI survivors aged 37-81 years in 6 countries across Europe for follow-up of inflammatory markers. At baseline, history of coronary heart disease and other comorbidities was assessed, as well as blood lipids. Candidate genes were genotyped for selected SNPs.

Results: Several SNPs in TLR4 were associated with angina pectoris, arrhythmia, total cholesterol, HDL cholesterol as well as the ratio of HDL to total cholesterol at baseline.

Discussion: This study in a sample of MI patients provides evidence that TLR4 is of importance for cardiovascular and metabolic phenotypes in MI survivors. In particular, TLR4 seems to be intimately involved in aspects of lipid regulation, supporting its reported role in modifying the treatment effect of statins.

Beta Evaluation of the NanoChip 400 *CFTR* assay for Cystic Fibrosis carrier detection in a tertiary care hospital.
N.I. Lindeman, P. Flatley, D. Hall, P. Jarolim, J.A. Longtine Pathology, Brigham & Women's Hospital, Boston, MA.

Background: The NanoChip 400 (Nanogen, Inc., San Diego, CA) is a semi-automated array-based hybridization system that uses microelectronics to address individual biomolecules to different positions on a microchip array for multiplexed hybridization testing of amplified DNA. The ability of this system to perform testing for Cystic Fibrosis carrier assessment was evaluated on clinical samples from patients at the Brigham and Women's Hospital (Boston, MA) to aid in establishing performance characteristics for CE-IVD labeling. **Methods:** Whole blood samples from patients undergoing CF carrier screening were separated into two aliquots, one of which was sent to a referral laboratory (Genzyme Genetics, Framingham, MA) for diagnostic testing, while the other was stored in a refrigerator until analysis. 65 samples, 21 with and 44 without *CFTR* mutations, were tested in duplicate using the NanoChip 400, using beta reagents and protocols supplied by the manufacturer. In addition, 12 DNA samples from cell lines with *CFTR* mutations were also tested. Results were compared with those obtained by the reference laboratory and by in-house testing with an INVADER (Third Wave Technologies, Madison, WI) assay. **Results:** All samples (100%) gave the correct results, in both duplicate measurements, when compared with the reference laboratory and the INVADER results. The assay was technically straightforward, although the manual set-up procedures required a moderately high level of technologist concentration to prevent human error, and hardware failures involving the waste container, reagent sensor, and one lot of cartridges necessitated repeat analysis of 3 of 11 assay runs. Overall technologist time was comparable to the INVADER assay. **Conclusions:** The NanoChip 400 beta *CFTR* assay performed accurately and precisely, and no diagnostic errors were encountered in 65 clinical samples and 12 cell line samples. All 23 mutations on the ACOG/ACMG-recommended panel were genotyped properly. Minor modifications to hardware and software could improve the overall system performance, by minimizing instrument failure and the potential for human error during set-up.

Target DNA Production for Chip Resequencing. *D. T. Okou, M. E. Zwick* Human Genetics, Emory University School of Medicine, Atlanta, GA.

Resequencing genomic regions using high-density resequencing arrays (RAs) requires efficient methods of target DNA production. Current RAs can resequence up to 300kb per chip. We are exploring methods of target DNA production that are scalable to large genomic regions. One approach, Transformation-Associated Recombination (TAR) cloning technique allows direct isolation of up to 300 kb of specific chromosomal regions and genes from mammalian genomes. The technique is based on homologous recombination between a vector containing a gene-specific sequence and genomic DNA fragment during co-transformation into yeast spheroplasts. It results in the rescuing of chromosomal regions in yeast as linear or circular Yeast Artificial Chromosomes (YACs). We will present data contrasting TAR cloning with traditional Long PCR (LPCR) methods of target DNA production from both BACs and human genomic DNA. The performance of 300kb RAs using target DNA generated from these methods will be presented.

Genome scanning of chromosome 21 identifies DYRK1A gene as a risk factor for late-onset Alzheimer disease. *R. Kimura[1], K. Kamino[1], M. Yamamoto[1], T. Tanaka[1], T. Kudo[1], H. Akatsu[2], H. Yamagata[3], T. Miki[4], M. Takeda[1]* 1) Post-Genomics and Diseases, Osaka University Graduate School of Medicine, Suita, Osaka, Japan; 2) Choju Medical Institute, Fukushimura Hospital, Toyohashi, Aichi, Japan; 3) Preventive Medicine, Ehime University Graduate School of Medicine, Toon, Ehime, Japan; 4) Geriatric Medicine, Ehime University Graduate School of Medicine, Toon, Ehime, Japan.

Late-onset Alzheimer disease (LOAD) is caused by genetic and environmental factors upon aging. Chromosome 21 is triplicated in Down syndrome, known as a condition of very early-onset AD, and genome scanning of familial LOAD also supported a risk locus at chromosome 21. To elucidate risk loci at this chromosome, we performed a genome scanning of chromosome 21, using SNPs spaced at 100kb-interval including at least one SNP in each coding region. By linkage disequilibrium (LD) mapping using 378 AD and 375 population-based controls, eight loci indicated significant LD with LOAD by allele frequency at $p<0.05$. The most significant association was found in DYRK1A (dual-specificity tyrosine regulated kinase 1A) gene ($p<0.003$), encoded within Down syndrome critical region (DSCR). The transcript of the DYRK1A gene in AD hippocampus was significantly higher than that of non-demented control. In SH-SY5Y cells, beta amyloid induced the expression of Dyrk1a protein, and overexpression of the DYRK1A gene increased phosphorylation of tau at Thr212. These results indicate that the DYRK1A gene is a genetic factor of LOAD encoded at chromosome 21, mediated by the interaction with beta amyloid and tau phosphorylation.

A clinical retrospective study of orofacial clefting frequency in different ethnic populations from the UCSF craniofacial clinic database shows Hispanics have a high frequency of additional anomalies. *E.W.Y. Hsieh[1], R-F. Yeh[2], S. Oberoi[3], K. Vargevik[3], A.M. Slavotinek[1]* 1) Department of Pediatrics, Division of Genetics, UCSF School of Medicine, San Francisco, CA; 2) Center for Bioinformatics and Molecular Biostatistics, UCSF, San Francisco, CA; 3) Center for Craniofacial Anomalies, UCSF, San Francisco, CA.

Opitz G/BBB syndrome is a multiple congenital anomaly syndrome characterized by developmental anomalies affecting the midline including hypertelorism, cleft lip and/or cleft palate (CLP), and hypospadias. This syndrome and orofacial clefting greatly affect the Hispanic population but their relative frequency in this population is unknown. Our goal is to determine if there are ethnic differences in the frequency of patients who have CLP, either as part of a syndrome, such as Opitz G/BBB, or as an isolated finding. We performed a retrospective analysis of 296 medical records of CLP patients referred to the UCSF craniofacial clinic. We recorded information about patient age, sex, type of cleft, presence of additional anomalies, syndrome diagnosis if present, and ethnicity, and analyzed our results using chi-squared tests. Our analysis revealed that the maternal ethnic distribution of patients with CLP with additional anomalies is different from the ethnic distribution of the patient population at UCSF craniofacial clinic. Hispanics represented 35.96% of the UCSF craniofacial clinic patients with CLP and multiple congenital anomalies while they constituted only 34.71% of the UCSF craniofacial clinic total patient population (p-value of 0.0476). There were a total of 90 CLP cases with additional anomalies in the 296 medical records analyzed, 35 of which were of Hispanic ethnicity (38.9%). Only 36/90 (40%) of CLP patients belonging to all ethnicities who had additional anomalies received a diagnosis, most frequently Van der Woude syndrome (10/36 = 27.78%) and Opitz syndrome (4/36 = 11.11%). In conclusion, amongst the UCSF craniofacial clinic patients with CLP, Hispanic CLP patients had a higher than expected frequency of additional anomalies, warranting careful examination and evaluation for signs of a syndrome diagnosis.

Population genetic data set of hundreds of thousands of SNPs free of ascertainment bias. *A. Keinan[1], J.C. Mullikin[2], N. Patterson[3], D. Reich[1,3]* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) Program in Medical and Population Genetics, The Broad Institute, Cambridge, MA.

One of the hoped-for products of the International Haplotype Map Project (HapMap) was a large data set that could be used for making inferences about human demographic history. Unfortunately, the first 1.1 million SNPs (Phase I) were identified using different strategies by each of the participating centers and in ways that changed over time, which made it very difficult to make inferences about demographic history from these data. From Phase II of HapMap, however, we were able to identify a subset of SNPs that were free of ascertainment bias and useable for demographic analysis. We took advantage of the fact that for Phase II, essentially every SNP that was available in public databases at the time of marker picking was chosen for genotyping.

The key insight was to focus on Self-SNPs, defined as all the SNPs obtained by comparison of shotgun sequencing reads from a specific individual. These SNPs have a simple ascertainment as they are obtained by comparing two chromosomes from the same ancestral background (an individuals two haplotypes). Our initial analysis focused on self-SNPs from seven individuals: 2 European Americans, 2 East Asians, 2 African Americans, and a Mbuti Pygmy. We studied the frequency distribution of each Self-SNP set (tens to hundreds of thousands of SNPs) in the 420 worldwide chromosomes genotyped in HapMap.

Initial analysis of the unbiased frequency distributions focused on comparing the European Americans with the East Asians, two populations that are commonly assumed to share a very similar demographic history. Our rigorous full-likelihood analysis points to a significantly more severe out-of-Africa population bottleneck in the history of East Asians. We further estimated the intensities and timing of the main demographic events experienced by these two populations.

Serotonin Transporter mRNA Levels are associated with the Methylation of an CpG Island. *A. Madan, R. Philibert, A. Anderson, R. Cadoret, H. Packer, H. Sandhu* Neurosurgery, University of Iowa, Iowa City, IA.

The serotonin reuptake transporter (5HTT) is thought to be the principal regulator of serotonergic activity and epigenetic effects at this locus are thought to be important moderators of vulnerability to neuropsychiatric illness. In attempt to understand the basis of this regulation, several gene polymorphisms that affect 5HTT mRNA levels have been described. But to date, no clear mechanism linking these polymorphisms to vulnerability to epigenetic effects have been described. We describe a CpG island in the 5 region of the 5HTT gene that contains an alternative exon 1 and possible promoter for 5HTT. We then confirm the existence of this transcript and ascertain the methylation status of this CpG island in 49 lymphoblast cell lines and analyze the relationship between methylation and 5HTT mRNA levels. We demonstrate that methylation at this CpG island is associated with decreased levels of 5HTT mRNA, but that this effect is evident only when 5HTTLPR genotype is taken into account. We suggest that these findings have significant implications for the understanding of the role of this locus in behavioral illness.

Metabolic polymorphisms as markers for pediatric cancer risk following genotoxic exposure. *H.E.J. Kendall, P.M. Vacek, B.A. Finette* University of Vermont, Departments of Pediatrics, Microbiology and Molecular Genetics, and Medical Biostatistics, Burlington, VT.

Polymorphisms in metabolic enzymes can affect the detoxification of chemicals by varying rates of biotransformation. This can increase internal doses of mutagenic substances, susceptibility for acquiring mutations, and cancer risk. We are investigating whether the prevalence of polymorphisms in metabolic enzymes are associated with pediatric cancer risk following exposure to genotoxic chemicals. Our focus is on children from a pediatric cancer cluster in Toms River, NJ from 1979-1995, who were shown to have a 70% higher incidence of cancer as a consequence of consuming contaminated drinking water. Specific aim: Determine the frequency of 26 polymorphisms in 13 metabolic genes, in (A) children from Toms River, who developed cancer and were exposed to contaminated drinking water, (B) exposed siblings who did not develop cancer, (C) children with no known genotoxic exposure who developed cancer, and (D) healthy children with no known genotoxic exposure who did not develop cancer. Polymorphism analysis was performed using TaqMan allelic discrimination, PCR, restriction analysis and single-nucleotide extension. To date, we have analyzed 7 polymorphisms from 121 subjects. Analysis at the *EPHX1* (T/C: Tyr113His) locus revealed a statistically significant association with the number of copies of the C allele in the exposed Toms River cancer cases. Although the remaining polymorphisms showed no statistically significant difference in prevalence, likely due to limited power, there are a number of potentially important observations. The Neg/Neg genotype for the *GSTT1* deletion polymorphism occurred in 27.6% of the exposed cancer cases, compared to 18.4% in the siblings and 16.3% in healthy controls. The Pos/Pos *GSTT1* genotype occurred in 34.5% of the exposed cancer cases, compared to 46.9% of siblings. *NAT2* polymorphisms (T341C C/C; A803G G/G; G857A G/A) were all higher in the exposed cancer cases compared to exposed non-cancer siblings. Continued analysis will determine the utility of metabolic polymorphisms as biomarkers for pediatric cancer risk following genotoxic exposure.

Investigation of age-related cognitive decline and memory loss among *FMR1* premutation allele carriers. *J.E. Hunter[1], E.G. Allen[1], A. Abramowitz[2], M. Rusin[3], R. Letz[4], M. Leslie[1], L. Shubeck[1], G. Novak[1], S. Sherman[1]* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Psychology, Emory University, Atlanta, GA; 3) Department of Rehabilitation Medicine, Emory University, Atlanta, GA; 4) Department of Behavioral Sciences and Health Education, Rollins School of Public Health, Emory University, Atlanta, GA.

Fragile X mental retardation gene (*FMR1*) alleles with long unmethylated CGG repeats in the range of ~59-199, termed premutation alleles, have recently been associated with a tremor/ataxia syndrome (FXTAS) in older males. This condition is unrelated to the fragile X syndrome phenotype associated with highly methylated alleles with greater than 200 repeats. Cognitive decline and short-term memory loss are well-documented symptoms of FXTAS. To examine the progression of symptoms associated with FXTAS, we investigated the age-related decline of memory and cognition in a cross-section study of 131 males and 364 females age 18-84 with varying repeat size. The Wechsler Adult Intelligence Scale (WAIS-III) provided cognition measures including full-scale IQ (FSIQ), verbal IQ (VIQ), and performance IQ (PIQ) as well as a working memory index (WMI). The Wechsler Memory Scale (WMS-III) provided visual and logical memory measures for immediate and delayed recall as well as delayed recognition. Among cognitive measures, only VIQ showed a significant negative association with repeat size ($p<0.05$). For memory, WMI was significantly lower for premutation carriers compared with noncarriers ($p<0.05$) only when repeat size groups were used. When repeat size was defined as continuous, logical memory immediate and delayed recall scores were positively associated with repeat size ($p=0.05$ and $p=0.03$, respectively), but only explained about 1% of the variance. Age and gender by repeat size interaction were not significant for any measures. Results indicate that there is not a detectable difference in the age-related rate of memory or cognitive decline between premutation carriers and noncarriers. However, independent of age, premutation carriers seem to have relative deficits in working memory and verbal IQ.

Association of Progerin-Interactive Partners with Lamina Proteins. *W. Ju, G. Radu, W.T. Brown, N. Zhong* Dept Human Genetics, New York State Inst Basic Res, Staten Island, NY.

The Hutchinson-Gilford progeria syndrome (HGPS or progeria) is a premature aging disorder of childhood. It results from a dominant negative effect of progerin, which is the truncated protein encoded by a mutant LMNA gene carrying G608G mutation. The detailed pathogenic mechanism of progerin involved in HGPS is yet unclear. To study this unknown mechanism, we have earlier identified four novel progerin-interactive partner proteins (PIPs), including hnRNP E1, EGF, Mel18, and UBC9. These PIPs were found to have no differential interaction with normal lamin A/C when compared to progerin. To further investigate whether there is any abnormality that PIPs associate with lamina proteins, we performed co-immunoprecipitations in both normal and HGPS cells. Our results showed that (1) all PIPs but Mel18 associate with lamin B1, (2) all PIPs but UBC9 associate with emerin, (3) UBC9, EGF, and hnRNP E1 associate with SREBP, and (4) UBC9 and hnRNP E1 associate with LAP2a. The co-immunoprecipitations showed that UBC9 was able to pull down Mel18, EGF, and hnRNP E1; EGF pulled down UBC9 and hnRNP E1; and Mel18 pulled down hnRNP E1. Although our earlier results demonstrated that PIPs were co-immunoprecipitated with lamin A/C and progerin, the current study showed that progerin only pulls down hnRNP E1 but not EGF, nor UBC9. No significant difference could be noticed between normal and HGPS conditions. We also investigated if PIPs change their subcellular localization in the HGPS condition. Immunostaining of PIPs with nuclear markers, including progerin, showed that immuno-signals of all PIPs were within nuclei and there was no difference between normal and HGPS cells. Our results indicated that PIPs associate with lamina proteins; however, they are unlikely involved in the pathogenesis of HGPS.

Clinical Predictors of risk of Optic Pathway Glioma in Neurofibromatosis Type-1 patients. *A. Mian[1], J. Perentesis[1], E. Schorry[2], H.S. Lee[3], R. Chakraborty[3], B. Chakraborty[4]* 1) Div of Hematology-Oncology, Cincinnati Children's Hospital, Cincinnati, OH; 2) Div. of Human Genetics, Cincinnati Children's Hospital, Cincinnati, OH; 3) Center for Genome Info, University of Cincinnati, Cincinnati, OH; 4) Dpt Env Health, University of Cincinnati, Cincinnati, OH.

Neurofibromatosis type-1 (NF-1), an autosomal dominant disease, is characterized by widely variable clinical features. These patients are at an increased risk of developing wide variety of benign and malignant neoplasia. Optic pathway glioma (OPG) occurs in almost 20% of NF-1 patients. There is poor genotype-phenotype correlation and limited data to quantify the risk of tumor development when preceded by specific clinical features. We hypothesized that presence of specific clinical features in NF-1 patients can predict their risk for subsequent OPG development. Based on logistic regression modeling of data on 75 cases (NF-1 patients with subsequent development of OPG) and 215 controls (NF-1 patients without OPG or co-existing neoplasia), we observed that patients with ages 4 years or less at diagnosis of NF-1 (odd ratio, OR=3.8, p=0.002), presence of T-2 hyperintense lesions (UBOs) on imaging (OR=3.3, p=0.005), developmental delay (OR=1.8, p=0.04) and seizures (OR=13.0, p=0.07) appear to be at an increased risk of developing subsequent OPG compared to the patients without these clinical features. Race (Caucasian) appears to have a disease modifying effect on progression. Early age of diagnosis of NF-1 and presence of seizures also have an interaction effect (OR=5.3, p=0.029). In an attempt to define the high risk group of NF-1 patients who may develop OPG subsequently, a composite score with these risk factors was computed, based on the estimated coefficients of the logistic regression model. This score provides an appreciable sensitivity (82%), but modest (47%) specificity in predicting subsequent development of OPG in NF-1 patients. These findings indicate that combinations of clinical features of NF-1 may be used to define the high risk group of NF-1 patients who are prone to develop OPG. Consequently, such high risk patients may benefit from frequent screening and follow up for early detection of OPG.

A Practical View of Genome-Wide Association Studies. *M. Li[1], W. Guan[2], R.S. Spielman[1], C. Li[3]* 1) Univ Pennsylvania; 2) Univ Michigan; 3) Vanderbilt Univ.

Genome-wide association studies (GWAS) are a powerful approach to identify common genetic variants that predispose to complex diseases. Its success will depend on many factors, including the effect size of disease genes, the degree of LD between tagSNPs and disease loci, and the sample size. In this project, we examine the impact of these factors on power of GWAS. Based on the phased HapMap CEU sample, we simulated 300K SNP genotype data using SNPs of Illuminas HumanHap300. We also selected 100K and 500K SNPs from the HapMap by deleting or adding SNPs to the 300K set. These three SNP sets represent the current available commercial SNP panels that most investigators will use. We simulated case-control data assuming a model with 6 unlinked disease loci with different levels of effect on disease risk and placed them in regions with various levels of LD. The simulated data show similar patterns of LD as the HapMap sample. We evaluated power using both 1- and 2-stage designs. Our results indicate that: 1) High LD coverage is crucial for GWAS. The power is dramatically reduced if the disease locus is in a region of moderate LD as compared to a region of strong LD (61% vs 90% for 2000 cases and 2000 controls and s=1.02 using 300K SNPs), indicating the importance of selecting more tags in regions of moderate/weak LD as it is unknown where the disease genes reside; 2) Power generally increases as the number of markers increases; however, if the disease locus is in a region of strong LD, then power can decrease due to the correction for an increased number of tests; 3) As noted by others, for a study with a 2-stage design, if a smaller proportion of subjects are used in stage 1, then a larger proportion of markers should be followed up in stage 2 in order to have power comparable to that of a 1-stage study. Many GWAS will rely on the HapMap for tagSNP selection. However, its limited sample size may lead to over-estimation of LD for some regions and an under-powered study if the disease genes fall in such regions. We therefore evaluated the extent of power loss when tags are selected based on such a small sample. Our results shall give researchers a practical view of GWAS and provide useful guidance when designing such large-scale studies.

Mach 1.0: Rapid Haplotype Reconstruction and Missing Genotype Inference. *Y. Li, J. Ding, G.R. Abecasis* Center for Statistical Genetics, Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI.

Missing genotype imputation and haplotype reconstruction are valuable for many analyses in revealing disease genetic mechanisms. We present a fast and flexible markov chain haplotyping method that resolves haplotypes, and thus missing genotypes, from unphased genotypes in samples of genetically unrelated individuals. The method is motivated by coalescent theory, particularly the observation that only a limited number of similar haplotypes are observed over short regions of the genome. As in other haplotyping methods motivated by the coalescent, our method captures the block-like pattern of haplotypes and the local nature of recombination by making each individual haplotype a mosaic of the currently resolved haplotypes of other individuals. Our method has been demonstrated to be faster and more accurate than existing methods in both missing genotype imputation and haplotype inference when applied to simulated or real datasets. In addition to the most likely genotype at each position, we provide two additional summaries that reflect model uncertainty: (1) a quality score for each inferred genotype and (2) an estimated allele dosage, that reflects estimated counts for a reference allele and which can be used in subsequent statistical analyses. The method is implemented in our MACH (MArkov Chain Haplotyping) software and freely available with C++ source code.

Demography and selection affection human prtoein coding genes. *R. Nielsen[1], M. Hubisz[2], C. Bustmante[2], A. Andres[3], S. Williamson[2], A.G. Clark[3]* 1) Dept of Biology, University of Copenhagen, Kbh Ø, Denmark; 2) Dept. of BSCB, Cornell University, Ithaca, NY; 3) Dept. of Mol. Biol. Genet., Cornell University, Ithaca, NY.

We analyze directly sequenced data from more than 10,000 loci from 20 European-American and 19 African-American individuals. We establish a nd fit a demographic model to the data which includes admixture, divergence, migration and changes in population size - and show that this model adequately fits the observed allele frequency distributions. We then scan the data for loci targeted by natural selection and identify a number of genes with variants targeted by natural selection that have not previously been identified by studies of natural selection in humans. These genes include a number of genes that have been shown directly to affect higher cognitive functions and several genes relating to human disease. Our approach for detecting natural selection in humans differ from previous approaches in adequately accounting for demography while not being challenged by ascertainment biases influencing many other studies based on publicly available SNP genotyping data.

SLOS like phenotype in two sisters with low serum cholesterol and normal enzymatic activities of cholesterol pathway, a new cholesterol disorder? *M. Michelson[1,2], C. Vinkler[1,2], T. Lerman-Sagie[2,3], D. Lev[1,2]* 1) Genetics Institute, Wolfson Medical Center, Holon, Israel; 2) Metabolic- Neurogenetic Clinic,Wolfson Medical Center, Holon, Israel; 3) Pediatric Neurology Unit,Wolfson Medical Center, Holon, Israel.

Recent publications point at an increasing importance of the role of cholesterol and cholesterol intermediates in the development of the fetus. Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive, multiple malformation/mental retardation syndrome with typical dysmorphic features. The metabolic basis is a reduction in the activity of 7-dehydrocholesterol reductase. We present two sisters with SLOS-like features, low serum cholesterol and normal levels of intermediates in the cholesterol pathway. These sisters, aged 6 and 4 years old, had normal birth weight and developed severe FTT thereafter. They had similar dysmorphic features: microcephaly, small nose, anterverted nostrils, depressed nasal bridge, low set ears, prominent metopic suture, epicantal folds, light and sparse hair, micrognathia, short neck and syndactyly of the II and III toes. They both had hypotonia and developmental delay. Extensive metabolic, cytogenetic and molecular tests were normal. Brain imaging studies were unremarkable in both sisters. Plasma bile acids by GC-MS were normal. Sterol pathway studies were normal except for a slight elevation of lathosterol relative to cholesterol. These findings might point out an increased rate of cholesterol synthesis or a relative block in intracellular trafficking of precursor sterols. Based on the distinct dysmorphic features with low levels of cholesterol we suggest that this is a new autosomal recessive syndrome involving cholesterol metabolism. Further assays evaluating cholesterol transport are being done.

Discovery of DNA methylation sites in MYOD1, MLH1, and RB1 in heterogeneous DNA samples with a modified quantitative sequencing method. *A. Lakdawalla, V. Boyd, K. Hunkapiller, C. Brown, E. Gerber, S. Chen* Applied Biosystems, Foster City, CA.

DNA methylation of cytosine in promoter regions has been shown to produce transcriptional silencing and resultant changes in phenotype. Conversely, phenotype can be associated with a unique DNA methylation signature. Therefore, significant effort is underway to discover specific C residues in DNA sequences that are associated with methylation and gene silencing. Bisulfite treatment of gDNA is used to convert non-methylated Cs to uracil (U). 5methyl-C is resistant to conversion therefore a change from Cytosine to Thymine indicates that the C residue was not methylated. As methylation signatures can be different due to cell - to - cell heterogeneity, discovery of DNA methylation requires extensive cloning and sequencing to discover rare methylation events in a mixed DNA population.

To circumvent the laborious cloning step, we have modified standard PCR-DNA sequencing to directly discover and quantitate putative DNA methylation sites in mixed samples. The modified method was utilized to effectively discover DNA methylation sites associated with differential expression of MYOD1, MLH1 and RB1 in normal and abnormal tissue samples.

Evaluation of the effect of the $Pl^{A1/A2}$ dimorphism, of the $P2Y_1$ receptor gene 1622A/G mutation and of the COX-1 gene 22C/T mutation on platelet response to aspirin. *M. Lordkipanidzé[1,2], C. Pharand[1,2], J.G. Diodati[1,2], D.A. Palisaitis[1,2], F. Bélanger[2], Y.K. Sia[1], E. Schampaert[1,2], J. Turgeon[2]* 1) Hôpital du Sacré-Coeur de Montréal, Québec, Canada; 2) Université de Montréal, Québec, Canada.

Background: The antiplatelet drug aspirin is widely used to prevent acute ischemic events. However, platelet response to aspirin is highly variable, which may be partly explained by genetic variability affecting platelet enzymes or receptors. Objective: To evaluate the impact of the dimorphism on the 3 allele of the 2b3 integrin (PlA1/A2), of the P2Y1 receptor gene mutation (1622A/G) and of the COX-1 gene mutation (22C/T) on platelet response to aspirin. Method: One hundred and ninety-two stable CAD patients under daily aspirin therapy were recruited. Platelet aggregation was measured by light transmission aggregometry (LTA) with arachidonic acid at 1.6 mM as the agonist. Genotyping was performed by standard PCR method. Results: The genotype frequency of PlA1A1:PlA1A2:PlA2A2 was 72.8%:25.6%:1.6%. The genotype frequency AA:AG:GG of the P2Y1 receptor gene at the 1622 position was 70.7%:25.5%:3.6%. The genotype frequency CC:CT:TT of the COX-1 gene at the 20 position was 84.9%:14.6%:0.5%. Mean platelet aggregation (%) with the PlA1A1:PlA1A2:PlA2A2 genotypes was 5.4, 4.8, and 6.5%, respectively ($p=0.95$); with the AA:AG:GG genotypes of the P2Y1 receptor gene, it was 5.0, 3.0, and 25.6% ($p<0.0001$); with CC:CT:TT of the COX-1 gene, it was 5.7, 2.5, and 3.0% ($p=0.46$). Aspirin resistance, defined as LTA > 20%, was associated with the 1622A/G polymorphism of the P2Y1 receptor gene ($p=0.002$); neither PlA1/A2 nor the polymorphism of the COX-1 gene was linked to aspirin resistance ($p=0.933$ and $p=0.476$, respectively). Conclusion: In our population, the mutation affecting the P2Y1 receptor gene was linked to aspirin resistance.

Utility of genetic markers used in human identification to detect genetic structure of global populations. *W. Niu, H.S. Lee, R. Chakraborty* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

Hypervariable short tandem repeat loci used in DNA forensics and for human identification were originally chosen for their ubiquitous polymorphic status in global populations. High level of polymorphisms at these loci, caused by their high rate of mutations, produce a small coefficient of gene differentiation across populations (generally less than 1% in cosmopolitan populations within continents, and around 3-5% between isolated populations within geographic regions). Nonetheless, multilocus DNA profiles generated by these loci aids in human identification, since the chance of observing the same profile given that it is observed in another person is often quite small. This research attempts to determine the utility of these forensic markers in detecting structure in global populations. Using data on 1,981 13-locus DNA profiles from 10 worldwide populations (representing Africans, Asians, Europeans, Native Americans, as well as admixed Africans, such as Jamaicans and Brazilian Blacks, and Hispanics), we used the STRUCTURE software to determine the genetic structure revealed by these loci. We observe that a four-component structure model fits these DNA profiles adequately. The continental populations are well separated, and the individuals from the admixed populations show a remarkable consistency of contributions from the component structures. These observations imply that even though the coefficient of gene differentiation at these forensic loci is small, their high degree of polymorphism still allows for a rather good degree of geographic separation of profiles, with admixed individuals showing the structure of their admixture history at least as a group level. Of course lesser polymorphic ancestry-informative markers (AIMs) are better suited for such purposes, specifically for admixture estimation at individual level, though the ability of the AIMs for identification purposes may be compromised. (Research supported by US Public Health Service Research Grant GM 41399).

Knowledge among universitary women about folic acid and its importance during pregnancy: a survey in the Pontificia Universidad Javeriana Colombia. *A. Ordoñez, F. Suárez* Intituto de Genética Humana, Pontificia Universidad Javeriana, Bogota D.C.

Neural tube defects (NTDs) affect about 7,28 of every 10.000 deliveries in Colombia. Periconceptional folic acid supplementation is recommended to prevent NTDs. To reduce the risk for NTDs women are encouraged to supplement with 400 mcg folic acid daily during their reproductive years. This study examines folic acid knowledge, and supplementation practices among women of childbearing (WCBA) age in one of the principal private Universities of Colombia. We conducted a survey in 390 women over a calculated random sample of 356 women. We calculated the relative frequencies for the answers with the respective confidence intervals. The model of the survey was based in the Pregnancy Risk Assessment Monitoring System of the CDC (centers for disease control and prevention) at the end of the survey every women received patient education materials. Mean age of women was 21 years old. We found that 189 women (49%, CI, 95%: 43.02 - 52.98) had listened or read some information about folic acid, but are not sure about the benefits. 197 women (51%, CI, 95%: 46.01 - 55.99) did not have any information about the vitamin in relation to pregnancy and birth defects, but have heard about the vitamin. 128 women (33.2%, CI, 95%: 28.32 - 37.69) know something about the benefits in pregnancy and 258 women (66,8%, CI, 95%: 61.27 - 70.73) did not have information and know nothing about the benefits in pregnancy. None of the women actually consume folic acid at the recommended doses. 96 women (24.9%, CI, 95%: 19.74 - 28.26) consume some other kind of multivitamin supplementation. The women with less knowledge of folic acid had a greater consumption of multivitamin and folate-rich fruits and vegetables (p 0.0005). In Colombia, there is not information about periconceptional folic acid, as we demonstrate in this particularly educated women population. A major educational campaign and fortification of grain with folic acid may be the best practical solution. Fortification of food may need to be used to increase folate consumption in those with unplanned pregnancy.

Heritability of plasma amino acid levels in different nutritional states. *K.L. McBride[1], J.W. Belmont[2], W.E. O'Brien[2], T.J. Amin[2], S. Carter[2], B.H. Lee[2]* 1) Dept Molecular & Human Gen, Columbus Child Res Inst, Columbus, OH; 2) Dept of Molecular & Human Gen, Baylor College of Medicine, Houston TX.

Plasma amino acid (PAA) levels are impressively regulated to maintain a tight range of values that are consistent across ethnic groups. Ranges do vary dependent on age, sex, fasting status and protein intake. Previous studies have indicated a genetic component to PAA homeostasis for several amino acids, but they have been hampered by a combination of mixed fed and fasting samples or variability in the preceding protein intake. We had the unique opportunity to study the heritability of PAA levels before and during a steady-state of low protein intake, from data obtained for nitrogen flux stable isotope studies. Subjects were fed frequent, small meals totaling 0.4 grams of protein /kg of body weight per day, for 3 days. A total of 71 individuals in 21 families from that study were included in this analysis, consisting of 11 with a urea cycle defect (UCD), 10 UCD heterozygotes, 13 OTC heterozygous females, 26 unknown status, and 13 unaffected or controls. Samples were drawn on hospital admission (regular diet), after 2 days on the steady-state diet after overnight fast, and while on the low protein steady-state diet (fed every 2 hours). The program SOLAR was used for Heritability (h2) estimates, with covariates sex, weight and age. PAAs with high h2 on a regular diet were Ser, Thr, Gly, and Pro (h2=0.82, 0.53, 0.66, 0.78); while fasting were Cys, Gly, Ala, Pro, Asn, and Tyr (0.75, 0.83, 0.83, 0.74, 0.84, 0.83); and on steady-state were Tyr, Phe, and Trp (0.75, 0.79, 0.55), which utilize the same large neutral amino acid transporters. Heritability of PAAs varied by nutritional state and could be grouped by common metabolic fates or transporters. This confirms previous work on fasting subjects, and expands this to include additional PAAs whose homeostasis in different nutritional states demonstrates significant genetic control. We speculate genetic and environmental influences on individual PAA homeostasis vary throughout the feed-fast cycle, are influenced by previous and current amount of protein, and cannot be appreciated without careful controlled study.

The function of BLOC-2 in lysosome-related organelle biogenesis. *A. Helip Wooley[1], W. Westbroek[1], H. Dorward[1], P. Held[1], M. Ayub[1], R. Boissy[2], M. Huizing[1], W.A. Gahl[1]* 1) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Department of Dermatology, University of Cincinnati College of Medicine, Cincinnati, OH.

Hermansky-Pudlak syndrome (HPS) is a disorder of oculocutaneous albinism and prolonged bleeding due to defects in the formation of lysosome-related organelles (LROs), specifically melanosomes in melanocytes and dense bodies in platelets. Eight genes are associated with different types of HPS in humans. HPS3, HPS5 and HPS6 proteins interact with one another in the Biogenesis of Lysosome-related Organelles Complex-2 or BLOC-2. The function of BLOC-2 is unknown. Ultrastructural studies of BLOC-2 deficient melanocytes revealed predominantly immature melanosomes. Tyrosinase and TYRP1 reside mainly on small vesicles, not on melanosomes, as in normal melanocytes. The abundance of TYRP1, a melanosomal protein, is markedly reduced in HPS-5 melanocytes. We previously demonstrated that HPS3 interacts with clathrin, and that GFP-HPS3 localizes to small vesicles and endosomal structures in normal melanocytes. We have now performed subcellular fractionation of human melanoma cells (MNT1) to study the localization of endogenous BLOC-2 components on the different organelles. Differential centrifugation fractions were characterized by immunoblotting and electron microscopy. BLOC-2 components were enriched on a single high-density fraction that contained larger endosomal structures as well as small vesicles; the fraction was positive for EEA1, an early endosomal marker. Markers of early and late melanosomes were absent from this fraction. We hypothesize that BLOC-2 functions at a sorting endosome-like structure and is necessary for the proper sorting of a subset of melanosomal proteins into transport vesicles. BLOC-2 may also play a role in the subsequent trafficking of these vesicles to maturing melanosomes. In the absence of BLOC-2, these melanosomal proteins may be randomly incorporated into vesicles that are incapable of efficient trafficking to early melanosomes. Alternatively, they may remain in an endosomal structure and follow a default pathway toward degradation.

Androgen Receptor (AR) and Estrogen Receptor alpha (ER) Variants Have Minimal Impact upon Cancer Susceptibility in BRCA1 Mutation Carriers. *S. Harbord[1], C.J. Brown[1], D. Horsman[1,2], S. Young[2], W.P. Robinson[1]*
1) Depts. of Medical Genetics and Pathology, UBC; 2) BC Cancer Agency; Vancouver BC Canada.

A mutation in the BRCA1 gene dramatically increases a womans chance of developing breast and/or ovarian cancer, however, penetrance is incomplete. Epidemiological data implicates hormones in both the presence and the severity of breast and ovarian cancers, and hormone receptor activity has been linked to BRCA1 protein activity. Polymorphisms in hormone receptors may act as genetic modifiers and influence risk of breast and/or ovarian cancer in BRCA1 mutation carriers. Androgen Receptor (AR) and Estrogen Receptor alpha (ER) contain polymorphisms that have been associated with breast cancer, though results have been inconsistent. Here we have studied AR CAG repeat length, ER TA repeat length and two ER SNP polymorphisms at -397 and -351 in 42 affected BRCA1 mutation carriers, 15 unaffected BRCA1 mutation carriers, 24 BRCA2 mutation carriers, 24 familial controls and 152 population controls. Repeat length was determined using a conventional PCR-based assay, while ER SNP polymorphisms were analyzed by allelic discrimination with Real Time PCR. Despite previous reports, no patient group was significantly different from controls for any hormone receptor polymorphism considered. Neither affected BRCA1 mutation carriers nor affected non-BRCA1 mutation carriers had an increase in long AR alleles when compared to pooled familial and population controls (BRCA1: 7/42, non-BRCA1: 4/33, controls: 30/186). Affected BRCA1 mutation carriers had a non-significant trend towards a decrease in long AR alleles when compared to combined controls (BRCA1: 12/42, controls: 33/186). Long ER TA repeats were also not increased in affected BRCA1 mutation carriers (29/42) or affected non-BRCA1 mutation carriers (20/33) compared to combined controls (80/128). In addition, no ER SNP polymorphism is overabundant in either affected BRCA1 mutation carriers or affected non-BRCA1 mutation carriers compared to controls. Though sample size is small, it seems that androgen receptor and estrogen receptor a variants do not largely affect breast and/or ovarian cancer risk in BRCA1 mutation carriers.

Evaluation of the effect of the H2 haplotype and CYP3A5 polymorphisms on the antiplatelet response to clopidogrel given before elective percutaneous coronary intervention. *J. Turgeon[2], M. Lordkipanidzé[1,2], C. Pharand[1,2], J. G. Diodati[1,2], T. A. Nguyen[1], D. A. Palisaitis[1,2], F. Bélanger[2], Y. K. Sia[1], E. Schampaert[1,2]* 1) Hôpital du Sacré-Coeur de Montréal, Montréal, Québec, Canada; 2) Université de Montréal, Montréal, Québec, Canada.

Clopidogrel needs to be metabolized by the CYP450 3As enzymes to be active. CYP3A5*1 confers higher levels of expression while CYP3A5*3 confers low expression. The active metabolite prevents ADP-induced platelet aggregation by irreversibly binding the ADP P2Y12 receptor. Four polymorphisms (including the i-T744C SNP) in the P2Y12 gene define two haplotypes: H1 and H2. H2 is associated with higher maximal platelet aggregation in response to ADP. Objective: To evaluate the impact of the presence of the H2 haplotype and of the CYP3A5*1 and *3 polymorphisms on the antiplatelet response to clopidogrel. Method: A total of 116 patients with stable CAD were recruited prior to elective angiography. They received clopidogrel for 1 to 7 days prior to the procedure. Blood samples were obtained before clopidogrel initiation and at the time of angiography. Platelet aggregation was measured by light transmission aggregometry with ADP 20 M as the agonist. Genotyping was performed by standard PCR method. Genetic screening was performed to identify active (*1/*1 or *1/*3) or inactive (*3/*3) CYP3A5. Genotyping of P2Y12 H2 haplotype was performed by targeting the i-T744C SNP. Results: The genotype frequency of CYP 3A5 *1*1:*1*3:*3*3 was 0%:9.5%:90.5%, giving a frequency of the non-expressor (*3) and expressor (*1) alleles of 95.3% and 4.7% respectively. The genotype frequency of the ADP i-T744C wild-type WT/WT:WT/variant:variant/variant was 72.4%:24.1%:3.4%, giving a frequency of the WT allele of 84.5%. Mean absolute decreases in % platelet aggregation with clopidogrel were 23.7 and 27.7% (p=0.56) with the CYP 3A5 *1*3 and *3*3, respectively, and 28.7% and 23.3% (p=0.23) with the ADP i-T744C WT/WT and WT/variant (or variant/variant), respectively. Conclusion: In our population, the presence of the i-T744C and CYP3A5 polymorphisms does not appear to affect the antiplatelet efficacy of clopidogrel.

QTL-ALL: software for QTL linkage analysis using score statistics and other new approaches. *N. Mukhopadhyay, S. Bhattacharjee, C-L. Kuo, D.E. Weeks, E. Feingold* Dept Human Genetics, Univ Pittsburgh/Sch Pub Health, Pittsburgh, PA.

There has been extensive development of new statistics for QTL mapping over the last few years, but a number of the most promising new methods are not yet available in end-user software. This is particularly true of methods such as score statistics that are important for studies using selected (non-population) samples. Our new "QTL Analysis and Linkage Library" (QTL-ALL) is a software package designed to make as many as possible of these new statistics widely available. The software consists of a Mega2-like interface for data analysis preparation and a library of R routines that computes linkage statistics. QTL-ALL reads in input data, creates re-formatted output data files, calls external IBD-generation software such as MERLIN or SimWalk2, then computes statistics using our R library, and finally produces tables and plots of statistics and p-values. This entire sequence is highly automated, requiring minimal user-intervention. The initial release of the software computes a number of newer QTL-mapping statistics, including several score statistic variants, and can handle nuclear family data, including specialty designs such as discordant and concordant (affected) pairs. QTL-ALL will be available from http://watson.hgen.pitt.edu/register/.

A case of Whistling face autosomal dominant. *P.M. Hurtado, I. Zarante* Instituto de Genetica Humana, Pontificia Universiadad Javeriana, Bogota, Colombia.

Introduction. Freeman-Sheldon syndrome is a rare disorder, and the diagnosis is clinical by unusual facial features and skeletal abnormalities. It was first described by Freeman and Sheldon in 1938; since then, cases of Freeman-Sheldon syndrome have been reviewed extensively. There is genetic heterogeneity, but most cases are thought to be sporadic. Case report. We reported a mother of 32 year-old, a son (2 year-old) and a daughter (4 year old), with physical features and with a peculiar aspect of "whistling face". Both siblings had deep-set eyes, prominent supraorbitary edge, epicanthus, blepharophimosis, microstomia, mask-like face, high-arched palate, nasal speech, long philtrum. The Mother had almost the same physical findings, especially in her face. They had also thumb adduction contracture. We found in both sibs a history of global retardation of development. Discussion. The Freeman-Sheldon syndrome is heterogeneous not only in its clinical presentation but also in its genetic transmission. It is very important to be informed about the existence of more than one form of hereditary transmission of this syndrome, since genetic counseling should take into consideration all possibilities. Freeman-Sheldon syndrome, also called "whistling-face syndrome," is a very rare genetic condition, occurring both sporadically and by transmission through autosomal dominant or recessive mode, which affects primarily the face and skeleton. Characteristics include microstomia of the mouth, which gives the person a whistling appearance, a flat face, club feet, contracted joint muscles of the fingers and hands, and underdeveloped nose cartilage. In our case, clearly it corresponds to an Autosomal Dominat presentation of Freeman Sheldon Syndrome.

Methamphetamine-dependence whole genome association identifies genes including WDR1. *A. Hishimoto[1], T. Drgon[1], C. Johnson[1], Q.R. Liu[1], J. Drgonova[1], D. Walther[1], H. Ujike[2], T. Komiyama[2], M. Harano[2], Y. Sekine[2], T. Inada[2], N. Ozaki[2], M. Iyo[2], N. Iwata[2], M. Yamada[2], I. Sora[2], G.R. Uhl[1]* 1) Molecular Neurobiology Branch, NIDA/IRP/NIH, Baltimore, MD; 2) Japanese Genetics Initiative on Drug Abuse (JGIDA), Japan.

Dependence on methamphetamine and other substances displays substantial complex genetic underpinnings, including many that are shared by multiple addictive substances and some that are substance-specific. To identify SNP markers and genes whose alleles distinguish methamphetamine-dependent from control individuals, we used 100k SNP arrays and DNA from 200 Japanese methamphetamine-dependent and matched control individuals to assess allele frequencies at 98,398 autosomal SNPs. SNPs clustered in 47 small genomic regions that contain both genes and positive results from other abuser *vs* control comparisons display nominally-significant abuser/control allele frequency differences that are very unlikely to be due to chance. One of these genes, WDR1, is expressed in brain, encodes common missense and alternative splicing variants, and contains SNPs that display significant ($p = 3 \times 10^{-6}$- 6×10^{-4}) individual abuser vs control genotypes. A haplotype tagged by *Val*185*Ile* missense rs13441 displays association with methamphetamine abuse and also correlates with levels of amphetamine abuse in two separate NIDA samples ($r^2 = 0.29 - 0.44$; $p < 0.02 - 0.005$). By contrast, this haplotype does not predict significant allele specific expression in mRNAs from postmortem brains. While many of the genomic variants identified here are likely to contribute to vulnerability to various abused substances, WDR1 variation marked by *Val*185*Ile*/ rs13441 is a strong candidate variant for selective predisposition to develop or resist methamphetamine dependence *(Support: DHSS/NIH/IRP/NIDA)*.

Community accessibility of family health history tools. *J. O'Leary[1], J. Williams[2], M. Taualii[3], P. Kyler[4], S. Terry[1]* 1) Genetic Alliance, Washington, DC; 2) Clinical Genetics Institute, Intermountain Healthcare, Salt Lake City, UT; 3) Urban Indian Health Institute, Seattle Indian Health Board, Seattle, WA; 4) Genetic Services Branch, MCHB, HRSA/DHHS, Rockville, MD.

We hypothesize that engaging families in the collection of family health history may well be the ideal tool to promote positive health behavior and basic genetics education. Family health history is ideal because it combines clinical utility (as a predictor of health) with accessibility (by featuring folklore and genealogy). However, the amount of diversity and number of individuals in any community make creating a one-size-fits-all family health history tool nearly impossible. The varied needs of different cultures require a flexible approach, one best vetted by the organizations that already serve those communities directly. Of course, existing tools are an important resource, but they must be paired with complementary materials. The Coalition for Accessible Family Health History Tools was formed in order to promote family health history within all types of communities via the creation and dissemination of *Using Family Health History Tools: A Guide to Making Tools Accessible to Your Community*. The Guide is aimed at national, community, and disease-specific advocacy organizations interested in promoting the collection of family health history among their members and in their locality. The goal of the Guide is to help organizations use existing family health history tools and create complementary materials that will increase the accessibility of those tools. It provides techniques for developing new materials and tools while simultaneously highlighting dissemination techniques and promoting the distribution of existing materials. Finally, the Guide outlines how to lead a successful family health history initiative, from assessment of community knowledge to targeted dissemination of materials.

TRISOMY 8 RESCUE IN A PRENATAL CASE WITH MOSAIC STRUCTURAL CHROMOSOME REARRANGEMENTS. *A. Hajianpour, A. Zhang, K. Mac, J. Cary, B. Diaz, D. Burkhardt, M. D'addario, L. Dong, R. Habibian* Genzyme Genetics 655 East Huntington Drive Monrovia, CA 91016.

Amniocentesis was performed on a 23 year old woman at a gestational age of 18.6 weeks due to abnormal maternal serum screen and increased risk for chromosome abnormality. There were no abnormal ultrasound findings. Cytogenetic analysis revealed a mosaic karyotype consisting of two cell lines, one as a normal cell line and the second cell line containing a supernumerary marker chromosome as well as additional material attached to the short arm of one chromosome 8. Fluorescence in situ hybridization (FISH) using whole chromosome paint 8 probe revealed that both the marker chromosome and the additional material on the abnormal chromosome 8 were derived from chromosome 8: 47,XX,add(8)(p22),+mar[19].ish der(8)t(8;8)(p23.1;q21.2)(wcp8+),+r(8)(wcp8+)/46,XX[2]. It is speculated that the initial event leading to the formation of both the derivative and the marker chromosome 8 was the presence of trisomy 8 in the zygote or early embryo. A phenomenon known as trisomy rescue presumably followed in which all or part of one of the trisomic chromosome is lost. The resulting chromosome imbalance is therefore less severe than a full trisomy due to the selective survival of the rescued cells, hence the fetus may consequently survive to term. Rather than full trisomy 8, the net imbalance of the abnormal cell line in this case is monosomy 8p23.1-pter, trisomy 8q21.2-qter, and partial trisomy of the pericentromeric region of chromosome 8 (present as very small ring chromosome). Further studies are in progress to better understand the origin of the abnormal cell line, including re-examination of the slides to search for trisomy 8 and additional FISH studies. The pregnancy is still ongoing.

Identifying transcriptional targets in cancer. *K. Johanson, A. Sidhu, A. Hollenbach* Department of Genetics, LSU Health Sciences Center, New Orleans, LA.

Changes in gene expression are an integral part of a cells transition into a malignant state and are often brought about by alterations in the expression or binding capacity of transcription factors. This fact is illustrated by Alveolar Rhabdomyosarcoma (ARMS), which is characterized by a t(2;13)(q35;q14) chromosomal translocation that results in the fusion of two myogenic transcription factors Pax3 and FKHR (FOX01a). ARMS is an aggressive solid muscle tumor in children that has a event-free four-year survival rate of only 17%. Despite the identification and characterization of the oncogenic fusion protein Pax3-FKHR, little is known about the genes directly regulated by Pax3 or FKHR, and how their expression may be altered by Pax3-FKHR. While many techniques exist to investigate the possible gene targets and binding specificity of different transcription factors, the majority of these are too labor-intensive to be adapted for use in a genomic screen. The ability to easily and quickly screen an entire genome for potential transcription factor targets would provide valuable information about some of the molecular mechanisms behind cancer development. Therefore, we developed a modified yeast one-hybrid assay using Pax3, FKHR, and Pax3-FKHR as a model system. This assay provides a method of identifying gene targets of specific transcription factors by testing their ability to directly bind genomic elements in vivo. This method has a distinct advantage over other current screening applications in that it involves an assay that is directly dependent on the binding of Pax3, FKHR, or Pax3-FKHR to promoter elements and therefore allows for a full examination of the natural in vivo substrates of all three proteins. The identification of genes directly regulated by Pax3 and FKHR will help elucidate the role that these factors play in myogenic differentiation. In addition, by comparing how the expression of these genes is altered by Pax3-FKHR and identifying possible novel targets of the fusion protein, we will be able to develop a mechanism for Pax3-FKHR aids in the development of ARMS. This project also establishes a general method that could be adapted for use in identifying the targets of any known transcription factor.

Prioritized subset analysis in genome-wide association studies. *C. Li[1], M. Li[2], E.M. Lange[3], R.M. Watanabe[4]* 1) Ctr Human Genetics Research, Dept Biostatistics, Vanderbilt Univ, Nashville, TN; 2) Dept Biostatistics, Univ Pennsylvania, Philadelphia, PA; 3) Dept Genetics, Univ North Carolina, Chapel Hill, NC; 4) Dept Preventive Medicine, Keck School of Medicine, Univ Southern California, CA.

Genome-wide association (GWA) studies are a popular approach to study the genetics underlying complex diseases. Since GWA studies generate large volumes of data, it would be desirable to prioritize these data for analyses. Often a list of candidate genes or candidate regions (e.g. determined through linkage studies) exists such that it may be more efficient to use such information to prioritize the genome in data analysis. Traditional approaches to GWA such as Bonferroni and the false discovery rate (FDR) ignore such information, inherently treating all markers equally. We evaluate a prioritized subset analysis (PSA), in which markers are partitioned and prioritized into subsets based on supplemental data and FDR is then applied to each subset. We simulated 300K SNP genotypes from Illuminas HumanHap300 set, based on a phased HapMap CEU sample. The datasets we simulated show similar patterns of LD as the HapMap sample. We simulated case-control datasets assuming a disease model with six unlinked disease loci across the genome with various levels of effect on disease risk (s=1.01 to 1.05) and placed them in regions with different levels of LD. We evaluated power using both whole-genome and PSA approaches. Our results indicate that: 1) When the priority subset contains a higher fraction of disease genes than the genome, PSA significantly increases power to detect these genes compared to the whole-genome approach; 2) The higher the fraction of disease genes in the priority subset, the higher the power to detect them; 3) If a disease gene is not included in the priority subset, power is similar for both approaches. This is an advantage of FDR over the Bonferroni approach, for which power will decrease for disease genes not included in the priority subset to control the overall false positive rate. We also note that the overall false discovery rate is practically under control if the genome is partitioned into a few subsets (5), but can inflate as the number of subsets increases.

Limited instability of fragile X full mutation alleles. *S.L. Nolin, X. Ding, G.E. Houck, W.T. Brown, C. Dobkin* Human Genetics Dept, NYS Insttitute for Basic Research in Developmental Disabilities, Staten Island, NY.

Fragile X full mutation alleles are thought to be highly unstable during early embryonic development. This hypothesis is based on the heterogeneous molecular pattern, often referred to as a smear, that is typically observed in Southern analyses of full mutation alleles. Studies in different tissues of affected fetuses and also in affected monozygotic twins suggests that the heterogeneity occurs in early development (Devys et al., AJMG 43:208, 1992; Malmgren et al., Eur J Hum Genet 2:103,1994; Kruyer et al., AJHG 54:437, 1994). Additional studies demonstrating clonal stability of full mutation alleles in cultured somatic cells further support this conclusion (Worhle et al., Nat Genet 4:140, 1993).

We have re-examined the issue of somatic heterogeneity in DNA from 52 males and 29 females with full mutation alleles. In a modification of Southern analysis procedures, the samples were digested with EcoR I/Eag I and separated by agarose gel electrophoresis without the inclusion of ethidium bromide or other DNA intercalating dye during or following electrophoresis. The resulting molecular patterns were remarkably different from the heterogeneous pattern for full mutation alleles seen in standard Southern analysis. Nearly all samples exhibited 1 to 5 discrete fragments for full mutations with an average of 2.5 fragments/sample. Approximately 15% of the 81 samples analyzed also included a faint heterogeneous pattern. Parallel analyses of selected samples showed a smear in the presence of ethidium bromide and a few discrete fragments in its absence.

The use of ethidium bromide appears to alter the migration of the fragile X CG-rich fragments during electrophoresis giving an exaggerated impression of heterogeneity. These studies suggest that most full mutation alleles have only limited instability in early embryogenesis and other developmental periods, consistent with the clonal stability observed in cell culture. Finally, eliminating ethidium bromide during Southern analysis makes the diagnosis of females with full mutation alleles more reliable.

Bardet-Biedl syndrome mice have defective hippocampal development associated with mislocalization of neuronal primary cilia receptors. *K. Mykytyn[1,2], N.F. Berbari[1], L.M. Bohn[1], G.A. Bishop[3]* 1) Department of Pharmacology, Ohio State Univ, Columbus, OH; 2) Department of Internal Medicine Division of Human Genetics, Ohio State Univ, Columbus, OH; 3) Department of Neuroscience, Ohio State Univ, Columbus, OH.

Cilia are hair-like appendages that extend from the basal bodies of cells and are classified as either motile or primary. Motile cilia and flagella are responsible for generating flow or movement. Primary cilia are generally immotile, are present on almost all human cell types, and provide important cellular sensory and signaling functions. Defects in primary cilia formation or function have been implicated in many diseases. Although neurons throughout the brain possess primary cilia, their functions are unknown. We have found that hippocampal development is profoundly altered in mouse models of Bardet-Biedl syndrome (BBS), a human genetic disorder whose etiology has been linked to cilia dysfunction. The primary features of BBS include obesity, retinal dystrophy, renal abnormalities, polydactyly, cognitive deficits, and mood disorders. We find that mice lacking Bbs4 display progressive hippocampal dysplasia concomitant with an increase in neuronal cell death. We demonstrate that hippocampal neurons are ciliated during development and ciliary membranes contain functional receptors. Strikingly, neurons from *Bbs4*$^{-/-}$ mice have defective localization of neuronal ciliary receptors, suggesting that neuronal ciliary signaling is necessary for normal hippocampal development. Our findings may explain the pathophysiology of the cognitive and behavioral features of BBS patients, and thereby implicate defective cilia-mediated neuronal signaling as a basis for the development of cognitive and neuropsychiatric diseases.

Family Functioning, Age, & Coping Mechanisms in Smith-Magenis Syndrome (SMS). *R.S. Morse, R.A. Bernert, W. Introne, A.C.M. Smith* OCD, NHGRI/NIH/HHS, Bethesda, MD.

Introduction: A paucity of research has investigated family coping strategies and communication skills within rare genetic syndromes, including SMS. Few studies have evaluated child age and sex according to these areas of psychosocial functioning. **Methods:** Baseline data was collected among 39 parents with a cytogenetically-confirmed SMS (del 17p11.2) child. Administered measures: *Family Crisis-Oriented Personal Evaluation Scales* (F-COPES) & *Family Assessment Device* (FAD). **Results:** A one-way ANOVA revealed no significant mean sex differences on FAD & F-COPES ($p > .05$). Two multiple linear regressions were conducted to test associations between age and F-COPES & FAD subscale and total scores; age was the predictor variable. F-COPES analysis dependent variables (DV) included *Social Support Seeking, Spiritual Support Seeking, Passive Appraisal, Reframing*. When all 4 DVs were entered into the regression, as a set, a nonsignificant trend emerged (R^2=.17, F4,34=1.73, P=.167). With regard to the unique contribution of each DV to the prediction of age, *Seeking Spiritual Support* was significantly linked with age (=.37, t=2.08, P<.05); the link between age & *Acquiring Social Support* emerged as a ns trend (=-.35, t=-1.94, P=.06). *Passive Appraisal* (=-.21, t=-1.27, P>.05) & *Reframing* (=.14, t=.84, P>.05) subscales did not contribute to the variance beyond that contributed by the first two DVs. FAD analysis DVs included the *Global Functioning Scale* (GFS) & the *Communication Scale* (CS). When DVs were entered into the regression as a set, a ns trend emerged for the model (R^2=.09, F2,36=1.8, P=.18). With regard to the unique contribution of each DV to the prediction, the link between age & CS emerged as a ns trend (B=-.39, t=-1.89, P=.066), but not with GFS (=.22, t= 1.12, P=.27). **Conclusions:** Cross-sectional results indicated that increasing age was associated with decreasing levels of social support seeking, yet increasing levels of spiritual support seeking. Results also revealed that greater age was associated with less effective familial communication. Research is needed to clarify whether this is mediated by increased syndrome severity or age at diagnosis.

The Pompe Registry: Observations of diagnostic practices around the world. *P. Kishnani[1], L. Merlini[2], B. Byrne[3], W. Mueller-Felber[4], A. van der Ploeg[5]* 1) Duke Univ Medical Ctr, Durham, NC, USA; 2) University of Ferrara, Ferrara, Italy; 3) University of Florida, Gainesville, FL, USA; 4) Friedrich-Baur-Institut, Munich, Germany; 5) Sophia Childrens Hospital, Rotterdam, The Netherlands.

Background: Pompe disease is a rare, and often fatal muscle disease caused by a deficiency of lysosomal acid alpha-glucosidase (GAA). Patients span a spectrum of phenotypes ranging from infantile (cardiomyopathy, skeletal/respiratory muscle weakness, death within first year of life) through late onset (little/no cardiac involvement, progressive skeletal/respiratory muscle weakness, longer survival). Methods: To better understand disease natural course, an international Registry has been developed to collect anonymous data on patients with a confirmed diagnosis of Pompe disease. Participation is voluntary. Preliminary Data Overview: The Pompe Registry was launched September 2004 and contained 202 natural history patients from 16 countries as of April 18, 2006. Preliminary data indicates regional differences in diagnostic methods. Relative to ROW, participating North American physicians were at least three times less likely to use DBS [Dried Blood Spot] (5% vs. 14%), two times less likely to use muscle biopsy (18% vs. 31%) and four times (5% vs. 20%) less likely to use DNA analysis. In North America the most common tissues for enzymatic assay was via skin fibroblasts and blood lymphocytes. Summary: Early registry data indicates that regional differences may exist in the diagnostic algorithms used for Pompe diagnosis. With the availability of less invasive techniques such as DBS in diagnostic laboratories in the US it is likely that these tests will be used more frequently as the first tier approach to help identify new cases, followed by fibroblasts for confirmation. The Pompe Registry is sponsored by Genzyme Corporation with oversight provided by an independent committee of disease experts.

Strong Evidence for a Prostate Cancer Susceptibility Gene at Chromosome 17q22. *E. Lange[1], C. Robbins[2], E. Gillanders[3], S. Zheng[4], J. Xu[4], Y. Wang[1], K. White[5], B. Chang[4], L. Ho[1], J. Trent[2], J. Carpten[2], W. Isaacs[6], K. Cooney[5]*
1) Univ North Carolina, Chapel Hill, NC; 2) Translational Genomics Research Instit, Pheonix, AZ; 3) NHGRI, Bethesday, MD; 4) Wake Forest Univ, Winston Salem, NC; 5) Univ Michigan, Ann Arbor, MI; 6) Johns Hopkins Medical Instit, Baltimore, MD.

Prostate cancer linkage studies have previously suggested the existence of a prostate cancer susceptibility gene on chromosome 17q21-22. Herein, we report multipoint nonparametric linkage results from 453 prostate cancer pedigrees from the University of Michigan Prostate Cancer Genetics Project and Johns Hopkins University using 24 chromosome 17 microsatellite markers. This study includes 95 new multiplex prostate cancer families and 9 additional microsatellite markers not previously reported. The maximum LOD score for all 453 pedigrees was found to be 2.99 at approximately 81 cM. The evidence for linkage at 81cM was similar in the 34 African-American (LOD = 1.90) and 415 European-American (LOD = 1.86) families. The European-American pedigrees had a second peak (absent in the African-Americans) at 53 cM (LOD = 2.75). An approach that has been widely used in linkage studies of complex traits is to focus on subsets of pedigrees that are more likely to segregate highly penetrant susceptibility alleles. Thus restricting the analysis to the subset of 147 families that had four or more prostate cancer cases and that had an average age of prostate cancer diagnosis < 65 years resulted in a maximum LOD score of 5.49 at 78 cM, including a LOD of 1.70 in the 27 new families belonging to this subset, with a corresponding 1-LOD support interval of 10 cM. These results represent one of the strongest reported linkage findings for prostate cancer to date and lead to a substantial reduction of the 17q21-22 candidate region. This large set of pedigrees with four more prostate cancer cases characterized by early-onset disease will serve as a useful resource for identifying the 17q21-22 prostate cancer susceptibility gene.

Utilization of whole genome SNP panels for efficient genetic mapping in the mouse. *J.L. Moran[1], A. Bolton[1], J. Moore[2], D. Mirel[2], S. Gabriel[2], D.R. Beier[1]* 1) Genetics Div., Brigham and Women's Hospital/Harvard Medical School, Boston, MA; 2) Center for Genotyping and Analysis, The Broad Institute of MIT and Harvard, Cambridge, MA.

We have previously described a whole genome panel of 394 mouse SNPs that we used to successfully map 44 loci, including ENU-induced and spontaneous mutations, modifier loci, quantitative trait loci and loci that demonstrate loss-of-heterozygosity (Moran et al., Genome Research 2006). The average number of affected mice genotyped for 22 monogenic mutations mapped using a wide variety of strain combinations was 8, and map locations have been obtained by genotyping as few as 4 affected mice. The average recombinant interval was 43 Mb. Thus, for monogenic mutations the 394 SNP panel proved useful for moderate resolution genetic localization with small numbers of mice in a high-throughput manner. The major utility of a whole genome SNP panel is that complete genome haplotype characterization is obtained in a single analysis. This facilitates the efficient discrimination between true and false positive association, as well as the discovery of unexpected modifier effects. We have now developed a new whole genome panel of 768 SNPs that is analyzed using the Illumina genotyping platform. SNP density averages 3 Mb across autosomes and 7 Mb across Chr. X. The panel was designed to maximize the number of markers that would be informative for crosses made using C57BL/6J, such that the average number of informative SNPs between C57BL/6J and common inbred strains is 550. However, to insure that the panel is suitable for many strain combinations, a haplotype binning strategy was used to maintain informativeness across the genome between other strains. The new panel and analysis protocol allows for genetic mapping at higher resolution and higher throughput. Initial results demonstrate this panel is extremely robust with respect to both informativeness and allele discrimination, and we have successfully mapped several loci that were not detected using our 394-marker panel. Cost-effective, high through-put, whole genome SNP analysis should have wide applicability for genetic investigation in model systems.

Power considerations for the Affymetrix 100K and Illumina 300K platforms. *L. Ho, F. Zou, H. Huang, Y. Wang, F. Wright, E. Lange* University of North Carolina.

Genome-wide association (GWA) analyses using commercially available highly-multiplexed genotype arrays are becoming increasingly popular for genetic association studies of complex traits. One of the first and most important steps in planning a GWA study is the accurate estimation of the power under a proposed study design and sample size. A critical element of these calculations is the specification of the significance threshold. Typically, this threshold is chosen to ensure a desired overall family-wise error rate (FWER) after accounting for uninformative markers and correlated tests between markers in linkage disequilibrium. We have performed a simulation study, based on bootstrap resampling, to empirically estimate the appropriate significance threshold when analyzing genotype data from the Affymetrix GeneChip Mapping 100K Assay and the Illumina HumanMap300 BeadChip platforms to ensure an overall FWER of 0.05. Specifically, we have performed 5000 simulations where we have randomly sampled from 120 phased autosomal haploid genomes containing the SNPs in the Affymetrix and Illumina platforms, using the HapMap Phase I/II CEU data, under the null hypothesis of no association and determined the significance threshold to achieve a desired FWER. These simulations were performed for both 1- and 2-stage genotyping designs, samples based on 1000 cases/controls and 2500 cases/controls and when analyzing all markers versus restricting the analyses to markers with a minor allele frequency >0.10. For each simulation condition, we estimated the ratio of the Bonferroni threshold p-value over the threshold p-value value obtained via the simulation. These ratios varied considerably over the different scenarios. Using a 1-stage design, the ratios ranged from 0.53 for the Affy 100K panel, 1,000 cases/controls, and no SNP removal to 0.90 for the Illumina 300K panel, 2,500 cases/controls, with removal of SNPs with minor allele frequency <0.10. Some 2-stage designs had a 10% further ratio reduction. Simulations performed under alternative models suggest that the significance threshold can impact the estimated power substantially when the underlying effect size is modest.

GENZ-112638: A novel orally available ceramide-based inhibitor of glucosylceramide synthase for treating Gaucher disease. *K. McEachern[1], C. Siegel[1], J. Fung[1], S. Komarnitsky[1], W.L. Chuang[1], J. Johnson[1], E. Hutto[1], K. Zhang[1], C. Sung[1], L. Blankstein[1], M.J. Peterschmitt[1], G.A. Grabowski[2], J. Marshall[1], D.P. Copeland[1], S.H. Cheng[1]* 1) Genzyme Corp., Framingham, MA; 2) Cincinnati Children's Hospital Research Foundation, Cincinnati, OH.

Inhibitors of glucosylceramide synthase (GCS) are being evaluated for substrate inhibition therapy of Gaucher disease. We have developed a novel ceramide-based inhibitor of GCS (GENZ-112638), and assessed its activity and safety in an animal model of Gaucher disease as well as in healthy volunteers in Phase I clinical trials. In vitro characterization of GENZ-112638 showed significantly increased potency and specificity in comparison to sugar-based inhibitors of GCS. GENZ-112638 demonstrated up to 3500-fold greater potency (IC50) for inhibition of glucosylceramide (GL-1) synthesis and specific inhibition of GCS. Using a Gaucher mouse model (D409V/null), we demonstrated that treatment with GENZ-112638 was efficacious at well-tolerated oral doses in young mice prior to substrate accumulation and in older mice with established disease. In young mice treated with GENZ-112638 for 10 weeks, Gaucher cell formation was greatly reduced, and GL-1 accumulation significantly inhibited in the spleen (25%), lung (60%), and liver (45%). In older mice with established disease, treatment with GENZ-112638 resulted in a quantitative reduction of Gaucher cells in spleen, lung, and liver (~80%) and reduced tissue levels of GL-1 by 40-60%. In a clinical Phase Ib trial in normal volunteers, exposure levels at and above the in vitro IC50, which are expected to be in the efficacious range, were achieved with doses of 50 and 200mg BID and were well-tolerated. Plasma GL-1 reductions were observed after 4-10 days of dosing. These pre-clinical and Phase I data suggest that GENZ-112638 may be a promising orally available inhibitor of GCS for the treatment of Gaucher disease. A Phase II study is underway to investigate the pharmacokinetics, long-term safety, and efficacy of GENZ-112638 in type 1 Gaucher patients.

The genetics of Hermansky-Pudlak Syndrome. *R. Hess, A. Helip-Wooley, R. Kleta, M. Huizing, W.A. Gahl* MGB, NHGRI, NIH, Bethesda, MD.

Hermansky-Pudlak syndrome (HPS) comprises a group of autosomal recessive disorders of lysosome-related organelle (LRO) biogenesis. Eight HPS-causing genes (HPS1-HPS8) have been reported in humans and are associated with eight clinical subtypes. Oculocutaneous albinism, due to abnormal melanosome formation, and prolonged bleeding, due to the absence of platelet dense bodies, define all HPS subtypes. We have studied 168 HPS patients at the NIH Clinical Center. These studies have provided insights into genotype-phenotype characteristics. An accurate diagnosis of each subtype has important prognostic and therapeutic implications and also provides insights into the cell biology of LROs. HPS-1 and HPS-4 patients are at increased risk for developing pulmonary fibrosis and granulomatous colitis. A diagnosis of HPS-1 or HPS-4 also allows us to enter patients into our clinical trial of pirfenidone, an antifibrotic agent previously shown to slow the decline in pulmonary function in HPS-1 patients. HPS-1 (110 patients, 13 mutations) comprises the largest group due to a founder mutation in NW Puerto Rico. We also identified 10 HPS-4 patients (8 mutations). HPS-2 results from mutations in AP3B1, a gene encoding the beta3A subunit of adaptor complex-3, a coat protein that mediates vesicle formation. We identified 3 HPS-2 patients, harboring 4 different mutations. Our study of HPS-3 (20 patients, 10 mutations), HPS-5 (5 patients, 7 mutations), and HPS-6 (3 patients, 5 mutations) concluded that these subtypes are clinically milder, with no apparent pulmonary involvement. HPS3 has founder mutations in Central Puerto Rico and in Ashkenazi Jews, along with other scattered mutations. We have not identified any HPS-7 or HPS-8 patients and only one patient/family of each subtype has been reported. Our 17 unclassified HPS patients provide opportunities to identify new HPS-causing genes. Several genes, some corresponding to HPS mouse models that manifest both hypopigmentation and a platelet storage pool deficiency, are good candidates. Any new genetic causes of HPS will aid in elucidating the mechanism by which melanosomes, dense bodies, and lysosomes are created.

Preimplantation Genetic Diagnosis (PGD) for numerical and structural chromosome abnormalities: a laboratory experience. *R. Habibian[1], A. Hajianpour[1], S.Y. Kou[1], Q.Q. Huang[1], L. Drugan[1], L. Dong[1], D. Drugan[2]* 1) Genzyme Genetics, Monrovia, CA; 2) Occidental College, LA, Ca.

Genzyme Genetics has been one of the leading centers to offer PGD by fluorescence in situ hybridization (FISH) for chromosomal aneuploidy/imbalances since 2002 (then Alfigen). A retrospective PGD data analysis was performed herein on 8001 blastomeres from 800 consecutive patients. FISH was performed using Vysis probe mixtures including: X & Y, MultiVysion PGT (X/Y/13/18/21), MultiVysion Custom 5A (8/9/15/16/22), and subtelomere probes for the detection of chromosomal rearrangements. In one case, the STS probe for the detection of X-linked ichtyosis was used. Table 1 shows the number of patients/blastomeres tested for different probe mixtures according to indications.

	PGT+5A-prob	PGT-probe	Gender det.	Transloc.	STS	Total
Patients	257 (32.1%)	425 (53.1%)	100 (12.5%)	17* (2.1%)	1 (0.1%)	800
Blastomeres	2398 (30%)	4417(55.2%)	1009(12.6%)	166 (2.1%)	11 (0.1%)	8001

* One patient with 22 blastomeres was tested for translocation and 5-probe panel. The average turn around time was 0.93 days. The mean patient age was 37 (range 20.8-53). The average number of blastomeres tested was 10 per patient (range 1-41). Table 2 shows the PGD FISH results on 747 of 800 patients with known age. The abnormality rates were 50.5%, 54%, and 59% for the age groups <35, 35-39, and 39, respectively. Of 8001 blastomeres tested overall, 2793 (34.9%) were normal, 4313 (53.9%) were abnormal, 286 (3.6%) showed no signals, 162 (2%) had inconclusive results, and in 448 (5.6%) no nuclei were found. Of 800 patients tested, 115(14.4%) with mean age of 38.5 years showed no normal blastomeres. The average number of blastomeres tested in this group was 6.1 (range 1-17). More data, detailed description of data, and follow up information will be presented.

Paternal uniparental disomy (UPD) of chromosome 1 results in both Gaucher disease type 3 and hereditary sensory motor neuropathy. *K.S. Hruska[1,3], W.S. Benko[2,3], M.J. Eblan[1], O. Goker-Alpan[1], P.S. Hart[1], R. Schiffmann[2], E. Sidransky[1]* 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Developmental and Metabolic Neurology Branch, NINDS/NIH, Bethesda, MD; 3) These authors contributed equally to this work.

We report the first identified case of Gaucher disease (GD) caused by uniparental isodisomy. A 3½-year-old child presented with congenital sensorineural deafness, persistent eczema, tonic pupils, generalized hypotonia and lower extremity areflexia. This child had been diagnosed with GD type 3 at 22 months with hepatosplenomegaly, nystagmus, and Gaucher cells on bone marrow biopsy. Molecular diagnosis at that time revealed homozygosity for the c.1448T>C (L444P) allele of glucocerebrosidase (GBA), the enzyme deficient in GD. The family history was negative for consanguinity, but was remarkable for demyelinating Charcot-Marie-Tooth (CMT) disease in the probands father, paternal grandfather and great-grandfather. This history, coupled with the hearing loss and pupillary abnormalities, led to evaluation of the myelin protein zero (MPZ) gene, which causes CMT2J, as well as CMT1B and other polyneuropathies. Both GBA and MPZ are located on chromosome 1q21-22. Mutational analysis of the proband demonstrated homozygosity for the c.263C>T (S78L) allele of MPZ and confirmed homozygosity for the GBA mutation. The probands father was found to be heterozygous for mutations in both genes, while neither was identified in the mother. Further genotyping of the parent:child trio for five microsatellite markers spanning chromosome 1 showed no maternal contribution for three, while two were inconclusive. The proband was homozygous at all marker loci. Heterozygosity for the MPZ S78L allele is associated with a late-onset, mild form of CMT, so this early atypical presentation may reflect a gene dosage effect or be attributable to the influence of homozygosity for other loci on chromosome 1. While presumably rare, this case indicates that UPD should be considered in GD when the proband is homozygous for a disease allele in a non-consanguineous family and underscores the importance of obtaining parental genotypes whenever possible.

MOSAIC STRUCTURAL REARRANGEMENTS AND THE CHALLENGES THEY POSE TO CYTOGENETIC LABORATORY. *K. Mac, A. Zang, J. Cary, M. Samy, L. Drugan, R. Habibian, A. Hajianpour*
Genzyme Genetics 655 East Huntington drive Monrovia, CA 91016.

Mosaic structural rearrangements can be easily overlooked at the microscope, often detected only when extra effort and closer scrutiny are applied. We present three cases with mosaic structural rearrangements found at later stages of analysis. Case 1: Blood chromosome analysis was performed on a newborn girl for unspecified congenital abnormalities. Two cell lines were detected, one normal, and a second that was only detected when questioning an overlapped chromosome 2 in one of the karyotypes. Examining of additional cells revealed an interstitial deletion in the short arm of one chromosome 2 in 12 of 23 cells examined, resulting in a mosaic karyotype: 46,XX,del(2)(p21p22)de novo[12]/46,XX[11]. Parental chromosomes were normal. Case 2: Blood chromosome analysis indicated for family history of undefined chromosome abnormality was performed on a 44 year old female and revealed two cell lines, one normal, and a second that was first seen while analyzing the twentieth cell. It showed a paracentric inversion in one chromosome 13. Reexamination of the slides revealed three additional cells with the same inversion, and the karyotype was reported as 46,XX,inv(13)(p12q22.1)[4]/46,XX[19]. Inverted and recombinant chromosome 13s had been reported in this individuals daughter and grandchild, respectively. Case 3: Chromosome analysis, indicated for a history of missed abortions was performed on a POC specimen from a 40 year old female. Two cell lines were discovered. Five cells showed an apparent deletion in the short arm of one chromosome 5, and 15 cells were normal. The karyotype was reported as: 46,XY,del(5)(p14)[5]/46,XY[15]. Parental chromosome analysis was requested, but since the karyotype in this male fetus is mosaic, it is unlikely that a balanced rearrangement will be found in one of the parents. These cases each show how mosaic structural rearrangements challenge the technologists to avoid dismissing single abnormal cells as artifacts, and encourage them to check additional cells while heightening their awareness of the significance of family history.

The Role of MMP2 and COL1A1 Genes in High Myopia in Young Taiwanese Men. *H.Y. Hsieh[1], W.S. Zhang[1], K.S. Hung[2], H.S. Wang[2], C.L. Liang[2,3], S.H. Juo[1]* 1) Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Chang Gung University, Taiwan; 3) Bright-Eye Clinic, Kaohsiung, Taiwan.

Purpose: Sclera contains approximately 90% collagen and the majority is type I collagen. The matrix metalloproteinase-2 (MMP2) is responsible for degradation of sclera extracellular matrix, which may contribute to myopia. This study was aimed to investigate the relationship between high myopia and polymorphisms of MMP2 and type I collagen, alpha 1 (COL1A1) genes.

Design: A case-control study

Methods: The study subjects were recruited from military conscripts in Taiwan. A case was defined as refraction less than -6 D as well as control greater than -1.5 D. A total of 382 cases and 358 controls were genotyped for the MMP2 gene. Besides, there are 307 cases and 678 controls were genotyped for the COL1A1 gene. Ten tagging single nucleotide polymorphisms (tSNPs) at COL1A1 gene, and 17 SNPs at MMP2 gene were genotyped.Statistical analyses included Hardy-Weinberg equilibrium (HWE) test, chi-squared test to evaluate the genotypic effect.

Results: All SNPs are in HWE. Three SNPs at MMP2 had significance ($p<0.05$). Among them, a functional promoter SNP is particularly interesting. Using more stringent cutoff points to re-define high myopia, we found this SNP remains significant. The most significant result was the CT genotype of the promoter SNP had an OR of 0.53 ($p=0.006$) compared with the reference CC genotype. The risk C allele has a higher prevalence in Chinese (~90%) than in Caucasians (~70%). The results for the other two SNPs were not consistent across different cutoff points to re-define high myopia. For the COL1A1 gene, all 10 tSNPs did not yield promising results.

Conclusions: This is the first human study to comprehensively study the MMP2 and COL1A1 genes for high myopia. Our study indicated that the functional promoter polymorphism of MMP2 may play a role for the status of high myopia in human subjects. This promoter SNP may partially account for a higher susceptibility to myopia in Chinese.

SOS1 mutation alteres cell cycle progression in hereditary gingival fibromatosis. *S.I. Jang[1], E.J. Lee[1], P.S. Hart[2], M. Ramasawmi[1], D. Pallos[3], T.C. Hart[1]* 1) Section of Human and Craniofacial Genetics, National Institute of Dental and Craniofacial Research, NIH, Bethesda, MD; 2) Office of the Clinical Director, NHGRI, National Institutes of Health, Bethesda, MD 20892; 3) Periodontics Research and Graduate Studies Division, Department of Dentistry, University of Taubate, Sao Paulo, Brazil.

Hereditary gingival fibromatosis (HGF) type 1 is a rare autosomal dominant form of gingival overgrowth with some cases due to mutation of the son of sevenless-1 (SOS1). A single base insertion results in a frame shift that leads to premature termination and abolishes multiple SH3 binding domains. Cell proliferation studies show that fibroblasts of HGF1 have higher proliferation rates compared to normal control fibroblasts and the presence of mutant SOS1 leads to constitutive activation of ERK signaling which showed higher magnitude and longer duration in HGF1 fibroblasts. To further understand how the sustained ERK signaling affects the expression of cell cycle regulators, total RNA were obtained from cultured HGF1 fibroblasts and controls and cRNA probes were synthesized. Using focus oligoarray membranes containing more than 100 key genes involved in cell cycle regulation, the expression profiles of transcripts were analyzed and compared between normal control and HGF1. The results reveal that a significant increase on several cell cycle regulators including cyclin C (7-fold) which regulating S phase transition; cyclin D (4-fold) which regulating early stage of G1 phase; cyclin E1 (4-fold) and E2 (5-fold) which only elevates markedly in tumor-derived cells and functions in late G1 and early S phase. Also, while there is a modest increase of E2F1, E2F2 transcription factors, the expression of DP1 and DP2 show 6- and 11-fold increase, respectively. In addition, Rb and retinoblastoma binding protein 8 (RBBP8) show about 4- and 15-fold increase in HGF1. Taken together, these data support that mutant SOS1 of HGF1 fibroblasts causes continuous activation of MAP kinase signaling pathway which then results in up-regulation of cell cycle regulators that play a major role in cell cycle progression from G1 phase to S phase.

A sequence variation of the Myelin Oligodendrocyte Glycoprotein (MOG) gene in the HLA-Class I region is involved in susceptibility to Multiple Sclerosis (MS). *P. Momigliano-Richiardi[1], N. Barizzone[1], F. Guerini[2], P. Naldi[3], S. Calzoni[3], M. Trojano[4], S. D'Alfonso[1]* 1) Dept. Medical Sciences and IRCAD, Eastern Piedmont University, Novara, Italy; 2) Laboratorio di Biologia, Fondazione Don Gnocchi, IRCCS , Milano; 3) Clinica Neurologica, Ospedale Maggiore della Carità, Novara; 4) Dipartimento di Scienze Neurologiche e Psichiatriche, Bari.

Several studies suggest that the HLA class I region harbours genes modulating MS susceptibility independently from the effect of class II alleles. A candidate gene in this region is MOG, encoding the Myelin Oligodendrocyte Glycoprotein. A significant association with the missense variation V142L, in the transmembrane region, was previously reported in a small sample of 50 Italian MS patients. We confirmed this result both by a case-control test (L142 allele frequency in 617 Italian MS patients vs 573 matched controls: 0.15 vs 0.20, p=0.003, OR: 0.73) and TDT in 255 trio families (44T : 79NT L142 alleles, p=0.002). Combining allele frequencies from the two sample sets L142 had an OR = 0.71 (p=0.0003). This result was independent of DR15. We further tested by TDT in 199 trio families the involvement of additional MOG polymorphisms, namely 7 previously described SNPs in the 5 flanking (positions -1077, -910, 875, -93) and coding region (S5S, L22del, V145I), 4 newly detected SNPs in the 3UTR, and 2 microsatellites in the 5 flanking and 3UTR, respectively. None of these alleles or their haplotypic combinations showed a significant transmission distortion, in the absence of the V142L marker. To test whether the association observed for V142L extended outside the MOG gene, we analysed in the same 199 trio families the association with MS of 4 microsatellites (MIB, D6S265, D6S1683 and D6S2239) localized in the HLA-class I region from HLA-B to HFE. None of the microsatellite alleles showed a significant transmission distortion indicating that there is no further detectable effect on MS susceptibility. These data suggest the presence of a second MS susceptibility factor in the Class I region, independent from the effect of class II alleles. It is located in the MOG gene and it likely corresponds to the V142L variation.

Analysis of *IC140*: An IDA intermediate chain dynein as a candidate gene for Primary Ciliary Dyskinesia (PCD).

M.R. Knowles[1], M.W. Leigh[1], M.P. Kennedy[1], P.G. Noone[1], S.M. Lyons[1], E. Escudier[2], H. Omran[3], S. Amselem[2], M.A. Zariwala[1] 1) Dept. Medicine, pediatrics and Pathology & Lab. Medicine, University of North Carolina, Chapel Hill, NC, USA; 2) Institut de la Sante et de la Recherche Medicale, Creteil, France; 3) Dept. Pediatrics & Adolescent medicine, University Hospital Freiburg, Freiburg, Germany.

Primary ciliary dyskinesia (PCD) is caused by abnormalities in the structure and function of cilia and flagella of sperm. It is inherited as an autosomal recessive trait and characterized by oto-sino-pulmonary disease. Half the patients have situs inversus (Kartagener syndrome). It is a genetically heterogeneous disorder which complicates identification of disease-causing mutations. The ultrastructural defects identified in ~90% of PCD patients involves either the outer dynein arm (ODA), inner dynein arms (IDA) or both. Thus far, disease-causing mutations have been identified in *DNAI1* and *DNAH5* (both encoding ODA proteins) and account for 38% of PCD patients; however, no disease-causing mutations have been detected in IDA candidate genes. The flagella of biflagellate protozoa, *Chlamydomonas*, shares a high degree of structural homology with human cilia; therefore, gene mutations identified in motility defective mutant *Chlamydomonas* are likely candidates for PCD. We have identified the human orthologue of *IC140* gene from the human genome database designated as NYD-SP29. *IC140* is an intermediate chain of IDA which is paralogue of *DNAI1*of ODA. We carried out mutation analysis by sequencing all of the 22 coding exons and intron/exon junctions of human *IC140* in 126 unrelated well-characterized PCD patients (n=63 had ODA defect and n=51 had isolated IDA defects). Almost 70% of the sequence analysis is completed thus far, but no disease-causing mutations have been identified. Our results currently suggest that *IC140* is not frequently mutated in human PCD. This abstract was funded by UNC/URC, GCRC#00046, MO1 RR00046-42, 1 RO1 HL071798, 5 U54 RR019480.

Whole genome association study of chronic inflammatory arthritis. *S. John[1], A. Hinks[1], N. Shephard[1], M. Cargill[2], Y. Turpaz[2], E. Wang[2], A. Barton[1], S. Eyre[1], W. Thomson[1], J. Worthington[1], G. Kennedy[2]* 1) ARC Epidemiology Unit, Univ Manchester, Manchester, United Kingdom; 2) Affymetrix, Santa Clara, USA.

Rheumatoid arthritis (RA) and juvenile idiopathic arthritis (JIA) are both chronic inflammatory conditions with an autoimmune pathology. In common with other autoimmune diseases, both RA and JIA are heritable and are associated with genes in the MHC. The recent association of the PTPN22 R620W SNP with several autoimmune diseases confirms the hypothesis that there is an underlying common genetic basis in autoimmunity. Aim: To identify novel inflammatory arthritis susceptibility loci. Methods: 184 healthy adult controls and 449 cases with a chronic autoimmune arthritis and an age at onset <40 years were available for study. Of the cases 168 had a clinical diagnosis of RA and 281 a diagnosis of JIA. Genotyping was performed using the Affymetrix GeneChip mapping 100K array. The Armitage test for trend was employed to test for association with disease and the false discovery rate (FDR) q-value method was applied to account for the multiple comparisons performed. Results: 82,500 SNPs with a MAF>5%, a HWE p>0.0001 in controls and a >80% call rate were analysed for evidence of association to disease. Applying a FDR of 5%, the q-value method generated 118 SNPs that remained significantly associated after correction for multiple testing. An additional 65 SNPs were selected after applying more stringent quality control; p<0.001 and with a call rate >95% in both cases and controls and 32 SNPs that mapped to peaks of linkage. These SNPs (n=215), which included two within the HLA region and four within the PTPN22 gene region, were genotyped in a second cohort of 553 (405 RA and 128 JIA) cases and 426 controls. To date eleven SNPs have evidence of association with inflammatory arthritis (p<0.05) in both cohorts and will be investigated further. Discussion: Detection of known disease susceptibility loci (HLA and PTPN22) in this study is a proof of principle that whole genome SNP association studies have the potential to identify novel arthritis genes.

Extending Mendelian Mutation Prediction Models to Account for Medical Interventions: Application to Incorporating Oophorectomy into BRCAPRO. *H.A. Katki* Divison of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD.

Mendelian models for predicting who may carry an inherited deleterious mutation of known disease genes based on family history are used in a variety of clinical and research activities. Family members who carry the mutation or are otherwise at high risk for disease may undergo medical interventions to reduce their disease risk. For example, oophorectomy, the removal of the ovaries, is a drastic intervention that is being increasingly offered to women at high risk of breast or ovarian cancer, and so oophorectomy is increasingly being reported in family histories of breast and ovarian cancer. Mendelian models should account for medical interventions because interventions modify the mutation penetrances and thus also the carrier probability estimate. In this work, we extend Mendelian models to account for medical interventions. We show that ignoring medical interventions undergone by a family member can seriously affect the mutation carrier probability estimate, especially when the family member has lived many years post-intervention. Incorporating medical interventions into Mendelian models requires only an extra factor accounting for post-intervention disease history. This post-intervention factor can be estimated from published studies of the effects of interventions. We apply our results to the BRCAPRO model that predicts a woman's risk of carrying mutations in *BRCA1* and *BRCA2* based on her family history of breast and ovarian cancer. We apply this methodology to incorporate oophorectomy into BRCAPRO, and this extension is available for clinical use at: http://www.cancerbiostats.onc.jhmi.edu/BayesMendel/.

A Case Report of Perinatal Lethal Gaucher Disease. *J. Oliver[1], S. Bhatt[1], M. Bocian[2], N. Narula[2], J. Bonadio[2]* 1) Genzyme Genetics, Orange, CA; 2) University of California, Irvine Medical Center, Orange, California.

We present a case of a 25-year-old G2P1 woman of Palestinian ancestry, referred at 19 weeks gestation for a positive triple marker screen with a Down syndrome risk of 1/80 and Smith Lemli Opitz syndrome risk of 1/16. The patient and her husband are consanguineous and this pregnancy was achieved using a frozen embryo transfer from eggs harvested at age 21. Fetal ultrasound was abnormal with increased nuchal thickness of 8 mm, abdominal ascites, absent stomach bubble, and bilateral club feet. Fetal karyotype was normal, 46,XY; AF-AFP and 7-dehydrocholesterol were also normal. Worsening of ultrasound findings led the patient to elect pregnancy termination. The most significant finding on fetal autopsy was the identification of typical Gaucher cells in brain, spleen, liver, thymus, lymph nodes, and placenta. Enzyme analysis on cultured cells revealed absent beta-glucosidase activity, confirming the diagnosis of perinatal lethal Gaucher disease. Gene sequencing revealed that the fetus appears to be homozygous for the rare C342Y mutation; although DNA testing of the parents will be required before the possibility of compound heterozygosity for a large deletion and the C342Y mutation can be excluded. Family history was significant for four female family members with significant developmental problems and decreased life span. Their neonatal course was characterized by low or high blood sugar, seizures, and brain damage. Three who survived the neonatal period had severe developmental delay and remained curled up in a ball; two died at ages 13 and 19, respectively, while one is reportedly still alive. It is possible that some of these individuals may have been compound heterozygotes resulting in a subacute course with death before age 20. This case shows the importance of offering the fetal autopsy to arrive at a diagnosis, especially in the presence of unexplained family histories and non-specific ultrasound abnormalities. The diagnosis of perinatal lethal Gaucher in this pregnancy, confirmed by molecular methods, will allow for prenatal diagnosis in this couples future pregnancies and identification of other at-risk family members.

A Complex Chromosomal Rearrangement of Chromosome 14- a prenatal case. *C. Lee, A. Hajianpour, S.Y. Kou, P.C. Ng, R. Habibian* Genzyme Genetics, Monrovia, CA.

We present a prenatal case of stable non-Robertsonian dic(14;15) found in all metaphase cells examined from an amniotic fluid specimen on a 35 year old G3, P2 female at 16.1 weeks gestation due to omphalocele finding. Cytogenetic analysis revealed trisomy 18 as well as an abnormal chromosome 14 with a classic acrocentric short arm, an unusual banding pattern below the centromere, and additional chromatin material on the long arm. FISH using whole chromosome paint 14 probe revealed an unexpected result. Hybridization of the probe was not observed either on the short arm nor on the terminal long arm of the abnormal chromosome 14, might suggesting that another acrocentric chromosome be involved. Additional FISH performed utilizing probes specific for the centromeres of acrocentric chromosomes, subtelomere 14q and Prader-Willi/Angelman syndrome chromosome region (SNRPN). It showed that the primary constriction and the short arm initially assumed to be of chromosome 14 is of chromosome 15 origin with breakpoint at 15q11.2 and lacking SNRPN region. The telomere 14q was juxtaposed to 15q11.2. The 14/22 probe hybridized to the opposite end (non-constricted end) of the abnormal chromosome 14, representing an inactive centromere 14. The abnormal chromosome 14 was subsequently re-interpreted as a pseudodicentric chromosome comprised of chromosome 14 and 15 material with breaks and reunion at bands 14q32.3 and 15q11.2. The resulting net imbalance in addition to trisomy 18 is partial trisomy 15pter-15q11.2. The karyotype was determined as follows: 47,XY,der(14),+18.ish psu dic(15;14)(q11.2;q32.3)(wcp14-,D15Z4+,SNRPN-;wcp14+,14qter+,D14Z1/D22Z1+). The pregnancy was terminated due to the presence of trisomy 18. Parental chromosome studies are pending. The presence of three active centromeres 15 and an inactive centromere 14 is most likely clinically insignificant as they are reported in phenotypically normal individuals with a gain of marker chromosome 15 or Robertsonian translocation involving chromosome 14. This case may represent a rare trisomy rescue mechanism. However, re-examination of the slides did not reveal the presence of a trisomy 15 cell line.

PRELIMINARY RESULTS OF AN OPHTHALMOLOGICAL EVALUATION AND MOLECULAR STUDIES IN A DEAF COLOMBIAN POPULATION. *M. Olarte[1, 2], N. Gelvez[1], G. Mariluz[1], S. Florez[2], D. Medina[2], M. Tamayo[1, 2]* 1) Inst de Genetica Humana, Univ Javeriana, Bogota , Colombia; 2) Fundación Oftalmológica Nacional, Bogotá, Colombia.

We performed a preliminary study for non-syndromic deafness in Bogotá, Colombia. The Connexin 26 gene was sequencing in a total of 112 individuals with non-syndromic deafness. The inclusion criterias for the selection were: individuals with non-syndromic deafness with familiar history of deafness and sporadic cases with unknown cause. The first step of the selection of our population was the ophthalmological examination as important criteria. From 276 deaf individuals, the 74.3% (205/276) showed normal fundoscopy, while in the 19.9% (55/276) we found salt and pepper retinopathy and the remaining 5.8% (16/276) presented other ocular alterations. A complete medical history, prenatal antecedents and clinical examination were performed in the 205 selected deaf individuals. All the confirmed acquired deafness were excluded. In total, 112 deaf individuals were studied, which were classified in two groups: the 59.9% (67/112) as recessive nonsyndromic hearing loss (RNSHL) and, the remaining 40.1% (45/112) as sporadic cases without known cause. We identified three mutations and two polymorphisms in Cx26 gene: mutations 35delG, S199F and 167delT reported in the literature and, the polymorphisms V27I and M34T. Among the total of 224 alleles in the studied population, S199F was the most frequent (17.9%), follow by 35delG (17.0%) and 167delT in 0.4%. We identified some mutation in the GJB2 gene in 50.7% of the group with genetic etiology, and in the 33.3% of the sporadic cases with unknown cause. The frequency of S199F mutation in our nonsyndromic deaf population is higher than other reported studies, while the frequency of the 35delG mutation was similar to reported in Caucasian population. This frequency reported in Bogotá is a preliminary data in Colombia.

False evidence for imprinting using linkage data. *M.C. Monti[1,2], J. Zhang[1], L.J. Strug[1], B. Feenstra[1,3], D.A. Greenberg[1]* 1) Div Stat Genet, Dept Biostat, Columbia Univ, NY, NY; 2) Dept. Applied Health Sci, Pavia Univ, Italy; 3) Royal Vet & Agricult Univ, Dept Natural Sci, Denmark.

We previously studied two methods to detect imprinting: lod score maximization with respect to parent-of-origin-based penetrances (PP) and lod score maximization with respect to independent male-female recombination fractions (RF). We found that the PP method had more power to detect imprinting than the RF method; however, under sex-specific penetrance, the PP method could falsely indicate imprinting. To better understand when either method provides false evidence for imprinting, we studied the distribution of the likelihood ratio test statistic under the null hypothesis, for the PP and RF method. We simulated nuclear family and extended pedigree data with and without imprinting, which we defined as the parental-origin-dependent penetrance in offspring. We maximized two-point lod scores over parent-of-origin penetrances (PP) and, in separate experiments, over combinations of male-female recombination fraction (RF). In both cases, we examined the power to detect, and the probability of falsely detecting, imprinting. We tested a range of data set sizes as well as determined the effects of reduced penetrance, heterogeneity, and ascertainment criteria. When there is no imprinting, the type I error rate is strongly affected by locus heterogeneity and the ascertainment criteria. Without heterogeneity or reduced penetrance in the generating model, the likelihood ratio test was quite conservative for both PP and RF methods. However, the type 1 error rate exceeded the 5% level when genetic heterogeneity was present in the data, and worsened with increasing heterogeneity. Families selected for having a high density of affected members also resulted in an increased Type I error rate. Thus, ascertainment criteria and heterogeneity are important confounders in detecting imprinting, whether via the RF or PP method, in linkage analysis.

A loss of function mutation in the fibulin-4 gene causes a severe form of recessive cutis laxa. *V. Hucthagowder[1], N. Sausgruber[1], K.H. Kim[2], B. Angle[2], L.Y. Marmorstein[3], Z. Urban[1,4]* 1) Department of Pediatrics, Washington University School of Medicine, St.Louis, MO, USA; 2) Childrens Memorial Hospital, Chicago, IL, USA; 3) Department of Ophtalmology and Vision Science, University of Arizona, Tucson, AZ, USA; 4) Department of Genetics, Washington University School of Medicine, St.Louis, MO, USA.

Cutis laxa (CL) is a heterogeneous group of inherited or acquired disorders characterized by pendulous and redundant skin with lack of elasticity. We have begun the mutational evaluation of fibulins, a recently recognized family of extracellular matrix proteins, as candidate genes for CL. A collection of 65 unrelated CL patients were analyzed for mutations in the fibulin-4 gene by direct DNA sequencing of genomic amplimers. We identified a homozygous missence mutation (169G>A) E57K in a patient. Both of her parents were heterozygous, suggesting autosomal recessive inheritance. The patient had multiple fractures at birth and was diagnosed with vascular tortuosity, ascending aortic aneurysm, developmental emphysema, inguinal and diaphragmatic hernia, joint laxity and pectus excavatum by age 2 years. Histological evaluation of her skin revealed smaller than normal collagen bundles, increased vascularization of the upper dermis and severely underdeveloped elastic fibers. RT-PCR analysis showed comparable expression of fibulin-4 mRNA in skin fibroblasts from the patient to healthy controls and sequencing confirmed the presence of mutation E57K in the patient. Immunoblots showed normal abundance of fibulin-4 in patient cell lysates, but extracellular matrix extracts of patient fibroblast cultures showed greatly reduced fibulin-4 content. Pulse-chase immunoprecipitation studies further confirmed that E57K mutant fibulin-4 was not secreted and degraded inside the cell, suggesting that this mutation results in loss of fibulin-4 function. Our results demonstrate for the first time, that a homozygous mutation in fibulin-4 is associated with a new recessive cutis laxa syndrome characterized by severe systemic connective tissue abnormalities.

CARD8 is associated with Crohns disease in the Puerto Rico population. *L. Mei[1], E.A. Torres[2], Y. Picornell[1], X. Su[1], F. Gregory[2], R. Mera[2], P.J. Nieves[2], D. Dutridge[1], K. Taylor[1], H. Yang[1], J.I. Rotter[1]* 1) Medical Genetics, Cedars-Sinai Medical Center, Los Angeles, CA; 2) University of Puerto Rico, San Juan, Puerto Rico.

Background: Caspase-associated recruitment domains (CARD) are key modules in proteins that play important roles in the NFB signaling pathway, which is important in the activation of genes involved in immunity, inflammation, and apoptosis. CARD15/NOD2, the first susceptibility gene identified in Crohns Disease (CD), indicated the role of a disturbed innate immune response in CD. Recently a new member of CARD-containing family, CARD8 located in the IBD6 region (19p13), was reported in abstract to be associated with CD in adults and Ulcerative Colitis (UC) in children. Aim: To investigate the association between CD and CARD8 variant in the Puerto Rican (PR) population. Methods: 38 trio families with one affected offspring, 128 unrelated CD cases and 110 healthy controls were ascertained from Puerto Rico (PR). The SNP (23192A/T) at codon 10 which the variant codes for a stop codon in CARD8 was genotyped using the TaqMan MGB platform (ABI). The transmission disequilibrium test (TDT) was employed to test association with CD using Haploview 3.2. Multiple logistic regression was carried out to analyze the case-control sample. Results: There was significant distortion of transmission of the CARD8 A allele, the common allele, in CD parent-offspring trios (T: U=22:9, P=0.02). The A allele also had a higher frequency in cases than in controls (77% vs 69%, p=0.05). Multivariable analysis showed that the AA genotype was associated with increased likelihood of CD (AA vs. AT+TT: p=0.04, OR 1.8, 95% CI: 1.03-3.1) after controlling for age and gender. Conclusions: This is the first report of a CARD8 association with CD in a Hispanic population. Recent studies have suggested that CARD8, like other CARD family proteins, is involved in apoptosis and NFB activation. The data herein further underscore the existence of a genetic basis for alteration in the innate immune response pathway in the pathogenesis of CD.

Summary of clinical implementation of Chromosomal Microarray Analysis (CMA) in 2668 cases. *X.Y. Lu, J. Li, A. Patel, M.L. Cooper, W.R. Wells, C.M. Sullivan, T. Sahoo, S.A. Yatsenko, Z. Ou, P. Stankiewicz, J.R. Lupski, C. Chinault, A.L. Beaudet, S.W. Cheung, P.A. Ward* Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Array CGH is a powerful molecular cytogenetic technology that enables detection of genomic imbalances with higher resolution than current clinical methods. We report the outcome of array CGH studies, termed Chromosomal Microarray Analysis (CMA), performed clinically in 2668 postnatal patients referred with variable clinical phenotypes. The initial 930 samples were studied using CMA version 4.0 (V4.0, 362 BAC/PAC clone coverage) and the remaining 1738 samples used CMA version 5.0 (V5.0, 830 BAC/PAC clone coverage). Overall, CMA identified clinically relevant genomic imbalances in 215 patients (8.1%) [V4.0, 66/930 (7.1%) and V5.0, 149/1738 (8.6%)]. Abnormal CMA findings were seen in 95 of 1975 patients (4.8%) with normal karyotypes, and there was a 44.7% higher detection rate among samples studied on V5.0 versus V 4.0. Among 121 cases referred for additional investigation of a known cytogenetic rearrangement, CMA identified genomic imbalances in 72 cases (59%); the remaining 41% had normal results. For 572 cases with unavailable cytogenetic results, 48 (8.4%) had abnormal CMA results. Improved diagnostic potential of CMA is illustrated by 89 cases identified with cryptic microdeletions (57) and the predicted reciprocal microduplications (32) within 12 specific chromosomal regions associated with known genomic disorders; conventional cytogenetics failed to detect 75% of microdeletions and 91% of microduplications in a subset of 68 patients in this group. Overall, CMA identified copy number variations (CNVs) of uncertain significance in 276 probands, requiring parental studies. Of these, 192 (70%) were interpreted as familial variants and 11 (4%) were de novo; the remaining 73 (26%) await parental study to resolve clinical significance. Our experience using CMA in a large clinical cohort demonstrates the significantly improved sensitivity of this technology for diagnosis of genomic imbalances and highlights the need for comprehensive genetic counseling to facilitate accurate clinical correlation.

Minimal Phenotype Resulting from Mosaic Deletion of 11p12p14 in a Patient with Primary Dopamine beta-Hydroxylase Deficiency: Identification and Characterization by High-Resolution Array-CGH. *J. Li[1], M.L. Cooper[1], M.T. Geraghty[2], D.E. Mensing[1], K.D. Vonalt[1], Z. Ou[1], A.N. Pursley[1], A.C. Chinault[1], A. Patel[1], S.W. Cheung[1], T. Sahoo[1]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Childrens Hospital of Eastern Ontario, ON, Ca.

Deletions involving the short arm of chromosome 11 have been well characterized in the context of WAGR syndrome (Wilms tumor, Aniridia, genitourinary abnormalities and mental retardation) involving 11p13, and the Potocki-Schaffer syndrome resulting from more proximal deletions at 11p11.2. Mosaic deletions of 11p13 in WAGR syndrome are extremely rare. Large deletions involving contiguous segments between 11p12 and 11p14, in a mosaic form, have not been reported earlier in the absence of WAGR phenotype. We report here the characterization of the cytogenetic abnormality and genotype-phenotype correlations in a 16 year-old female with primary dopamine beta-hydroxylase (DBH) deficiency, bilateral iris coloboma, short hands and short, high-arched feet and having normal intelligence and development. High-resolution array-CGH revealed a loss for a segment of at least 1 Mb across 11p13 that included the PAX6 and WT1 genes within the WAGR syndrome critical region. The array-CGH results were suggestive of mosaicism for the deletion. Analysis of G-banded chromosomes and fluorescence in situ hybridization revealed a deletion of the region between 11p12 and 11p14.3 in only 28% of cells analyzed. Utilizing a genome-wide oligonucleotide array, the deletion segment was estimated to encompass approximately 11 Mb including the 11p13 segment seen by array-CGH. Since the patient is known to be homozygous for two disease causing mutations in the DBH gene that maps to 9q34.2, the 11p12p14 deletion is unlikely influence her manifestations from DBH deficiency. It is possible that her bilateral iris colobomata might be a manifestation, albeit abbreviated, of the haploinsufficiency for PAX6. This unusual combination of genetic and cytogenetic abnormalities is probably coincidental and helps explain some components of her phenotype, and further characterization is in progress to elucidate a stronger genotype-phenotype correlation.*PAX6 WT1 DBH*.

Prevalence of somatic alterations in sporadic prostate cancer genomes. *N. Makridakis[1], T. Phipps[1], J. Reichardt[2]* 1) Biochem/Mol Biol/Inst Gen Med, Univ Southern California, Los Angeles, CA; 2) Medical Foundation Building (K25), University of Sydney, Sydney, NSW, Australia.

Little is known about the prevalence of somatic alterations in most human cancers. In order to assess global mutation rates in the prostate cancer genome, we analyzed 100 kb of total sequence using DNA from blood lymphocytes (constitutional), normal prostate and tumor prostate taken from 6 men with prostate cancer. Specifically, each genomic DNA was cut with AluI, subcloned, and then 50-100 colonies were sequenced from each sample. Comparison of the sequencing results with the nr-database in Genbank identified a total of 62 variations in the tumors, 32 in the normal prostates, and 31 in the blood DNAs, using approximately equal sequence lengths of 34 kb. This PCR-free method resulted in a significant over-representation of variants in the tumor compared with the normal prostate ($p= 0.002$). Extrapolation of this difference in variation rate between the normal and prostate tumor DNA suggests that there are 1-6 million somatic alterations per tumor cell genome in most (5 out of 6) patients. These results are in contrast to previously published results obtained in colorectal cancer by PCR-based methods. Further analysis demonstrated that 71% of the tumor variations occur in the sequence motif we previously identified (THEMIS motif; Makridakis et al., submitted), while only 39% of the normal prostate variations occur in this motif (with one mismatch allowed; $p= 0.009$), and 40% of the blood variations occur in the motif. Thus, many of the somatic alterations in the prostate tumor genome may have similar etiology. These results are consistent with the mutator phenotype model for prostate tumorigenesis and have implications for the cancer genome project.

Genotype-phenotype correlations at the MKS1 and MKS3 loci in Meckel syndrome and related phenotypes. *R. KHADDOUR[1], L. BAALA[1], U.M. SMITH[2], C. OZILOU[1], J. MARTINOVIC[1], S. AUDOLLENT[1], C. ESCULPAVIT[1], N. KADHOM[1], M. KYTALLA[3], A. MUNNICH[1], F. RAZAVI[1], E. GENIN[4], J. ROUME[5], M.C. GUBLER[6], M. VEKEMANS[1], C.A. JOHNSON[2], T. ATTIE-BITACH[1]* 1) Genetics and INSERM U781, Hopital Necker, Paris, France; 2) Medical and Molecular Genetics, University of Birmingham Medical School, Birmingham; 3) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 4) INSERM U535, Hôpital Paul Brousse, Villejuif; 5) Génétique Médicale, CHI Poissy, Saint Germain en Laye; 6) INSERM U574, Hopital Necker, Paris.

Meckel syndrome (MKS) is a lethal autosomal recessive disease characterized by cystic kidneys, a brain malformation (usually occipital encephalocele), polydactyly, and hepatic developmental defects. Recently, two genes have been identified: *MKS1* on 17q in Finnish kindreds and *MKS3* on 8q in families from Pakistan and Oman, encoding ciliary proteins. We report on the sequence analysis of the *MKS1* and *MKS3* genes in a large multhiethnic cohort of 56 cases of MKS as defined by Salonen and 45 related phenotype or Meckel-like. *MKS1* recessive mutations were identified in 6 families with classical MKS phenotype. Most mutations abolished the B9 conserved domain of the protein. One case had a situs inversus. Two cases, from families of French origin, carried the Finnish major mutation allowing us to estimate its age to 4350 years. Seven fetuses carried MKS3 mutations or a large intragenic deletion. All missense mutations lied in the extracellular domain of the protein. Polydactyly was significantly less frequent when carrying *MKS3* (2/12) than *MKS1* mutations (8/10). All had bile duct proliferation of liver. In contrast to *MKS1*, brain phenotype varied from occipital encephalocele, isolated Dandy-Walker malformation to normal brain in one case. Two sibs presented vermis agenesis and small cysts in renal medulla, a phenotype not usually observed in MKS. Our results indicate that *MKS1* and *MKS3* genes are each responsible for at least 10 % of MKS cases with various mutations in different populations. A strong phenotype/genotype correlation was observed concerning the polydactyly, brain and kidney anomalies.

Mutational analysis of mitochondrial tRNALeu(UUR) gene in 740 Chinese subjects with type 2 diabetes. *J. Lu[1], D. Wang[1], WeL. Wei[1], J. Ji[1], W. Ye[1], J. Zhao[1], R. LI[2], M. Guan[1,2]* 1) Medical Genetics, Wenzhou Medical College, Wenzhou, Zhejinag, China; 2) Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio.

Mutations in mitochondrial DNA, especially in the tRNA-Leu(UUR) gene, have been associated with type-2 diabetes. With the aim of investigating the prevalence and clinical features of Chinese subjects with type-2 diabetes, a systematic and extended mutational screening of mitochondrial DNA has been initiated in the large clinical population at the Wenzhou Medical College, China. In the current study, we performed the mutational screening of tRNA-Leu(UUR) gene in 740 Chinese subjects with type 2 diabetes. Of these subjects, one subject carried the A3243G mutation, one individual harbored the T3253G mutation, 5 patients had T3258G mutation, one subject carried the G3277A mutation, 10 individuals contained T3290C mutation and one subject has T3300C mutation. The prevalence of A323G mutation in Chinese type-2 diabetes seems to be lower than other ethnic populations. Further molecular analysis of the mitochondrial DNA in the Chinese pedigree carrying the A3243G mutation revealed the presence of the A3243G mutation and 37 other variants, belonging to the Asian haplogroup D5. The A3243G mutation is present at heteroplasmy in matrilineal relatives of this Chinese family. None of other variants showed evolutionarily conservation and functional significance. These suggest that mutations in tRNA-Leu(UUR) gene are one of molecular basis in type-2 diabetes in Chinese population.

Neanderthal Genomics. *J.P. Noonan[1,2], G. Coop[3], S. Kudaravalli[3], D. Smith[2], J. Krause[4], J. Alessi[2], F. Chen[2], D. Platt[2], S. Pääbo[4], J.K. Pritchard[3], E.M. Rubin[1,2]* 1) Genomics Division, Lawrence Berkeley National Laboratory, Berkeley, CA; 2) US DOE Joint Genome Institute, Walnut Creek, CA; 3) Department of Human Genetics, University of Chicago, Chicago, IL; 4) Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany.

Our knowledge of Neanderthals is based on a very limited number of remains and associated artifacts from which we must make tenuous inferences concerning their biology, behavior and relationship to ourselves. Here we describe a new dataset with significant potential for characterizing these extinct hominids from a new perspective based on the development, high-throughput sequencing and analysis of Neandertal metagenomic libraries. The first library studied was created from the remains of a 45,000-year old Neanderthal. Multiple lines of evidence indicate the vast majority of the 66,643 bp of hominid sequence so far identified in the library are of Neanderthal origin, the strongest being the identification of sequence changes in humans at sites where Neanderthal and chimpanzee genomic sequences are identical. These findings have enabled us to calculate the human-Neandertal divergence time based on multiple, randomly distributed autosomal loci, in contrast to previous studies that relied on only a few mitochondrial loci. Our analyses suggest that the Neanderthal genomic sequence we obtained and the reference human genome sequence diverged ~730,000 years ago. We also estimate that the ancestral populations that gave rise to the modern human and Neanderthal lineages diverged 370,000-470,000 years ago, prior to the emergence of anatomically modern humans. Based on these results, we are able to exclude a substantial Neandertal contribution to modern human genetic diversity. In order to identify Neanderthal orthologs of human sequences of specific interest without having to sequence the entire genome, we have also developed a directed genomic selection method that we have successfully used to recover targeted sequences from Pleistocene metagenomic libraries. These studies advance our understanding of the evolutionary relationship of *Homo sapiens* and *Homo neanderthalensis* and signify the beginning of Neanderthal genomics.

Genetic Tools: An online resource to help primary care faculty integrate genetics into primary care training.

A.M. Laberge[1], K. Fryer-Edwards[1,2], S.B. Trinidad[2], W. Burke[1,2] 1) Institute for Public Health Genetics, U. of Washington, Seattle; 2) Medical History and Ethics, U. of Washington, Seattle.

Genetics is increasingly relevant to primary care, but genetics content in primary care training remains limited. Building on the work of the HRSA-funded Genetics in Primary Care (GPC) project, an online resource was developed to help primary care faculty integrate genetics content into their teaching. The Genetic Tools website (www.genetictools.org) contains 41 case-based modules on 25 different topics and a section on general genetics concepts and skills. All materials underwent external review by experts in both genetics and primary care. The Genetic Tools website was advertised to GPC participants and advisory committee members, the American Academy of Family Physicians, and the National Coalition for Health Professional Education in Genetics. Visitors to the website are asked to answer an exit survey about the content and format of the website. Preliminary results are available (n=30). Respondents include family physicians(11), pediatricians(1), internists(4), ob/gyn(1), genetics professionals(8), and others(5). The majority of users found the website easy to use (87%), clear and easy to understand (90%), and relevant for primary care providers (90%). Of the 25 case topics, breast cancer (50%), colorectal cancer (27%), hearing loss (27%), and developmental delay (27%) were appreciated the most. The multiple ways of indexing cases (by disease, mode of inheritance, or age group) were found to be very useful (77%). Among the subjects covered in the genetics concepts and skills section, respondents preferred the modules on family history and red flags (indicators of a genetic diagnosis) (43% and 40% respectively). The majority of respondents would definitely use this website for teaching (70%), but 37% anticipate barriers to its use, such as lack of time or online access. The majority (77%) would definitely recommend this website to their colleagues. The Genetic Tools website seems to fulfill a need for an easily accessible and up-to-date genetic teaching resource for primary care faculty. Further evaluation is needed to identify ways to continue to improve the website.

A Comparison of genomewide linkage results for autism spectrum disorders using different diagnostic criteria.

M. Liu[1], C. Chrysler[2], P. Szatmari[2], L. Zwaigenbaum[2], A.D. Paterson[1,3] 1) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Offord Centre for Child Studies, McMaster University, Hamilton, Ontario, Canada; 3) Department of Public Health Sciences, University of Toronto, Toronto, Ontario, Canada.

Background: Genetic studies for susceptibility genes for autism typically use two well-known diagnostic instruments, the Autism Diagnostic Interview-Revised (ADI-R) and the Autism Diagnostic Observation Schedule (ADOS), to define affected individuals. However, a diagnostic scheme that combines the ADI, ADOS and other instruments may produce a more reliable diagnostic trait for genetic analysis of children with the broader category of autism spectrum disorders (ASD). Objectives: To compare the effects of different ASD diagnostic definitions on linkage results. Methods: Non-parametric linkage analyses, using multiplex families from the Autism Genetic Resource Exchange (AGRE) data, were performed on ASD defined using 3 different criteria: ADI (broad definition); ADOS (definition of ASD); and the combination of ADI and ADOS (combined definition). There were 292, 113 and 104 informative families in each group, respectively. Results: A locus on chromosome 5p13.3 reached suggestive linkage (LOD score = 2.34, p = 0.0005) for ASD using the ADOS definition, while the LOD scores were 0.25 (p = 0.14) and 1.23 (p = 0.009) at this locus using the ADI broad and combined definitions, respectively. Conclusion: Linkage analysis results varied dramatically when different diagnostic schemes were used to derive ASD affection status. Finding a trait that optimizes the genetic component in ASD is important for future genetic analysis.

A genome-wide scan for quantitative trait loci of serum lactate dehydrogenase -- the Framingham Offspring Study. *J-P. Lin*[1], *L.A. Cupples*[2], *C.J. O'Donnell*[3] 1) Office of Biostatistics/DECA/National Heart, Lung and Blood Institute, Bethesda, MD; 2) Dept. of Biostatistics, Boston University School of Public Health, Boston, MA; 3) Framingham Heart Study/DECA/National Heart, Lung and Blood Institute, Framingham, MD.

Serum lactate dehydrogenase (LDH) is widely used in diagnosing heart, liver, and muscle diseases, especially to help monitor a heart attack. Family studies have reported that serum LDH variation is significantly determined by genetic factors with heritability estimates ranging from 40-60%. Four isoforms have been previously mapped to chromosome 11q15, 12p12 and 16q22. To date, no linkage analysis on serum LDH levels has been reported. We carried out a 10 cM genome-wide scan for quantitative trait loci of LDH in a community-based Caucasian cohort, the Framingham Heart Study. LDH was measured in the first examination of the offspring cohort. Our study population consisted of 330 families with 1260 individuals being both genotyped and phenotyped, including 1329 full-sibling pairs, 52 half-sibling pairs, 669 cousin pairs, and 89 avuncular pairs. Using variance-component linkage methods implemented in SOLAR, the heritability was estimated as 40% after age and gender adjustment. The genome-wide linkage analysis yielded several chromosomal regions with LOD scores between 1-2: LOD scores of 1.51, 1.10, 1.54, 1.63, 1.18, 1.27, 1.02 and 1.16 on chromosomes 4, 7, 8, 9, 14 (three peaks) and 19, respectively. Our study suggests that instead of a single gene with a large effect, there may be several genes with small effects in controlling the variation of serum LDH. Those genes appear to reside in chromosomal regions that differ from those containing the genes encoding LDH isoforms.

Clinical, cytogenetic and molecular analysis of a female with partial trisomy X and a de novo Xp;Yq translocation. *L. Miravalle, P.R. Delk, W. Torres-Martinez, D.D. Weaver, R. Stohler, V.C. Thurston, G.H. Vance*
Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN.

We report detailed clinical, cytogenetic, and molecular studies on a 7-month-old female with a partial trisomy X associated with a de novo unbalanced X;Y translocation. The proband was born at 36 weeks gestation to a 21-year-old G4P3 Caucasian female. Ultrasound studies at 16 weeks gestation identified an echogenic lesion located in the left ventricle, hypoplastic right ventricle, hypoplasia of the middle segment of the fifth digit, and a hypoplastic nasal bone. Conventional cytogenetic analysis on amniotic fluid cells and cultured peripheral blood lymphocytes demonstrated a karyotype of 47,XX,+der(X)t(X;Y)(p22.3;q12). FISH analysis showed that the abnormal chromosome X was negative for the Y- satellite centromeric probe, the LSI SRY probe, and the Yp subtelomeric region probe, but was positive for the heterochromatic region of the Y chromosome probe at Yq12. In addition, it was negative for the LSI STS probe at Xp22 and the Xp subtelomeric region probe, but was positive for the LSI KAL probe at Xp22. FISH analysis for the *SHOX* and *VCX-A* genes and X-inactivation studies are currently in progress. At birth, the patient presented with pulmonary valve atresia with intact ventricular septum, hypoplastic right ventricle, severe aortic stenosis, hypertrophied left ventricle, atrial septal defect, and other dysmorphic features. Birth measurements were below the 3rd percentile for both weight and length, and her head size was below -2 SD. At age 7 months her weight and length were still below the 3rd percentile and her head size below -2 SD. At this time she had developmental delay and was receiving physical and occupational therapies. The clinical phenotype resembles the phenotype found in individuals carrying deletions in chromosome Xp. Clinical findings compatible with the triple-X syndrome were not observed. Translocations t(X;Y)(p22.3;q11.2) have been described in the literature in patients with a modal number of 46 chromosomes. We present here the first case with partial trisomy X coupled with an unbalanced X;Y(p22.3;q11.2) translocation.

Splicing products of dystrophin pre-mRNA in 49 cases with intraexonic small mutations in the dystrophin gene.
A. Nishiyama, Y. Takeshima, M. Yagi, H.T.T. Tran, Y. Habara, M. Matsuo Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Hyogo, Japan.

Splicing is the maturation process of pre-mRNA by which introns are removed. Mutations at splicing consensus sequence located at intron / exon boundaries result in splicing errors. Recently exonic mutations are attracting much attention as a cause of splicing errors. In the dystrophin gene, a limited number of intraexonic small mutations have been shown to induce splicing errors. In order to further characterize splicing errors caused by intraexonic small mutations in the dystrophin gene, dystrophin mRNA in lymphocytes was analyzed in dystrophinopathy cases with intraexonic small mutations by RT-nested PCR. Forty nine cases were enrolled in this study: 36 had a single nucleotide substitution leading to a nonsense mutation and 13 had one or a few nucleotides deletion / insetion mutations, creating a premature termination codon. In 10 cases, skipping of the exon encoding the mutation was disclosed in a fraction of the PCR product, but not in the other 39 cases. Particularly enough, two nonsense mutations was found to induced not only exon skipping but aberrant splicing due to creation of new splice site. Dystrophin mRNA in muscles was further analyzed in 3 of these 10 cases. Unlike in lymphocytes, splicing error was disclosed only in one case. This suggested the difference of splicing reaction between lymphocytes and muscles. In conclusion, 20% of intraexonic small mutations in the dystrophin gene induced splicing errors in lymphocyte mRNA. Further detail splicing analysis will make it possible to clarify the function of exonic sequence for splicing reaction.

CYP8B1 gene associated with gallstone disease in Chinese population. *T. Han[1], J. Qin[1], Z. Niu[2], K. Zhang[2], Z. Jiang[1], Z. Jiang[1], S. Zhang[1], W. Huang[1, 2]* 1) Ruijin Hospital, School of Medicine, Shanghai Jiaotong University, Shanghai, China; 2) Chinese National Human Genome Center at Shanghai, Shanghai, China.

In the previous study, we identified the association between the locus D3S1266 within 3p22-21.3 on chromosome 3 and the gallstone disease in Chinese population. In this study, we re-sequenced the two genes in this region, cholecystokinin (CCK) and sterol 12-hydroxylase (CYP8B1), in 24 patients and 24 normal individuals. Totally, we discovered 11 SNPs including 5 SNPs in promoter, 1 in coding region and 5 in 3UTR of CYP8B1, in which 6 SNPs allelic frequency exceeded 5%. Therefore, a further large scale association study for these 6 SNPs was carried out in 190 patients and 189 normal subjects. One SNP E/3310(A/G)polymorphism in 3UTR region of CYP8B1 gene showed a significant difference of allelic frequency between patients and controls (p=0.022). The allelic frequency of G allele was higher in control group than that in case group. However, there was no significant difference in the distribution of the SNPs of CCK gene between cases and controls. This preliminary study implicated a strong correlation between the polymorphism of E/3310(A/G)of CYP8B1 gene and gallstone disease, and G allele may play a protective role in the gallstone formation though the further related investigation should be needed.

Ring chromosome 14: characterization of the phenotype with a novel finding, CGH delineation, long-term follow-up and literature review. *I. Kalampokis[1], A. Iglesias[1], M. Macera[2], J. Breshin[2], A. Babu[2]* 1) Division of Genetics, Department of Pediatrics, Beth Israel Medical Center, New York, NY; 2) Division of Molecular Medicine and Genetics, Department of Medicine, Wyckoff Heights Medical Center, Brooklyn, NY.

A Hispanic male with ring chromosome 14 is described. The patient is a 4 year old male with micro/dolicocephaly, downslanting palpebral fissures, blepharophimosis, epichanthal folds, corneal opacities, micrognathia, downturned upper lip, high-arched narrow palate, bilateral clinodactyly of the 5th fingers, joint hyperextensibility, hypertrichosis, generalized hypotonia, mental retardation, global developmental delay, failure to thrive, gastro-esophageal reflux, asthma, tracheomalacia, multiple episodes of otitis media and pneumonia as well as massive adenoid hyperplasia resulting in a cyanotic episode secondary to upper airway obstruction. Incidentally, he was found to have an elevation of aPTT which was attributed to coagulation factor XI deficiency. He had exhibited seizures since age 3½ months. Following 24-hour video EEG recording, the patient was diagnosed with atypical infantile spasms. Brain MRI revealed hypoplastic corpus callosum. Cytogenetic analysis (GTW banding technique) of peripheral blood chromosomes revealed a 46,XY,r(14)(p11.2q32.3) karyotype. Due to the nature and size of the ring 14 chromosome, CGH analysis was used and a deletion was detected at 14q31q32.3. The patient is monosomic for the chromosome segment 14q31-qter. The karyotype was revised to 46,XY,r(14).ish cgh r(14)(?p11q31). In summary, we describe a patient with ring chromosome 14 exhibiting several phenotypic features commonly associated with this chromosomal condition. This is the second case of ring chromosome 14 in the literature with hypoplastic corpus callosum to our knowledge. An extensive literature review summarizing the most commonly described phenotypic features of ring chromosome 14 on a table format is included as an attempt to further delineate the basic phenotype and its variants. Knowledge of the phenotypic spectrum and its natural history will help clinicians in the long term care of these patients.

SDHB and SDHD Mutations in Malignant Pheochromocytomas. *R. Klein, L. Jin, K. Rumilla, R. Lloyd* Dept Lab Medicine & Pathology, Mayo Clinic, Rochester, MN.

Background: Germline mutations in the genes encoding the B (SDHB) and D (SDHD) subunits of the heterotetrameric protein succinate dehydrogenase (mitochondrial complex II) are important causes of inherited and apparently sporadic paragangliomas. Mutations in SDHB appear to be found more frequently in association with extra-adrenal and malignant pheochromocytomas, while mutations in SDHD are more often identified in benign head and neck paragangliomas. In an effort to further investigate the role of SDHB and SDHD in apparently sporadic malignant intra- and extra-adrenal pheochromocytomas, we screened a series of tumors for mutations in the SDHD and SDHB genes. Materials and Methods: Mutation testing was performed on DNA extracted from formalin fixed, paraffin embedded tumor and adjacent normal tissue by PCR amplification and direct sequencing of the coding regions and intron-exon junctions of the SDHB and SDHD genes. Results: Among 17 extra-adrenal pheochromocytomas with proven metastatic disease, 4 nonsense, 1 splice site, 1 insertion causing a frameshift, and 3 probable missense mutations were found in SDHB. No mutations were detected in SDHD. Mutations in SDHD and SDHB were not identified in 9 malignant intra-adrenal pheochromocytomas. The identical SDHB mutation was detected in DNA extracted from accompanying normal tissue for each of the 7 cases on which this analysis was performed. Conclusions: Germline mutations in SDHB are common in patients with malignant extra-adrenal pheochromocytomas, while SDHD mutations rarely occur. The disparate mutational spectra in malignant intra- and extra-adrenal pheochromocytomas may reflect differences in tumor biology.

Idiopathic Mental Retardation:A Brazilian study. *M. Mulatinho[1,4], L. Moraes[2], T. Reis[2], L. Carvalho[2], M. Camilo[2], V. Moura[2], J. Santos[3], R. Boy[3], D. Horovitz[2], R. Zlot[2], M. Pimentel[3], H. Ramos[2], N.P. Rao[4], J. Llerena[1,2]* 1) Genetics,Universidade Federal do Rio de Janeiro,Brazil; 2) Instituto Fernandes Figueira; 3) Universidade do Estado do Rio de Janeiro; 4) Univ. of California of Los Angeles,CA.

In order to set up a clinical strategy to study Idiopathic Mental Retardation (IMR) in a Brazilian population, 121 patients with dysmorphism to behavioral disorders, attending two institutions in Rio de Janeiro were selected. The common clinically recognizable syndromes were excluded. Cytogenetic analysis at 400-bands and screening for FRAXA and FRAXE loci were done. They were further studied with 550 bands-HR-GTG and subtelomeric FISH. 42 individuals were analyzed so far. Of these 6 had an abnormal karyotype. Two had features characteristic of chromosomal syndromes. Case A appeared to have the Potocki-Shaffer syndrome, 46,XX,del(11)(p11.2p11.2). Case B had a deletion of 1p36 [46,XX,del(1)(p36)]and features of Monosomy 1p36 syndrome. FISH confirmed the deletion. There were four other cases, all de novo, with the following karyotypes:C)46, XX, add(13)(q34); D)46, XX,t (5;6)(q35.1;p22.2); E) 46,XX,ins(2)(pter->q12::?::q14->qter), F) 46, XY, add(3)(p25). Although Case E had an apparently balanced translocation, the patient had large and malpositioned central incisors, partial cutaneous syndactyly in hands, small hands and feet, centripetal obesity, IUGR, myopia, genu valgum. FISH with the subtelomeric probes did not identify any aberrations in 17 of the 42 cases. The remaining are currently being screened by Subtelomere FISH, and the complete results will be presented. Genetic counseling was provided to the 6 families involved. Samples from patients that are normal by HR-GTG and FISH will be subjected to Oligonucleotide Array-CGH technology to determine the frequency of submicrocipic aberrations in this select group of IMR patients. With the methodologies used we could identify 6 cases. These data reinforces the suggestion of studying all MR with HR-GTG banding. While the yield may be limited, chromosomal abnormalities can be found regardless of the severity of MR, and the number of abnormal physical findings.

A genetic network in age-related macular degeneration. *R.J. Klein[1], M. Othman[2], J.-Y. Tsai[3], S. Zareparsi[2], M. Campos[2], P. Atmaca-Sonmez[2], K.H. Branham[2], A. DeWan[4], A.K. Henning[5], E.Y. Chew[3], F.L. Ferris[3], H. Grossniklaus[6], G. Abecasis[7], C. Barnstable[8], A. Swaroop[2,9], J. Hoh[4,8]* 1) Laboratory of Statistical Genetics, Rockefeller Univ, New York, NY; 2) Dept of Ophthalmology & Visual Sciences, Univ of Michigan, W.K. Kellogg Eye Center, Ann Arbor, MI; 3) National Eye Institute, Bethesda, MD; 4) Dept of Epidemiology and Public Health, Yale Univ School of Medicine, New Haven, CT; 5) The EMMES Corporation, Rockville MD; 6) Dept of Ophthalmology, Emory Univ School of Medicine, Atlanta, GA; 7) Center for Statistical Genetics, Dept of Biostatistics, School of Public Health, Univ of Michigan, Ann Arbor, MI; 8) Dept of Ophthalmology and Visual Science, Yale Univ School of Medicine, New Haven, CT; 9) Dept of Human Genetics, Univ of Michigan, Ann Arbor, MI.

Age-related macular degeneration (AMD) is the leading cause of blindness in the elderly in the developed world. The risk for developing AMD is determined by the complex interplay of genetic variants, many of which are as yet unidentified. Several chromosomal regions have been repeatedly linked with AMD in family-based linkage studies. SNPs in two of these regions - in the genes CFH and LOC387715 - have been previously found to be associated with AMD.

To understand more fully the network of genes influencing AMD, we looked at the region around hypothetical gene LOC387715 in our genome-wide association data set of AMD. We confirm an association between LOC387715 and AMD. Using a new method to test for interactions, we identify two SNPs in our genome-wide data that show a statistically significant genetic interaction with LOC387715. While our screen could have identified SNPs anywhere in the genome, these two SNPs are found within two additional regions that show strong evidence for linkage to AMD. The interaction of these three loci, along with CFH, appears to account for considerable genetic risk for AMD.

Tachyon: A new frontier for exact multipoint likelihood calculations on large pedigrees. *J.R. O'Connell* Div Endo/Diabetes/Nutrition, Univ Maryland, Baltimore, MD.

Exact multipoint likelihood calculations are the core of pedigree-based gene mapping methods. Current exact methods are limited to only a few markers on many relatively small pedigrees. We introduce a new approach to exact multipoint likelihood calculations whose complexity scales linearly in the number of loci that can tackle pedigrees significantly beyond the maxbits limit of the Lander-Green-Kruglyak algorithm. Conceptually the approach decomposes the pedigree into two types of overlapping components: G components with substantial genotype data and M components with none except on overlaps. The likelihood calculation is then a joint sum over the intersection of the components with summand the products of the likelihood of the components, creating a potentially large sum of smaller problems. The M component is in general the source of intractability, however, gene flow in this component contains rich symmetry that we exploit to eliminate its complexity. To illustrate our approach we create a pedigree with G component a fully genotyped CEPH pedigree with 5 offspring and M component the four CEPH grandparents connected as N^{th} cousins. The pedigree has four loops, maxbits equal to 4N+20, and intractable if N > 5. The M component has maxbits 4N+6. Using a novel algebra on grandparent-to-founder gene flow vectors we can write the M component transition probabilities between two loci as a hidden Markov model in closed form as a function of N. Thus for N large enough the exact likelihood can be computed faster manually than by any current program. The G component transition probabilities can be computed locus by locus using current methods. The likelihood of the full pedigree is the sum over joint genotypes of the grandparents of products of conditionally independent G and M component probabilities. We can compute the exact likelihood of the full pedigree using 250 markers in less than two minutes independent of N. We present examples of currently intractable real data pedigrees that this approach easily solves. We discuss limitations and the potential of TACHYON to exploit the power of larger pedigrees for linkage and association mapping of complex diseases.

Comparative analysis of serum proteomes for the discovery of biomarkers in Wilson disease. *S.H. Heo, G-H. Kim, S-W. Park, H-W. Yoo* Genome Research Center for Birth Defects & Genetic Disorders, Asan Institute for Life Sciences, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

Wilson Disease(WD) is an autosomal recessive inherited disorder leading to impaired intrahepatic trafficking and biliary excretion of copper, resulting in the accumulation of copper in various organs including the liver, cornea, and brain. The excess copper and oxidative stress maybe produces several proteins different from wild type. To date, no diagnostic biomarker for WD has been identified except ceruloplamsin. In order to identify diagnostic biomarkers for WD, efforts have been made to correlate the serum protein profiles of three asymptomatic WD patients with two normal controls, whose age and sex were matched. Fractionated serum proteins were displayed on two-dimensional electrophoresis (2-DE) gel using multiple affinity removal columns (MARC) to remove six high-abundant proteins. Analyses of these gels allowed us to identify two differentially expressed proteins that were remarkably reduced in the group of WD patients as compared to the control group. These reduced spots were analyzed by matrix assisted laser desorption - ionization time of flight/ ionization-time of flight (MALDI-TOF/TOF). The reduced proteins were complement component C3c (C3c), carbonic anhydrase 1 (CAH1), peroxiredoxin-2 (thiol-specific antioxidant), dihydropyrimidinase-like 1 variant (DPYSL2), and complement factor B (BF). It indicated that enhanced oxidative stress caused by excessive copper accumulation might down regulate the expression of thiol-specific antioxidant, C3c, and BF, which were known to be associated with oxidative stress. In addition, six of the protein spots were significantly down regulated in the 2-D gel of whole serum of nine WD patients. These spots were identified as haptoglobin-1 precursor. And further identification of the spots at different pathological grades was confirmed by western blotting using polyclonal anti-heptoglobin antibody. Our strategy using comparative analysis of parallel protein quantification on 2-D gels will provide us with cues to accelerate the discovery of novel serum protein biomarkers for the diagnosis of WD.

Identification of early gene expression changes in two mouse models of motor neuron degeneration using whole genome microarrays. *L.C. Kudo, M. Wiedau-Pazos, S.L. Karsten* UCLA Department of Neurology, Los Angeles, CA 90095.

Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease selectively affecting motor neurons in the central nervous system (CNS). A subset of familial ALS patients carries a mutation of the superoxide dismutase1 gene (SOD1). The crucial question of how and why only motor neurons degenerate in the presence of the ubiquitously expressed SOD1 mutation remains to be answered. Factors that may contribute to motor neuron degeneration have been identified, including but not limited to, disruption of axonal transport, glutamate metabolism, oxidative stress, copper metabolism, and the availability of growth factors. Yet, it is still not clear how these factors may act together in the etiology of ALS. In order to characterize the molecular events involved in initiation of neurodegeneration in ALS, we studied motor neuron-specific gene expression in two mouse models of ALS: familial ALS linked to SOD1 (G93A-SOD1) and frontotemporal dementia with ALS linked to mutant TAU (P301L-TAU). DNA microarray technology in combination with laser-capture microdissection was used to discover gene expression changes at the early stages of the disease prior to neurodegeneration. Spinal cords were dissected from 3 months old female transgenic mice and their non-transgenic littermates. Axial cryostat sections from the lumbar spinal cords of transgenic and non-transgenic control animals were fixed in ethanol and stained with Cresyl violet. Motor neurons from the ventral horns were microdissected on a PixCell Arcturus LCM device. RNA extracted from the collected motor neurons was subjected to microarray experiments using Agilents Mouse Whole Genome Oligonucleotide Microarray. In addition to gene expression changes found in both mouse strains, we have identified a set of genes specific for a particular genotype. Here, we discuss the relevance of these findings with respect to the mechanisms of motor neuron dysfunction and death. Supported by MDA grant #20050289.

Physician Awareness of genetics (PHAGEN) among primary care physicians in Israel. *G. Hirsch-Yechezkel[1], R. Grossman-Yahalom[2], Y. Shachar[1], E. Friedman[3]* 1) Gertner Institute of Public health, Tel-Hashomer, Israel; 2) Clalit HMO center Rehovot, Israel; 3) The Susanne Levy Oncogenetics Unit, Sheba Medical center, Tel Hashomer, Isarel.

In order to provide adequate patient care, primary care physicians (PCP) are required to have a basic understanding in genetics. This trend of using modern genetics tools is forecasted to increase in the near future. In order to define the subset of PCP who would benefit most from an intervention program, we wanted to assess the baseline level of knowledge of genetics among PCP) in Israel. To that end, a 10-point, multiple-choice questionnaire was administered and completed in person by 120 (of 298 eligible) PCP. Recruitment was during semi annual conferences. The questions ranged from classical genetics scenarios to cancer genetic counseling issues, with the maximal score 40 points. The majority of participants were women (n=70-58.3%), age range of 41-50 years (n=64 - 53.3%), and graduated from medical schools 20+ years prior to questioning (n= 66- 55%). The mean score was 29+ 5.4 (range 14-38), there was an inverse correlation between age and high score (34/40 -85%): 4/26 (15.4%) PCP age 56+ years scored 85% compared with 9/21 (42.3%) PCP aged 32-40 years (OR 0.24 95% CI 0.05-1.13; P for trend <0.05). In addition, an inverse correlation was noted between time from graduation from medical school and score: 6/10 (60%) PCP who graduated up to 9 years prior to questioning scored 85% or higher compared with 3/24 (12.5%) that graduated 30+ years (OR 0.1 -95% CI 0.01-0.71; p<0.05). There were no gender differences. We conclude that older physicians, who graduated from medical school before 1985, should be targeted for intervention in order to enhance their knowledge in genetics, in order to facilitate better patient care and rational use of genetic tools.

Parent of Origin Effects and HLA-DRB1 Risk in Systemic Lupus Erythematosus. *L.K. Komorowski[1], L.F. Barcellos[1], P.P. Ramsay[1], R.R. Graham[2], G. Artim[1], M.F. Seldin[3], J.B. Harley[4], T.W. Behrens[5], L.A. Criswell[6]* 1) University of CA, Berkeley, CA; 2) Broad Institute of M.I.T. and Harvard, Boston, MA; 3) University of CA, Davis, CA; 4) Oklahoma Medical Research Foundation, Oklahoma City, OK; 5) University of Minnesota, Minneapolis, MN; 6) University of CA, San Francisco, CA.

Genetic susceptibility for systemic lupus erythematosus (SLE) has been associated with HLA class II loci within the MHC, yet the contribution of this region explains only part of the conferred genetic risk. To date, HLA-DRB1*0301, *1501 and *0801 alleles have demonstrated the strongest evidence for association with SLE. Parent-of-origin effects operating at DRB1, such as imprinting, may contribute to SLE, and if so, may result from underlying epigenetic mechanisms. The role of microchimerism due to maternal-child cell transfer during pregnancy has also been linked to risk for autoimmune disease, and is mediated by parent-of-origin HLA effects. We examined parent-of-origin effects for DRB1 and disease risk in a large SLE family dataset. Paternal and maternal transmission frequencies of DRB1 alleles to affected offspring in 714 Caucasian SLE families were compared to identify evidence for imprinting. Maternal-child histocompatibility relationships in SLE cases and unaffected siblings were also examined. Discordant sibpairs from families were grouped by maternal-child DRB1 profiles as compatible (mother-child, child-mother, bidirectional) or not compatible. Differences would provide evidence to support a role for microchimerism mediated by HLA in SLE. No difference between paternal and maternal transmission frequencies for any DRB1 allele was observed, including for known risk alleles, DRB1*0301, *1501 and *0801. TDT results confirmed that maternal and paternal transmissions for the known DRB1 risk alleles were very similar. Furthermore, no evidence was observed for SLE risk due to maternal-child histocompatibility relationships based upon DRB1 genotypes. These results indicate that novel mechanisms such as imprinting and maternal-child histocompatibility relationships involving DRB1 are not contributing a major role to SLE risk.

Analysis of Iranian patients with hearing loss For the second most prevalent locus DFNB4. *M. Mohseni[1], K. Kahrizi[1], F. Azizi[4], C. Nishimura[2], N. Bazazzadegan[1], G. Asaadi Tehrani[1], M. Sayfati[1], M. Taghdiri[1], P. Jamali[1], A. Daneshi[3], R.J.H. Smith[2], H. Najmabadi[1]* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran (Islamic Republic of); 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology Head and Neck Surgery, University of Iowa, Iowa, IA, United States; 3) Research Center of Ear, Nose, Throat, and Head and Neck Surgery, Tehran, Iran(Islamic Republic of); 4) Endocrine Research Center , Taleghani hospital. Tehran, Iran.

Background: Mutations in the SLC26A4 gene in DFNB4 locus is responsible for syndromic (Pendred syndrome) and non-syndromic hereditary hearing loss(HHL). In many populations mutations in this gene have been reported as a second cause of HHL. The objective of our study was to investigate the prevalence of SLC26A4 mutations in our HHL consanguineous families. Materials and methods: After complete clinical examination the consent form was taken from each family. We included 87 families with two or more than two affected individuals, who have been referred to our center. All families had previously been tested negative for the DFNB1 locus were candidates for homozygosity mapping using STRs for DFNB4 locus. Families localized to this region were subjected complete DNA sequencing. Results: Twelve out of eighty seven families were mapped to DFNB4. Sequence analysis of six linked families revealed seven mutations (T420I, 1197delT, G334Y, R409H, T721M, R79X, S448L). The T420I , G334V and R79X were novel mutations. Mutations detection for the other families is being performined. Conclusion: We have been able to localize total of 12 families (13.8%) to the DFNB4 locus. Nine families had thyroid dysfunction(pendred syndrome) and in three families we couldn't find any symptoms of thyroid impairment. This investigation, demonstrated that the SLC26A4 gene mutation is the second most prevalent cause of HHL in Iran. This result is in accordance with reports from other countries. Key words: DFNB4, SLC26A4 gene, hereditary hearing loss.

Glucocorticoid-induced granzyme A expression can be used as a marker of glucocorticoid sensitivity for acute lymphoblastic leukemia therapy. *A. Myoumoto[1], K. Nakatani[1], T. Koshimizu[1], H. Matsubara[2], S. Adachi[2], G. Tsujimoto[1]* 1) Dept. Genomic Drug Discovery Sci., Grad. Sch. Pharmaceu. Sci., Kyoto Univ; 2) Dept. Pediatrics, Grad. Sch. Med., Kyoto Univ.

Glucocorticoids (GC) sensitivity is an important prognostic factor in the treatment of patients with acute lymphoblastic leukemia (ALL). However, the clinical assessment for GC sensitivity is very time-consuming. We have recently found that granzyme A (GZMA) mediates GC-induced apoptosis in human ALL-derived cell line 697 (FASEB J. M. Yamada *et.al.*). In this study, we examined whether GC-induced GZMA expression could predict the GC sensitivity leading to apoptosis of seven established cell lines derived from ALL patients.

We have treated seven established ALL cell lines derived from pre-B ALL patients with GC (100 nM DEX or 800 nM prednisolone) or vehicle for 24-h. The 697 and 697Bcl2 cell lines were used as a positive and negative control, respectively. The 697Bcl2 cells stably express Bcl2 and thus were protected from GC-induced apoptosis. We have analyzed cellular indicators of apoptosis, such as cell death and mitochondrial transmembrane potential depolarization using flowcytometry in pre-, vehicle- and GC-treated groups. GZMA mRNA expression was analyzed by quantitative RT-PCR in each group.

The apoptosis assay showed four cell lines were GC-sensitive, while three cell lines were GC-resistant. GC treatment markedly enhanced GZMA mRNA expression only in GC-sensitive cell lines, but not in GC-resistant cell lines. Moreover, GC-induced GZMA mRNA expression correlated well with the extent of GC-induced apoptosis.

We found a highly significant correlation between the GC-induced GZMA expression and apoptosis at 24-h by using seven cell lines established from ALL patients. Therefore, we propose that GC-induced GZMA mRNA expression at 24-h could be such a biomarker to asses GC sensitivity. Further studies will be required to establish 24-h GC-induced GZMA expression as an early biomarker for personalized ALL therapy.

Reconsideration of the inheritance mode of febrile seizures. *Y. Nagao*[1, 2] 1) Department of Pediatrics, Social Health Insurance Medical Center, Shinjuku, Tokyo, Japan; 2) Department of Pediatrics, School of Medicine, The University of Tokyo.

Febrile seizures (FS) are rather common disorders. Especially prevalence of FS in Japanese population is high and is reported 0.06 - 0.09. The inheritance mode of FS had been discussed, and FS are now accepted as multi-factorial diseases. Efforts to identify a single gene locus for FS have been performed utilizing non-parametric linkage analysis, because this method can be applied for multi-factorial diseases, and an apparent disease-sensitive gene for FS has not yet been identified. But is there no possibility that FS are disorders caused by a single major gene? In this paper I show the calculation of the recurrence risk of the sibling of a FS patient. With assumption that penetrance is less than 1, the recurrence risk of a sibling is calculated both by autosomal recessive model and by autosomal dominant model, and the calculated risk was significantly consistent with the reported incidence of a sibling. But when the incidence of a parent is considered, the autosomal recessive model is more consistent. The result of calculation does not exclude the multi-factorial inheritance of FS, but when the single major gene hypothesis is applied, the parametric linkage analysis can be performed because the frequency of mutant allele and the penetrance are also calculated. Therefore the calculation of these parameters based on a single major gene hypothesis might simplify the linkage analysis of the possible major gene for FS.

Not sequence, but structure: palindrome-mediated translocation. *H. Inagaki[1], T. Ohye[1], H. Kogo[1], B.S. Emanuel[2], H. Kurahashi[1]* 1) Division of Molecular Genetics, Fujita Health University ICMS, Toyoake, Aichi, Japan; 2) Division of Human Genetics, the Childrens Hospital of Philadelphia, Philadelphia, PA.

The t(11;22)(q23;q11) is a recurrent constitutional translocation in humans. The breakpoints on both chromosomes have been located within palindromic AT-rich repeats (PATRRs). We propose that the PATRRs form cruciform structures in vivo and induce double-strand-breaks (DSBs) that are illegitimately repaired through non-homologous end joining (NHEJ). However, there is to date no evidence for cruciform formation in living cells. To elucidate how the PATRRs induce DSBs, we established a plasmid-based model system using a mammalian cell line as host. We independently cloned the PATRRs from 11q23 and 22q11 into plasmids. Plasmids were manipulated topologically so as to extrude or not extrude the cruciform structure and then transfected into HEK293 cells. Using translocation-specific PCR and a fluorescence-based reporter system, we demonstrated that the cruciform-extruded plasmids introduced into cells were cleaved and rejoined at the PATRRs. Sequence analysis demonstrated that the breakpoint sequences were quite similar to those of human t(11;22) junction fragments. By contrast, no rearrangement was observed with cruciform-negative plasmids. Southern analysis indicated that this rearrangement is initiated by diagonal cleavage of the cruciform DNA prior to the subsequent cleavage of hairpin tips at the ends of the broken DNA. This is then followed by NHEJ. Our results strongly suggest DNA secondary structure-specific cleavage as a mechanism leading to palindrome-mediated translocations.

Why do de novo t(11;22)s arise only in sperm?: Analysis using a yeast model system. *T. Ohye[1], H. Inagaki[1], H. Kogo[1], B.S. Emanuel[2], H. Kurahashi[1]* 1) Div Molecular Genetics, Inst Compre Med Sci, Fujita Health Univ, Aichi, Japan; 2) Div Human Genetics, Childrens Hosp Philadelphia, Philadelphia, PA.

?The constitutional t(11;22)(q23;q11) is the most frequently occurring non-Robertsonian translocation in humans. The breakpoints of the t(11;22) were identified within palindromic AT-rich repeats on chromosomes 11 (PATRR11) and 22 (PATRR22), suggesting that cruciform structures mediate double-strand-breaks (DSBs) leading to this recurrent translocation. De novo t(11;22)s are detected in sperm from healthy men at a frequency of $1/10^4$-10^5, but never in lymphocytes or fibroblasts. To investigate the mechanism of sperm-specific generation of the t(11;22), we utilized a yeast model system for the t(11;22). We created a diploid yeast harboring the 445bp PATRR11 at the TRP1 locus on chromosome IV and the 595bp PATRR22 at the LEU2 locus on chromosome III. We isolated genomic DNA and performed translocation-specific PCR using primer pairs flanking the PATRR both on chromosomes IV and III. As a result, we successfully detected de novo translocation-specific PCR products. Based on our previous observation that the PATRRs prefer to adopt a cruciform conformation in a temperature-dependent manner, and the fact that the temperature of the testis is lower than that of other tissues, we examined translocation frequency at various temperatures in yeast cultures. As a result of this analysis we determined that the translocation frequency was significantly higher at 25C than at 34C. Next, we determined the translocation frequency either in vegetative or meiotic yeast, finding a higher translocation frequency during meiosis. Our results suggest that complex factors such as temperature-dependent DNA conformation and meiosis-specific recombination machinery during spermatogenesis are likely to be involved in sperm-specific generation of the t(11;22) rearrangement. These results begin to elucidate the factors that influence the formation of structural chromosomal aberrations that are primarily derived during male gametogenesis.

Neonatal screening for Pompe disease: result from the Taiwan screening program. *W.-L. Hwu[1], J. Keutzer[2], S.-C. Chiang[1], X. Zhang[2], Y.-H. Chien[1], N.-C. Lee[1], S. Young[3], D. Millington[3], M. Fietz[4]* 1) Department of Pediatrics and Medical Genetics, National Taiwan University Hospital and National Taiwan University College of Medicine, Taipei, Taiwan; 2) Genzyme Corporation, Cambridge, MA, USA; 3) Department of Pediatrics, Duke University Medical Center, Research Triangle Park, NC, USA; 4) Department of Chemical Pathology, Women's and Children's Hospital, North Adelaide, Australia.

Pompe disease is caused by the deficiency of acid-alpha-glucosidase (GAA). Recently, recombinant human GAA has been used to treat infantile-onset Pompe disease (IOPD) with good success, resulting in prolonged survival, reversal of cardiomyopathy, and growth and motor gains, although not all patients achieve ambulation. Best motor outcomes are reached when treatment is initiated early. A neonatal screening program for Pompe disease started in Oct. 2005. Blood spots were obtained from babies around 3 days of age, and GAA activities were measured using 4-MU-glucoside as the substrate, with acarbose as an inhibitor of maltase-glucoamylase (MGA). The assay employed an initial screen for GAA activity and a retest assay measuring the GAA to neutral maltase ratio and percent inhibition. The recall rate was below one percent. After screening 55,897 newborns, one case was found to have IOPD, and the other case either the late infantile or juvenile form of Pompe disease. In 36 other babies who received confirm blood testing, 7 had GAA activities between 5 and 10% of the normal mean. However, none became symptomatic after a follow up period of 1 to 4 months. Low GAA activities in their blood spot were further confirmed by the immune-capture enzyme activity assay, but none of them showed elevation of urine glucose tetrasaccharide, a biomarker for the disease. Molecular analysis showed that 5 of the 36 cases were heterozygous carriers of a common mutation, with all mutant alleles inherited from their parents. During this period, two cases of IOPD were diagnosed clinically at the ages of 4 and 5 months, respectively. They were not screened, but their newborn bloodspot GAA activity was in the deficiency range when assayed retrospectively.

DigiTag2 assay for multiplex SNP typing. *N. Nishida[1, 2], T. Tanabe[2], M. Takasu[1], A. Suyama[3], K. Tokunaga[1]* 1) Dept Human Genetics, University of Tokyo, Tokyo, Japan; 2) Biomedical Business Incubation Division, Olympus Corporation, Tokyo, Japan; 3) Dept Life Sciences, University of Tokyo, Tokyo, Japan.

There are a number of single nucleotide polymorphisms (SNPs) to be candidate susceptibility or resistance genetic factors for multifactorial disease. Genome-wide search for disease susceptibility regions followed by high-resolution mapping of primary genes requires high-throughput, cost-effective and highly reliable technology. At present, a variety of SNP genotyping applications exist, however, many applications need to select relevant SNPs for their assay by in silico assay design, and then a part of candidate SNPs will be excluded from investigation. To accomplish successful typing for all candidate SNPs at a low cost, new technologies must be developed.

We developed a new multiplex SNP typing method, named DigiTag assay. In the DigiTag assay, all of the SNP genotypes are encoded to the well-designed oligonucleotides, named DNA coded numbers (DCNs). The assignment of the DCNs to the SNPs is unconstrained, therefore, the DNA chips prepared to read out the types of DCNs are universally available for any types of SNPs. We have reported in the ASHG2005 that the DigiTag assay have the potential to analyze almost all kind of the SNPs with high accuracy and reproducibility. However, the DigiTag assay needs the washing step with magnetic beads, which is laborious step in manipulation. And also, the biotinylated probes, which are necessary for the washing step, are expensive.

For the next version of the assay, we improved the protocol to exclude the washing step and named DigiTag2 assay. The DigiTag2 assay uses non-labeled primers and probes, which lead to save the cost of the assay. We investigated the feasibility of the DigiTag2 assay using the SNPs located in the 500 kb genomic region including *IL-4* and *IL-13* genes. The success rate, which is defined by the proportion of successfully genotyped SNPs in the total number of SNPs examined, was revealed to be over 90%, and the typing result was 100% identical to the result from direct sequencing.

Knockdown of frataxin causes loss of aconitase activity, induction of oxidative stress and induction of heme transcripts. *C. Lu, G.C. Cortopassi* department of molecular biosciences, University of California, Davis, Davis, CA.

Friedreichs ataxia (FRDA) is an autosomal recessive disease characterized by neurodegeneration and cardiomyopathy. It is caused by the mutations in the frataxin gene which decrease frataxin protein expression. Frataxin is expressed in the cytoplasm and mitochondria. In order to isolate the primary consequences of frataxin deficiency, we generated a cell model using a frataxin-specific siRNA driven by a tetracycline inducible promoter in HEK293 cells. By immunoblot assay of frataxin and mitochondrial marker proteins, we demonstrated that the weight of cytoplasmic frataxin is equal to or exceeds mitochondrial frataxin. Half-depletion of cytoplasmic frataxin upon tetracycline induction occurred at 1.5 days, 3 days earlier than that of the mitochondrial frataxin. Thus cytoplasmic frataxin turns over three times faster than mitochondrial frataxin. In parallel with cytoplasmic frataxin depletion, the activity and amount of the cytoplasmic iron-sulfur cluster proteins aconitase and ISU1 declined, respectively, at 2 days. The antioxidant cytoplasmic CuZnSOD protein was induced from day 2 onward, and increased protein oxidative damage was observed from day 4 onward, consistent with the induction of unfolded protein response transcription factors ATF4 and CHOP. By contrast, mitochondrial aconitase activity started to decline only at 7 days, i.e. after frataxin protein levels were depleted in the mitochondria by 60%. The heme-dependent transcripts ALAS1 and MAOA were induced only after day 8, coincident with the decrease in heme-containing cytochrome c protein. Overall, these results suggest that the earliest consequences of frataxin deficiency occur in cytoplasmic iron-sulfur proteins and result in oxidative damage and stress, and trigger the unfolded protein response, and that the deficiency of mitochondrial cytochrome c and induction of ALAS1 occur only after mitochondrial frataxin depletion. These data suggest that the consequences of extra-mitochondrial frataxin deficiency could be as important as the mitochondrial ones and should be taken account of in the Friedreichs ataxia pathophysiological mechanism.

Human-specific differences in the rates of peroxisomal lipid metabolism relative to the great apes. *J. Hacia[1], A. Moser[2], K. Ramaswamy[1], M. Karaman[1], O. Ryder[3], P. Watkins[2]* 1) Department of Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA; 2) Kennedy Krieger Institute, Baltimore, MD; 3) Zoological Society of San Diego, San Diego, CA.

Meat, fish, and dairy consumption have resulted in significant differences in the lipid composition of human and great ape (chimpanzee, bonobo, gorilla, and orangutan) diets. In order to identify adaptive biochemical changes occurring in the human lineage in response to dietary lipids, we analyzed rates of fatty acid metabolism in primary cultures of human and great ape fibroblasts. Relative to those of the great apes, human cells had approximately two-fold higher catabolic rates of phytanic acid, a branched chain fatty acid present in ruminant fats unique to historical human diets. These catabolic rates are consistent with the species-specific message levels of PHYH, a peroxisomal enzyme involved in the initial step of phytanic acid -oxidation prior to complete catabolism via -oxidation. Interestingly, inactivation of the *PHYH* gene in humans leads to Refsums Disease, an autosomal recessive disorder involving peripheral sensory neuropathies as well as cardiovascular and skeletal abnormalities. Remarkably, the rates of other peroxisomal lipid metabolic processes, including pristanic acid catabolism and plasmalogen biosynthesis, did not show significant interspecies differences. Likewise, rates of mitochondrial -oxidation of long chain (LCFA) and very long chain (VLCFA) fatty acids were similar across all species. Overall, this indicates that specific adaptive changes in peroxisomal metabolic pathways have occurred in human cells that may be linked to increased levels of potentially toxic lipids unique to human diets. In turn, this may have influenced the evolution of human phenotypes involving the nervous, cardiovascular, and skeletal systems.

MITOCHONDRIAL DNA HAPLOGROUP J ALTERS THE SUSCEPTIBILITY TO INHERITED TYPE 2 DIABETES AND COMPLICATIONS. *D. Mishmar[1], J. Feder[1], I. Blech[2], O. Ovadia[1], J. Wainstein[3], I. Raz[4], S. Dadon[1], B. Glaser[2]* 1) Dept of Life Sciences, Ben-Gurion University, Beer-Sheva, Israel; 2) Endocrinology and Metabolism Service, Internal Medicine Department, Hadassah-Hebrew University Medical Center, Jerusalem, Israel; 3) Israel Diabetes Research Group (IDRG), Wolfson Hospital, Holon, Israel; 4) Diabetes Unit, Internal Medicine Department, Hadassah-Hebrew University Medical Center, Jerusalem, Israel.

Type 2 Diabetes Mellitus (T2DM) has a well-established genetic component, yet linkage to specific genetic loci is apparent only in few studies. Therefore, combinations of predisposing common genetic variants may underlie T2DM. Evidence from numerous human, animal and in-vitro studies show dysfunction of mitochondrial bioenergetics in T2DM. It has been proposed that certain mitochondrial DNA (mtDNA) common genetic variants are associated with prolonged aging, adaptation to different climatic conditions and with the susceptibility to certain age-related disorders. Nevertheless the association of such mtDNA common variants with T2DM is yet to be deciphered. To assess the contribution of mtDNA to the etiology of T2DM we analyzed the mtDNA genetic variability in 765 T2DM Ashkenazi Jewish patients. Strikingly, haplogroup J1, was underrepresented in sporadic T2DM patients (11/249, 4.4%) as compared to offspring of T2DM parents (41/425, 9.6%) (G test, P=0.01), suggesting that mutations defining haplogroup J1 alter the susceptibility to T2DM depending on additional inherited factors. Interestingly haplogroup J1 was over-represented among patients with nephropathy (33/308, 10.7%, P = 0.007) and retinopathy (14/118, 11.9%, P=0.05) as compared to patients without these complications (23/431, 5.7%; 40/614, 6.5%, respectively) implying that this haplogroup alters the susceptibility to these diabetic complications. Since haplogroup J1 is defined by mutations altering highly conserved positions in the mtDNA, to our knowledge this is the first support for mtDNA functional involvement in the etiology of T2DM. As haplogroup J alters the susceptibility to Parkinsons disease, and supports longevity, our results strongly suggest its general involvement in aging.

Genetic Investigation of Hearing loss in Iranian Population (a seven year survey). *H. Najmabadi[1], N. Meyer[2], K. Kahrizi[1], Y. Riazalhosseini[1], A. Daneshi[3], M. Farhadi[3], M. Mohseni[1], N. Bazazzadegan[1], F. Esteghamat[1], M. Avenarius[2], C. Nishimura[2], M. Malekpour[1], S. Arzhangi[1], R.J.H. Smith[2]* 1) Genetics Research Center, University of the Social Welfare and Rehabilitation Sciences, Tehran,Iran; 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA, United States; 3) Rasoul Akram Hospital, Iran University of Medical Sciences, Tehran, Iran.

Since 1999, total of 1711 families with hearing loss have been referred to our center for genetic testing. Thirty eight families had syndromic hearing loss. Majority of families had autosomal recessive non syndromic hearing loss (ARNSHL) pattern of inheritance. In 135 probands, no other affected relative could be identified - we classified these as simplex cases. GJB2 mutation screening was complete in 1523 patients with presumed ARNSHL; initially we tested for 35delG mutation. Persons either negative or heterozygous for this mutation were analyzed by denaturing high performance liquid chromatography and direct sequencing. We found GJB2-related hearing loss in 244 of 1523 (16.02%) ARNSHL cases. Identified deafness-causing allele variants included 22 mutations which 507insAACG, 329delA, 363delC and Q80L are the novel mutations and they have not been reported in other populations. The objective of this study is to identify the gene(s) involve in ARNSHL in Iranian Populations. As the first step the 14 known loci of ARNSHL with three and more affected individuals are being investigated by homozygosity mapping using STRs Markers. Whole Genome Screening using SNP typing has been performed for the families which can not be localized to the known loci. So far over 7 years, we have been able to collect over 772 families with two or more affected deaf and our linkage result have identified 3 new Loci which have not been mapped previously.

A critical evaluation of phenotypes associated with mutations in the TGF receptor genes. *B. Loeys[1], U. Schwarze[2], T. Holm[3], B. Callewaert[1], G. Thomas[3], J. De Backer[1], P. Coucke[1], A. Braverman[4], A. De Paepe[1], H. Dietz[3,5]* 1) Ghent Univ Hosp, Ghent; 2) Univ of Wash, Seattle; 3) Johns Hopkins Univ, Baltimore; 4) Wash Univ, St Louis; 5) HHMI.

TGFBR1/2 mutations are associated with Loeys-Dietz syndrome (LDS), a pleiotropic connective tissue disorder with particularly agressive vascular disease characterized by aortic root dissections at small dimensions and in early childhood and a predisposition for aneurysms throughout the arterial tree. Others have suggested that a subset of individuals with Marfan syndrome (MFS) or familial thoracic aortic aneurysm (FTAA), conditions usually associated with less aggressive and isolated involvement of the ascending aorta, can also be caused by TGFBR2 mutations. If individuals with TGFBR mutations cannot be distinguished clinically, the practical implication is that all patients with MFS and FTAA require genotyping to identify those at extreme vascular risk. To address this issue, we performed clinical and molecular analyses of diverse patient groups. We found no TGFBR mutations in 90 patients with ascending aortic aneurysms without specific connective tissue disorder and in 143 consecutive unrelated patients with classic MFS. In the latter, we found FBN1 mutations in 132 patients including 3 large intragenic deletions/duplications (identified by MLPA) that were missed by standard screening procedures. Of the 90 LDS patients from 52 families with TGFBR mutations, virtually all had clinical features that were distinguishing from either MFS or FTAA, including hypertelorism, cleft palate/bifid uvula, arterial tortuosity, aneurysms beyond the aortic root, craniosynostosis, club foot, easy bruising, atrophic scarring, translucent skin and visceral rupture. Natural history studies confirmed the aggressive nature of vascular disease. Mean age at death, due to thoracic (66.6%), abdominal (22.2%) and cerebral (7.4%) vascular events, was 26.0 yrs (0.5-47). For one third of patients, surgery or death occurred under age 19, a clear distinction from MFS or FTAA. Taken together, our data suggest TGFBR mutations underlie a clinically distinct phenotype requiring specialized management and counseling.

Contiguous hemizygous deletion of TBX5, TBX3, and RBM19 resulting in a combined phenotype of Holt-Oram and ulnar-mammary syndrome. *W. Borozdin[1], A.M. Bravo Ferrer Acosta[1], E. Seemanova[2], M. Leipoldt[1], M. Bamshad[3], S. Unger[1], J. Kohlhase[1]* 1) Institute for Human Genetics and Anthropology, Freiburg University, Freiburg, Germany; 2) Institute for Biology and Medical Genetics, 2nd Medical Faculty, Charles University, Prague, Czech Republic; 3) Dept. of Pediatrics, Division of Genetics & Developmental Medicine, University of Washington School of Medicine, Seattle, Washington.

Heterozygous mutations in the gene *TBX5* cause Holt-Oram syndrome (HOS), an autosomal dominant disorder characterized by radial ray upper limb malformations in combination with congenital heart defects and/ or cardiac conduction anomalies. Mutations in the gene *TBX3* result in ulnar-mammary syndrome (UMS). HOS and UMS are thought to result from haploinsufficiency of *TBX5* and *TBX3*, respectively. Although both genes are closely linked on chromosome 12, no contiguous deletion of both had yet been described. While performing deletion screening for *TBX5* by quantitative Real Time PCR we detected a heterozygous deletion in a family diagnosed with HOS. Further mapping showed that the 2.2 Mb deletion encompassed only three genes, *TBX5*, *TBX3*, and *RBM19*. Clinical re-examination revealed mild limb features of ulnar-mammary syndrome, i.e. clinodactyly of the fifth digits and hypoplastic hypothenar eminences in the affected mother and both affected daughters. The radial involvement was also rather mild, with only one daughter showing unilateral radial aplasia and the two other affected family members having small but mostly functional hands. Other features of HOS in this family included cardiac septal and conduction defects, whereas UMS features were mammary hypoplasia, axillary gland and hair hypoplasia, and subglottic stenosis. This is the first report of a contiguous deletion of both *TBX5* and *TBX3*, which results in a combined phenotype of Holt-Oram and Ulnar-Mammary syndrome with rather mild radial and ulnar malformations.

Characterisation of genomic instability in Dukes B2 colorectal cancer. *D. Marchetti[1], M.R. Iascone[1], G.D. Beretta[2], A.R. Lincesso[1], S. Mosconi[2], R. Labianca[2]* 1) Laboratorio di Genetica Molecolare; 2) USC Oncologia Medica; Ospedali Riuniti, Bergamo, Italy.

Colorectal cancer (CRC) is one of the most common malignancies in developed countries. The TNM system represents the main tool for identifying prognostic differences among patients. Although the Dukes B2 CRC is an homogeneous histopathological class, 30% of patients has recurrences during lifetime and the role of adjuvant therapy is still unclear in this class. Genomic instability is a driving force in the initiation of CRC development. The molecular genetics of human cancers can be used to categorise CRC in two major types: chromosomal instability and microsatellite instability (MSI). The aim of our study is the evaluation of genomic instability in Dukes B2 CRC patients. After histopathological classification, we studied specimens from 73 Dukes B2 CRC patients. Genomic DNA was extracted from normal and neoplastic microdissected paraffin-embedded tissues. Ten microsatellite markers were used to detect MSI and LOH at 18q and 17q, the chromosomes most frequently affected by LOH in CRC. The product of PCR was sized by WAVE System DNASep Cartridge (Transgenomics) eluted through a linear gradient of TEAA at 50 degree. Four samples were not analysed for scarcity of tumour tissue, 9 (13%) showed MSI, whereas LOH was observed in 25 (36%) at 18q, 5 (7%)at 17q and 15 (22%) at both loci. Fifteen of 69 Dukes B2 CRC (22%) don't show neither MSI neither LOH (noMSI-noLOH). This finding suggests that alternative pathways may be involved in CRC development. To evaluate this hypothesis, 2 noMSI-noLOH cases were tested by 32K array-CGH (TechnoGenetics). The analysis confirmed the absence of LOH at 18q and 17q and showed a common amplification at 13q12-q14 and several different chromosomal gains/losses. This preliminary finding could indicate that 13q12-q14 region may be critical for the progression of CRC but other rearrangements could characterise each tumour progression. Further studies are necessary to verify this hypothesis and to evaluate its clinical utility for the risk stratification of Dukes B2 patients.

MYO7A mutation screening in Usher syndrome type I patients from diverse origins. *T. Jaijo[1], E. Aller[1,2], M. Beneyto[1], C. Najera[2], C. Graziano[3], M. Seri[3], F. Moreno[4], C. Ayuso[5], J.M. Millan[1]* 1) Unit of Genetics, Hospital La Fe, Valencia, Valencia, Spain; 2) Department of Genetics. University of Valencia. Valencia. Spain; 3) U.O. e Catedra di Genetica Medica. Policlínico S. Orsola-Malpighi. Bologna. Italy; 4) Department of Molecular Genetics. Hospital Ramon y Cajal. Madrid. Spain; 5) Department of Genetics. Fundacion Jimenez Diaz. Madrid. Spain.

INTRODUCTION Usher syndrome type I (USH1) is an autosomal recessive disorder which displays severe to profound sensorineural hearing loss, prepuberal onset or RP and vestibular areflexia. Mutations in the MYO7A gene cause USH1B and has been reported as the main responsible of USH1. PURPOSE Screening of the MYO7A gene in probands with USH1 from diverse origins in order to identify the disease-causing mutations. PATIENTS AND METHODS Forty USH1 patients from Spain, Italy, Morocco, Turkey and Czech Republic were screened for mutations in the MYO7A gene. Genomic DNA was extracted from peripheral blood and PCR was used to amplify individual exons. SSCP analysis was performed and fragments displaying different migration pattern were directly sequenced to identify the sequence variant. RESULTS In this study, nineteen different mutations have been found. All mutations were private, with the exception of p.R241G which was found in three Italian families from the same region. Intragenic haplotypes were constructed and the same haplotype linked to this mutation was found. CONCLUSIONS The MYO7A gene is implicated in about 45% of USH1 patients. Most of mutations are private and no hotspots have been found. A common origin has been determined for the mutation p.R241G.

Two novel NOTCH3 mutations not involving cysteine residues in CADASIL patients. *R. Mazzei, C. Ungaro, M. Liguori, F.L. Conforti, A. Gambardella, T. Sprovieri, A. Patitucci, A. Magariello, A.L. Gabriele, A. Qualtieri, M. Muglia* ISN-CNR, C.da Burga, Mangone, Cosenza, Italy.

CADASIL is a cerebrovascular disease caused by mutations in the Notch3 gene. All described mutations resulted in an odd number of cysteine residues. Recently, we reported the first evidence of a small deletion, which did not involve a cysteine residue in an Italian family. The aim of the present study was to confirm that cysteine-sparing Notch3 mutations could cause CADASIL and that these mutations could determine a different phenotype. Two patients suspected of having CADASIL were referred at our Institute. The molecular analysis of Notch3 gene was performed by DHPLC and direct sequencing. A skin biopsy on both patients was also performed. The MRI scans showed a diffuse subcortical leukoencephalopathy suggestive of CADASIL in both patients. The molecular examination showed an amino acid variation in both patients: the R107W and the Q151E mutations. No additional mutation was found. The relatives of the first patient were not available. Three sisters of the second patient underwent to MRI and molecular analysis. The Q151E mutation segregated with the MRI phenotype. Both the two mutations have not been found in 500 control chromosomes. Skin biopsies from the two probands did not show deposits of GOM.Very recently, a novel cysteine-sparing Notch3 mutation causing CADASIL was described in four patients from Korea. T2-weighted hyperintensities of anterior temporal lobe, considered a characteristic MRI feature in CADASIL, were less often detected in patients with cysteine-sparing mutations. Furthermore, electronic microscopy examination of the skin biopsy showed GOMs only in 2 out of 5 patients reported until now with mutations not involving a cisteine residue, and in none of the 2 patients examined in the current study. The description of several patients with clinical features of CADASIL associated with mutations that do not involve cysteine residue, could change the axiom that all patients carry cysteine-related mutations suggesting that they may have some peculiar clinical and pathologic features different from those commonly observed in the classical phenotype.

Quantifying the effects of allele frequency differences and allelic phase on LD captured by tag SNPs derived from incompletely ascertained data: Theoretical basis, models and impact on LD mapping. *R. Lazarus, B. Raby, W. Qiu, E.K. Silverman, S.T. Weiss* Channing Laboratory, Brigham and Womens Hospital and Harvard Medical School, Boston, MA.

Population genetic effects on linkage disequilibrium (LD) are well understood, but the importance of minor allele frequency (MAF) differences and allelic phase are less widely appreciated. For 2 SNPs with MAF of 0.2 and 0.4, the maximum possible pairwise LD (as r^2) is 0.37, falling to 0.17 when the minor alleles are in repulsion. These effects will impact mapping with LD tag SNPs if there are SNPs not known (hidden or HSNPs) at the time of tagging, since HSNP likely have a different MAF spectrum. We tested data from the ten HapMap ENCODE regions using tags from a commercial whole-genome LD tagging SNP panel, designed using HapMap phase I data (Illumina HumanHap300). We quantified the effects of non-tag SNP MAF, the absolute difference in MAF between the best tag and the non-tag SNP, and repulsion between the tag and the non-tag SNP, as independent variables in a regression model for the best LD values captured by the tags. On average, captured r^2 decreased by 0.12 for each 0.1 increase in MAF difference, by 0.04 for each 0.1 decrease in non-tag SNP MAF and by 0.1 for non-tag SNPs in repulsion with the best available LD tag SNP. Similar patters were found in genotypes obtained from dbSNP, for 9590 SNPs with a MAF >= 0.1, discovered by resequencing 240 genes in the 23 CEPH Program in Genomic Applications (PGA) samples. The MAF distribution in the 240 resequenced genes differed substantially from the ENCODE regions (KS D=0.07, p=6.52e-12). The regression model for this data was similar, but captured LD was much lower. A similar pattern was observed among genotypes for 24 African American PGA samples in the same 240 genes, but with even lower levels of captured LD. We conclude that MAF differences and allelic phase differences cause a substantial and predictable loss in LD tagging efficiency when LD tags derived from pilot data with incomplete SNP ascertainment are used, or when tags derived from one population are applied to another population with a substantially different population history.

SIX3, ZIC2 and SHH mutations in a series of holoprosencephaly patients. *J. Herbergs, S. Spierts, D. Tserpelis, H. Smeets* Dept Clinical Genetics, Academic Hosp Maastricht, Maastricht, Netherlands.

Holoprosencephaly (HPE) is a common severe malformation of the brain that involves abnormal formation and septation of the developing central nervous system. The prevalence is 1:250 during early embryogenesis, but the live born prevalence is only 1:16000. The etiology of HPE is extremely heterogeneous and can include both a teratogenic and/or genetic basis. We studied four genes known to be involved in HPE, namely SHH, ZIC2, SIX3 and TGIF by sequence analysis. A series of in total 48 sporadic and familial HPE cases with a variable clinical spectrum has been analysed. We detected 12 pathogenic mutations (25%), 4 out of 39 sporadic cases (10%) and 7 out of 9 familial cases (78%). One of the familial cases was caused by a mutation in parental germ cells. Seven mutations were detected in the SIX3 gene, three mutations in the ZIC2 gene and two mutations in the SHH gene. The familial mutations displayed great phenotypic heterogeneity of the disease, which makes it difficult to establish genotype-phenotype correlations. This phenotypic variability may be due both to environmental factors and to potential modifier genes. HPE development is probably a multihit process , which implicates more genes; illustrating the importance of further identification of new genes.

Distinguishing apparently sporadic CADASIL from other leucoencephalopathies: the role of MRI in the NOTCH3 gene screening. *M. Liguori, C. Ungaro, F.L. Conforti, A. Patitucci, A. Magariello, T. Sprovieri, A.L. Gabriele, M. Muglia, R. Mazzei* ISN, CNR, Mangone, Cosenza, Italy.

CADASIL is a genetically linked cerebrovascular disease resulting from mutations in the Notch3 gene. The aim of the present study is to verify whether MRI criteria might help in the Notch3 gene screening of subjects with sporadic subcortical leucoencephalopathy. We presented data derived from a retrospective analysis (from 2003 to date) on patients referred to the ISN (CS) for conventional brain MRI, whose scans showed subcortical infarcts and leucoencephalopathy. Detailed clinical interviews resulted negative for family history of cerebrovascular diseases. MRI lesions were graded 0 to 4 according to the following criteria: 0= small and scattered brain lesions; 1= periventricular confluence; 2= periventricular confluence + presence of at least one of the following three localizations: external capsule (EC) or anterior temporal pole (ATP) or talamic microbleeds (TM); 3= periventricular confluence + presence of at least two of the following three localizations:EC, or ATP or TM ; 4= periventricular confluence + presence of all the above-mentioned brain localizations. In patients who scored 3/4, a mutational screening of the entire Notch3 gene was performed by DHPLC and direct sequencing. Three-hundred-sixty-one patients with sporadic subcortical leucoencephalopathy were selected on the basis of MRI findings and scored as follows: 66 with score 0; 224 with score 1; 53 with score 2; 17 with score 3 and 1 patient with score 4. The 18 patients with score 3/4 underwent molecular analysis of the entire Notch3 gene; in all but two cases (11.1%), 2 new mutations involving a cysteine residue - in exon 10 (C553S) and in exon 11 (Y574C) of Notch3 gene, respectively - were identified. The present evaluation suggests that patients with a clinical picture suggestive of CADASIL who fulfil the MRI criteria 3/4 should be submitted to the mutation screening of the entire Notch3 gene, even in absence of a positive family history.

Genotype -Phenotype Correlation in Myotonic Dystrophy And CTG Repeat Polymorphism at the Myotonic Dystrophy Locus in Healthy Iranian Population. *K. Kahrizi[1], N. Moradin[1], B. Shojasaffar`[1], A.M. Cobo[2], S. Nafiisi[3], M. Hasanzad[1], A. Soltanzadeh[3], J. Lotfi[3], K. Gharegozli[3], H. Najmabadi[1]* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran - Iran; 2) Unidad de Genetica, 3a planta,Edificio Aranzazu, Hospital Donostia, Paseo Dr Begiristain s/n ,San Sebastian 20014 Spain; 3) Neurology Department of Shariati Hospital, Tehran - Iran.

Myotonic Dystrophy (DM) type I- the most common form of muscular dystrophy in adults , affecting 1/8000 individuals - is a dominantly inherited disorder with a multisystemic pattern .The normal copy number of 5 - 37 CTG repeat is exceeded in DM patients .There is a correlation between the prevalence of DM1 and the frequency of large size normal alleles in a population. The aim of this study was to determine clinical and genetic characteristics of DM1 and also, to determine the distribution of alleles in healthy Iranian population. Fifty nine patients (31 families) registered with DM were studied .Polymerase chain reaction and Southern Blot analysis were conducted to determine the size of the expansion alleles in DM1 patients and PCR performed for two hundred healthy individuals from different ethnic groups . We studied twenty two DM - families (a total of forty eight patients) out of thirty one families with single band of who thirty five patients were diagnosed with a trinucleotide repeat expansion. We could find correlation between the number of expansion and Muscular Disability Rating Scales (MDRS), a Sum of Symptoms Score (SSS) and age of onset. Also , our data reveals that in 200 healthy individuals , 23.7% of alleles had 5 repeats, 23.3 % had 6-8 repeats, 45.8% had 9-17 repeats and 7.3 % of alleles had CTG repeats of more than 18. Our results on DM1 patients proved correlation of the expansion size and muscular disability. There is no definite correlation of cataract and endocrine dysfunction and the expansion size in DM1 patients. What we have concluded from our data in normal population shows that the frequency of alleles with CTG>18 is comparative to Western Europe and Japan.

Identification of susceptibility genes for Behçets disease using the genomic convergence approach. *T. Krug[1], B.V. Fonseca[1], G. Jesus[2], M.F. Moraes-Fontes[1], A. Bernardino[2], M. Coutinho[2], C. Neves[2], J. Vedes[3], M.J. Serra[4], J. Vaz Patto[5], C. Resende[6], B. Martins da Silva[7], J. Correia[8], C. Vasconcelos[8], J. Demengeot[1], J. Crespo[2], S.A. Oliveira[1], Portuguese Group for the Study of Behçets Disease* 1) Instituto Gulbenkian de Ciência, Portugal; 2) Hospital Infante D. Pedro, Portugal; 3) Hospital de Sousa Martins, Portugal; 4) Hospital dos Capuchos, Portugal; 5) Instituto Português de Reumatologia, Portugal; 6) Hospital de Santa Maria, Portugal; 7) Instituto de Ciências Biomédicas Abel Salazar, Portugal; 8) Hospital de Santo António, Portugal.

Behçet's disease (BD) is a systemic immuno-inflammatory disorder affecting multiple organs with generalized vasculitis of veins and arteries, particularly at mucocutaneous territories (oral and genital ulcers) and eye. The disease etiology remains unknown, but the most widely held hypothesis of disease pathogenesis is that of a profound inflammatory response triggered by an infectious agent in a genetically susceptible host. Although there is evidence for environmental risk factors, epidemiological and family studies strongly support the existence of genetic risk factors. The only established genetic predisposition is the HLA-B*51 gene (chr. 6p21) and its contribution to the overall genetic susceptibility to BD has been estimated to be only 19%. Furthermore, a recent linkage study on Turkish families found strong evidence for linkage with BD at 6p22-24 and 12p12-13. Case-control association studies on biological candidate genes have so far mostly been inconclusive. To identify new susceptibility genes for BD, we are conducting a novel and multidimensional genomic convergence approach, which combines data from whole genome linkage screens with expression studies to determine which genes will be tested in association studies. We will present the results of our linkage screen on several Portuguese multiplex BD families, of our RNA expression studies on blood mononuclear cells from BD patients and controls, and of the association studies on genes differentially expressed in cases and controls which map to linkage peaks.

DNA secondary structure induces genomic instability leading to the recurrent 11;22 chromosomal translocation.

T. Kato[1, 2], H. Inagaki[1], H. Kogo[1], T. Ohye[1], B.S. Emanuel[3], H. Kurahashi[1, 2] 1) Div Molecular Genetics, Fujita Health Univ, Toyoake, Japan; 2) Development Center for Targeted and Minimally Invasive Diagnosis and Treatment, Fujita Health Univ, Toyoake, Aichi, Japan; 3) Div Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA.

Human mutations like chromosomal translocations are thought to be random events. However the constitutional t(11;22)(q23;q11) in humans occurs recurrently at restricted breakpoint regions. We identified palindromic AT-rich repeats (PATRRs) at the t(11;22) breakpoint cluster regions both on chromosomes 11 and 22, and suggested that the PATRR induces genomic instability by forming a DNA secondary structure. Recent findings of others regarding potential H-DNA at the t(14;18) breakpoints in follicular lymphomas support our hypothesis. We previously demonstrated polymorphisms of the PATRR that affect the frequency of *de novo* occurrence of the translocation. In this study, we have hypothesized that polymorphism of the PATRR affects its secondary structure-forming propensity, and performed the following experiments; (1) *in silico* calorimetric analysis using the DNA mfold server calculating the free energy for various PATRRs, (2) an *in vitro* cruciform extrusion assay to examine mobility shift in agarose gel electrophoresis using plasmids bearing various PATRR11s, and (3) *in vivo* deletion frequency of PATRR11 plasmids in wild-type *E. coli*. Using these methods, we validated the secondary structure-forming propensity of various PATRR11s, and compared them with the frequency of *de novo* occurrence of the t(11;22) translocation. The results demonstrate that secondary structure-forming propensity correlated well with translocation frequency, Our results provide indirect but strong support to the hypothesis that the PATRR adopts a cruciform conformation in living cells that induces genomic instability leading to the translocation.

Poly-Alanine tract expansion in Aristaless-related homeobox (ARX) causes cognitive impairment in MRX87 family. *M.G. Miano[1], C. Laperuta[1], P. D'Adamo[2], A. Maiorino[3], P. Chiurazzi[4], V. Ventruto[1], C. Carbone[1], M. DUrso[1], M.V. Ursini[1]* 1) Institute of Genetics and Biophysics A.B.Traverso, CNR, Naples, Italy; 2) Tigem, Telethon Institute, Naples, Italy; 3) C.A.R.S.I.C. Institute, Venafro, Italy; 4) Catholic University of Rome, Rome, Italy.

Genetic cognitive impairments are heterogeneous conditions with 10% of forms linked to the X human chromosome and mostly caused by defects of genes involved in brain development and plasticity. One of these is Aristaless (ARX) encoding a homeobox transcription factor of the Q50 Paired-like (Prd-like) class whose murine ortholog regulates the brain organogenesis and neurogenesis. Mutations in ARX comprise a continuous series of developmental brain disorders including macro-alteration of brain such as lissencephaly, and ends with a series of overlapping syndromes with cognition impairment and apparently normal brain structure. Here we report on the clinical and genetic analysis of an Italian family with a syndromic mental impairment segregating with X-linked inheritance (XLMR). Linkage evaluation delineates a new locus, MRX87, between DXS1740 and DXS1214, placing it in Xp22-p21. This is a hot spot region for mental handicap, which comprises many XLMR genes even included ARX. By direct sequencing, we identified in association with the disease a new ARX duplication causing a poly-alanine tract espansion. This mutation was observed to segregate with an intra-familial clinical heterogeneity and penetrance variability as showed by the affected males presenting a mixture of mental handicap and subtle congenital abnormalities. Its pathogenic mechanism is still unknown but similarly to other Ala expansions causing congenital defects, it could disturb the transcriptional properties of Aristaless. Our study of MRX87 locus is consistent with the notions that poly-Ala tract expansions are the main mutations of ARX, a gene hot spot for cognition disorders linked to Xp22-p21 region. Furthermore, our findings enrich the pictures of the correlated phenotypes raising Aristaless as a pivotal transcriptional factor essential to brain/head development and offering the opportunity of unmasking new pleiotropic actions in humans.

Gender-specific linkage of quantitative traits for obesity in Hong Kong Chinese. *M.C.Y. Ng, C.H.T. Tam, V.K.L. Lam, J.C.N. Chan* Department of Medicine & Therapeutics, The Chinese University of Hong Kong, Hong Kong.

Mapping complex traits is difficult due to the complex interaction between genetic and environmental factors. Gender is a key modulator affecting distribution of traits such as anthropometric measures. We hypothesized the presence of gender-specific effect on the quantitative trait loci for obesity measures.

We conducted autosomal genome scans with 355 microsatellite markers in 179 families (897 members, 46% males) ascertained through a proband with Type 2 diabetes from the Hong Kong Family Diabetes Study. We estimated heritability and performed variance component-based linkage analyses on three obesity-related traits: body mass index (BMI), waist circumference (WC) and body fat percentage as measured by bioimpedance (FAT) in all subjects as well as in males and females separately.

Males had significantly higher BMI (25.44.1 vs. 24.54.7 kg/m^2), WC (8610 vs. 7811 cm) but lower FAT (246 vs. 346 %) than females (P 0.05). Heritability estimates suggested stronger genetic loadings of these traits in females than in males: BMI (81% vs. 57% in females and males, respectively), WC (84% vs. 67%) and FAT (63% vs. 50%). Variance component linkage analyses revealed significant linkage at chromosome 1q24-25 for BMI (LOD = 4.4), WC (LOD = 3.7) and FAT (LOD = 4.4) in all samples. Stratification by gender showed similar linkage for BMI (LOD = 3.0 for males and 2.7 for females) and WC (LOD = 2.5 for males and 2.4 for females) in each gender. However, the linkage for FAT at the same region was largely attributed by females (LOD = 6.3) rather than by males (LOD = 0.1).

In summary, we found significant linkage of obesity measures at chromosome 1q24-25. The linkages for BMI and WC were contributed by both gender while the linkage for FAT was only contributed by females. The results suggest the presence of two or more independent loci in this region that contribute to obesity measures, with or without interaction with gender.

An age related homeostasis mechanism is responsible for spontaneous amelioration of hemophilia B Leyden. *K. Kurachi[1], J.S. Huo[2], A. Ameri[2], Z. Zhang[2], E. Kasama[1], T. Tanaka[1], J. Hoff[1], S. Kurachi[1]* 1) Age Dimension Research Ctr, AIST, Tsukuba, Japan; 2) Department of Human Genetics, University of Michigan.

Little has been known about genetic mechanisms regulating diseases with specific patterns of progression over the course of a lifetime. One example of such diseases is hemophilia B Leyden, a unique subset of hemophilia B that shows an unusual pattern of puberty-onset spontaneous amelioration. The mechanisms underlying hemophilia B Leyden have remained a mystery. We previously showed that two genetic elements, ASE and AIE, of the ASE/AIE-mediated genetic mechanism of age-related regulation of gene expression regulate age-related changes in gene expression, specifically from puberty into old age. Through construction of transgenic mouse models reproducing the Leyden phenotype, here we demonstrate that the ASE of this mechanism plays an essential role for puberty-onset expression of human FIX and amelioration of hemophilia B in a sex-independent manner. Binding of a specific liver nuclear protein to ASE parallels with the puberty-onset gradual increase in expression of human factor IX in these animals, and the binding protein was identified as a proto-oncogenic Ets family protein. Human factor IX expression in these transgenic animals was nullified by hypophysectomy, but fully restored by growth hormone, thus agreeing with the sex-independent amelioration of hemophilia B Leyden. This work identifies for the first time the molecular mechanism regulating puberty-onset changes in expression seen in hemophilia B Leyden, and demonstrates the clinical relevance of the ASE/AIE-mediated regulatory mechanism of age-associated changes in gene expression.

mtDNA point mutations are present at various levels of heteroplasmy in human oocytes. *L.J.A.M. Jacobs[1,2], M. Gerards[1,2], P.F. Chinnery[3], J.C.M. Dumoulin[2, 4], J.P.M. Geraedts[1,2], H.J.M. Smeets[1, 2]* 1) Genetics and Cell Biology, University of Maastricht, Maastricht, Netherlands; 2) Research institute GROW, University of Maastricht, Maastricht, The Netherlands; 3) Mitochondrial Research Group, University of Newcastle upon Tyne, Newcastle upon Tyne, UK; 4) Department of IVF, Academic Hospital Maastricht, Maastricht, The Netherlands.

Little is known about the load of mutations and polymorphisms in the mtDNA of human oocytes and the possible effect these mutations may have during life. To investigate this, we optimised at the single cell level the recently developed method to screen the entire mtDNA for mainly heteroplasmic mutations by denaturing high performance liquid chromatography (DHPLC) analysis. This method is sensitive (~1% heteroplasmy detectable), specific and rapid. The entire mtDNA of 26 oocytes of 13 women was screened by this method. Ten different heteroplasmic mutations, of which only one was located in the D-loop and of which two were observed twice, were detected in seven oocytes with mutation loads ranging from less than 5% to 50%. From 8 women more than one oocyte was received and in four of them heteroplasmic differences between oocytes of the same woman were observed. In one of these four also two homoplasmic D-loop variants were detected. Additionally, four oocytes of a single woman were sequenced using the MitoChip (which lacks the D-loop region), but all sequences were identical. It is concluded that heteroplasmic mtDNA mutations are common in oocytes and that depending on the position and mutation load they might give rise to OXPHOS disease early or later in life.

Proposition for a multi-step mutation detection in Hemophilia A. *N. Lannoy[1], I. Abinet[1], Ch. Verellen[1], Ch. Vermylen[2], C. Hermans[3], K. Dahan[1]* 1) Center of Human Genetics, UCL, Saint-Luc Hosp, Brussels, Belgium; 2) Departement of Pediatric, UCL,Saint-Luc hosp, Brussels, Belgium; 3) Departement of Haematology, UCL,Saint-Luc hosp, Brussels, Belgium.

With an incidence of one in 10000 males born worldwide, haemophilia A is the most common hereditary hemorrhagic disorders. Its is caused by a deficiency or dysfunction of blood coagulation Factor VIII (F8). Phenotypically, three classes of hemophilia A are distinguished according F8 residual clotting activity (severe, moderate and mild). Identification of causal mutation is important for proper management of affected boys and detection of female carriers. The size of the F8 gene (26 exons) as well as the large mutational spectrum including intronic inversions and various private small mutations represent a challenge for routine mutation screening. In this context, we developed a rapid multi-step approach for detection of F8 mutations in a large cohort of 74 unrelated hemophilia A patients (46 severe, 5 moderate and 23 mild forms) regulary followed at the Hemophilia Center of the Cliniques universitaires Saint-Luc, Brussels. The first step which includes the intron 22 inversion resulted in the detection of 23 mutations (23/46, 50%) among patients with severe disease. The second step based on the relative existence of hot spot exons (europium.csc.mrc.ac.uk) allowed by direct sequencing of exons 7, 8, 11, 14, 18, 23, 24 and 26 identification of 12 change mutations (4 deletion, 1 insertion, 4 missense, 2 non sense and 1 splice defect) in severe patients (12/46, 26%) and 14 missense mutations in 2 moderate (2 /5, 40 %)and 12 mild (12 /23, 52%) patients. In the third step, the remaining exons were analysed leading to the identification of 19 additional sequence changes in 5 severe, 3 moderate and 11 mild patients. No case of intron 1 inversion was detected. This multi-step approach which can be easily implemented in diagnosis laboratory allowed a rapid identification of 92% mutations (68/74) in a cohort of phenotypic heterogeneous families. Interestingly, 13 mutations identified in this study have, to our knowledge, not been previously reported.

Comparative analysis of the SCA10 ATTCT pentanucleotide repeat indicates the repeat sequence originates from retrotransposons. *T. Kurosaki[1], T. Matsuura[2], K. Ohno[2], S. Ueda[1]* 1) Department of Biological Sciences, Graduate School of Science, The University of Tokyo, Tokyo, Japan; 2) Division of Neurogenetics and Bioinfomatics, Center for Neurological Diseases and Cancer, Nagoya University Graduate School of Medicine, Nagoya, Japan.

Spinocerebellar ataxia type 10 (SCA10) is a dominantly inherited neurodegenerative disorder caused by unstable expansion of the ATTCT pentanucleotide repeat in the intron 9 of ATXN10 gene. There is a large gap between the documented normal (10-29) and the mutated repeat length (280-4500) associated with SCA10. The SCA10 expansion has also unique characteristics of instability in both somatic and germ line tissues, which is distinct from other repeat expansions. However, little is known about the underlying molecular basis, since the repeat size of the expansion is too large for its characterization.
For better understanding of the ATTCT repeat instability, we compared the genome sequences in mammals. Interestingly, the repeat was found only in primates. To gain a further insight into the origin and evolutional history of the ATTCT repeat, we performed long PCR and direct sequencing of apes, Old World monkeys and New World monkeys. We found the ATTCT repeat was not preserved throughout the primate lineage. In Old World monkeys, ATTCT was replaced by CTTGT. Moreover, the repeat was exactly placed on a boundary of LINE and Alu, and the 3.2-kb region surrounding the repeat was entirely deleted in New World monkeys. Taken together, it suggests that the repeat-containing fragment was retrotransposed into the intron 9 of ATXN10 in the common ancestor of catarrhines.

Development of a new array-MAPH methodology for detection of copy-number changes and screening of patients with X-linked mental retardation. *A. Kurg[1], L. Kousoulidou[2], K. Männik[1], S. Parkel[1], O. Zilina[1], N. Tõnisson[1], C. Sismani[2], P. Palta[1], H. Puusepp[1], M. Remm[1], P.C. Patsalis[2]* 1) Dept. of Biotechnology, Institute of Molecular & Cell Biology,Univ. of Tartu, Tartu, Estonia; 2) Dept. of Cytogenetics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.

Accurate and sensitive genome-wide screening to detect small genomic imbalances has been a technical challenge for a long time. The focus of this study was to introduce a novel methodology, based on a new type of microarray, using the basic principle of Multiplex Amplifiable Probe Hybridization (MAPH) for fast, accurate and reliable determination of copy-number changes of virtually any loci in complex genomes. We have developed a new methodology and software for designing PCR-amplifiable hybridization probes (200-600bp) that can be used for both array-MAPH and array-CGH and also a web interface called MAPHDesigner (http://bioinfo.ebc.ee/MAPH) for the developed programs. We have designed, amplified, cloned and spotted onto arrays 560 target sequences for human chromosome X to cover it uniformly with median spacing of 238kb, while in certain regions of interest with resolution up to 3kb. Another 107 probes from autosomal chromosomes were selected and used as normalization controls. For validation of the new methodology, several normal and patient DNA samples with known and unknown chromosome X aberrations were analyzed. Array-MAPH detected deletions and duplications, which were confirmed by PCR and/or FISH analyses, demonstrating the accuracy and sensitivity of the new approach. The new array-MAPH method was further applied for screening of 20 male patients from families with X-linked mental retardation (kindly provided by EURO-XLMR consortium). One deletion of 500kb and two duplications of 1.6Mb and 0.9Mb were detected and their segregation in the corresponding families was investigated. The new microarray methodology provides an alternative to array-CGH as well as several advantages for high-throughput diagnostic screening by enabling high flexibility to study virtually any region in the human genome.

The genetic variation and population history in the Baltic Sea region. *P. Lahermo[1], V. Laitinen[2], S. Koivumäki[3], P. Sistonen[4], P. Anderson[5], M-L. Savontaus[2,3], K. Huoponen[2], T. Lappalainen[1]* 1) Finnish Genome Center, University of Helsinki, Finland; 2) Department of Medical Genetics, University of Turku, Finland; 3) Department of Biology, Laboratory of Genetics, University of Turku, Finland; 4) Finnish Red Cross Blood Transfusion Center, Helsinki, Finland; 5) Department of Neurology, Umeå University Hospital, Sweden.

Sharp genetic borders within a geographically restricted region are known to exist among the populations around the northern Baltic Sea on the northern edge of Europe. We studied the population history of this area in greater detail from paternal and maternal perspectives with Y chromosomal and mitochondrial DNA markers. Over 1700 DNA samples from Finland, Karelia, Estonia, Latvia, Lithuania and Sweden were genotyped for 18 Y-chromosomal biallelic polymorphisms and 8 microsatellite loci, together with 18 polymorphisms from the coding area of mtDNA and sequencing of the HVR1. Y chromosomal haplogroups from the biallelic data indicate both various phases of gene flow and existence of genetic barriers within the Baltic region. Haplogroup N3, being abundant on the eastern side of the Baltic, differentiates between eastern and western sides of the Baltic Sea, just like R1b that has a reverse frequency pattern to N3. The typically Scandinavian haplogroup Ia1 has a high frequency of up to 40%, separating not only Sweden but also Western Finland from the other populations. The frequency of haplogroup R1a1, most characteristic to Slavic peoples, varied substantially across the populations. In addition to biallelic markers, Y-chromosomal microsatellite loci were analyzed for a more detailed approach to the history of the paternal lineages in the region. We also analyzed mtDNA markers with special interest for sub-haplogroups of H and U, that among other haplogroups, show substantial variation between the populations (e.g. haplogroups H1, H2, T and J1). In conclusion, our current Y-chromosomal and mtDNA data suggest various incidents of gene flow from different sources, each reaching partly different areas of the Baltic region, which can be thus seen as a meeting point of a not only culturally but also genetically diverse set of populations.

COL11A1-gene is Both Linked to and Associated with Human Stature. *J. Kettunen[1], E. Costiander[1], S. Sammalisto[1], L. Peltonen[3,4], M. Perola[1,2]* 1) Department of Molecular Medicine, Finland's National Public Health Institute, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Finland; 3) Academy Professor, University of Helsinki and National Public Health Institute, Finland; 4) Visiting Professor, the Broad Institute of MIT and Harvard, Boston, USA.

Stature (i.e. adult height) is a quantitative trait with high heritability. Various interesting regions in the human genome have been linked to adult stature but only few have been confirmed by later studies. Recently, we localized a quantitative trait locus locus for stature in chromosome 1p21 (multipoint LOD score 4.25 in sex-statified males-only sample). The most promising candidate gene in this region of interest was COL11A1. We genotyped 24 single nucleotide polymorphisms (SNPs) in 92 families totalling 921 genotyped individuals. In this study we show consistent evidence of linkage in a subset of previously linked families (n = 54, p = 0.05), which is further increased when we add additional family members (p = 0.002) and is replicated in a set of independent families (n = 38, p = 0.04) that have not been analyzed previously for linkage to stature. Joint analysis of all available families yielded yet greater evidence for linkage (p = 0.0004). Two markers in the COL11A1-gene show association to stature in the families with additional family members (n = 54): an intronic SNP with no known function (intron 58, p = 0.008) and a non-synonymous exonic SNP that changes an amino acid 1535 from proline to serine in the proteins major triple helix (p = 0.013). Thus, we have here both replicated the original linkage result in an independent sample and shown association to a genetic variant for human adult stature, implying that genetic variation in the COL11A1-gene contributes to the variation observed in human stature.

Preferential X chromosome loss but random inactivation characterize women with primary biliary cirrhosis. *M. Miozzo[1], C. Selmi[2], P. Invernizzi[3], S.M. Sirchia[1], S. Maitz[3], B. Gentilin[1], M. Zuin[3], M.E. Gershwin[4], M. Podda[3]* 1) Medical Genetics, San Paolo School of Medicine, University of Milan, Italy; 2) Internal Medicine, Department of Clinical Sciences Luigi Sacco, University of Milan, Italy; 3) Internal Medicine, San Paolo School of Medicine, University of Milan, Italy; 4) Division of Rheumatology, University of California School of Medicine, Davis, CA.

Primary biliary cirrhosis (PBC) is a chronic cholestatic autoimmune disease of unknown etiology characterized by 9:1 female predominance.The importance of the genetic background in PBC was demonstrated by the concordance rates among monozygotic twins and by the enhanced frequency of X monosomy in peripheral blood T and B cells in PBC women. We suggest that the genetic mechanism linking X monosomy to PBC relies on haploinsufficiency of genes escaping X inactivation(XCI), and that a non random X loss in monosomic PBC cells might unmask X-linked haplotypes related with autoimmunity. We determined the X dosage and XCI pattern in women with PBC and controls to establish whether: X monosomy is caused by the preferential loss of an X; PBC women display a skewed XCI; X monosomy rates correlate with specific XCI patterns;X defects are restricted to PBC peripheral blood mononuclear cells (PBMC). We performed X dosage in PBMC and buccal cells (BS) from 166 women with PBC and 177 age-matched healthy women by genotyping a panel of 4 X linked polymorphisms using QF-PCR.XCI was carried out by HUMARA test. The frequency of women with skewed XCI (75 or 90) in PBMC and in BS was similar in PBC and controls.The study of X-linked loci demonstrated a preferential X chromosome loss in 47% of PBCs and 18% of controls ($P<0.0001$),independent of the XCI pattern. No differences in X defects were observed between BC from women with PBC and controls. These data highlight that: X loss does not occur randomly in PBC; preferential X monosomy is specific for PBMC; Skewed XCI is similar in PBC to controls.We suppose that hemizygosity of genes escaping XCI, caused by preferential X loss unmask peculiar haplotypes conferring susceptibility to autoimmunity.

A cohort of patients with generalized Fibromuscular Dysplasia and features of Ehlers-Danlos Syndrome: A new phenotype. *N.B. McDonnell[1], J. Yang[1], W. Chen[1], B. Griswold[1], C.A. Francomano[1,2]* 1) National Institute on Aging, NIH, Baltimore, MD; 2) Harvey Inst Human Gen, Greater Baltimore Medical Center, Baltimore, MD.

The Ehlers-Danlos syndromes (EDS) are a heterogeneous group of hereditary disorders of connective tissue. Vascular dissections and aneurysms are a cardinal feature of the vascular form of EDS (VEDS) caused by mutations in COL3A1. Loeys-Dietz syndrome, a closely related phenotype, is caused by mutations in TGFBR1 or TGFBR2. We have identified a group of patients without mutations in COL3A1, TGFBR1 or TGFBR2 who presented with arterial dissections and aneurysms as well as stenotic lesions with a diagnosis of fibromuscular dysplasia (FMD) by pathology or radiology. Varying features of Ehlers-Danlos syndrome, such as atrophic scars, velvety or stretchy skin, joint hypermobility as evidenced by a high Beighton score, history of articular dislocations, uterine prolapse, joint pain, pectus deformities, pes planus and scoliosis were also present. Several of the patients had a family history of premature death from vascular events, as well as a family history of joint and skin abnormalities compatible with an autosomal dominant inheritance pattern. There were no reports of uterine or bowel rupture, or pregnancy related death in personal or family histories. The facial features were not characteristic of VEDS or Loeys-Dietz syndrome. The first patient identified was a 44 year old woman who had a history of carotid dissection, ruptured cerebral aneurysms, FMD of renal arteries and iliac vessels, multiple atrophic scars, frequent joint dislocations, and stretchy and doughy skin. A cohort of thirty patients with this syndrome has been identified and detailed phenotype and family history information has been assembled. The etiology of fibromuscular dysplasia is thought to be heterogeneous, with genetic and environmental factors proposed as possible contributors. Our findings suggest that there is a previously unrecognized variant of EDS, distinct from the VEDS and Loeys-Dietz syndrome, with FMD as a major clinical feature in addition to the skin and joint abnormalities.

MYH7 and MYBPC3 gene mutations in pediatric hypertrophic cardiomyopathy. *M.R. Iascone[1], D. Marchetti[1], A. Iacovoni[2], A.R. Lincesso[1], C. Mammana[2], S. Pentiricci[2], M. Triggiani[2], A. Gavazzi[2], P. Ferrazzi[2]* 1) Molecular Genetics Lab; 2) Cardiovascular Dept, Ospedali Riuniti, Bergamo, Italy.

Sarcomeric gene mutations are a well known cause of hypertrophic cardiomyopathy (HCM) in adults. Although these alterations may present before adult life, they were not extensively investigated in children. The present study is a description of clinical, pathological and genetic findings in a series of children (pts) with HCM referred to our Center. From 2001 to 2005, 40 HCM unrelated pts were investigated for MYH7 and MYBPC3 genes mutations. The disorder was diagnosed by echocardiography in 37 pts, while at autopsy in the other 3. At diagnosis, the age was <1yr in 8 pts, 1-6yrs in 8, 7-12yrs in 7 and 13-17yrs in 17. Among these 40 pts (27 males), 17 were previously transplanted, 14 were referred for transplant evaluation (3 died in waiting list), 6 were hospitalized for surgical myectomy, while 3 were diagnosed at autopsy because of sudden cardiac death. Myocardial tissue was available for histological analysis in 29 pts. The concordance between clinical and pathological diagnosis of HCM was good in almost all cases, except for 2 pts that had a different diagnosis after pathological examination. Re-examination of clinical records of these 2 pts revealed a latent neuromuscolar disorder and were excluded from the study. After informed consent, genomic DNA was extracted from blood and all exons and flanking intronic regions of MYH7 and MYBC3 genes were analyzed by DHPLC and direct sequencing. A gene mutation was present in 19/38 cases (50%). Six are de novo and 13 had a positive family history for HCM, confirmed by genetic analysis. Twelve mutations (57%) were not previously described in literature. Two pts showed a double mutation, 9 had mutations in MYH7 gene and 8 in MYBPC3 gene. There was no correlation between type of mutation or mutant gene and severity of clinical manifestations, although the double mutant patients were younger (age <1yr) and had a very severe phenotype. Our data show that sarcomeric gene mutations could play a major role in the pathogenesis of pediatric HCM. Further studies will improve our understanding of genetic causes in this cohort of patients.

ESRETNET: A Spanish network for the clinical and genetic study of inherited retinal disorders. *J.M. Millán[1], D. Valverde[2], M. Baiget[3], G. Antiñolo[4], M. Carballo[5], C. Ayuso[6]* 1) Unit of Genetics, Hospital La Fe, Valencia, Spain; 2) Department of Biochemistry, Genetics and Immunology. University of Vigo, Vigo, Spain; 3) Department of Genetics. Hospital Sant Pau, Barcelona, Spain; 4) Department of Genetics, Hospital Virgen del Rocio, Sevilla, Spain; 5) Laboratory, Hospital de Terrassa, Barcelona, Spain; 6) Department of Genetics, Fundacion Jimenez Diaz, Madrid. Spain.

EsRetNet is a Spanish network composed of six groups that arose in 1991 in order to achieve the following objectives: § Development of a National Retinal Degeneration (RD) Register § Create a Case Report Format § Review and Update of clinical and molecular procedures § Implementation of molecular technology (direct and indirect screening) § Mutational Screening of Known Genes § Identification of new loci/genes § Clinical and Genetic characterisation of syndromic forms of RD § Genotype-Phenotype correlation § Generation of homogeneous patient groups for future clinical trials § Spreading of results among patient organizations, researchers ophthalmologist, ENTs. Up to date, EsRetNet has collected DNA samples of over 3000 RD patients from over 2000 different families. Among them, 70% are patients suffering from isolated Retinitis Pigmentosa (RP), 18% syndromic retinitis pigmentosa (most of them Usher syndrome but also Bardet-Biedl syndrome and others) and 12% other RD (Autosomal dominant macular degeneration, Norrie disease, choroideremia, X-linked retinoschisis, Stargardt disease and Congenital Leber amaurosis). Further details about the genetic findings for every disorder will be shown.

Genetic Analysis of PHOX2B Gene in Congenital Central Hypoventilation Syndrome (CCHS). *C.C. Hung[1], Y.N. Su[2], W.L. Lin[1]* 1) Institute of Biomedical Engineering, National Taiwan University, Taipei, Taiwan; 2) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan.

BACKGROUND Congenital central hypoventilation syndrome (CCHS) is a rare neurological disorder which is characterized by abnormal autonomic central nervous system control of breathing during sleep. The mutation in PHOX2B gene, including point mutations, frameshift and a polyalanine expansion, is relevant to the pathogenesis of this disease.

METHODS We analyzed PHOX2B mutations in 7 CCHS patients, the family members and 1520 healthy individuals from general populations. Our approach is based on polymerase chain reaction (PCR), capillary electrophoresis (CE), denaturing high-performance liquid chromatography (DHPLC) and direct sequencing with high sensitivity and resolution.

RESULTS By applying this technique, we identified 7 mutations in PHOX2B gene, including 2 frameshift mutations and 5 polyalanine expansions in the 20-residue polyalanine tract. Additionally, allele and genotype distributions showed significant differences noteworthy. $(GCN)_{20}$ had the highest allele frequency of 94.84% in populations, and $(GCN)_{15}$ was the second common, whereas its frequency was 4.51%. The remaining allele were $(GCN)_{13}$ and $(GCN)_{7}$, with frequency 0.59% and 0.06% respectively.

CONCLUSIONS The homeobox gene PHOX2B mutations in CCHS patients present variable phenotypes suggest the size of expansion allele was associated with the risk of CCHS. We demonstrate that capillary electrophoresis can be used to improve detection of polyalanine expansions in the PHOX2B gene. It is a fast, simple, reliable and non-fluoresce tool for identification of PHOX2B gene mutations. We believe the described method will be suitable for routine clinical application and screening in trinucleotide repeat tracts.

The TRIM50 and TRIM37 complex: a link between Williams Beuren Syndrome and Mulibrey Nanism. *G. Merla[1], L. Micale[1], B. Augello[1], C. Fusco[1], C. Ucla[2], G. Meroni[3], L. Napolitano[3], A. Reymond[4]* 1) Medical Genetics Unit, IRCCS Casa Sollievo Della Sofferenza Hospital, S.G. Rotondo, Italy; 2) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 3) TIGEM, Telethon Institute of Genetics and Medicine, Naples, Italy; 4) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland.

Williams-Beuren Syndrome (WBS, OMIM#194050) is a neurodevelopmental disorder with multisystemic features caused by a microdeletion at 7q11.23. Using comparative genomics approaches we identified a TRIpartite Motif-containing gene (TRIM) in each of the three LCRs that flank the WBS deletion, TRIM50, 73 and 74. TRIM50, the only one hemizygous in WBS patients encodes a putative protein that contains a RING, a B-box type 2, a coiled-coil and an RFP-like domain, while TRIM73 and TRIM74 miss the last domain. Some TRIM proteins were recently shown to play a role in ubiquitylation. Consistently we show that the TRIM50 protein has ubiquitin-ligase activity and interacts with E2 ubiquitin-conjugating enzymes. Interestingly it colocalizes with TRIM37 in discrete cytoplasmic structures. This association was further confirmed by coimmunoprecipitation of the two proteins. TRIM37 encodes an additional E3-ubiquitin ligase, that when mutated is responsible for Mulibrey Nanism (MUL, OMIM # 253250). MUL is a recessive disorder that includes severe growth failure, dysmorphic features, pericardial constriction. The tissue expression of Trim50 shows significant positive correlation with expression of Trim37, being both genes highly expressed in testis, pancreas and brain. In conclusion we found an unexpected relationship between two apparently distinct disorders suggesting a possible common role for the TRIM50:TRIM37 complex in both Syndromes probably involved in the Proteasome-mediated degradation pathway.

Association of IL4R gene polymorphisms with asthma in Chinese population. *X. Kong[1,7], H. Zhang[1], Q. Zhang[1], L. Wang[2], H. Chen[3], Y. Li[4], T. Cui[5], W. Huang[6], L. Zhang[1], F. Yan[1], L. Wang[1], Y. Xu[2], L. Hu[1]* 1) Health Sci Ctr, Sibs, Shanghai, China; 2) Department of Respiratory Disease of Renji Hospital, Shanghai Second Medical University, 200025, Shanghai, China; 3) Department of Molecular Biology, Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences, Beijing 100005, China; 4) Department of Pediatrics, the First Affiliated Hospital of Zhengzhou University, Zhengzhou 450052, China; 5) Union Hospital, Tongji Medical School, Huazhong University of Science and Technology, Wuhan 430022, China; 6) Chinese National Human Genome Center at Shanghai, Shanghai 201203, China; 7) State Key Laboratory of Medical Genomics, Ruijin Hospital, Shanghai 200025, China.

Cytokines, having central functions in immunological and inflammatory process, are expected to play important roles in the pathogenesis of various diseases, such as asthma. Genetic polymorphisms of those cytokine and cytokine receptor genes are the focus of genetic association studies. In an effort to identify gene(s) whose variant(s) are associated with the asthma, we screened all exons and their flanking regions, as well as the promoter region (1.5kb) of eight genes, including IL4, IL13, IL12B, IL5, IL3, IL9, CD14 and IL4R. We identified 42 single nucleotide polymorphisms, 15 of which were novel. Then, we examined the genetic effects of 30 single nucleotide polymorphisms in eight cytokine and cytokine receptor genes on asthma in a Chinese asthma cohort (n=537). Genetic association analysis of polymorphisms revealed that six polymorphisms (c.899-2C>A, c.1199A>C, c.1242G>T, c.1291T>C, c.1299T>C, c.1507T>C) in IL4R gene, three of which resulted in an amino-acid change, showed significant association with the risk of asthma (P=0.00023). Further analysis indicates that these six polymorphisms segregated in strong linkage disequilibrium. The genetic association of IL4R with asthma might provide valuable insights into the pathogenesis of asthma.

A *de novo* mutation in *endoglin* gene in a Japanese family with hereditary hemorrhagic telangiectasia. *N. Matsui*[1], *Y. Izumi*[1], *H. Azuma*[2], *R. Kaji*[1] 1) Neurology,The University of Tokushima, Tokushima, Tokushima City, Japan; 2) Medicine and Bioregulatory Sciences, Institute of Health Biosciences, The University of Tokushima, Tokushima, Japan.

Hereditary hemorrhagic telangiectasia (HHT), also known as Rendu-Osler-Weber syndrome, is an autosomal dominant disorder that affects vascular malformations and hemorrhage. The *endoglin* (*ENG*), which is located on chromosome 9q33-34, is responsible gene for HHT1. HHT1 is associated with a higher incidence of pulmonary arteriovenous malformations (PAVMs). We had an 18-year-old Japanese woman, who suffered from a repeating epistaxis and an embolic stroke associated with PAVMs. Because her sister and mother also showed epistaxis, we examined the clinical course and gene related to the proband and her family history. We report here that a *de novo* mutation in the endoglin gene segregated perfectly with HHT1 in this Japanese family. More than 130 *endoglin* mutations have been reported all over the world so far. This mutation (IVS3+1GA), which is the second report in Japan, has been reported four times in three ethnic groups, Canadian, German and Japanese. Taking advantage of the past reports, we suggests that this splice site mutation resulted in skipping of exon3.

A Non-coding SNP Is Associated With Lethal Congenital Contracture Syndrome. *H. Nousiainen[1], N. Pakkasjärvi[1], R. Herva[2], M. Kestilä[1], L. Peltonen[1,3,4]* 1) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Department of Pathology, University of Oulu, Finland; 3) Department of Medical Genetics, University of Helsinki, Finland; 4) The Broad Institute, Boston, MA, USA.

Lethal Congenital Contracture Syndrome (LCCS) is a severe developmental disorder that results in the death of the fetus before 32nd gestational week. Affected fetuses display the FADS (Fetal Akinesia Deformation Sequence) phenotype, which includes joint contractures, small jaw, lowset ears, fetal hydrops, and pulmonary hypoplasia. Histopathological analysis reveals degeneration of muscles and the anterior horn of the spinal cord. LAAHD is another form of lethal arthrogryposis, in which the neuropathological findings are similar to LCCS, but the fetuses may survive to full term and the degeneration of muscles and the spinal cord is slightly less severe. Both syndromes are inherited in the autosomes recessively. The LCCS locus has been mapped to chromosome 9q34. By monitoring for shared haplotypes in affected individuals, we have restricted the critical chromosomal region to 1 Mb between markers D9S1827 and D9S972. We sequenced 27 regional genes and identified only one nucleotide variant differentiating patients and controls: a previously uncharacterized single nucleotide polymorphism (SNP) in the 3UTR region of the SLC27A4 gene that shows a strong association with LCCS and immediately provided us with a powerful diagnostic tool to help the families affected with the disease. 100% of the fetuses with an assertive LCCS diagnosis are homozygous for this previously uncharacterized nucleotide variant. By sequencing control samples we have estimated the carrier frequency of the variant allele to be 2% in the Finnish population. No homozygotes for the variant allele were found among the healthy family members of the affected fetuses or in the control samples; however, heterozygotes were found in families affected with LAAHD. Ongoing sequencing efforts of the LCCS and LAAHD alleles will reveal whether these two syndromes are truly allelic. Functional studies concerning the pathogenity of the 3UTR SNP are being carried out.

Prevalent filaggrin mutations are a major genetic factor for atopy, atopic dermatitis and eczema-associated asthma. *W.H.I. McLean[1], A. Sandilands[1], A. Terron-Kwiatkowski[1], S.P. Lee[2], Y. Zhao[1], H. Liao[1], G. O'Regan[3], A.D. Irvine[3], C.N.A. Palmer[2], F.J.D. Smith[1]* 1) Human Genetics Unit, University of Dundee, Dundee, Scotland, UK; 2) Biomedical Research Centre, University of Dundee, Scotland, UK; 3) Our Lady's Children's Hospital, Dublin, Ireland.

The FLG gene on chromosome 1q21 encodes 10-12 repeats of the 37 kDa filaggrin peptide essential for skin barrier formation. We recently reported the first FLG mutations, R501X and 2282del4, leading to complete loss of filaggrin expression. These mutations, carried by up to 10% of European-origin populations, cause mild or severe ichthyosis vulgaris (IV) and importantly, are a genetic predisposing factor for AD and related atopic phenotypes. Here we ascertained a cohort of 150 Irish children with AD and identified further loss-of-function mutations, 3702delG in filaggrin repeat 3, R2447X in repeat 7 and S3247X in repeat 9, all of which are carried by <1% of the population. These variants allow synthesis of 3-9 repeats but biochemical analysis showed that these truncated profilaggrin molecules cannot be processed into mature filaggrin and so act as null-alleles. Consistent with this, homozygosity for these mutations, or compound heterozygosity with R501X or 2282del4, causes severe IV accompanied by AD. In this cohort with moderate-severe AD, ~48%; carried one or more of these 5 FLG variants. Comparing our cohort to the Irish population gave a Chi-square p value of $<10^{-50}$ and Fishers exact test odds ratio of 7.13 with 95%CI 4.9-10.6. We have also replicated the association of FLG null-alleles with AD and other atopic phenotypes, including AD-associated asthma, in a total of 10 independent studies within 6 different European populations. In addition to association studies, we used genetic linkage analysis, transmission disequilibrium testing and a longitudinal association study, all of which gave highly statistically significant correlations. These data conclusively demonstrate that in European populations at least, FLG is a major predisposing gene for atopy.

Is alpha-1-antitrypsin a modifier gene for Cystic Fibrosis? *R. Mirfakhraie[1,2], M. Gorgipoor[3], F. Mirzajani[1]* 1) Medical Genetics, NIGEB, Tehran, tehran, Iran; 2) Science and Research Campus, Islamic Azad University of Tehran; 3) Khatam University.

Cystic Fibrosis (CF) transmembrane conductance regulator (CFTR)genotype does not explain the heterogeneity observed in CF pulmonary disease severity. Modifier genes are implicated for this heterogeneity. Alpha-1-antitrypsin (Alpha-1-AT) is one of the few antiprotease capable of inactivating neutrophil elastase. We investigated whether Alpha-1- AT alleles (Z, S deficient alleles and the 3 G1237 A mutation) are associated with increased disease severity and Alpha-1-AT acute phase response during pulmonary exacerbations. 70 CF patients were genotyped for the S and Z, mutations and G1237 A polymorphism using PCR-RFLP Method. 200 control individuals were also screened for GA polymorphsm in order to find the frequency of this polymorphism in Iranian population. Our result suggest no correlation between allelic alterations in Alpha-1- AT gene and CF.

Development of a densely genotyped Population Reference Sample (POPRES): a resource for population, disease, and pharmacological genetics research. *M.R. Nelson[1], M. Klotsman[1], A.M. McNeill[2], Y. Maruyama[1], C.E. Bowman[1], D. Morris[2], M.E. Ehm[1], E.H. Lai[1]* 1) Genetics Research, GlaxoSmithKline, Research Triangle Park, NC; 2) Medicine Development Centers, GlaxoSmithKline, Research Triangle Park, NC.

Recent technologic and scientific advances, stemming in large part from the Human Genome and HapMap projects, have made large-scale, genome-wide investigations feasible and cost-effective. These advances have the potential to dramatically impact drug discovery and development by identifying genetic factors that contribute to variation in disease risk as well as drug pharmacokinetics, treatment efficacy, and adverse drug reactions. In spite of the technological advancements, successful application in biomedical research would be limited without access to suitable sample collections. To facilitate exploratory genetic research, we are developing an extensive DNA resource collected from a large number of participants, sampled throughout the world. This nascent sample resource is being initially genotyped using a commercially available genome-wide 500,000 SNP panel. This project currently includes over 2500 subjects of Mexican, Chinese, Japanese, European, and Indian Asian origin. Approximately 2,500 additional samples that are broadly representative of the global population will be ascertained and genotyped. As the genotypic data from these samples are assembled, they will be made publicly available for use by the wider genetics community. To further develop such a public resource, we welcome the opportunity to work with academic, non-profit, and industry partners to populate this resource with representative and genetically diverse collections, while maintaining the highest ethical standards. Here we present the goals and design of this collection, a summary of the samples and data currently available, as well as initial exemplary applications in the study of the genetic basis of adverse drug reactions.

Generation of *Trim37* knock-out mice. *R.H. Hämäläinen, A.L. Träskelin, A.E. Lehesjoki* Folkhälsan Institute of Genetics and Neuroscience Center, University of Helsinki, Helsinki, Finland.

TRIM37 is a peroxisomal ubiquitin E3 ligase that belongs to the TRIM-family of tripartite motif proteins. In humans, mutations in the *TRIM37* gene underlie a developmental disorder, mulibrey nanism. Mulibrey nanism patients manifest with prenatal onset growth retardation without later catch-up growth, typical craniofacial features, progressive cardiopathy, hepatomegaly, failure of sexual maturation, an increased risk for developing tumors and type 2 diabetes. The mouse *Trim37* gene is highly homologous to the human *TRIM37*, with 88 % identity between the cDNA sequences and 92 % identity on protein level, suggesting that mouse would be a suitable organism to model the human disease. Further, the *Trim37*$^{-/-}$ mice may provide tools to study growth and development in general as well as serve as a model for type 2 diabetes and metabolic syndrome. Towards understanding the disease mechanisms underlying mulibrey nanism, we are currently generating *Trim37*$^{-/-}$ mice. A search for *Trim37*-deficient mouse strains or ES cells in the IMSR (International Mouse Strain resource) resulted in identification of a BayGenomics genetrap ES cell line (RRO307) that was ordered from UC Davis, California. In these ES cells, we found that the -geo insertion vector is localized in intron 2 of *Trim37* and we developed a PCR based analysis for genotyping the mice. The ES cells were microinjected into C57Bl wild-type blastocysts and altogether 10 chimeric male mice were born. Thus far three of the chimeric mice have shown germ line transmission and produced heterozygous offspring, which we are currently breeding. In homozygous offspring we first aim to study the developmental effects of nonfunctional Trim37 in embryos. If viable offspring is produced, our primary aim is to characterize the mice to evaluate their potential to mimic the human disease.

Mapping trait loci using inferred Ancestral Recombination Graphs. *M.J. Minichiello, R. Durbin* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Large-scale association studies are being undertaken with the hope of uncovering the genetic determinants of complex disease. We will describe a computationally efficient method for inferring genealogies from population genotype data, and will show how these can be used to fine map disease loci and dissect association signals.

These genealogies take the form of the Ancestral Recombination Graph (ARG). The ARG defines a genealogical tree for each locus, and as one moves along the chromosome, the topologies of consecutive trees shift according to the impact of historical recombination events. There are two stages to our analysis. First, we infer plausible ARGs using a heuristic algorithm, which can handle unphased and missing data, and is fast enough to be applied to large-scale studies involving thousands of individuals. Second, we test the genealogical tree at each locus for a clustering of the disease cases beneath a branch, thus determining whether a causative mutation occurred on that branch. Since the true ARG is unknown, we average this analysis over an ensemble of inferred ARGs.

We have characterised the performance of our method across a wide range of simulated disease models. Compared to single marker and haplotype based tests, our method gives increased power and accuracy in positioning untyped causative loci. It can also be used to estimate the frequencies of untyped causative alleles and the haplotypic background on which causative mutations occurred. We have applied our method to Ueda et al.'s association study of CTLA4 and Graves' disease, showing how it can be used to dissect the association signal, giving interesting results suggesting allelic heterogeneity and epistasis.

Similar approaches analysing an ensemble of ARGs inferred using our method may be applicable to many other problems of inference from population genotype data, such as detecting population substructure and selection.

New evidence on the molecular evolution of the ADH gene cluster in primates. *H. OOTA[1,3], R. KAUL[2], K. HUI[1], W.C. SPEED[1], A.J. PAKSTIS[1], J.R. KIDD[1], M. OLSON[2], K.K. KIDD[1]* 1) Department of Genetics, Yale University School of Medicine, 333 Cedar St., New Haven, CT; 2) Department of Medicine, University of Washington Genome Center, 225 Fluke Hall, Seattle, WA; 3) Department of Integrated Biosciences, University of Tokyo, Chiba 277-8562, Japan.

We are sequencing the alcohol dehydrogenase (ADH) gene cluster (370kb in humans) in 10 primates (3 great apes, 3 old world monkeys (OWMs), 2 new world monkeys (NWMs), 2 prosimians) and one bat to explore the evolutionary mechanisms for the duplicated genes in the primate lineage. A preliminary comparison shows that both the OWMs and prosimians have 7 ADH genes including 3 Class I-like genes. Mice and rats have only one Class I gene. Thus, the Class I duplication event(s) seem to have occurred after primates diverged from rodents but before the primate radiation. Other mammals (sheep, horse, rabbit) studied have two Class I genes making the timing of the duplication event(s) unclear since their homologies to the 3 primate genes are unclear. The three Class I genes in OWMs and great apes show very high nucleotide similarity both in exons (90%) and introns (70%) implying recent duplication events and/or possible gene conversion(s). Our analyses show no indication of any gene conversions, suggesting the Class I genes have evolved independently in higher primates.

The 7 ADH genes, located on human chromosome 4 in tandem, are classified into five classes: the Class I (*ADH1A*, *ADH1B*, *ADH1C*) and the Class II (*ADH4*) genes are expressed primarily in liver, the Class IV (*ADH7*) gene is in stomach, and the Class III (*ADH5*) gene is in all tissues. The expression pattern of the Class V (*ADH6*) gene remains unclear. Mice have six *ADH* genes located on mouse chromosome 3 in the same order as humans. In addition to the Class I triplication in primates, differences between primates and rodents include two genes and one pseudogene of Class V in mice. We shall present analyses of our new sequence data for the whole *ADH* cluster on various primate species as well as comparisons with published rodent (mouse, rat) sequence. Supported in part by US NIH AA09379.

Sleep Disturbance in Ehlers-Danlos Syndromes: Related to Chronic Pain or an Independent Entity? *K.W. Mandel[1], B. Griswold[1], C.A. Francomano[1,2], N.B. McDonnell[1]* 1) National Institute on Aging, Baltimore, MD; 2) Harvey Inst Hum Genetics, GBMC, Baltimore, MD.

Patients with Ehlers-Danlos Syndomes (EDS) often complain of disturbed and non-refreshing sleep. There is a paucity of data available on the etiology of this complaint in EDS. Since many patients also suffer from chronic musculoskeletal pain, we hypothesized that the reported sleep abnormalities are related to the chronic pain syndrome. Multiple sleep and pain assessment tools were administered to sixty five consecutive patients with a diagnosis of EDS enrolled in the National Institutes of Aging protocol 2003-086 on the natural history of hereditary disorders of connective tissue. Data was collected utilizing the Epsworth Sleepiness Scale (ESS), Pittsburgh Sleep Inventory (PSI) as well as a sleep questionnaire designed to elucidate the specific problem areas such as difficulty falling or remaining asleep, snoring, early morning awakening and non-refreshing sleep. Pain was assessed through the Brief Pain Inventory (BPI) and review of systems data focusing on musculoskeletal and generalized pain. Results indicate that 33/65 (50%) of patients had an ESS scale > 9, and 49/65 (75%) a PSI Quotient > 5, suggesting the presence of a sleep disorder. Almost all patients (62/65; 95%) had pain in at least one location, and 29/65 (44 %) reported chronic generalized pain. Of the patients with ESS > 9, a complaint of generalized pain was present in 15/33 (45 %). Of the 49 patients with PSIQ > 5, generalized pain was present in 24 (48 %). The discordance of sleep disturbance with chronic generalized pain in EDS suggests that the pathogenesis of sleep complaints in this disorder may be unrelated to the pain syndrome, at least in part. Further investigation regarding the etiology of this phenomenon in EDS, using formal sleep studies, is warranted.

Investigation of Leu/Lys tRNA gene mutation in Iranian Ataxia Telangiectasia patients. *S. Kasraie[1,2], S. EtemadAhari[1,2], M. Houshmand[2], M. Moin[3], M. Bahar[1]* 1) Azad uiversity of Science and research,Tehran,Iran; 2) Molecular Medical Genetic,National Institute for Genetic Engineering and Biotechnology (NIGEB),Tehran,Iran; 3) Immunology, Asthma & Allergy Research Institute, Tehran, Iran.

Ataxia-Telangiectasia (AT) is a rare human neurodegenerative autosomal recessive multisystem disease that is characterized by a wide range of features including, progressive cerebellar ataxia with onset during infancy, occulocutaneous telangiectasia, susceptibility to neoplasia, occulomotor disturbances, variable immunodeficiency with susceptibility to sinopulmonary infections, impaired organ maturation ,x-ray hypersensitivity ,chromosomal instability and growth and developmental abnormalities. About 20% of those with A-T develop cancer, most frequently acute lymphocytic leukemia or lymphoma. AT is the result of mutations in the AT-mutated (ATM) gene. ATM protein is required for radiation-induced apoptosis and acts before mitochondrial collapse. The tRNA gene mutations are the one of the hot spots cuase mitochondrial disorders, AT can be due to mutation in mitochondrial genes. We performed mutations screening of leu/lys tRNA genes and also ATPase6 genes in 20 patients who referred as Ataxia Telangiectasia. Mitochondrial leu/lys tRNA genes and ATPase 6 genes were studied by PCR method and automated DNA sequence to evaluate any possible mtDNA damage. We have found a mutation in patients that could be related to cause a disease. Now, were confirming the sequence results and finding mutations. Keywords: Mitochondrial tRNA gene, ATPase 6,Point mutation, Ataxia Telangiectasia.

Genetic association between interferon regulatory factor 5 (IRF5) and systemic lupus erythematosus in three ethnic groups. *J.A. Kelly[1], K.M. Kaufman[1,2], A.J. Adler[1], B.J. Herring[1], S.G. Frank[1], J. Kilpatrick[1], J.T. Merrill[1], J.A. James[1,3], G.R. Bruner[1], J.B. Harley[1,2,3]* 1) OMRF, OKC, OK; 2) US Dept of Veterans Affairs Medical Center, OKC, OK; 3) Oklahoma Univ Health Sci Ctr, OKC, OK.

Systemic lupus erythematosus (SLE) is a systemic autoimmune disorder with complex genetics. Two recent reports have demonstrated genetic association with the interferon regulatory factor 5 (IRF5) gene and SLE. This study evaluates IRF5 in our collection of European-American (EA), Hispanic (HI), and African-American (AA) SLE patients. A total of 3027 samples (1420 cases and 1607 controls) were genotyped at polymorphisms within the IRF5 gene. Population-based case-control association designs were employed. We observed significant association in our EA SLE samples with rs729302 (AIC: 8.82, ^{2}=10.83, p=0.001, OR=1.63 (95% CI: 1.22-2.19)), rs2004640 (AIC: 21.68, ^{2}=24.6, p=7x10^{-7}, OR=2.12 (95% CI: 1.57-2.86)), rs752637 (AIC: 13.83, ^{2}=15.98, p=0.00006, OR=1.81 (95% CI: 1.35-2.42)) and rs3807306 (AIC: 16.77, ^{2}=19.70, p=0.000009, OR=2.01 (95% CI: 1.47-2.75)), in our HI SLE samples with rs2004640 (AIC: 3.898, ^{2}=5.94, p=0.01, OR=1.89 (95% CI: 1.13-3.16)), rs752637 (AIC: 4.62, ^{2}=6.69, p=0.009, OR=1.95 (95% CI: 1.17-3.26)) and rs3807306 (AIC: 16.82, ^{2}=17.74, p=0.00003, OR=3.50 (95% CI: 1.47-2.75)) and in our AA SLE samples with rs729302 (AIC: 4.65, ^{2}=6.06, p=0.01, OR=1.72 (95% CI: 1.11-2.64)) and rs3807306 (AIC: 9.66, ^{2}=11.28, p=0.0008, OR=1.99 (95% CI: 1.33-3.0)), thereby confirming previously observed associations with IRF5 and EA and HI SLE and establishing association in AA SLE and with rs3807306. The greatest significance was observed in all three ethnic groups when using a recessive model. In addition, we confirm the previously identified rs729302-rs2004640-rs752637 haplotype, which was observed in all three ethnic groups (EA: 61% cases, 49% controls, ^{2}=22.91, p=0.00002; HI: 58% cases, 43% controls, ^{2}=12.81, p=0.0003; AA: 45% cases, 38% controls, ^{2}=4.64, p=0.03). In summary, we confirm association with IRF5 and SLE in European-Americans and Hispanics, establish association in African-Americans and confirm association with a three-marker haplotype that is enriched in the SLE cases.

Imprinted genes related with MECP2 in 7q21 are not major causative genes for autism. *N. Nakashima, T. Yamagata, M. Imai, M. Mori, M.Y. Momoi* Dept Pediatrics, Jichi Medical Sch, Shimotsuke, Tochigi, Japan.

MECP2 is a gene for Rett syndrome (RTT) that shows autistic phenotype. Therefore, downstream genes of MECP2 are candidate genes for autism. DLX5 is regulated by MECP2 and is maternally expressed. In MECP2 knockout mice, expression level of DLX5 in the brain is twice of wild type mice. And both of maternal and paternal alleles were expressed in lymphoblastoid cells from RTT patients. It is interesting to know whether the expression and imprinting status of DLX5 is altered in autistic patients to detect the presence of common mechanism between autism and RTT. DLX5 is located in the imprinted region of 7q21, and two MECP2 binding sites are reported to exist in this region, one is near DLX5 and DLX6 and the other is near PEG1. Therefore, we analyzed the expression level of the genes near MECP2 binding sites in lymphoblastoid cells to detect the alternation of imprinting status. In addition, we analyzed each gene for mutation among autistic patients using their DNA from lymphoblastoid cells for possible link for the cause of autism as the downstream molecular process of MECP2.Patients diagnosed as pervasive developmental disorder or autism according to the criteria of DSM-IV were enrolled in this study after the informed consents by their parents. The genes studied included DLX5, DLX6 and PEG10. Expression level of each gene in five autistic patients was compared with five control individuals, respectively. For mutation analysis, up to one hundred autistic patients were enrolled. All exons and promoter regions of these genes were amplified by PCR and the mutation was screened by DHPLC, and finally confirmed by direct sequencing. The expression level of each gene in lymphoblastoid cells were not different between patients and controls. No causative mutation was detected in all genes analyzed. It is considered that autism and RTT did not share common pathway after MECP2. Addition to the previous reports that no causative mutation of DLX5 and DLX6 was detected on autistic patients, both genes can be excluded from the candidate gene for autism. It is required to analyze another genes located in this region further to clarify the contribution to autism.

Whole Genome Association Scan for Alzheimer Disease Using Multiple SNP Panels. *L. Li[1], P.L. StJean[1], M.R. Barnes[1], S.L. Chissoe[1], S. Subramanian[1], N.P. Goodgame[1], R.A. Gibson[1], D.D. Kelly[1], K.S. King[1], E.H. Lai[1], J. Marchini[2], K.L. Nangle[1], M.R. Nelson[1], M. Owen[3], J.C. Richardson[1], A.D. Roses[1], P. Skelding[1], S. Stinnett[1], J. Williams[3], M.G. Ehm[1], GenADA Investigators (Investigator sites across Canada)* 1) GlaxoSmithKline; 2) University of Oxford, Oxford, UK; 3) Cardiff University, Cardiff, UK.

Alzheimer disease (AD) is a progressive neurological condition characterized by a gradual but persistent decline in memory and other cognitive, social and ultimately physical functions. Identifying variants associated with AD provides important information during for drug development. Variants that are associated with disease susceptibility and progression can be used to: validate target genes, identify biomarkers, and optimize disease indications for safe therapeutics. A genome-wide association study was carried out on 2584 Caucasian subjects using 500K common SNPs, 20K cSNPs, and 3000 cSNPs in druggable genes. This comprehensive scan tags greater than 70% of common variants and additional functional variants. This sample includes 850 Canadian and 450 British case-control pairs. To identify single variants associated with AD, we performed single point association analysis in the combined sample by controlling for the group effect. For SNPs showing the strongest signals, we examined the genetic effects in each subset under a variety of disease models. Analyses were also conducted by conditioning on ApoE carrier status. To detect SNPs exhibiting epistatic effects, a comprehensive interaction analysis was carried out for all pairs of SNPs using a full logistic model, followed by a detailed diagnosis of the interaction effects observed for promising pairs. We summarize the properties and information capture of these genome scans. Graphical summaries including the genomic context of these regions and interaction results are used to illustrate results. We will report the challenges and opportunities faced in conducting such comprehensive scans and implications for future research. Findings from this study provide evidence that comprehensive genome scans can provide important genetic findings.

Pilot Study of Patients Affected With Leber Congenital Amaurosis (LCA) Clinically Selected With Regard to the Previously Established Genotype-Phenotype Correlations. *S. Hanein[1], I. Perrault[1], N. Delphin[1], S. Gerber[1], J.L. Dufier[2], A. Munnich[1], J.M. Rozet[1], J. Kaplan[1]* 1) INSERM U781, Hopital des Enfants Malades, Paris, Cedex 15, France; 2) Ophthalmology, Hopital des Enfants Malades, Paris, Cedex 15, France.

The purpose of this study was to evaluate the improvement of the genotyping of new patients affected with LCA after pre-selection of genes to screen in priority with regard to the genotype-phenotype correlations previously established for the nine hitherto identified genes. This pilot study focused on the two major LCA genes, GUCY2D and CRB1, which account for about 1/3 of all patients. Thirty-nine unrelated patients were selected on their clinical history and ophthalmologic findings: i) 18/39 suggested the involvement of GUCY2D, the major LCA gene responsible for the most severe form (cone-rod type) of the disease and ii) 21/39 suggested the implication of CRB1, the major gene responsible for less severe forms (rod-cone type). In each group of patients, the selected gene only was screened for mutations using DHPLC and direct sequencing. Ten out of the 18 patients compatible with the involvement of GUCY2D were found to carry mutations in this gene i.e. 55.5% vs 22.1% in a non-clinically pre-selected population of LCA patients. Along the same lines, 11/21 patients of the CRB1 subgroup harboured mutations in this gene i.e. 52.4% vs 10.1% in a non-clinically pre-selected population of patients. In conclusion, this study emphasizes the absolute necessity to obtain full and detailed clinical findings for all patients affected with LCA. These data must include: i) the natural history of the disease since birth, ii) the early light behaviour of the child, iii) the exact measurement of the refraction, iv) a precise description of the fundus aspect including the existence or the absence of early macular rearrangements, and finally v) the visual acuity and the visual field recordings when possible.

Capillary array SSCP analysis of pooled DNA for association testings. *K. Hayashi, K. Masumoto, Y. Okazaki, A. Yoshinaga, K. Higasa, Y. Kukita, T. Tahira* Division of Genome Analysis, Res Ctr Genetic Info, Med Inst Bioreg, Kyushu Univ, Fukuoka, Japan.

Allele frequency estimation of SNPs using pooled DNA is a practical primary screening strategy in the association study, where hundreds to thousands of samples must be examined. However, the effectiveness of this approach depends on how accurately the frequency can be estimated. We evaluated the pooled DNA analysis using an SSCP-based method, PLACE-SSCP, and found that the estimation by this method is reproducible and accurate. In PLACE-SSCP, the PCR products are post-labeled with fluorescent dyes, subjected to automated capillary electrophoresis under nondenaturing (SSCP) conditions, and separated allele peaks are identified and quantified. To facilitate the analysis, we developed a new software, called *QSNPlite*, for a systematic and quantitative analysis of the SSCP data, and used in the evaluation. This software is designed, so that the allele frequencies are calculated from the peak height ratios of alleles in the pooled samples after correcting the different representation of each allele using the data of heterozygotes included in each PCR plate. Partially overlapped peaks can be deconvoluted and quantified using this software. We compared the results of this SSCP-based frequency estimation with the true frequencies that were obtained by counting the alleles after genotyping all individuals in the pool. The estimates and the counts agreed closely (R = 0.997), and the averaged absolute values of the differences between the estimates and true values (i.e., the mean absolute error) were 1.4%. Thus, we conclude that the present method is far more accurate than other methods, such as mass spectrometry or electrophoresis after primer extension. We applied this system in the association studies of systemic lupus erythematosus and breast cancer, and found that the PLACE-SSCP analysis of pooled DNA is useful, in the search for the disease responsible genes by the candidate gene approach.

Analysis of eQTL gene expression data for the identification of complex genetic interactions. *K.A. Kim[1], J. Huang[1], T.E. Scheetz[1], R. Swiderski[1], A.R. Philp[1], E.M. Stone[1,2], V.C. Sheffield[1,2]* 1) Univ of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute.

Identification of genes involved in complex and genetically heterogeneous disorders presents challenges and requires the use of diverse and integrated approaches. Recent advances in microarray technology have made it possible to perform experiments that examine the expression of thousands of genes in related individuals and to use these data to identify regions of the genome that regulate the expression of multiple genes. Such studies are referred to as expression quantitative trait locus (eQTL) mapping. In a novel application of eQTL data we have performed pair wise correlation of gene expression to identify sets of genes that appear to be co-regulated. The use of eQTL data has the potential to aid in the identification of interacting genetic loci involved in complex genetic disorders. However, it is essential that proper statistical methods be utilized for such applications of eQTL data. In a typical genome scan, linkage is evaluated at each marker locus or in between loci, assuming one eQTL (or QTL). The assumption of one eQTL is potentially inaccurate in cases of complex inheritance resulting from the presence of interacting genes. To enhance the statistical modeling of complex inheritance, in particular to better detect interactions, we propose two statistical models: Tukeys 1-df model for interaction (TM1) and a modified version of Tukeys model (TM2). The two models add only one additional parameter to estimate and test for interaction between two loci. TM2 has a novel interpretation of the interaction term when compared to TM1. We applied the two models to eQTL data to detect interaction effects of genetic loci on the expression of genes causing Bardet Biedl Syndrome (BBS; obesity, retinopathy, polydactyly, mental retardations and urogenital anomalies), as well as eye disease genes. The study involves profiles of 31,000 probes represented on an Affymetrix expression microarray from 120 F_2 rat eyes including 399 genetic markers. We detected a statistically significant interaction effect under TM2 for the expression of *Opn1sw*, a gene that encodes for blue cone opsin.

Identification of a new locus of an X-linked dominant male-lethal isolated microphthalmia/anophthalmia/coloboma (MAC). *N. Meola[1], D. De Brasi[2], M. Morleo[1], V. Ginocchio[2], T. Caramico[1], P. D'Adamo[1], O. Zuffardi[3], G. Sebastio[2], S. Banfi[1]* 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Department of Pediatrics, Federico II University, Naples, Italy; 3) Department of Medical Genetics, University of Pavia, Italy.

Microphthalmia, anophthalmia and coloboma (MAC) are major structural eye malformations. Anophthalmia is characterized by the complete absence of the eye, microphthalmia is characterized by a small eye while the coloboma results from a failure in the closure of the optic fissure. These disorders have a combined birth incidence of approximately 1 in 5000. Here we report the analysis of an Italian family characterized by the presence of isolated MAC with a highly variable expression. The five affected females show a variety of eye malformations either unilateral or bilateral, ranging from microcornea to complete anophthalmia . Moreover, no affected males are present in the family while there is a high frequency of spontaneous abortions some of which were documented to affect male pregnancies. These observations strongly suggested that the MAC phenotype in this family is transmitted with an X-linked dominant male-lethal pattern. Detailed cytogenetic analysis, including also high-resolution comparative genomic hybridization (CGH), failed to reveal the presence of any chromosomal rearrangement. Linkage analysis carried out with a panel of X-chromosome polymorphic markers using a model of X-linked dominant transmission allowed us to exclude two already known loci for X-linked dominant syndromic microphthalmia/anophthalmia, namely microphtalmia with linear skin defects (MLS) and oculocardiofaciodental syndrome (OFCD) and suggested a linkage of the disease to a region of approximately 8 cM on the short arm of the X-chromosome (Xp22.1). We are currently carrying out systematic mutation analysis on the genes present in the critical region and determining the X-inactivation status of the affected individuals to verify the presence of a skewed X-inactivation pattern. The identification of this novel MAC gene is expected to shed further light on the pathogenesis of this complex group of eye developmental disorders.

Pharmacokinetics and tolerability of miglustat in juvenile GM2 gangliosidosis. *G. Maegawa[1], B. Banwell[2], J. Hayes[3], S. Blaser[4], C. Hawkins[5], P. van Giersbergen[6], J. Clarke[1]* 1) Div. of Clinical and Metabolic Genetics Hospital for Sick Children; 2) Div. of Neurology Hospital for Sick Children; 3) Div of Anaesthesia Hospital for Sick Children; 4) Dept. fo Diagnostic Imaging Hospital for Sick Children; 5) Dept. of Paediatric Laboratory Medicine Hospital for Sick Children; 6) Dept. of Clinical Pharmacology Actelion Pharmaceuticals Ltd.

GM2 gangliosidosis (GM2) is an inherited neurodegenerative disorder caused by lysosomal -hexosaminidase A deficiency. Substrate reduction therapy is currently one of the therapeutic options for GM2. Objective: To establish the pharmacokinetics (PK) of miglustat (Zavesca) given as single and multiple doses in juvenile GM2, and evaluate its safety and tolerability in a 12-month follow-up period. Methods: Five patients (mean age 14.6$\pm$4.5 yrs) receiving oral miglustat at the dose of 100-200 mg t.i.d. based on body surface area. Patients underwent two PK assessments at day 1 and month 3. Blood samples were drawn immediately before and at intervals within 24 hours after drug administration. Results: The mean plasma Cmax after multiple dose regimen was statistically higher than the one performed after the single dose regimen. The accumulation index was 1.80. No differences were found between t_{max}, Cmax, and $t_{1/2}$ for single and multiple dose administration. The major side effects observed among the 5 studied patients were diarrhea, vomiting and weight loss. Diarrhea responded well to diet modification, lactaze and loperamide. Four patients had weight loss, and only one recovered previous weight. Two patients who showed frequent and severe diarrhea showed the highest values mean Cmax in multiple dose profile. Laboratory tests showed mild hypernatremia, mild elevation of AST, ALT and low WBC with low neutrophils. One patient developed peripheral neuropathy after the 12 month-studied period thought possibly due to disease progression. Conclusion: The PK of miglustat was similar after single- and multiple-dose administration. The exposure to and plasma concentration of miglustat appeared to correlate with the severity of adverse events. Basic biochemical and haematology test should be done routinely for patients on miglustat.

Clinical and genetic correlations in subjects with the *puratrophin-1* (-16C>T) genetic change. *K. Ishikawa, T. Amino, N. Sato, T. Ishiguro, T. Tsunemi, S. Toru, H. Mizusawa* Dept Neurology, Tokyo Medical & Dental Univ, Tokyo, Japan.

Autosomal dominant cerebellar ataxia (ADCA) is a group of heterogeneous neurodegenerative conditions showing late onset progressive cerebellar ataxia as a cardinal neurologic manifestation. We have identified that a single-nucleotide (C-to-T) change in the 5-untranslated region (-16C>T) in the gene, *puratrophin-1*, is strongly associated with the ADCA linked to chromosome 16q22.1 region (Ishikawa K and Toru S et al. Am J Hum Genet 2005) (OMIM #117210). This chromosomal region is also known as the spinocerebellar ataxia type 4 (SCA4) locus (OMIM %600223), although this genetic change has not been observed in SCA4 subjects. The gene product puratrophin-1, a novel protein with spectrin repeat and Rho GEF domains, is predicted to have a role in maintaining the cytoskeletal structure particularly related to the Golgi apparatus. Although the -16C>T genetic change completely segregated with the 16q22.1-linked ADCA in more than 100 families, one affected individual without this genetic change has recently been reported. This finding may suggest that the *puratrophin-1* (-16C>T) genetic change is not sufficient for the diagnosis of 16q22.1-linked ADCA. We examined correlations between the clinical finding on 60 ADCA families linked to 16q22.1 and the presence of *puratrophin-1* genetic change. Among our cohort of the 60 families with the *puratrophin-1* (-16C>T) genetic change, we found that only one family showed questionable correlation. In this family, two individuals with the -16C>T genetic change showed obvious ataxia, whereas one individual (P87-II-03) without the genetic change also showed down-beat nystagmus, suggestive of presence of cerebellar dysfunction. Haplotype analysis demonstrated that this individual P87-II-03 had different haplotype for the region where all 16q22.1-linked ADCA patients show a founder haplotype. The present observation indicates that both detailed clinical investigation and haplotype analysis are important for the diagnosis of 16q22.1-linked ADCA.

Novel autosomal dominant syndrome in a three-generation family with broad first digits, oral anomalies, and speech delay. *V. Mardo[1], E. Lisi[1], D. Riegert-Johnson[2], S.A. Boyadjiev[1,3]* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Division of Gastroenterology, Mayo Clinic, Rochester, MN; 3) Department of Pediatrics, MIND Institute, University of California-Davis School of Medicine, Davis, CA.

A characteristic combination of digital, facial, and oral anomalies was observed in a three-generation Caucasian family, with a segregation pattern suggestive of an autosomal dominant inheritance. The facial dysmorphisms included prominent forehead, almond shaped eyes with upslanting palpebral fissures and medial epicanthal folds, broad nasal bridge, short philtrum with thin upper lip, and posteriorly rotated ears. Observed oral anomalies included high arched palate and central groove of the lower lip. All affected family members had broad thumbs and great toes, speech delay, and mild mental retardation. Moreover, macrocephaly, somatic overgrowth, congenital heart defects (VSD with coarctation of the aorta), and cryptorchidism were also observed among various members of this family. Microsatellite analysis excluded linkage to CREBBP and EP300, the genes associated with Rubinstein-Taybi syndrome. Additionally, Simpson-Golabi-Behmel syndrome was considered, but X-linked inheritance was excluded by the presence of male-to-male transmissions and two affected females. Cytogenetic studies, including karyotype, subtelomere screen, and FISH for 22q11 deletion syndrome, were normal. Taken together, we believe that this condition represents a novel genetic syndrome. Further molecular analyses are currently in progress to identify the causative gene.

Sample recollection using an improved cytobrush methodology. *M.M. Jenkins[1], K.L. Rose[2], A. Woomert[3], P.A. Romitti[2]* 1) Battelle contractor to CDC, Columbus, OH; 2) University of Iowa, Iowa City; 3) Battelle Memorial Institute, Durham, NC.

A request for buccal cell samples from birth parents and index children was integrated into the National Birth Defects Prevention Study (NBDPS) in 1998. Samples were collected using cytobrushes that were stored and transported in air-tight tubes (wet brushes). These brushes did not dry during transport, and initial extractions showed considerable variation in DNA yield. In 2003, NBDPS sites modified sample collection to include cytobrushes that were stored and transported in open-to-air containers (dry brushes) allowing them to dry during transport. Use of dry brushes produced higher and more consistent DNA yield than wet brushes. To improve the quality of samples in the NBDPS tissue bank, two sites, Georgia (GA) and Iowa (IA), evaluated the feasibility of recollecting dry brush samples from families who initially provided wet brush samples. Eligible families were those of case children (n=68) diagnosed with spina bifida (SB) or longitudinal limb defects (LD) and those of unaffected control children (n=66) born between 1997 and 2003. Additional eligibility criteria were the index child was living and the family previously provided wet brush samples. Contact has been attempted with 49 IA case (SB=36; LD=13) and 47 IA control families and with 19 GA case (SB=11; LD=8) and 19 GA controls. Of the 96 IA families, 72 (75%) provided samples, 17 (18%) refused, and 7 (7%) were not located. Of the 38 GA families, 18 (47%) provided samples, 3 (8%) refused, 5 (13%) are pending, and 12 (32%) are being traced for a current address. Mean DNA yield for 11 GA families using wet brushes and dry brushes were 0.7g (0-2.6g) and 1.5g (0.1-4.3g), respectively. Among recollected samples, 99% had DNA yields >0.1g and successful microsatellite sequence amplification. Preliminary results showed that half or more families are willing to recollect buccal samples, providing support for extending recollection to additional case groups and NBDPS sites. Other genetic epidemiology studies might benefit from modifications to buccal cell collection methods the NBDPS has implemented to optimize DNA yield.

A new Bayesian method to detect complex multifactorial interactions in complex diseases using the variance-component-threshold model. *A. Narita, A. Tajima, I. Inoue* Dept. Molecular Life Science, Tokai University School of Medicine, Isehara, Kanagawa, Japan.

It is now well known that gene-gene and/or gene-environment interactions play an important role in etiologies of most common human diseases. The objective of this study is to introduce a new Bayesian method to investigate multifactorial interactions responsible for complex diseases in the variance-component-threshold model. In the variance component model, each genotype is regarded as a random effect and thus, instead of dealing with all the effects as independent parameters, we only have to estimate the mean and the variance of the most likely distribution of the genotypic effects. This reduces substantially the degrees of freedom that are required to investigate a high-dimensional interaction. In combination with the threshold model, where it is assumed that an apparently discrete trait is actually controlled by continuously-distributed liability, our method can be applied to binary, or even polychotomous, complex human diseases, as well as quantitative traits. Additionally, since the Markov chain Monte Carlo algorithm is adopted in our method, the most likely model is heuristically searched out of all the possible combinations of varying numbers of SNPs and thus its computational time and loads can be considerably reduced. The method also calculates weighting coefficients for respective loci that indicate the degrees of individual contribution of each locus. The genotypic relationship matrices that consist of the coefficients can also provide the estimated degrees of correlation between multilocus genotypes. In the present study, we demonstrate the effectiveness of the proposed method using both simulated populations and a real dataset. The versatility of the method will enable a later extension to analyze a variety of types of datasets, using not only genetic but also epidemiological and/or clinical information, for the diagnosis of diseases and the prediction of onsets.

Genetics of gene expression for Amyotrophic Lateral Sclerosis (ALS). *R.A. Ophoff[1,2,3,4], C.-Y. Lee[1], C.G.J. Saris[3], P. van Vught[3], S. Horvath[1], L.H. van den Berg[3]* 1) Human Genetics, Univ California Los Angeles, Los Angeles, CA; 2) UCLA Cntr for Neurobehavioral Genetics, Los Angeles, CA; 3) Rudolf Magnus Institute, University Medical Center, Utrecht, The Netherlands; 4) Dept of Medical Genetics, University Medical Genetics, Utrecht, The Netherlands.

ALS is the most common form of motor neuron disease in humans, characterized by progressive degeneration of motor neurons in brain and spinal cord leading to muscle weakness and death within 3 years for 50% of patients. The predominant presentation of ALS is sporadic with a familiar variant affecting <10% of the patients. Studies of ALS suggest a large degree of genetic heterogeneity but with extensive clinical homogeneity. This suggests that at the molecular level only a limited number of pathways are immediately involved in disease etiology. For this reason we set out to study pathways by means of gene expression profiling in peripheral blood of ALS patients. We collected genome-wide gene expression data from 30 ALS cases and 30 controls. Using the most informative 8,000 genes, an absolute T-statistic was calculated for each gene and a power adjacency function was used to calculated connectivity for the data set. The 3,600 most connected genes were included for subsequent module detection. Using average linkage hierarchical clustering, we used a dynamic cut tree algorithm to select branches (modules). Nine modules were obtained and each gene was clustered. The mean gene significance was calculated for each module, which represents the differential gene expression of genes in these modules between ALS patients and controls. Four modules were identified with differential expression. In two of these modules gene significance was strongly correlated with gene connectivity, suggesting that hub genes play an important role in these modules. We further applied functional enrichment analysis to identify gene categories within these modules based on their gene ontology. Our data clearly identified differential expression of genes in ALS patients within distinct functional modules. This approach allows for an unbiased approach of pathway reconstruction and may lead to new insight into the etiology of ALS.

Deletion 10q26 in a patient with inv(10)(p11.23q21.2): clinical report and characterization by comparative genomic hybridization (CGH) microarray analysis and FISH with locus specific probes. *S.C. Newman[1], P.I. Bader[1], F.J. Bader[1], S. Blend[2], D.E. Mensing[2], J. Li[2], S.W. Cheung[2]* 1) Northeast Indiana Genetic Counseling Center, Parkview Hospital, Fort Wayne, IN; 2) Department of Human and Molecular Genetics, Baylor College of Medicine, Houston, TX.

Clinical findings in patients with 10q deletion include mental retardation (MR), growth retardation (GR), congenital heart disease (CHD), genitourinary (GU) anomalies, microcephaly, and facial features such as broad nasal bridge with beaked or prominent nose, strabismus, and low-set malformed ears. Behavioral abnormalities are paramount in the disorder and may not correlate with the degree of MR. Attention Deficit Hyperactivity Disorder(ADHD), Autism Spectrum Disorder(ASD), and Bipolar Disorder have all been diagnosed in patients with 10q deletion.

We report a girl with inv(10)(p11.23q21.2), ADHD, MR, and ASD who had strabismus surgically corrected. Her height was at -3SD, weight at 10 %ile, OFC at -4SD. Facial features included a metopic ridge, hypotelorism, small palpebral fissures (-3SD), prominent nose and nasal bridge, thin upper lip, flat philtrum, chin cleft, heart murmur, clinodactyly, Sydney lines, poor balance. Echocardiogram revealed atypical PDA or an aortopulmonary window. Ultrasound showed a hypoechoic area in the superior right kidney. Her behavior was characterized by hyperactivity, repetitiveness, and mouthing/licking objects.

Chromosomal microarray analysis designed to interrogate clinically relevant genomic regions revealed haploinsuffiency at 10q26.2 with the following clones: starting from RP11-422P15 to RP11-140A10 encompassing approximately 7 Mb of subtelomeric region. Interestingly, high-resolution chromosome analysis revealed the deletion present in the inverted chromosome 10 at bands 10q26.2-q26.3. Candidate genes for behavioral anomalies/MR include dihydropyrimidinase-like 4(DPYSL4) involved in neuronal differentiation and dopamine receptor D1 interacting protein (DRD1IP) that encodes a protein interacting D1 domamine receptor.

Intravenous MCT Oil for Nutritional Support in a Preterm Infant with LCHAD Deficiency. *T. Markello* Dept of Genetics & Metabolism, Childrens Natl Med Ctr, Washington, DC.

Long Chain 3-Hydroxy Acyl CoA Dehydrogenase(LCHAD) deficiency, and trifunctional protein deficiency, both result in the partial inability to metabolize fat acyl chains. They both increase the risk for preterm delivery due to their association with the HELLP syndrome (Hypertension, Elevated Liver enzymes and Low Platelets during pregnancy). Oral MCT oil has been used to optimize the diet for older children with LCHADD. Its use has improved neurological development and growth. It may also aid in reducing the cardiac myopathy seen in LCHADD. Extremely preterm infants (birth weight <1500gm, gestational age <28weeks) frequently need extended time without oral intake, and are at risk for heart failure from a variety of mechanisms. Using MCT containing intravenous lipids in LCHADD preterm infants would extend the optimal LCHADD diet to this group of patients. It would also achieve increased caloric intake with less fluid administration than nutrition based on glucose solutions alone. The case of a 26 week infant with LCHADD is described. The course was complicated by critical fluid management and cardiac dysfunction. A single use FDA IND was obtained to administer intravenous MCT oil as part of total parenteral nutrition. The initial objective of decreasing the total daily fluid load was achieved while maintaining sufficient calories for growth. No adverse acute toxicity was detected. LCHADD diagnoses are expected to increase, due to implementation of extended newborn screening together with the increased awareness of the association between HELLP syndrome and LCHADD. A significant fraction of these infants will be preterm. The use of intravenous MCT oil in preterm LCHADD infants extends the range of therapeutic options for this condition as well as for trifunctional protein deficiency. Currently no USA/FDA approved form of intravenous MCT oil is commercially available. Advocacy for a commercially produced and FDA approved form of intravenous MCT oil, to be used in the nutritional support of LCHADD and other appropriate metabolic disorders, is warranted.

***SLC26A3* and *CFTR* variants in men with primary failure of spermatogenesis.** *S. Hihnala[1,2], R. Eklund[1], O. Hovatta[3], C. Holmberg[2], J. Kere[1,4], P. Höglund[1]* 1) Department of Medical Genetics, University of Helsinki, Finland; 2) Hospital for Children and Adolescents, University of Helsinki, Finland; 3) Department of Clinical Science, Karolinska Institute, Stockholm, Sweden; 4) Department of Biosciences at Novum, Karolinska Institute, Stockholm, Sweden.

A rare disease with an autosomal recessive inheritance is congenital chloride diarrhea (CLD), which results from over 30 different mutations in the *solute carrier family 26 member 3* (*SLC26A3* alias *DRA*) gene. *SLC26A3* is located on chromosome 7q22-31.1, near the *cystic fibrosis transmembrane conductance regulator* (*CFTR*) gene, and it encodes for an apical epithelial Cl^-/ HCO_3^- exchanger. In duodenum and ductal systems, interaction between the STAS-like domain of SLC26A3 and the R-domain of CFTR promotes secretion of HCO_3^- and fluid from the epithelium.

Finnish CLD-males with the founder mutation *V317del* are subfertile. Reduced fertility involves poor morphology and motility of sperm, and high seminal plasma Cl^- with a low pH. Interestingly, the low seminal plasma pH and poor sperm quality appear in males with cystic fibrosis (CF) as well, although the major cause for infertility among them is congenital bilateral absence of the vas deferens.

SLC26A3 is expressed at multiple sites of the male reproductive tract together with the interacting protein CFTR. In case of *CFTR* mutations, the only manifestation of CF can be male infertility, and even in carrier males, subfertility emerge. The aim of this study is to find whether *SLC26A3* mutations are associated with primary male infertility - alone or together with those of *CFTR*.

So far, direct sequencing of all coding regions and exon-intron boundaries of *SLC26A3* among Finnish men (n=83) with primary failure of spermatogenesis has revealed five new heterozygous variants. Additionally, one of these infertile men was carrier of the Finnish *V317del* genotype of CLD. Among control men (n=33) with known etiology of infertility, however, all these novel variants were non-existent. Future studies include variant analysis among men with proved fertility, in addition to analysis of possible compound heterozygosity for the novel variants and *CFTR* mutations.

SMN1 and SMN2 deletion of exons 7 and 8 concurrent in one family. *T. Majidizadeh, S. SABER, P. JAMALI, M. HOUSHMAND* medical genetic, NIGEB, Tehran, tehran, Iran.

Spinal Muscular Atrophy (SMA) is an autosomal recessive disorder that characterized by loss of - motor neurons due to degeneration in the lower motor neurons . The SMN gene exists in two highly homologous copies, telomeric (SMN1) and centromeric (SMN2). SMA is caused by mutations in SMN1 but not SMN2. In this study one family who were heterozygote for both SMN1 and SMN2 gene deletion screened for common deletion on exon 7 and 8 in both genes. They missed only their child because of SMA type I caused by deletion in exons 7 and 8 in SMN1 gene. Heterozygosity of parents was found when they referred to prenatal diagnosis in next pregnancy .PND showed deletion of exons 7 and 8 concurrent in SMN2 gene. It proved that parents were heterozygote for deletion of exons 7 and 8 in both genes SMN1 and SMN2. Mutations in SMN1 are responsible for SMA and mutations in SMN2 just influence on severity of SMA. Also, so far authors have not been observed any report about deletion of exons 7 and 8 together in SMN2 gene. Genetic counseling could have opinion about SMA because of found intact SMN1 gene in PND, but we can not ignore the possible role of homozygous SMN2 deletion in exons 7 and 8 either in SMA or other disorder such ALS and CMD that SMN2 gene can act as a prognostic factor and may be a phenotypic modifier in sporadic ALS.

The accuracy of family history questionnaires as a genetic counseling tool in a familial cancer setting. *J.M. McCuaig, S. Randall Armel, A. Finch, R. Demsky, B. Rosen* Familial Ovarian Cancer Clinic, Princess Margaret Hospital, Toronto, Ontario, Canada.

Over time, the number of people receiving genetic counseling at the Familial Breast and Ovarian Cancer Clinic (FBOCC) at Princess Margaret Hospital has steadily risen. To help reduce patient waiting times and shorten lengthy cancer counseling sessions, the use of family history questionnaires has been implemented. Currently across the province of Ontario, 22 familial cancer clinics exist: of these, 13 mail questionnaires to obtain family histories, 6 attain them by phone, and 3 acquire them during the counseling session itself. While many familial cancer clinics use questionnaires to obtain family histories, no literature exists on the validity of this approach. To explore the accuracy of the questionnaires used by the FBOCC, we compared the pedigrees generated from the questionnaires to those updated during the genetic counseling session for all new families seen between May 1st, 2005 and May 31st, 2006. All differences between the two pedigrees were scored based on the nature of the information changed and whether the changes altered the patients risk assessment and/or eligibility for BRCA1/2 genetic testing as set forth by the Ministry of Health. Of 80 families recruited, 70 (87%) had no change to their risk assessment and/or eligibility for genetic testing. To summarize the nature of the inaccuracies noted between the two pedigrees: 19 (24%) incorrectly provided information regarding relationship lines, 7 (1%) regarding ancestry or consanguinity, 24 (30%) regarding which family members were diagnosed with cancer, 17 (21%) regarding the type of cancer diagnosed, and 19 (24%) regarding biopsies/abnormal test results, or cancer reducing medications/surgeries. We therefore conclude that through carefully worded questionnaires, genetic counsellors can obtain accurate pedigrees without the need to devote valuable time to obtaining these pedigrees by phone or in person. Further, by using these questionnaires the average genetic counseling session can be reduced by approximately 20 minutes.

Dystrophin gene's hotspots in Iranian patients suspected to DMD or BMD. *M. Dehghan manshadi, T. majidizadeh, M. shafa, S.M. seyed hassani, M. houshmand* medical genetics, NIGEB, tehran, tehran, Iran.

The dystrophinopathiesDuchenne muscular dystrophy (DMD)and Becker muscular dystrophy (BMD)are the most common inherited disorders of muscle. Although reliable prevalence data are lacking, the prevalence of DMD is generally estimated at 1:3,500 live male births . Both DMD and BMD are due to mutations in the dystrophin gene , located at Xp21,which comprises 79 exons and 8 tissue-specificpromoters distributed across ~2.2 Mb of genomic sequencemaking dystrophin the largest gene yet described. Dystrophin gene deletions are found in ~55%of patients with BMD and 65% of patients DMD; point mutations account for ~30% of mutations, and duplications account for the remainder. Genetic testing for deletions relies on a multiplex PCR technique, with amplification of fragments containing 20 of the genes 79 exons and with deletions detected as absent or size-shifted bands on poly Acryl amide gel analysis. Because deletions tend to occur in hotspots within the dystrophin gene, analysis of this limited number of exons can detect 98% of dystrophin deletions. Hot spots are exons3-19 and 42-60.We studied all of these exons for 23 Iranian families. In our study most common of deletion were in exon6, exon44, exon50, exon4 respectively.

Association of the *GAD1* candidate gene with autism. *M. Martins[1,2], C. Correia[1,2], A. Currais[2], A.M. Coutinho[2], C. Marques[3], A. Ataíde[3], T.S. Miguel[3], J. Almeida[3], C. Bento[3], T. Morgadinho[4], G. Oliveira[3], A.M. Vicente[1,2]* 1) Neurogenetics & Mental Health Unit, Instituto Nacional de Saúde Dr Ricardo Jorge, Lisbon, Portugal; 2) Genetic Epidemiology Group, Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Hospital Pediátrico de Coimbra, Coimbra, Portugal; 4) Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal.

Autism, a childhood-onset neurodevelopmental disorder, is characterized by marked deficits in communication and social interaction skills, language impairment, and by repetitive and stereotyped behaviors. Although there is considerable evidence for a strong genetic component to idiopathic autism, the underlying genetic causes have yet to be identified. Several genome-wide scans for susceptibility genes have been carried out and, among others, a putative susceptibility locus on chromosome 2q31-33 has been identified. In the present study we tested the candidate gene glutamate decarboxylase 1 (*GAD1*), mapping to this linkage region, for genetic association with autism. The *GAD1* gene encodes GAD67, a protein responsible for the conversion of glutamic acid into GABA which has been found reduced in autistic patients. We have examined the association of autism with five SNPs within the *GAD1* gene, two located in the 5UTR region, and three in intronic regions, in a sample of 174 nuclear families and 132 controls. The Extended Transmission Disequilibrium Test (ETDT) showed significant association with autism for the marker rs3749034 (P=0.0190), in the 5UTR region. The Transmit test showed a significant transmission for six haplotypes ($0.0061<P<0.02$), suggesting association with autism. Moreover, given the known interactions between the glutamate, GABA and serotonin neurotransmission systems, we tested the hypothesis of an involvement of *GAD1* in the occurrence of hyperserotonemia in autism. Quantitative transmission disequilibrium test (QTDT) results showed no evidence of association between serotonin distribution and *GAD1* variation. The positive results obtained for ETDT of the 5UTR marker and the significant transmission for six haplotypes are suggestive of a contribution of the *GAD1* gene to autism pathogenesis.

Assessing the roles of GABABR2, DDC, and CHRNA4 in clefting of the lip in a large sample of Norwegian case and control triads. *A. Jugessur[1], R.T. Lie[1], A.J. Wilcox[2], H.K. Gjessing[3], R.M. Nilsen[1], J.C. Murray[4]* 1) University of Bergen, Bergen, Norway; 2) National Institute of Environmental Health Sciences, Durham, North Carolina, USA; 3) Norwegian Institute of Public Health, Oslo, Norway; 4) University of Iowa, Iowa City, Iowa, USA.

Genetic variants of DDC, CHRNA4 and GABABR2 have recently been linked to nicotine dependence. These variants might also be associated with clefting, since maternal smoking is a known risk factor. A maternal effect alone could reflect confounding from smoking, whereas an effect in the child could point to a direct effect of these genes, contributing to an apparent effect of maternal smoking. Twelve SNPs (GABABR2: rs10985765, rs1435252, rs3780422, rs2779562, and rs3750344; DDC: rs2060762, rs3757472, rs1451371, rs3735273, and rs921451; CHRNA4: rs4522666 and rs1044393) were genotyped on 377 case and 762 control triads from Norway. The software HAPLIN was used to estimate relative risks for a single or double dose of a haplotype in the mother or the child. Mothers with a single dose of haplotype GGCGC of DDC had a 2.5-fold risk of having a child with cleft lip (95%CI:1.4-4.3, $p<0.01$). For a double dose, the risk was 5.8-fold (95%CI:1.1-31.0, $p=0.04$). This haplotype was not overrepresented among the control mothers. Maternal haplotypes of CHRNA4 were not associated with cleft lip. For GABABR2, mothers with the haplotype CGTG in single dose had a reduced risk (RR=0.4, 95%CI:0.2-0.9, $p=0.03$). None of these haplotypes were associated with risk when present in the child. Children with a GC haplotype of CHRNA4 had a 2-fold risk (95%CI:1.3-3.2, $p<0.01$). In double dose, the risk was 2.1-fold (95%CI:1.1-4.0, $p=0.02$). Other associations were observed, but no clear pattern emerged. We also found a few irregularities in the haplotype distribution among control triads, but no deviations from Hardy-Weinberg equilibrium. To conclude, maternal haplotypes of DDC and GABABR2 were associated with cleft lip, consistent with an increased propensity to smoking in mothers with certain genetic variants of these genes. A haplotype of CHRNA4 in the child raised the risk of cleft lip, but not enough to explain the association with maternal smoking.

The mouse ortholog of KIAA2022, a candidate gene for mental retardation is highly expressed in the postnatal ventral premammillary nucleus. *A. Lossi[1], V. Cantagrel[1], L. Van Maldergem[2], L. Villard[1]* 1) INSERM U491, Faculte de Medecine La Timone, Marseille, France; 2) Institut de Pathologie et de Genetique, Loverval, Belgique.

We have previously reported a family in which a pericentric inversion of the X chromosome was segregating and in which two male individuals were affected by severe mental retardation. In this family, we demonstrated the complete absence of expression of the KIAA2022 gene in the two affected patients following its disruption by the intrachromosomal rearrangement. However, despite the subsequent screening of many additional patients affected by mental retardation, we failed to detect additional mutations in this gene, thus questioning its contribution to the observed neurological phenotype. In order to determine if KIAA2022 could be involved in the development or normal function of the central nervous system, we have cloned its murine ortholog, Kiaa2022, and we have studied its expression during the development. Using quantitative RT-PCR and in situ hybridization, we show that Kiaa2022 is preferentially expressed in the nervous system although its transcript can also be detected in other tissues. The expression pattern of this gene is temporally and spatially regulated. Kiaa2022 transcripts are detected at E11 in postmitotic cells of the central nervous system and Kiaa2022 expression increases rapidly during the development to reach a maximum a few days after birth at P3. The postnatal peak of expression is detected in hippocampus, in enthorinal cortex and in a discrete area of the hypothalamus, the ventral premammillary nucleus where Kiaa2022 is highly expressed. This nucleus was shown to be an important target of melatonin and also involved in conspecific agression and sexual behavior in rats. After P3, the expression of Kiaa2022 subsequently decreases and it is maintained at low levels during adulthood. Taken together, our results suggest that Kiaa2022 could play a role in the developing brain perhaps through a specific action in ventral hypothalamic nuclei.

Molecular pathogenic studies of Hutchinson-Gilford progeria syndrome. *Y.H. Li[1], W. Ju[2], W.T. Brown[2], N. Zhong[1,2]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) New York State Institute for Basic Research, Staten Island, NY.

Hutchinson-Gilford progeria syndrome (HGPS, OMIM176670) is an early-onset premature aging disorder. It is caused by a heterozygous silent mutation at cordon 608 (G608G: GGC>GGT) of LMNA gene that encodes nuclear lamin A/C. This mutation creates a cryptic splice donor site in exon 11 of LMNA gene and consequently produces a truncated progerin with a deletion of 50 amino acid (50-aa) residues near the C-terminus of lamin A. Presently, the pathogenic mechanisms underlying HGPS are yet unknown. Earlier, we have proposed that progerin may have a dominant-negative effect on lamin A/C. This effect may interfere with the normal functions of lamin A/C or generate novel associations with non-lamina proteins. We identified four novel progerin-interactive partner proteins (PIPs) and showed that the PIPs did not differential interact with lamin A/C, compared to progerin. Further studies (Ju et al., in this meeting) demonstrated that these PIPs associate with lamina proteins in both normal and HGPS cells without significant difference. Considering that progerin lacks the 50-aa of pre-lamin A, we hypothesize that the truncated 50-aa may have a critical function in the development of HGPS. We propose that there might exist unidentified proteins that normally can be interacted by lamin A while not with progerin in the HGPS condition due to the loss of function that progerin lacks the 50-aa residues. Therefore, we undertook an investigation to search for the unidentified protein(s) that may be uniquely interacted by the 50-aa resides with a yeast two-hybrid system. Ten candidate proteins interacted by the bait peptide of the missing 50-aa were identified, including fibulin C and filamin B. The fibulins are a family of proteins that are associated with basement membranes and elastic extracellular matrix fibres. We therefore investigated if there is any differential association between the lamin A/C and the progerin. Our data did not provide any difference between normal and HGPS cells. Further studies on the other candidates such as filamin B are being undertaken.

Clinical and molecular characterization of patients with microdeletions of 6p21. *R. Mendoza-Londono[1], S.A. Yatsenko[2], D. Napierala[2], L. Medne[3], E.H. Zackai[3], K. Armfield Uhas[4], F. Kendall[5], S. Unger[6], A. Hunter[7], P. Stankiewicz[2], B. Lee[2,8]* 1) Div Clin & Metab Genetics, Hosp Sick Children, Toronto, Canada; 2) Dept of Mol & Hum Genetics, Baylor College of Medicine, Houston, TX; 3) Div of Hum Gen & Mol Biol, The Childrens Hospital of Philadelphia; 4) Childrens Healthcare of Atlanta, Atlanta, GA; 5) Horizon Molecular Medicine, Atlanta, GA; 6) Institute for Human Genetics, Freiburg, Germany; 7) Childrens Hospital of Eastern Ontario, Sudbury, Canada; 8) Howard Hughes Medical Institute, BCM,Houston, TX.

Chromosomal microdeletions have become an important diagnostic consideration in patients with developmental delay and multiple congenital anomalies. The advent of systematic testing for these defects, available in chromosomal microarray platforms, has increased the identification of these common disorders, but the delineation of some of them is limited. We present the clinical and molecular characterization of patients with microdeletions of chromosome 6p21. We have identified 4 patients with microdeletions that range between 3 and 5 Mb in size in the 6p21 region. The region of the microdeletion harbors over 30 known and hypothetical genes including *VEGF* and *RUNX2*. Three of the patients presented with features of cleidocranial dysplasia (CCD) and developmental delay, and their samples were referred to our laboratory for mutation analysis of *RUNX2*. The fourth patient was identified through diagnostic microarray analysis. Patients with microdeletion 6p21 have characteristic facial features expressed as wide open fontanels in infancy, metopic groove, and frontal bossing. The patients have short stature and moderate developmental delay. Additional skeletal findings explained by haploinsuficiency for RUNX2 include supernumerary teeth, clavicular hypoplasia, and delayed ossification of the pubic bone. Other characteristics seen only in some of the patients include, congenital heart disease, hypospadias, growth hormone deficiency and megalocornea with signs of glaucoma in-utero. Further evaluation of patients with 6p21 microdeletions will allow us to refine the characterization of this under recognized syndrome.

Interstitial deletion of the long arm of chromosome 2 in a child with severe limb abnormalities and craniosynostosis : implication of the HOXD cluster? *N. Marle[1], L. Faivre[2], P. Callier[1], A.L. Mosca[1], S. Beer[3], C. Thauvin[2], F. Mugneret[1]* 1) Laboratoire de Cytogénétique, CHU Le Bocage, Dijon, France; 2) Centre de Génétique Clinique, Hôpital d'Enfants, Dijon, France; 3) Service de Néonatologie, Hôpital d'Enfants, Dijon, France.

Interstitial 2q deletion including the band 2q31 are associated with a large spectrum of limb malformations. This band contains the HOXD gene cluster, whose five most 5 members (HOXD9 through HOXD13) are known to play major roles in the growth and patterning of the developing limb. Here we report on the second child of healthy parents born from intracytoplasmic sperm injection. A cystic hygroma was evidenced at 12 weeks of gestation, investigated with normal cytogenetic studies. Examination at birth revealed a birth length of 46 cm with normal OFC at 36 WG. Facial dysmorphism included a high forehead, hypertelorism with broad nasal bridge, down-slanted palpebral fissures, small and low-set ears, a short neck and retrognathism. Only four fingers on the right hand with the presence of a thumb, an hypoplastic forearm and a luxation of the right elbow were noted, as well as a syndactyly between the 2nd-3rd and 4th-5th toes bilaterally and hypoplastic 5th toe. Examination of the left arm and mammary development were normal. X-ray studies revealed hypoplastic and curved left radius and ulna with four metacarpals. Other investigations showed an atrial septal defect with persistant ductus arteriosus. Follow-up at 4 months of age revealed cranial asymmetry and 3D CT scan confirmed a craniosynostosis of the metopic suture. Postnatal cytogenetic analysis with high resolution banding revealed a male karyotype with a deletion of the band 2q31 : 46,XY,del(2)(q31.1-q31.3. The deletion was confirmed by FISH study with BAC probe RP11-387A1 spanning the 2q31.1 band and including the HOXD gene cluster. Both parents had a normal karyotype. Further molecular studies using BAC probes are in progress in order to evaluate the size of the deleted segment. We compare clinical features and cytogenetic findings in our case with the previously reported observation and discuss the potential implication of HOXD in the phenotype.

Suggestive evidence for linkage to chromosome 4qter for autosomal dominant distal motor neuronopathy. *M. Muglia[1], A. Magariello[1], L. Citrigno[1], L. Passamonti[1], A. Patitucci[1], F.L. Conforti[1], A.L. Gabriele[1], R. Mazzei[1], T. Sprovieri[1], C. Ungaro[1], M. Bellesi[2], A. Quattrone[1,3]* 1) ISN-CNR, Mangone Cosenza, Italy; 2) Institute of Neurological Sciences, Ospedale Regionale "Torrette", University Ancona, Italy; 3) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Distal hereditary motor neuronopathy (dHMN)is a rare genetically and clinically heterogeneous early-onset disorder, characterized by weakness and wasting of distal limb muscles with possible pyramidal dysfunction, in absence of overt sensory abnormalities. To date nine clinically different forms have been recognized, and seven loci have been identified for autosomal dominant distal HMN on chromosomes 2p13, 2q14, 7p14, 7q11, 9q34, 11q12, 12q24. A large four generation family with autosomal dominant dHMN was studied. All known loci responsible for dHMN were previously investigated. A genome wide search was performed by using 206 microsatellite markers from the ABI PRISM Linkage Mapping Set LD 20. Additional markers for fine mapping were obtained from Marshifield Genetic map. The two point lod scores obtained for all the analysed markers were negative. Suggestive positive Lod scores at =0 were obtained in region 4qter with three consecutive markers D4S424 (1.15), D4S415 (0.48) and D4S426 (1.07). Ten additional markers were tested in the family, and a maximum LOD score of 2.71 at D4S1607 in the absence of recombinants was obtained. Multipoint linkage analysis with markers D4S1607-D4S3041-D4S3051 resulted in a maximum LOD score of 3.78 at D4S1607 allowing assignment of a novel dHMN locus to this region. Two recombination events occurred in the family: in an affected individual with the proximal marker D4S2991 and in an unaffected subject with the distal marker D4S426. Haplotype construction and analysis of recombination narrowed this locus to a 20cM region between markers D4S2991 and D4S2924. Many genes are known to be located in this region; we screened the SNX25 gene, but no mutations have been identified. Further studies are needed to demonstrate the specific gene alteration.(Supported by a Telethon-Italia grant NGUP04009).

Development of a genotyping microarray for Usher syndrome. *H. Kremer[1], W.J. Kimberling[2], M. Külm[3], H. te Brinke[1], C.W.R.J. Cremers[1], L.H. Hoefsloot[4], F.P.M. Cremers[4]* 1) Dept Otorhinolaryngology, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 2) Center for the study and treatment of Usher syndrome, Boystown National Research Hospital, Omaha, NE; 3) Asper Biotech, Tartu, Estonia; 4) Dept Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

Usher syndrome, a combination of retinitis pigmentosa (RP) and sensorineural hearing loss with or without vestibular dysfunction, displays a high degree of clinical and genetic heterogeneity. Three clinical subtypes can be distinguished, based on the age of onset and severity of the hearing impairment and the presence or absence of vestibular abnormalities. In addition, there are patients with atypical Usher syndrome. Thus far, 8 genes have been implicated in the syndrome, which together comprise 347 protein coding exons. Therefore, sequence analysis and the most routinely used mutation scanning techniques are not cost-effective for molecular diagnostics of the syndrome. To improve DNA-diagnostics for patients with Usher syndrome, we developed a genotyping microarray based on the arrayed primer extension (APEX) method. Allele-specific oligonucleotides corresponding to virtually all 298 Usher syndrome-associated sequence variants known to date were arrayed. Approximately half of these variants were validated using original patient DNAs which yielded an accuracy of >98%. The efficiency of the Usher genotyping microarray was tested using DNAs from 370 unrelated European and American patients with the syndrome. Sequence variants were identified in 64/140 (46%) patients with Usher syndrome type I, 45/189 (24%) patients with Usher syndrome type II, 6/21 (29%) patients with Usher syndrome type III, and 6/20 (30%) patients with atypical Usher syndrome. The chip also identified two novel sequence variants, c.400C>T (p.R134X) in PCDH15 and c.1606T>C (p.C536S) in USH2A. The Usher genotyping microarray represents a versatile and affordable screening tool for Usher syndrome. Its efficiency will improve with the addition of novel sequence variants with minimal extra costs, making it a very useful first-pass screening tool.

A bivariate whole-genome linkage analysis identified several shared genomic regions contributing to both total body lean mass and femoral neck bone geometry in a Caucasian sample. *S.F. Lei[1], F.Y. Deng[1], P. Xiao[2], D.H. Xiong[2], L.J. Zhao[2,3], H.W. Deng[1,2,3]* 1) College of Life Sciences, Hunan Normal University, China; 2) Osteoporosis Research Center, Creighton University, USA; 3) School of Medicine, University of Missouri-Kansas City, USA.

Our previous study found that the two highly heritable traits of total body lean mass (TBLM) and femoral neck cross-sectional (FNCS) geometry had highly genetic correlation. To identify the specific genomic regions shared by them, a bivariate whole-genome linkage analysis (WGLA) was performed in a large Caucasian sample with 4,498 individuals from 587 pedigrees. Bone mineral density (BMD) and bone size at the femoral neck, and TBLM were measured by Hologic DXA scanners. FNCS geometric parameters, including sub-periosteal diameter (W), cross-section area (CSA), cortical thickness (CT), section modulus (Z), and buckling ratio (BR), were calculated from BMD and bone size of femoral neck. Peak bivariate multipoint LOD scores were 1.74 (17p13), 3.32 (20q13), 3.88 (20q13), 2.39 (20q13), 1.89 (14q32) between TBLM with Z, BR, CT, CSA, and W, respectively. Other genomic regions with bivariate multipoint LOD score over 2.0 were 3p13 (LOD score = 2.18) and 6q27 (2.24) between TBLM and CT; 20p11 (2.30) between TBLM and CSA; and 3q12 (2.49) between TBLM and BR. Interesting, peak LOD scores in 20q13 are consistent between the three pairs of TBLM with CT, CSA and BR. Subgroup analysis also demonstrated the presence of sex-specific genomic regions shared by TBLM and FNCS geometry such as 7q11 and 10q24. We also performed bivariate WGLA between TBLM and two principal components derived from the above five parameters, and found the results supported the above findings. The results suggested that some functional loci in the shared genomic regions may exert pleiotropic effects on both TBLM and bone geometry, or that the loci respectively regulating TBLM and bone geometry are in linkage disequilibrium. In addition, due to the high phenotypic correlation between TBLM and other important bone strength phenotypes such as BMD, bivariate WGLA between them is also ongoing, with some preliminary interesting results found.

Expression of Proteins in Cortical Neurons Following DNA Damage. *M. Hosseini[1], K. Parivar[2], M.H. Ghahremani[3], N. Ostad[3]* 1) Science, Islamshahr Branch-Islamic Azad University, Tehran, Asia, Iran; 2) Dept. Animal Biology, Science & Research Campus, Islamic Azad University, Tehran,Asia, Iran; 3) Dept.Toxicology-Pharmacology, Faculty of Pharmacy, Tehran University of Medical Sciences, Tehran,Asia, Iran.

DNA damage, as an important initiator of neuronal cell death, has been implicated in numerous neurodegenerative conditions. In this experimental model, primary embryonic cortical neurons were prepared from E14-16 rat embryos.A density of 1.2×105 cells/well plated on the wells, pre-coated with poly-D-lysine. Camptothecin (10-5 M)was added to neuronal culture after 24 hours. After 4,6,24 and 48 hours , expression of the P38 and ATF-2 was studied using primary antibody in the Immunocytochemistry technique,and number of healthy and death nuclei were counted by cell lysis buffer.Then percentage of the healthy , death and expression of the cells was analyzed by one way ANOVA followed by Tukeys post test . Percentage of the expression of P38 was 4%, 20%, 40% and 55%, and percentage of the survival was 95%, 85%, 64% and 50% for 4, 6, 24 and 48 hours, respectively.The expression of ATF-2 was also 3%, 20%, 30% , 45% and percentage of the survival was 97%, 85%, 64% and 50% , respectively. Percentage of the expression and survival of the P38 neurons for 24 hours were 40 and 64 percent and it was for ATF-2 , 30 and 64 percent respectively which these results compared to control were increased significantly ($p<0.05$). Expression of the proteins at 4 hours was not changed significantly.This study revealed that expression of the P38 and ATF-2 was increased simultaneously.Thus, in this model, Camptothecin induces neuronal death by stimulation P38-ATF-2 pathway.

Identification of RNAs interacting with N-Terminal Domain of FMRP (NDF). *B. He[1,2], W. Ju[1,2], W.T. Brown[1], N. Zhong[1,2]* 1) Human Genetics, New York State Institute for BAsic Research, Staten Island, NY; 2) Peking University Center of Medical Genetics.

Fragile X syndrome, as one of the most common inherited mental retardations, is caused by methylation-induced transcriptional silencing of fragile X mental retardation 1 gene (FMR1), which leads to absence of its translational product FMRP, the FMR1 encoded protein. FMRP was found to interact with protein and RNA molecules both in vitro and in vivo, suggesting that it may be involved in a complicated network of protein-protein and protein-RNA interactions. FMRP contains two known types of RNA-binding motifs: an RGG box and two heterogeneous nuclear RNP K homology (KH) domains. Previous studies have identified RNA partners of these two motifs. Recently, an N-terminal domain of FMRP (NDF) was determined to be a new RNA-binding domain in FMRP by using RNA homopolymers as partners. However, little study was performed to characterize the RNA-binding feature of NDF. Here, we undertook a study to determine the RNA-binding function of NDF by screening a yeast three-hybrid cDNA library we constructed earlier. Three RNA candidates, tubulin, alpha 3 (TUBA3); v-rel reticuloendotheliosis viral oncogene homolog B, nuclear factor of kappa light polypeptide gene enhancer in B-cells 3 (avian) (RELB); latent transforming growth factor beta binding protein 4 (LTBP4) have been identified to bind to NDF. Among them, TUBA is able to interact with metabotropic glutamate receptor 7, which mediates a variety of responses to glutamate in the central nervous system. Further characterization of these candidates will be presented.

A missense mutation in the canine ortholog of *ATF2* in standard poodles with neonatal seizures and encephalopathy. *G.S. Johnson[1], X. Chen[1], R.D. Schnabel[2], J.F. Taylor[2], H.G. Parker[3], E.E. Patterson[4], T. Awano[1], S. Khan[1], D.P. O'Brien[5]* 1) Veterinary Pathobiology, University Missouri, Columbia, MO; 2) Animal Sciences, University of Missouri, Columbia, MO; 3) Cancer Genetics Branch, NHGRI, NIH Bethesda, MD; 4) Veterinary Clinical Sciences, University of Minnesota, St Paul, MN; 5) Veterinary Medicine and Surgery, University of Missouri, Columbia, MO.

A previously undescribed autosomal recessive neonatal seizures and encephalopathy syndrome of standard poodles is characterized by decreased cerebellar size, cerebellar dysplasia, and hypomyelination in the cerebrum. Affected pups nursed poorly and were smaller than their littermates. Puppies surviving to 3 weeks of age were weak, ataxic, and mentally dull. By 4 to 6 weeks, they developed severe generalized clonic-tonic seizures. Weakness progressed to lateral recumbency with extensor rigidity, opisthotonus, and death. A panel of microsatellite markers was used to genotype DNA from a 73-member Standard Poodle family containing 20 affected puppies. Linkage analysis localized the disease locus to an 8.7 Mb segment of CFA36 between markers REN179H15 and REN252E18. The maximum two-point LOD score was 3.31. Fine mapping with 12 additional markers restricted the target region to a 3.76 Mb chromosomal segment containing 29 orthologs of genes from HSA2 including LOC478806, the canine ortholog of *ATF2* which encodes activating transcription factor 2. A LOC478806 missense mutation changes the ancestral methionine-51 to an arginine at a position immediately adjacent to a key alpha helix within the transactivation domain in the gene product. The mutant allele co-segregated with the disease in our standard poodle family: all 20 affected poodles were homozygous for the mutant allele; whereas, the normal relatives were either heterozygous (n = 44) or homozygous for the normal allele (n = 9). One hundred and eighteen representatives of other breeds were all homozygous for the ancestral allele. A pyrosequencing-based DNA test that identifies heterozygous carriers of the disease is available to standard poodle breeders.

Rapid implementation of MLPA using synthetic probes increases the mutation detection rate in DNA diagnostics.
L.H. Hoefsloot, M.H.A. Ruiterkamp-Versteeg, G.M.G. Schobers, K.P. van der Donk, I.J. de Wijs, W.M. Nillesen, H. Scheffer, E.A. Sistermans Dept Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

For the identification of genomic mutations during the forthcoming years sequence analysis will stay the golden standard. The major drawback of this technique is that heterozygous (multiple) exon deletions and duplications will not be detected. Deletion/duplication analysis for genes such as BRCA1, BRCA2 and MECP2 has demonstrated that such changes may be important sources of pathogenic mutations. Multiplex ligation-dependent probe amplification (MLPA) is a recent addition to routine DNA diagnostics allowing detection of copy gains or losses in an efficient, low-cost, robust way, with a high sensitivity and specificity. MLPA-kits have become available commercially for several genes with known deletions, including those mentioned above We have developed a system in which we can rapidly implement MLPA-analysis for any desired gene by the use of fully synthetic probes, as we expected that exon deletions and duplications would be an important source of pathogenic changes in other genes as well. Briefly, 5 control probes with different lengths have been designed to be included in all kits. Additional gene-specific synthetic probes can be added to up to 15 fragments in total, each fragment 4 nucleotides longer than the previous one. To date, we have been successful for the autosomal genes CHD7 , EYA1, LMX1B, and SPG4, and X-linked CHM, NDP and EHMT1. Preliminary data indicate that indeed 1-5% of mutations in the autosomal genes is an exonic deletion or insertion. For the X-linked disorders, it allowed us the easy diagnosis of female carriers with a deletion.

Mapping quantitative personality trait loci in opioid receptor genes: utility of stepwise MANCOVA and Roy Bargmann Stepdown ANCOVA. *X. Luo[1,2], H.R. Kranzler[3], L. Zuo[1,2], H. Zhang[1,2], S. Wang[4], J. Gelernter[1,2]* 1) Dept Psychiatry, Yale Univ Sch Medicine, West Haven, CT; 2) VA CT Healthcare System, West Haven, CT; 3) Dept Psychiatry, Univ CT Sch Med, Farmington, CT; 4) Dept Biostatistics, Columbia Univ Mailman Sch Pub Health, New York, NY, USA.

Human personality traits are among the most complicated quantitative traits. Certain personality traits are associated with substance dependence (SD); genetic factors may influence both. Associations between opioid receptor (OPR) genes and SD have been reported. We aimed to investigate the relationship between *OPR* genes and personality traits in the present study. We assessed dimensions of the five-factor model of personality in 250 subjects with SD [181 European-Americans (EAs) and 69 African-Americans (AAs)] and 306 healthy subjects (266 EAs and 40 AAs). We genotyped twenty *OPRM1* markers, eight *OPRD1* markers, and seven *OPRK1* markers, and thirty-eight unlinked ancestry-informative markers in these subjects. The relationships between *OPR* genes and personality traits were comprehensively examined using Multivariate ANalysis of COVAriance (MANCOVA), controlling for gene-gene interaction effects and potential confounders. Then, associations were decomposed by Roy Bargmann Stepdown Univariate ANalysis of COVAriance (ANCOVA). Generally, SD patients, older individuals, males, and African-Americans scored higher on Neuroticism and lower on other personality factors (i.e., Extraversion, Agreeableness, Conscientiousness, and Openness to Experience). There were main or interactive effects of haplotypes, diplotypes, alleles or genotypes at all three *OPR* genes. We demonstrate that *OPRM1*, *OPRD1*, and *OPRK1* may contribute to variation in personality traits, both directly and through gene-gene interactions.

Negative association between polymorphism rs225014 of DIO2 gene and bipolar disorder. *T. Zhang[1], B. He[1,2], N. Zhong[1,2]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) New York State Institute for Basic Research.

Bipolar disorder (BPD) is a form of mood disorders that involves one or more episodes of serious mania and depression in affected individuals. The etiology of BPD may include genetic, developmental, social, cultural and environmental factors. Multiple genealogical£¨twin and adoption research showed that genetic background played an important role in the pathogenesis of BPD. Molecular genetic studies have identified several genes that may be associated with BPD, including 5-HTT, HTR, MAOA, COMT, IMPA1, DAOA, BDNF, etc. In previous studies, associations between depression and hypothyroidism and between mania and hyperthyroidism were described. A recent study demonstrated that patients hospitalized with hypothyroidism have a greater risk of readmission with BPD. Taking into consideration these data, together with other evidence such as association between the level of thyroid hormones (T3, T4) and mood instability, we are interested in exploring the relationship between T3, T4 and BPD. The deiodinase, which is encoded by DIO gene, is a key enzyme in the process of conversion between T3 and T4 and regulates the absolute and relative amount of T3 and T4. The DIO2 gene, a tissue-specific regulator of intracellular T3 concentrations in the brown fat, brain and pituitary, is particularly important for the conversion from T4 to T3 in the brain. In this study, we took DIO2 as our target to investigate the possible association with BPD. Eighty-two clinically diagnosed BPD patients were recruited as experimental subjects, while ninety-two normal individuals were included as controls. In both groups the DIO2 gene polymorphism rs225014 was in Hardy-Weinberg equilibrium. Our results reveal that (1) there is no significant difference between rs225014 allele frequencies of BPD patients and normal controls and (2) no significant difference was found among rs225014 allele frequencies of BPD patients with different features (gender, family history and suicide tendency). Our preliminary study indicates that there is no association between polymorphism rs225014 of DIO2 and BPD. Further investigations, such as more markers and haplotype assay will be pursued.

Fanconi Anemia: Congenital abnormalities in patients homozygous for the *FANCG637-643* deletion mutation. *T. Haw, L. Wainwright, J. Poole, A. Krause* Division of Human Genetics, National Health Laboratory Service and University of the Witwatersrand, Johannesburg, South Africa.

Fanconi anemia (FA) is a chromosome breakage disorder caused by mutations in one of at least twelve different genes. Individuals with FA have diverse clinical features but the disease is characterized by aplastic anemia (AA). There has been evidence to show genotype phenotype correlations. A deletion in the *FANCG* gene (*FANCG637-643*) accounts for 78% of all FA mutations in the black South African (SA) population. We aimed to delineate the congenital abnormalities associated with this mutation and to determine whether hematological outcome could be predicted from the number of congenital abnormalities a patient had.

The frequency of congenital abnormalities in 25 black SA patients homozygous for *FANCG637-643* was compared to FA patients described by two other research groups, one from Europe and one from the US. The US group was composed of patients with mutations in unknown FA genes (mixed group) while the patients in the European group had mutations only in *FANCG*.

No significant differences in the frequency of congenital abnormalities were found between the SA group and the *FANCG* cohort. However, significantly more patients from the SA group had head abnormalities, including dysmorphic features and microcephaly, and significantly fewer had developmental delay and hearing impairment compared to the mixed group. Therefore mutations in the different genes may be associated with specific abnormalities. We have identified that thumb abnormalities, head abnormalities and growth retardation are the congenital abnormalities most frequently associated with *FANCG637-643*.

It was reported previously that the greater the number of congenital abnormalities, including developmental delay, heart, kidney, hearing and head abnormalities, in a FA patient, the larger their risk for developing AA. We found that *FANCG637-643* is associated with a high risk of early development of AA even though individuals have a low number of these congenital abnormalities.

Identification of a novel risk gene for Progressive Supranuclear Palsy by a genome-wide scan of 500,288 SNPs. *S. Melquist[1], M.J. Huentelman[2], D.W. Craig[2], M. Baker[1], R. Crook[1], J.V. Pearson[2], V.L. Zismann[2], J. Gass[1], J. Adamson[1], S. Szelinger[2], J. Corneveaux[2], A. Cannon[1], K.D. Coon[2], D.W. Dickson[1,3], D.A. Stephan[2], M. Hutton[1]* 1) Neuroscience, Mayo Clinic College of Medicine, Jacksonville, FL; 2) Neurogenomics, Translational Genetics Research Institute, Phoenix, AZ; 3) Pathology, Mayo Clinic College of Medicine, Jacksonville, FL.

We hypothesized that additional genetic loci may be involved in conferring risk for Progressive Supranuclear Palsy, which could be identified through genome-wide association methods. Affymetrix 500K SNP chips were therefore used in a pooled genome-wide association analysis of a large, pathologically-confirmed PSP case and control set. The *MAPT* H1 haplotype, a previously identified risk locus, was strongly detected by this methodology, providing proof of concept. In addition, a second major locus on chromosome 11p11.2 and a minor locus on chromosome 4 showed evidence for association at a genotypic (p=0.0002, p=0.004, respectively) and haplotypic level. The chromosome 11p11.2 locus could be narrowed to a small region containing just a few candidate genes, with the well-described DNA repair gene *DDB2* showing the strongest evidence for association. The identification of *DDB2* as a gene likely harboring risk for PSP suggests that alteration in DNA repair capacity could play a vital role in the neurodegenerative process in PSP and perhaps other related disorders.

Candidate gene analyses for nonsyndromic cleft lip (CL) with or without cleft palate (CP) in families from six countries. *M.L. Marazita[1], B.S. Maher[1], J.C. Murray[2], A. Lidral[2], L.L. Field[3], T. Goldstein McHenry[1], M.E. Cooper[1], S. Daak-Hirsch[2], A. Jugessur[2], B. Riley[2], L. Moreno[2], P. Chines[4]* 1) Ctr Craniofacial and Dental Genet, U of Pittsburgh, PA; 2) U of Iowa; 3) U of British Columbia, Canada; 4) Genome Technology, NHGRI.

Our research group identified several chromosome regions that reached genome-wide significance for containing susceptibility loci for CL/CP, including 1q, 2p, 3q, 9q, 14q, 16p (Marazita et al 2005). To follow-up those results 1,476 SNPs from candidate genes and regions were genotyped using the Illumina platform by the Center for Inherited Disease Research (CIDR). The study population consisted of 5,232 individuals (2,850 genotyped of whom 1,008 were affected) from 499 families ascertained from six countries (Philippines, China, India, Turkey, U.S.A., Spain). Reported here are the family-based-association-test (FBAT) results. To control for multiple testing and to include information from our previous genome scans we performed a weighted approach to false discovery rate (FDR; Roeder et al 2006). In this approach, per marker FBAT p-values were adjusted using a weighting scheme devised from our published genome scan meta-analysis (Marazita et al, 2004) allowing for a maximum 20% FDR. Analyses were done for the TOTAL dataset, CL, CLP and CLCLP subsets (CL=families with CL-alone affecteds, CLP=all affecteds have CL plus CP, CLCLP=some affecteds with CL and some with CLP). SNPs in IRF6 are the only ones reaching formal FDR-adjusted significance in the TOTAL ($p<10^{-7}$) and CLCLP ($p=7x10^{-5}$) datasets. Although not reaching formal significance, notable results include SNPs on 9q in TOTAL ($p<0.001$) and CLCLP ($p=0.001$), and on 6q in CLP (gene DDO, $p<0.001$). The 6q region has a 90% probability of containing a gene for CL/CP (Govil et al, this meeting). Further genotyping suggests that FOXE1 is likely to be the associated gene on 9q (Mansilla et al, this meeting). In summary, IRF6 is confirmed as a susceptibility locus for CL/P, and genes on 9q and 6q require additional confirmatory studies. NIH grants R01-DE09886, R01-DE012472, R37-DE08559, R01-DE016148, P50-DE016215, M01-RR00084; CIDR NIH contract N01-HG-65403.

Genotyping of Common Variants Near the HNF4A Locus in a Norwegian Population-Based Sample of 1850 Diabetes Cases and 1879 Controls. *S. Johansson[1,2], H. Raeder[1], S.A. Eide[1], K. Midthjell[3], O. Søvik[1], A. Molven[4], P.R. Njolstad[1,5]* 1) Department of Clinical Medicine, University of Bergen; 2) Center for Medical Genetics and Molecular Medicine, Haukeland University Hospital; 3) Department of Public Health and General Practise, Norwegian University of Science and Technology; 4) The Gade Institute, University of Bergen; 5) Department of Pediatrics, Haukeland University Hospital, Norway.

Introduction: Several recent publications from different populations have shown an association between SNPs near the P2 promotor of the HNF4A gene and Type 2 diabetes, whereas no effect has been seen in other populations. Hence, it is still not clear whether genetic variations in this region might predispose to diabetes. We therefore genotyped four common SNPs near the HNF4A gene in a Norwegian population. Material: 1850 patients with diabetes and 1879 controls were recruited from a large population based study (HUNT) in a county (Nord-Trøndelag) in Norway. Genotyping was performed using the Sequenom single base extension technology. Results: When comparing all diabetes patients with controls a non-significant trend towards increased OR was seen for the minor alleles at the two SNPs flanking the P2 promotor rs1884613 (OR=1.09, 95% CI: (0.97-1.23)) and rs2144908 (OR=1.11, (0.98-1.25)) and for the major allele at rs3818247 (OR=1.09 (0.99-1.20)) located downstream of the gene (three-marker- haplotype p=0.07). The putative effect remained similar in size for all three SNPs after exclusion of subjects with possible autoimmune diabetes as measured by GAD autoantibodies or C-peptide <150 pmol/L: OR=1.08-1.10 (95% CI range 0.95-1.25). Conclusion: The results from this Norwegian population, although not significant, are consistent with the associations found both in the Swedish and Danish population. These populations are considered genetically similar and we hypothesize that the discrepant results between different populations may reflect differences in LD-pattern with unidentified disease-associated SNPs in the region.

Is the $GABA_A$ receptor a possible target for drug therapy in fragile X syndrome? *F. Kooy[1], C. D'Hulst[1], P.P. De Deyn[2]* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Department of Neurochemistry and Behavior, Institute Born-Bunge, Univ Antwerp, Antwerp, Belgium.

After our initial discovery of under expression of the $GABA_A$ receptor subunit in a genome wide expression profiling study in fragile X mice, a mouse model for the most frequently inherited form of mental retardation, we analyzed expression of the 17 remaining subunits of the $GABA_A$ receptor by real-time PCR. We found significant under expression of the $_{1, 2 \text{ and } 3}$, $_{1 \text{ and } 2}$, and $_{1 \text{ and } 2}$ in the cortex of fragile X mice. $GABA_A$ receptors are the main inhibitory receptors in brain, implicated in anxiety, epilepsy, sleep-wake cycles and learning and memory, processes also disturbed in fragile X patients. Many factors lead us to believe that the $GABA_A$ receptor is a novel target for drug therapy in fragile X syndrome. Patients with 1p36 deletions, lacking the $GABA_A$ receptor subunit among other genes, show neurological and neuropsychiatric anomalies as well as epilepsy, and it was suggested that the subunit contributes to this phenotype. In addition, evidence for involvement of the $GABA_A$ system in fragile X syndrome is strengthened by recent observations that the ratio between inhibitory (taurine+GABA) and excitatory (aspartate+glutamate) amino acids in fragile X mice brain is decreased. Other groups analyzed differential expression of the -subunits at protein level and found, in line with our results at RNA level, 2-fold under expression of these subunits in cortex. Powerful new therapeutic opportunities may arise from the $GABA_A$ receptor pharmacology. Numerous drugs of clinical importance bind to various types of the $GABA_A$ receptor, including benzodiazepines like diazepam (Valium), barbiturates, such as phenobarbital and neuroactive steroids, like ganaxolone. Currently we are investigating whether fragile X mice have an altered susceptibility to these drugs by testing their effect in a battery of behavioural tests. This may elucidate the physiological consequences of under expression of the GABA-ergic system in fragile X mice.

***FGFR1* overexpression and 5' CpG Island hypomethylation in primary rhabdomyosarcoma tumors.** *A. Orr-Urtreger[1,2], M. Goldstein[1,2]* 1) Genetics Inst, Tel Aviv Sourasky Medical Ctr, Tel Aviv, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel-Aviv, Israel.

Rhabdomyosarcomas (RMS) are highly aggressive tumors likely to result from deregulation of proliferation and differentiation during skeletal myogenesis program. The three histopathological RMS subtypes are: the prevalent embryonal (ERMS), the more aggressive alveolar (ARMS) and the rare adult variant pleomorphic RMS (PRMS). The association between genetic alterations in the *PAX3*, *PAX7* and *FOXO1A* genes and RMS tumorigenesis was well established, however, the entire spectrum of genetic changes underlying the development and progression of this neoplasm remains to be studied. Recently, we reported multiple novel genetic aberrations in a series of primary RMS tumors, including 2 ERMS, 7 ARMS and one PRMS (Goldstein, et al., Neoplasia 2006). Notably, the amplification of the *Fibroblast Growth Factor Receptor 1* (*FGFR1*) gene was detected in the PRMS tumor. We further investigated *FGFR1* involvement in RMS tumorigenesis by quantitative mRNA expression and methylation analyses, as well as mutation screening in the 10 primary RMS tumors and in 4 RMS cell-lines. *FGFR1* overexpression was detected in all primary RMS tumors and cell-lines tested. Using DHPLC and sequencing, activating mutations were ruled-out in the entire *FGFR1* coding sequence and exon-intron boundaries. However, hypomethylation of a CpG island upstream to *FGFR1* exon 1 was identified in the primary RMS tumors by the sodium bisulfite modification method, suggesting a molecular mechanism for *FGFR1* overexpression. Expression analysis of three additional genes, the cell survival regulator *AKT1*, *NOG* (*Noggin* homolog) and its antagonist *BMP4* (*bone morphogenetic protein 4*), which interact downstream to FGFR1, demonstrated significant expression differences between the primary RMS tumors and normal muscle. Thus, our data suggest that aberrant sustained or reactivated FGFR1 transduction signals in RMS cells may lead to deregulation of the downstream network and perturbation of the delicate equilibrium between proliferation and differentiation in skeletal myoblasts.

Prenatal detection of pure complete trisomy 1q: A case report. *N. Le Meur[1], S. Patrier[2], V. Ickowicz[3], A. Laquerriere[2], M. Trehin[1], E. Verspyck[4], P. Leboullenger[5], T. Frebourg[6], A. Rossi[1]* 1) Laboratory of Cytogenetics, EFS-Normandie, Bois-Guillaume, France; 2) Department of Pathology, University Hospital, Rouen, France; 3) Department of Radiopediatry, University Hospital, Rouen, France; 4) Department of Obstetrics, University Hospital, Rouen, France; 5) Department of Obstetrics, Mathilde Hospital, Rouen, France; 6) Department of Genetics, University Hospital, Rouen, France.

We report on cytogenetic, ultrasonographic, foetopathological and neuropathological description of a fetus with pure complete trisomy 1q. Prenatal chromosome analysis was performed because of intra-uterine growth restriction and showed, in a mosaic state, a translocation of the entire long arm of chromosome 1 on chromosome 22: 46,XX,der(22)t(1;22)(q12;q11)[5]/46,XX[32]. Subsequent ultrasound examination revealed craniofacial dysmorphism with low set malformed ears, hypertelorism and micrognathia and multiple congenital malformations including cerebral ventriculomegaly, vermis hypoplasia, and camptodactily. In agreement with the french law, the parents decided to terminate the pregnancy at 27 weeks of gestation. Autopsy confirmed sonographic findings and showed bilateral abnormal lung lobulation, an accessory spleen and asymmetric kidneys. Neuropathological examination displayed hypertrophy of ventricular septum, corpus callosum, olfactif bulbs and internal capsule. Cytogenetic analysis performed in lung, thymus, skin, liver, muscle and placenta confirmed the mosaicism. Only 9 cases of trisomy of the long arm of chromosome 1 have previously been reported. The fetus that we described shared therefore physical features with other reported cases but some phenotypic features had never been described (hypertrophy of ventricular septum, corpus callosum, olfactif bulbs and internal capsule). Trisomy 1q is obviously a very rare condition but the frequency of trisomy 1q mosaic may be underestimated. This case report highlights the importance to perform extensive cytogenetic analysis on different tissues from fetus or newborns with multiple congenital malformations when trisomy 1q phenotype is suspected.

Association of Eukaryotic Translation Initiation Factor 2-alpha Kinase 3(*EIF2AK3*/*PERK*) with Bone Mineral Density in the Old Order Amish. *N. Hoppman[1], E.A. Streeten[1], A.R. Shuldiner[1,2], J.R. O'Connell[1], B.D. Mitchell[1], D.J. McBride[1]* 1) University of Maryland School of Medicine, Baltimore, MD; 2) GRECC, Veterans Administration Medical Center, Baltimore, MD.

The Amish Family Osteoporosis Study (AFOS) was designed to identify genes influencing bone mineral density (BMD) in the Old Order Amish. Based on observations in humans and mice, we identified *EIF2AK3*, also known as *PERK*, as a candidate gene for osteoporosis. *PERK* spans approximately 71 kb of chromosome 2p12 and consists of 16 exons with 6 known splice patterns. The function of PERK is to phosphorylate the alpha subunit of eukaryotic translation-initiation factor 2, resulting in its inactivation and thus a rapid reduction of translation initiation and repression of global protein synthesis. Mutations in *PERK* have been shown to cause Wolcott-Rallison syndrome, a rare, autosomal recessive disorder characterized by permanent neonatal or early infancy insulin-dependent diabetes. These patients develop epiphyseal dysplasia, osteoporosis, and growth retardation at later ages. Additionally, *Perk* -/- mice display pancreatic and skeletal defects including deficient mineralization, osteoporosis, and abnormal compact bone development.

Sequence analysis of a subset of AFOS subjects (n=40) was used to identify *PERK* SNPs in this population. All 16 exons, including UTR and splice junctions, and approximately 5kb upstream of exon 1 were sequenced. Eleven SNPs were identified: 4 in the promoter, 3 nonsynonymous coding SNPs, 1 synonymous coding SNP, 1 intronic SNP and 2 just 3 to the gene. We genotyped all 4 promoter variants and 2 nonsynonymous coding variants in AFOS participants (n=900) and compared mean BMD by genotype to test for associations. All 6 polymorphisms were significantly associated with BMD of the forearm ($P < 0.001$), spine ($P < 0.01$), and/or hip ($P < 0.05$). In stratified analyses, some SNPs were significantly associated with BMD in both sexes separately (one promoter and both nonsynonymous SNPs) while the others were associated in only one sex. These findings suggest that sequence variation in *PERK* may influence BMD.

Balanced interchromosomal insertional translocation resulting in partial trisomy 3p in two brothers with mental retardation. *A.L. Mosca[1], N. Marle[1], C. Thauvin[2], P. Callier[1], L. Faivre[2], F. Mugneret[1]* 1) Laboratoire de cytogénétique, CHU le Bocage, Dijon, France; 2) Centre de Génétique, Hôpital d'Enfants, Dijon, France.

Interchromosomal insertional translocations are rare chromosomal rearrangements with an incidence of about 1:80,000. Most insertional translocations are familial with a maternal origine and lead to pure trisomy or monosomy. Balance carriers have a high risk of unbalanced offspring, theoretically up to 50%. Here, we report on 2 brothers with moderate mental retardation. The elder brother was 3.5 years old and presented with normal growth, minor dysmorphic features including long eyelashes, thin lips and a pointed chin and severe behavioural abnormalities. The younger brother was 2.5 years old and presented with high forehead, a pulmonary valve stenosis and speech difficulties. Familial history revealed mental retardation in two maternal cousins. High resolution chromosomal analysis performed in the both children showed the presence of extra material on the short arm of chromosome 6. FISH with a whole chromosome- specific paint for the chromosome 6 (Vysis) was normal and FISH analysis using the 3p ter probe showed two signals on both chromosome 3p homologs. CGH studies revealed that the additional material was of chromosome 3p. Parents karyotype showed an insertional translocation of the short arm of the chromosome 3 into the long arm of chromosome 6 in the father. The karyotype was defined as follows : 46,XY,ins(6;3)(p23;p25.3p26.1) while the children karyotype was: 46,XY,der(6)ins(6;3) (p23;p25.3p26.1). Further FISH studies using BACs and PACs of the 3p region are in progress in order to characterise the chromosomal breakpoints and the size of the trisomic region. This familial case is of interest in defining the phenotype of 3p25-26 pure trisomy.

Screening and testing using the same data set: A strategy for case/control genomewide association studies. *J. Lasky-Su[1,3], M. McQueen[2,3], N. Laird[3], C. Lange[3]* 1) Psychiatry, SUNY Upstate Medical University, Syracuse, NY; 2) University of Colorado, Boulder, CO; 3) Harvard School of Public Health, Boston, MA.

We propose a 2-stage testing strategy for case/control studies that applies the screening step and the testing step to the same data set. The screening step is constructed so that it is statistically independent of the association tests that are computed in the testing step. The most "promising" SNPs that are identified by the screening step can therefore be tested for association in the testing step without the need to adjust the significance level for the statistical analysis in the screening step. In simulation studies for 100k scans, we observe substantial power differences by several magnitudes between the proposed testing strategy and standard case/control testing methodology. The practical relevance of the approach is illustrated by an application to a genome-wide association studies in which SNPs are identified and reach genome-wide significance that would not have been detected by standard case/control testing methodology.

Microsatellite Instability in Chinese Epithelial Ovarian Carcinoma. *X.S. Liu[1], Y. Lu[1], N. Zhong[2,3]* 1) Dept. Gynecology, OBGYN Hospital, Shanghai, China; 2) Peking University Center of Medical Genetics; 3) New York State Institute for Basic Research.

Ovarian carcinoma (OC) is one of the most lethal cancers of women in China. About 90% of OC are epithelial ovarian tumors. The association of microsatellite instability (MSI) with several cancers has been shown to play a significant role in the development of cancers. However, The role and incidence of MSI in ovarian cancer are matters of great controversy. In some studies, MSI frequencies have ranged from 0 to 53% in sporadic ovarian cancers. These studies varied greatly in terms of the type and number of loci studied, the criteria used for defining MSI, and the histological subtypes of ovarian cancer analyzed. The role and incidence of MSI in epithelial ovarian tumor remains unknown. Our current study is to evaluate the frequency of MSI in epithelial ovarian tumors and its relationship with clinicopathologic features. Ninety fresh specimens of epithelial ovarian tumors (primary 74, secondary 16) were collected from our gynecology clinic of Medical Center of Fudan University from 2004 to 2005. Microsatellite analysis was carried out using 5 mono- and dinucleotide markers from the National Cancer Institute Consensus Panel by fluorescence-labeled polymerase chain reaction. Of the 90 epithelial ovarian tumors analyzed, 18 demonstrated a high level of MSI (MSI-H), 30 demonstrated a low level of MSI (MSI-L), and the remaining 42 exhibited microsatellite stability (MSS). Frequency of MSI at loci BAT-25 was higher than that at any other loci. No correlation was found between MSI level and patient age, tumor type, tumor differentiation ($P > 0.05$). But the microsatellite instability-high phenotype correlate with clinical stage, it tended to occur more frequently in early-stage tumors ($P = 0.03$). Our results indicate that there are frequent MSI in epithelial ovarian tumors. It is an early event and it is involved in the development of epithelial ovarian tumors.

Detection of large deletions and duplications in genomic DNA using a semi-quantitative multiplex PCR-based assay on capillary electrophoresis systems. *S. Karudapuram[1], S. Jankowski[2], M. Barrois[3], A. Miniere[3], A. Rico[2]* 1) Applied Biosystems, Foster City, CA; 2) Applied Biosystems France, 25 Avenue de la Baltique B.P.96, 91943 Courtaboeuf Cedex, France; 3) Laboratoire de Génétique, Institut Gustave Roussy, Villejuif, France.

Deletions and duplications in genomic DNA have been implicated as pathogenic mutations in many diseases. Traditionally, detection of these types of mutations is done using southern blot hybridization or fluorescence in situ hybridization, techniques which can be laborious, time-consuming and require high quantities of starting material. In this study we present a semi-quantitative multiplex PCR-based method that uses relative quantitation of fluorescently-labeled short fragments. Fragments from BRCA1, BRCA2, 9p21 and MMR (MSH2) regions were amplified using FAM-labeled primers from DNA that had been isolated from blood. Amplified samples were then run on an Applied Biosystems capillary electrophoresis platform and the data was analyzed in GeneMapper software. After normalization to a control amplicon, peak regions that had undergone deletions or duplications were identified using the GeneMapper software v4.0 report manager feature and verified using the dye scale functionality. Our results will highlight an easy to use, optimal system that can be used for both small and large scale studies.

Assessment of specimen storage and DNA integrity for optimal aCGH results. *H.A. Marble, M. Lucas, T. Perez, M. Ziegler, K. Wilber, E. Pestova* Abbott Molecular, Inc., Des Plaines, IL.

Array Comparative Genomic Hybridization (aCGH) is a multiplex molecular technique that detects chromosomal gains and losses, as well as high-resolution genomic disparities such as microdeletions and microduplications, across the entire genome by measuring differences in DNA copy number of a test sample relative to a normal reference standard. In this study, we describe limitations of aCGH imposed by the test specimen quality, demonstrate the effect of DNA integrity on aCGH performance, and show the importance of standardized quantitative software algorithms in evaluating the reliability of aCGH results. We assessed performance of DNA from cell lines, blood, and archived peripheral blood lymphocytes on a BAC array of 333 clones, printed in triplicate, using an image quality assessment software algorithm, Overall Quality Rating (OQR), that rejects suboptimal array results based on an experimentally selected quality measure cutoff. In a set of 200 hybridizations, the distribution of OQR scores varied dramatically depending on the DNA source. Archived blood lymphocyte DNA exhibited the greatest performance variability (10-20% failure rate). In these specimens, we showed the dependency between test DNA size distribution (fragmentation below 9 KB) and poor aCGH results. Furthermore, we proved that the integrity of DNA purified from blood lymphocytes fixed in Carnoys reagent was affected by specimen storage conditions. Fresh whole blood specimens afforded the least variability in aCGH assays (failure rate 6%). However, regardless of the type of collection/storage vessel, 3-week blood storage resulted in deterioration and low DNA yields, leading to suboptimal aCGH performance. The effect of DNA integrity on aCGH was further confirmed by artificial enzymatic degradation of test DNA. In these experiments, we observed a strong linear correlation between the DNA size distribution and OQR scores. Finally, we demonstrated the feasibility of modifying aCGH assay conditions to recover suboptimal-quality specimens for aCGH analysis. Together, these results provide guidelines for specimen storage and DNA sample integrity assessment to achieve reliable aCGH results.

Preconceptional or prenatal Fragile X screening. Experience of 14 years in a Belgian Center for Human Genetics. *P. Hilbert, S. Boulanger, L. Van Maldergem, Y. Gillerot, Ch. Verellen-Dumoulin* Centre de Genetique Humaine, Institut de Pathologie et de Genetique, Loverval, Belgium.

Fragile X syndrome is one of the most frequent cause of inherited mental retardation. The high frequency of this disease seems to justify the prenatal or preconceptional screening of women but the question raised is controversial. We present here the results of 14 years of premutation screening in a Belgian Center for Human Genetics. Prenatal or preconceptional screening was performed on request of clinicians, mainly geneticists and gynaecologists, for women with no known family history of fragile X syndrome. On a total of 8043 women, a full mutation was found in a patient and a premutation in 34 patients (1/237). The cut-off for premutation was set at 59 repeats which seems to be the smallest repeat who ever amplified to a full mutation in one generation With the frequently used premutation threshold of 55 repeats, we obtain a premutation frequency of 1/149. The availability of a prenatal diagnosis was offered to all the premutated women. On a total of 36 foetus from 23 different women, the premutated allele was transmitted 16 times. In 11 cases, mothers had expansion below 70 repeats and the inherited premutation in the foetus ranged from -3 to +12 repeats compared to the mothers premutation. In 5 cases, the mothers expansion was over 70 repeats. In 4 males, the transmission resulted in 3 full mutations and 1 mosaïcism for full mutation and premutation and , in one female, in an unmethylated expansion of about 200 repeats. Pregnancy was terminated in the 4 affected males. This confirms that alleles over 70 repeats are at high risk of expansion to full mutations when transmitted. Such alleles concerned 15 of the 34 premutated women which means 1/536 women of an unselected population. Based on theses results, we suggest that either preconceptional or prenatal screening is to be recommended to women in childbearing age.

Single nucleotide polymorphism-comparative genomic hybridization (SNP-CGH) of PBMC and buccal DNA from B-CLL subjects using the Illumina Human -1 SNP Genotyping BeadChip. *A. Lee[1], N. Chiorazzi[1], K. Rai[2], A. Liew[1], P. Gregersen[1]* 1) Dept Genomics & Human Genetics,The Feinstein Institute for Medical Research, Manhasset, NY; 2) Dept Hematology/Oncology Long Island Jewish Hospital, New Hyde Park, NY.

B-cell chronic lymphocytic leukemia (B-CLL) accounts for 30% of all leukemias in Western countries and is characterized by the clonal proliferation and accumulation of neoplastic B lymphocytes, which can account for more than 90% of total PBMCs in some patients. Chromosomal changes are common and have some prognostic value in disease outcome. Deletion of 13q14 is more often associated with indolent/benign B-CLL while trisomy 12 and deletions of 17p and 11q22-23 are associated with aggressive disease. The aim of this study was to compare and contrast PBMC and buccal DNA from the same subjects in order to distinguish somatic from germline genetic variation. To accomplish this we performed single nucleotide polymorphism-comparative genomic hybridization (SNP-CGH) on PBMC and buccal DNA using the Illumina 109K SNP Human-1 beadchip. This whole genome genotyping assay allows for the high resolution of chromosomal changes in DNA copy number, allelic imbalance/loss of heterozygousity (LOH) and other chromosomal aberrations. The SNP-CGH analysis was concordant with FISH data available for 4 PMBC B-CLL samples. In addition, several other chromosomal aberrations were observed throughout the genome that were not detected by the B-CLL FISH panel. Consistent with the somatic origin of these changes, these chromosomal aberrations were observed in PBMC DNA, but were not present in the buccal samples. Thus, SNP-CGH appears to be a more sensitive method of detecting somatic genetic changes in B-CLL. Furthermore, these results emphasize that linkage or association studies of B-CLL may be confounded by the use of DNA derived from PBMCs, and buccal DNA may be more appropriate for studying the effect of germline polymorphisms in disease susceptibility.

Influence of MTHFR genotype on the teratogenic effects of antiepileptic drugs. *U. Kini[1], R. Lee[3], A. Jones[3], S. Ramsden[3], A. Fryer[4], J. Clayton-Smith[2]* 1) Dept of Clinical Genetics, Churchill Hospital, Oxford, United Kingdom; 2) Regional Genetics Service, St. Mary's Hospital, Manchester; 3) Regional Molecular Genetics Service, St.Mary's Hospital, Manchester; 4) Dept. of Clinical Genetics, Alder Hey Children's Hospital, Liverpool.

Antiepileptic drug(AED) therapy in pregnancy has an additive effect on the physiological reduction in folate levels. This may be further enhanced by the presence of the common C677T polymorphism in the MTHFR (methylenetetrahydrofolate reductase) gene which lowers the activity of the MTHFR enzyme. Folate deficiency has been linked to birth defects eg. neural tube defects,seen frequently with exposure to AEDs such as valproate and carbamazepine. Aim: To examine the influence of the maternal and childs MTHFR genotype on the rate of major malformations (MM) and developmental delay (DD) in children with AED exposure. Methods:Between January 2000-August 2004,in a prospective, population-based study women on AED treatment (cases) and matched control mothers (without epilepsy)were recruited from antenatal clinics. Buccal cells from the mother and child were screened for the C677T variant by PCR. Children were examined for MM, as defined by EUROCAT criteria and DD was assessed using the Griffiths Test. Fishers exact test was used to analyse the statistical significance of the results. Results: We studied a total of 343 mothers -128 cases (102 on monotherapy and 26 on polytherapy) and 215 controls.6.1% (4/66) of case mothers with C677T variant had children with MM compared to 1.9% (2/107) controls(p=0.262).11.8% (2/17) of TT homozygote case mothers had a child with MM (both exposed to valproate) compared to 0% in controls (p=0.56).The rate of MM was found to be similar between the wild type cases(4.4% or 2/45) and controls(4.8% or 4/84)(p=1.000). There was no correlation between the maternal or childs MTHFR genotype with DD at the age of 2 years or between the child's MTHFR genotype and the rate of MM. Conclusion: Although these results do not reach statistical significance due to small sample size, they show a trend for increased risk of MM in children of case mothers who are C677T heterozygotes or TT homozygotes.

Managing gene-specific information at NCBI. *D.R. Maglott* NCBI, National Institutes of Health (NIH;NLM), Bethesda, MD.

The Entrez Gene database at the National Center for Biotechnology Information (NCBI) represents the result of identifying, annotating, and integrating information about genes from an increasing number of key genomes. The data flow includes close coordination with NCBI's Reference Sequence group (RefSeq), model organism databases and nomenclature committees, and multiple annotation projects. The GeneID assigned to each gene, and the sequences used to define that gene, provide a standard for communication about genes among databases within and external to NCBI.

This presentation will summarize key aspects of the dataflow used by Entrez Gene and other databases within NCBI that manage gene-specific information, such as GEO, HomoloGene, Map Viewer, OMIM, and UniGene. Recent efforts to improve the scope of and access to the data will be reviewed. Highlights will include web interfaces for multiple NCBI databases, genomic gene-specific RefSeqs, and reports from Gene and Map Viewer. Methods to review sequence and functional annotation, including phenotype, will be emphasized.

Compound heterozygous mutations in *LMNA* cause MADA phenotype. *F. Lombardi[1], F. Gullotta[1], C. Catalli[1], V. Brugiati[1], S. Considera[1], A.M. Nardone[1], E. Grosso[2], G. Lattanzi[3], N.M. Maraldi[3], M.R. D'Apice[1], G. Novelli[1]* 1) Dept. of Biopatology Diagnostic Imaging, University of Rome "Tor Vergata" Roma, Italy; 2) Laboratory of Medical Genetics, A.O. S.G Battista Torino, Italy; 3) Laboratory of Cell Biology, Istituti Ortopedici Rizzoli, Bologna, Italy.

Mandibuloacral dysplasia type A [MADA; OMIM # 248370] is a phenotypically heterogeneous, rare autosomal recessive disorder. Almost all MADA patients carry the same homozygous missense mutation (R527H) in C-terminal tail domain of *LMNA* gene, encoding lamin A/C, an intermediate filament component of the nuclear envelope. We report a 27-yr-old Italian girl with MADA clinical features. The patient shows hypoplastic mandible (micrognathia), acro-osteolysis of the finger distal phalanges, pointed nose, generalized loss of subcutaneous fat, acrogeric features. She also presents muscular hypotrophy and generalized hypotonia. We examined the *LMNA* gene, identifying a compound heterozygous with the classical R527H mutation and the rare V440M allele in exon 7, previously detected in a patient with a Dunnigan-type partial lipodystrophy (FPLD). In order to investigate the effects of these mutations on the nuclear architecture, usually affected in MADA fibroblasts, we examined the nucleus morphology and the distribution pattern of the nuclear lamina proteins lamin A and lamin C and the unprocessed toxic precursor pre-lamina A protein. Lamins A and C resulted not strongly altered in their expression and localization, but a percentage of nuclei showed accumulation of pre-lamin A in the nuclear envelope, associated with formation of intranuclear pre-lamin A-labeled structures. These results shows a MADA-like cellular phenotype suggesting that the R527H in compound heterozigosity state with V440M behaves as dominant mutation.

Variants in the 3'UTRs of different isoforms of the *NTRK3* candidate gene for panic disorder. *M. Muiños-Gimeno[1], M. Gratacòs[1], R. Martín-Santos[2], ML. Ímaz[2], M. Torrens[2], X. Estivill[1,3], Y. Espinosa-Parrilla[1]* 1) Genes and Disease Program, Center for Genomic Regulation, Barcelona; 2) Psychiatry Department, Hospital Mar & Pharmacology Research Unit, IMIM, Barcelona; 3) Department of Health and Life Sciences, Pompeu Fabra University, Barcelona, Catalunya, Spain.

Neurotrophins and their receptors have been implicated in the common pathophysiology of depression and anxiety and in the therapeutic action of some antidepressant drugs. Due to its involvement in synaptic transmission, survival and differentiation of neurons and in neuronal plasticity, the neurotrophin-3 receptor gene (*NTRK3*) is a good candidate for these psychiatric disorders. The *NTRK3 loci* encode a variety of isoforms, including the full-length (FL) receptor and a truncated kinase-deficient form (TF) with a different and longer 3UTR. Recently, and in contrast to previous hypothesis, it has been shown that these two isoforms are able to activate different pathways. Moreover, levels of mRNA and protein of the different *NTRK3* isoforms are discordant during human lifespan suggesting that factors other than direct transcriptional control may contribute to their regulation. We suggest that 3UTRs of *NTRK3* isoforms may be involved in the genetic susceptibility to psychiatric disease, particularly anxiety and depression. 3UTRs are important for post-transcriptional regulation mechanisms involving polyadenilation or miRNAs silencing. Therefore, according to their conservation in evolution and the presence of putative miRNA target sites, we have re-sequenced the 3UTRs of the TF (3kb) and FL (2kb) of *NTRK3*. Re-sequencing was performed in 62 chromosomes of patients with panic disorder with/without major depression. We have identified 3 previously known SNPs (MAF>0.4 for all of them), and 6 new sequence variants (3 with MAF>0.1) in the TF. A known SNP (MAF= 0.45) and a new sequence variant (MAF=0.02) were identified in the FL. Case-control studies are being performed in a group of 261 patients and 340 controls. Finally, the possibility that these variants disrupt the sites of regulation by miRNAs has been analyzed by the use of *in silico* approaches. Supported by the Spanish Government (SAF2005-01005; FI05/00061; G03/184).

Enhancement of SMN2 gene expression by the DNA demethylating agent 5-aza-2'-deoxycytidine. *E. Hahnen, J. Hauke, B. Wirth* Institute of Human Genetics, Institute of Genetics and Center for Molecular Medicine Cologne (CMMC), University of Cologne, Germany.

Spinal muscular atrophy (SMA) is an autosomal recessively inherited neuromuscular disorder. The disease determining survival motor neuron gene 1 (SMN1) is homozygously deleted or mutated in approximately 97 % of all SMA patients. Within the SMA region (5q13), the SMN genes exist in two almost identical copies, SMN1 and SMN2, which are ubiquitously expressed and encode identical proteins. Since all SMA patients lacking SMN1 carry at least one SMN2 copy, transcriptional activation of the SMN2 gene is likely to be clinically beneficial. We and others have shown that histone deacetylase (HDAC) inhibitors such as valproic acid (Brichta et al., 2003) and the highly potent second generation HDAC inhibitors SAHA and M344 (Hahnen et al., 2006; Riessland et al., 2006) increase SMN2 expression levels in fibroblast cell lines derived from SMA patients as well as in several neuroectodermal tissues, including rat and human hippocampal brain slice cultures and motoneuron-rich cell fractions. Here we report for the first time that the DNA demethylating agent 5-aza-2'-deoxycytidine (5-Aza) increases SMN2 transcript- and protein levels in SMN1-deleted fibroblasts. This finding indicates that both, histone acetylation and DNA methylation, regulate SMN2 gene activity. SMN2 promoter analyses indicated that the human SMN2 gene contains 4 putative CpG islands (CpG1-4). Bisulfite treatment of DNA derived from SMN1-deleted fibroblasts followed by methylation-specific PCR, cloning of PCR products and sequencing revealed methylation of specific cytosine residues within and adjacent to the predicted SMN2 CpG-1, CpG-2 and CpG-4, while CpG-3 appears to be not methylated. The SMN2 methylation patterns were subsequently analyzed using DNA isolated from blood samples of 10 type I SMA patients. In each case we found almost identical SMN2 methylation patterns, while the analyses of other tissues are in progress. These results improve the understanding of how expression of the SMN2 gene is regulated and may contribute to the development of a treatment of SMA.

Simultaneous detection of changes in copy number and CpG methylation of the differentially imprinted chromosome 11p15 BWS locus using Methylation-specific MLPA (MS-MLPA). *A.O.H. Nygren[1,2], B. Baskin[3], R.R.T. Brekelmans[2], D.J.G. Mackay[4], J.P. Schouten[2]* 1) DNA Diagnostics Lab, Free University Medical Center, Amsterdam, Netherlands; 2) MRC-Holland bv, Amsterdam, Netherlands; 3) The Hospital for Sick Children, Toronto, Canada; 4) Wessex Regional Genetics Labs, Salisbury District Hospital, Salisbury United Kingdom.

Beckwith-Wiedemann Syndrome (BWS) is a clinically heterogeneous overgrowth syndrome associated with an increased risk for embryonal tumor development. This condition is either caused by a genetic or an epigenetic alteration within two domains of imprinted growth regulatory genes on human chromosome 11p15 leading to dysregulation of the expression of the imprinted genes within this region. The incidence of BWS is estimated to be approximately 1 in 15000 and around 85% of the cases are sporadic. 60-70% of these have imprinting abnormalities at one of two imprinted domains H19DMR or KvDMR. Other causes of BWS are Uniparental disomy (UPD)(20%), maternally inherited translocations (1%), trisomy with paternal duplication (1%), mutations in the CDKN1C gene (10%) as well as small deletions. We have developed a novel application of Methylation-Specific MLPA (MS-MLPA) capable of detecting most causes of BWS, including UPD, in a single reaction. Besides, this MS-MLPA assay can distinguish H19DMR and KvDMR methylation defects. The MS-MLPA assay was validated on DNA samples from BWS patients and identified methylation defects as well as chromosome 11p15 duplications. Apart from generating next day results of both copy numbers and methylation status using only 20ng of DNA, the MS-MLPA assay for BWS might also be a great aid in the screening of childhood cancers, in particular Wilms tumor. A strong linkage between methylation of the H19DMR locus, but not KvDMR, has been described in these patients resulting in biallelic expression of the IGF2 gene.

Fatal form of KID syndrome. *S. Hadj-Rabia[1], D. Hamel-Teillac[1], C. Parsy[1], C. Thibaud[2], L. Jonard[3], M. Levêque[3], D. Feldmann[3]* 1) Service de dermatologie Hôpital Necker, Paris, France; 2) Service de gynécologie Centre Hospitalier Intercomunnal, Créteil, France; 3) Laboratoire de Biochimie et Biologie Moléculaire, Hôpital A Trousseau, AP-HP Hôpital Trousseau, Paris, France.

Keratitis-ichtyosis-deafness syndrome (KID) is a rare ectodermal dysplasia caracterized by vascularizing keratitis, profound sensorineural hearing loss (SNHL) and progressive erythrokeratoderma. Dominant mutations in the connexin 26 gene GJB2 cause KID syndrome. Most of the patients bared the D50N mutation. Recently, a de novo mutation, G45E, have been described in a fatal form of the disease. The G45E mutation has not been previously reported in Caucasian patients, however it is the third most common GJB2 mutation in Japanese patients with autosomal recessive nonsyndromic hearing loss. Different modes of action of G45E depending on genetic background have been suspected. We described a new family from Africa with twins affected by a fatal form of KID syndrome and a G45E de novo mutation. G,3 month old boy, had pachyderma and erythroderma, palmoplantar keratoderma, complete atrichia, dystrophic nails, congenital absence of foreskin, hyperplasic vocal cord hyperplasia. Ophthalmologic examination and immunity exploration were normal.Several episodes of uncontrolled septicaemia lead to death at 5 months. His brother, with the same phenotype, died at 1 month. Molecular analysis of GJB2 revealed an heterozygous transition 134G-A causing an exange of glycine 45 by glutamic acid in the twins only. In order to search for other genetic variation that could modify the phenotype, analysis of mitochondrial DNA and of the CX 30 gene GJB6 was performed. The mtDNA sequence differed from the revised Cambridge reference sequence by 67 variations including 3308T-C and 5655T-C. The patients mtDNA sequence belongs to African haplogroup L1b. But no deleterious variation could be observed. Sequencing of GJB6 gene in the patients showed an heterozygous transition 15G-A that do not change the aminoacid threonine 5. However 15G-A is a silent variation, it is possible that this rare variation could influence the expression level of CX30 and increase the potentially effect of mutant CX26 on the function of CX30.

Genetic liability to schizophrenia in Oceanic Palau: a search in the affected and maternal generation. *L. Klei[1], B. Devlin[2], J. Tiobech[3], C. Otto[3], M. Myles-Worsley[4], W. Byerley[5], K. Roeder[6]* 1) Computational Genetics Program, Dept of Psychiatry, UPMC, Pittsburgh, PA; 2) Dept. of Psychiatry, Univ. of Pittsburgh SOM, Pittsburgh, PA; 3) Belau National Hospital, Korror, Palau; 4) SUNY Upstate Medical Center, Syracuse, NY; 5) Dept. of Psychiatry, UCSF, San Francisco, CA; 6) Dept. of Statistics, Carnegie Mellon Univ., Pittsburgh, PA.

We postulate a two-hit model for Schizophrenia (Scz), in which initial liability is generated during fetal development. We hypothesize this hit to the developing fetal brain is precipitated by environmental stressors interacting with maternal genetic vulnerability to stress. The second hit occurs perinatally, again due to genetic vulnerability. To evaluate the putative genetic vulnerability, we search in the genome of affected individuals and their mothers for variation that differs from that in the general population. We used a sample from the Palauan population that contained 175 individuals who were diagnosed with Scz, broadly defined. DNA was available from these affected individuals, 87 of their mothers and 45 of their fathers; for analyses of parents, mothers were treated as affected, not offspring, and fathers were treated as controls. Pedigree and diagnostic data were available on 2953 living and deceased subjects, most clustering into one pedigree. DNA from 553 individuals was genotyped for STRs spaced every 10 cM across the genome. We tested for association between affection status and STR alleles, which was reasonable, despite the widely-spaced markers, because the population has far-ranging linkage disequilibrium. Results were consistent with the hypothesis of maternal genetic liability. For a recessive model and a test for excess allele matching across mothers, significant findings occurred for D20S481, D10S1221, D6S1021, D13S317, and D18S976. Other noteworthy results occur for D9S1118, D2S1356, D13S325, and D17S1290. Regions with two adjacent markers with substantial statistics include 2p12-11.2, 2q24.1-32.1, 6q12-14.1, 10q23.2-24.21, 12q23.2-24.21 and 17q23.2-23.3. Results for the truly affected individuals were modest. The strongest association occurs for D2S434, at 2q35.

SNP Regulation of LDLR Splicing Efficiency. *I.F. Ling, H.M. Tucker, S. Estus* Department of Physiology, University of Kentucky, Lexington, KY.

Low density lipoprotein receptor (LDLR) is critical to cholesterol homeostasis. We have identified a single-nucleotide polymorphism (SNP) that decreases the splicing efficiency of exon 12. The exon 12 deleted mRNA is predicted to produce a soluble form of LDLR. However, the mechanism whereby this SNP regulates splicing is unclear. We utilized a NucleofectorTM kit to co-transfect HepG2 cells with an LDLR mini-gene and several SR protein splicing factors. Twenty-four hours later, we purified the resulting mRNA and performed RT-PCR to evaluate the splicing efficiency of exogenous LDLR. We found that overexpression of SRp40 appeared to rescue the decreased splicing efficiency due to the SNP. In contrast, SC35 further exacerbated the splicing inefficiency. We interpret these results as implying that the splicing regulation of LDLR exon 12 is complex and the SNP modulates a functional exonic splicing enhancer (ESE) for SRp40. Therefore, we will mutate several nucleotides in LDLR exon 12 to define the functional ESE and investigate interactions between the ESE and splicing factors.

Integration of imaging and genetics: an analytical strategy to perform genome-wide studies for Imaging Genetic Phenotypes (IGPs). *F. Macciardi[1], J. Turner[2], L. Friedman[2], H. Stern[3], J. Fallon[2], S. Potkin[2]* 1) Dept. of Science and Biomedical Tehcnology, Univ of Milano, Milano, Italy; 2) Brain Imaging Center Dept. of Psychiatry and Human Behavior University of California Irvine; 3) Dept. of Statistics University of California Irvine.

Our goal is to develop novel approaches that address the interplay of imaging and genetics, within the context of a specific disease. Key to our approach is a general linear model (GLM) analysis of a quantitative imaging phenotype. The model can accommodate a range of factors expecting to affect the observed imaging activation (e.g., ethnicity, behavior/performance): in the most basic form, the GLM is: Imaging Phenotype = Overall Mean + Genotype Effect + Diagnosis Effect + Genotype-Diagnosis Interaction Effect To perform a genome-wide analysis with 500,000+ SNPs, we developed a method building on the work of Satagopan et al. (2004) and modifying their approach to use the GLM summary test statistic on imaging phenotypes instead of traditional test statistics comparing allele frequencies across diagnostic groups. Our approach is to assume that a set T of the 500,000+ SNPs are loci with true genotype-diagnosis interaction effects on the imaging phenotype. The goal is to identify a subset t of these T true disease-related loci using the loci corresponding to the highest t test-statistics. Note that the value of t is determined by considerations of power. The power of the statistical strategy is defined as the probability that the t highest test statistics correspond to t out of the T true disease (and imaging) related loci. This power can be calculated by simulation as a function of sample size, T and t, the minor allele frequencies in the patient and control groups and the interaction effect size.

Hutchinson-Gilford Progeria Syndrome (HGPS): Consistency of phenotype in 15 children. *W.J. Introne[1], M.A. Merideth[1], L.B. Gordon[2], M.B. Perry[3], M. Turner[4], S. Clauss[5], V. Sachdev[6], J. Graf[3], A.C.M. Smith[1], L.H. Gerber[7], J.C. Reynolds[3], J.A. Yanovski[8], R. Cannon[6], W.A. Gahl[1]* 1) NHGRI, NIH, Bethesda, MD; 2) Brown University, Providence, RI; 3) Clinical Center, NIH, Bethesda, MD; 4) NCI, NIH, Bethesda, MD; 5) CNMC, Washington, DC; 6) NHLBI, NIH, Bethesda, MD; 7) GMU, Fairfax, VA; 8) NICHD, NIH, Bethesda, MD.

HGPS, an extremely rare disorder (1/4-8 million), is considered a segmental premature aging syndrome. It is a sporadic autosomal dominant disease uniformly fatal at an average age of 13 y. Cardiovascular disease causes most of the morbidity and mortality, but the disease is multisystemic. Affected children generally lack clinical findings at birth, but progressively manifest stunningly consistent features. In 1972, DeBusk described the clinical features of HGPS, but no comprehensive evaluation of the clinical course has been performed. In February 2005, we initiated a natural history protocol at the NIH to document the clinical progression of HGPS. We have evaluated 15 children, ages 1 to 16 y. Sclerodermatous dermatologic changes, one of the first findings noted by parents, occurred in 14/15 children before 1 y of age. Resting echocardiograms were normal in 13/15 children. All 15 children had radiographic findings of clavicular blunting, acroosteolysis, and coxa valga. Joint involvement, with contractures, was present in all 15 children, but the pattern and extent of joint involvement was highly individualized. Mean hip flexion was 101.5 $\pm$ 17 degrees (nl 120), mean ankle total range of motion (ROM) was 36 $\pm$ 20 degrees (nl 70), and mean knee total ROM was 101.5 $\pm$ 28 degrees (nl 135). Percent body fat as measured by DXA showed a linear decrease with increasing age. Children under age 2 y had, on average, 24% body fat, but by 10 y, the average was 10% body fat. Z-scores of bone density were uniformly low, ranging from -1.5 to -6.6. Insulin resistance was seen in 6 of 13 children studied. The phenotypic presentation of children with HGPS is remarkably constant and involves multiple organ systems. Longitudinal studies will elucidate the disease progression and provide objective clinical markers to monitor the efficacy of potential treatments.

Morphological abnormalities of the mitochondrial network in fibroblasts of patients affected with autosomal dominant and recessive optic neuropathies. *N. Kadhom, S. Gerber, F. Barbet, A. Munnich, J. Kaplan, J.M. Rozet*
Genetics, INSERM U781, Paris, France.

Inherited non syndromic optic atrophy (OPA) are frequently inherited as an autosomal dominant trait. The most common of these autosomal dominant disorders are related to mutations in the OPA1 gene on chromosome 3q28. On the other hand, a second probably uncommon locus was reported on chromosome 18q12 (OPA4) and we recently mapped a third OPA locus (OPA5) on chromosome 22q12.3. Besides, autosomal recessive non syndromic OPA are very rare. Until now, only one locus has been reported on chromosome 8q23 (ROA1). Fibroblasts of patients related to OPA1 (n=1), OPA5 (n = 2) and ROA1 (n=2) have been labelled using MitoTracker Red CMXRos dye, a fluorescent mitochondrial marker that binds free sulfhydryls within the cells. Fibroblasts of age-matched controls were studied at the same time for each genetic subtype. Morphological abnormalities of the mitochondrial network were observed in the five patients compared to the respective controls. The cellular distribution of mitochondria in fibroblasts of patients related to OPA5 (n=2) and OPA1 (n=1) was superimposable: the labelling of the MitoTracker Red CMXRos dye appeared fragmented and highly concentrated around the nucleus of cells (ring-like aspect). Interestingly, the distribution of mitochondria in the fibroblasts of the two patients related to ROA1 was also superimposable but clearly different from that of patients related to dominant optic atrophies. The labelling of the MitoTracker Red CMXRos dye was highly heterogeneous and testified a fragmentation of the mitochondrial network but no nuclear ring-like aspect was noted. In conclusion, this study suggests that a selective vulnerability of the optic nerve to perturbations in mitochondrial function may underlie a final common pathway in all inherited optic atrophies. These findings provide a rationale in order to select candidate genes as genes encoding proteins with high mitochondrial targeting probability for both the OPA5 and ROA1 loci.

Array-CGH further defines constitutional supernumerary marker chromosomes (SMCs). *C.M. Higgins, D.L. Pickering, M. Wiggins, D. Zaleski, A.H. Olney, G.B. Schaefer, B.J. Dave, W.G. Sanger* Munroe Meyer Institute, Omaha, NE.

Microarray comparative genomic hybridization (aCGH) technology in the clinical cytogenetics laboratory not only allows for rapid and efficient characterization of supernumerary marker chromosomes but also detects the specific chromosomal region that defines the marker chromosome. This facilitates the precise identification of the abnormality which in turn helps genotype/phenotype correlation. We present two cases of males less than 2 months of age who were referred for cytogenetic studies. Karyotypic analysis revealed 47,XY,+mar in both cases. Case 1 was a 7 week male with large hands and feet and was greater than the 95th percentile for height and weight. He had thin, deep-set nails, retromicrognathia, downslanting palpebral fissures, a long philtrum and an umbilical hernia. Case 2 was a 2 week male with complex congenital heart disease, dysmorphic facial features and renal failure. Whole chromosome paint and centromere FISH studies determined that the origin of the SMCs were chromosome 5 (case 1) and chromosome 10 (case 2). Microarray studies utilizing the Spectral Chip 2600 further characterized the SMCs at 1MB resolution. In case 1, aCGH analysis identified a duplication of seven clones in the region of 5p13.3-5p13.1. The duplicated region did not include the most proximal bands of 5p and consequently was interpreted as a complex ring chromosome: arr cgh 5p13.3p13.1(RP11-5N11=>CTD-2142G21)x3. In case 2, aCGH detected a copy number gain of 4 clones in the proximal short arm of chromosome 10 indicating a duplication of 10p11.2-10p11.1. The nomenclature for this finding is as follows: arr cgh 10p11.2p11.1(RP11-174P15=>RP11-393J16)x3. SMCs result in isolated partial trisomies of the involved chromosome segment and may provide an opportunity to evaluate the clinical effects exclusive to the duplicated segment. These cases illustrate the importance of aCGH which, when used in conjunction with classical cytogenetics and FISH studies, helps to accurately define the specific chromosomal segments involved. This information is valuable in the management of patients presenting with SMCs.

Independent family study confirms an association between gap junction alpha 8 gene (GJA8) on chromosome 1q21 and schizophrenia. *X. Ni[1], J. Valente[2], M. Azevedo[2], M. Pato[3], C. Pato[3], J. Kennedy[1]* 1) Neurogenetics Section, Ctr Addiction & Mental Health, Toronto, ON, Canada; 2) Department of Psychiatry, University of Coimbra, Portugal; 3) Veterans Administration Hospital, Washington, D.C., USA.

Gap junction, called electrical synapse, permits the direct intercellular exchange of ions and molecules including glutamate and second messengers, and plays important roles in the central nervous system. Recently, we genotyped four polymorphisms in the GJA8 gene, rs989192, rs4950495, rs3766503 and rs1532399, in 220 DSM-IV schizophrenia patients and 220 matched (sex, age and ethnicity) healthy controls, collected from Toronto and Central Canada. A strong association between GJA8 haplotype, especially based on the first two markers, and schizophrenia (LRS=33.13, df=3, p=0.0000003) was found. To confirm this dramatic finding we studied an independent Portuguese families, 163 trios and small families with DSM-IV schizophrenia probands. Two polymorphic markers, rs989192 and rs4950495, were genotyped and the program TDTPHASE in the UNPHASE (v2.404) was used for individual marker and haplotype analyses. The G allele of rs989192 (T:UT=61:36.5, LRS=4.9, p=0.027) and the T allele of rs4950495 (T:UT=73:43.8, LRS=5.95, p=0.015) transmitted much often than the opposite alleles. G-T haplotype also showed a significant association with schizophrenia (T:UT=57.97:33.74, X2=5.07, p=0.024). These results replicate our previous finding in Toronto cases and matched controls, and indicate that the GJA8 gene may play a role in the genetic susceptibility to schizophrenia. Due to rs989192 and rs4950495 are both in the intron, we searched for polymorphic markers in the coding and promoter regions in the GJA8 gene in public SNP databases, and found only one, rs7536277, in the promoter region. Unfortunately, we did not detect any variant of rs7536277 in our samples. To screen and identify functional variants in GJA8 gene is warranted. This project is supported by the Young Investigator Award of NARSAD (X.N.).

The association of GABA related genes with autism. *D.Q. Ma[1], A.L. Collins[1], P.L. Whitehead[1], E. Martin[1], R.K. Abramson[2], H.H. Wright[2], J.P. Hussman[3], J.L. Haines[4], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) University of South Carolina School of Medicine, Columbia, SC; 3) The Hussman Foundation, Ellicott City, MD; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

GABA and gabaergic pathways are the major neural inhibitory system in human brain. It is considered one of the most important neurotransmitters and developmental signals and may relate to onset of autism and related developmental disorders. Our previous studies have confirmed association of the $GABA_A$ receptor (GABRA) subunit genes with autism and the interaction of GABRA4 with GABRB1 as contributing to increased autism risk. To test the possibility of a more general role for gabaergic pathways in autism, we examined 13 additional GABA related genes. An average 4-5 SNPs from different LD blocks within each gene were analyzed in 470 Caucasian autistic families using the family-based pedigree disequilibrium test (PDT) for allelic and genotypic association analysis and using extended multifactor dimensionality reduction (EMDR) for gene-gene interaction analysis. The only nominally significant associations were found at rs1054899 (PDT: p=0.037) on chromosome 6 within the ALDH5A1 gene; RS499368 (geno-PDT: p=0.036) on chromosome 12 within the SLC6A12 gene and RS1640989 (PDT: p=0.039) on chromosome 16 within the ABAT gene. Surprisingly, EMDR analysis did not identify any significant interactions among these markers as well between the previously reported GABRA4 and GABRB1 genes. These results do not suggest a major role for these GABA related genes in autism risk.

Genome-wide association analyses for Metabolic Syndrome on the Micronesian island of Kosrae. *J.K. Lowe[1,2,3], I. Pe'er[2,3], J. Salit[1], M.L. Blundell[1], M.L. Sullivan[1], H.E. Lee[1], R. Tewhey[2], A. Havens[1], W. Ji[5], J.-N. Foo[5], L. Garcia[1], P.E. Bonnen[1], N.P. Burtt[2], K.W. Jones[4], R.P. Lifton[5,7], J.L. Breslow[1], M.J. Daly[2,3,6], J.M. Friedman[1,7], D.M. Altshuler[2,3,6], M. Stoffel[1]* 1) The Rockefeller University, New York, NY; 2) The Broad Institute of MIT and Harvard, Cambridge, MA; 3) Massachusetts General Hopsital, Boston, MA; 4) Affymetrix, Inc., Santa Clara, CA; 5) Yale University School of Medicine, New Haven, CT; 6) Harvard Medical School, Boston, MA; 7) Howard Hughes Medical Institute.

The island of Kosrae in the Federated States of Micronesia was founded ~2000 years ago by Polynesians. Geographic isolation and multiple population bottlenecks reduced genetic diversity on Kosrae, producing an order of magnitude more extensive linkage disequilibrium in this population compared to Asians or Caucasians, with genetic markers being more effective in capturing population variation. This makes Kosrae an attractive population for mapping genetic components of complex diseases, even with marker density that is insufficient elsewhere.

We ascertained 3200 Kosraean adults in screenings carried out in 1994 and 2001. Patients were characterized for traits related to Metabolic Syndrome, including type 2 diabetes, obesity, dyslipidemia and hypertension. The high prevalence of Metabolic Syndrome in this population is illustrated by the diabetic cohort. Type 2 diabetics comprise 35% of Kosraean adults age 40-60, compared to 12-15% incidence in western European populations of similar age. A single extended pedigree with 4431 total individuals was reconstructed using both genetic and self-reported family data. Subjects were genotyped using the Affymetrix 100k Mapping Assay. We developed automated analysis tools to accommodate this large, population-based cohort. Signals of association from pedigree founders are combined with family-based transmission distortion tests and evaluated with empirical significance testing. We will present results from genome-wide analyses for components of Metabolic Syndrome, including type 2 diabetes, obesity, dyslipidemia and hypertension, as well as attempts to replicate the most promising loci observed in the Kosraean population.

DNA methylation at the human *IGF2* locus is highly heritable and associated with SNPs *in cis*. *B.T. Heijmans[1], D. Kremer[1], E. Tobi[1], D.I. Boomsma[2], P.E. Slagboom[1]* 1) Molecular Epidemiology, Leiden University Medical Centre, Leiden, The Netherlands; 2) Biological Psychology, Vrije Universiteit, Amsterdam, The Netherlands.

Little is known about epigenetic variation between individuals and the causes of this variation. Therefore, we studied DNA methylation of the insulin-like growth factor II (*IGF2*) locus in 196 adolescent (172 y) and 176 adult (457 y) twins. The *IGF2* locus is maternally imprinted and one of the best characterized genomic regions under epigenetic control. We assayed DNA methylation of two sequences associated with *IGF2* imprinting: the promoter of the *H19* transcript (10 CpGs/413 bp) and the *IGF2* DMR (6 CpGs/338 bp). To quantitatively measure DNA methylation of individual CpG sites we used a new mass spectrometry based method (Sequenom). The mean methylation of CpGs in the *H19* region varied between 23-30% and in the *IGF2* DMR region between 38-62%. Considerable inter-individual variation was observed, which was particularly apparent for two CpGs that displayed a bi- and trimodal distribution. To assess the influence of genetic and environmental factors on this variation, variance components analysis was performed. The heritability of methylation was substantial but lower for *H19* (.20-.74) than for *IGF2* DMR CpGs (.57-.97). Of note, the influence of environmental factors was not greater in the older twins. Next, SNPs were genotyped to trace the genetic variation underlying the heritability. The *MTHFR* Ala/Val variant, which is associated with genome-wide hypomethylation, did not affect methylation of the *IGF2* locus. In contrast, SNPs in the *IGF2* region did. Whereas modest associations were observed for *H19* methylation ($P<.05$), SNPs *in cis* strongly contributed to *IGF2* DMR methylation. Strikingly, a single SNP explained the bimodal distribution observed for one of the CpGs ($P<10^{-19}$). The trimodal distribution observed could be attributed to another SNP ($P<10^{-12}$). The associated SNPs were not located within the sequences assayed and the mechanism underlying our results is as yet unclear. In conclusion, methylation of the *IGF2* locus is highly heritable and strongly associated with genetic variation *in cis*.

Detection of aneuploidic mosaicism by a molecular method, co-amplification of artificial SNPs. *K.M. Hong[1], Y.B. Choi[1], M.H. Ko[1], S.H. Han[2]* 1) Research Institute, National Cancer Center, Goyang, Korea; 2) Seoul Clinical Laboratories (SCL), Seoul Medical Science Institute (SMSI), Dongbinggo-dong, Yongsan-gu, Seoul, Korea.

We showed that co-amplification of artificial SNP sequences (Co-aSNPs) is an accurate and rapid method for the detection of gene copy number changes. The SD values were only 1/2-1/3 of those from MLPA (multiplex ligation-dependent probe amplification) or MAPH (multiplex amplifiable probe hybridization) suggesting that this method might detect mosaic aneuploidies reliably. We tested this possibility by mixing EB-virus transformed cell lines of Downs syndrome and control samples. The cell lines were labeled with different tracking dyes and the ratio of two cell lines was monitored by confocal and fluorescent microscopy. DNAs were prepared from the mixed cell lines and were used for Co-aSNPs assay. The normalized relative ratios (nRRs) were 1.00 0.04 and 1.54 0.06 in control and trisomy 21 samples. In 50% mosaic samples, the nRR was 1.24 0.022 (nRRab) or 1.28 0.044 (nRRac). Our result shows that the Co-aSNP method can reliably detect 25-30% mosaic aneuploidy samples in 95% confidence.

The Clinical Utility of MLPA in Waardenburg Syndrome. *J.M. Milunsky*[1, 2, 3], *T.A. Maher*[1], *A. Milunsky*[1, 2] 1) Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Department of Pediatrics, Boston Univ Sch Medicine, Boston, MA; 3) Department of Genetics and Genomics, Boston Univ Sch Medicine, Boston, MA.

Waardenburg syndrome (WS) is an autosomal-dominant neurocristopathy characterized by sensorineural hearing loss, pigmentary abnormalities of the iris, hair, and skin, and is responsible for about 3 percent of congenital hearing loss. Point mutations in *PAX3* have been identified in more than 90 percent of affected individuals with WS1/WS3. *MITF* point mutations have been identified in 10-15 percent of individuals affected with WS2 (lacking dystopia canthorum). Multiplex Ligation-dependant Probe Amplification (MLPA) is now a standard technology in the molecular laboratory to detect copy number changes in targeted genes. We employed MLPA for *PAX3* and *MITF* in a cohort of 109 patients with a clinical diagnosis of WS1, 2, and 3 who were sequence negative for *PAX3* and/or *MITF*. All coding exons of *PAX3* and exons 1, 2, 3, and 10 of *MITF* were included in the MLPA assay. MLPA on 48 patients with WS1/3 revealed 3 *PAX3* whole gene deletions (2 WS1; 1 WS3), 2 *PAX3* partial gene deletions (WS1: exon 1; WS1: exons 5-9) and 1 partial *MITF* deletion (WS1: exons 3-10)(6/48 12.5%). MLPA on 41 patients with WS2 and 20 patients submitted with a diagnosis of either WS1 or WS2 revealed no copy number changes. *MITF* MLPA may be underestimating the frequency of copy number changes as only 4 of the 10 exons are included in the assay. The detection of both partial and whole gene deletions of *PAX3*/*MITF* in this clinical cohort increases the mutation detection yield by at least 6% and supports integrating MLPA into clinical molecular testing for patients with WS1, 2, and 3.

Statistical methods for modelling extended haplotypes. *P. McKeigue* Conway Inst, Univ Col Dublin, Dublin, Ireland.

Exploiting the new chip-based platforms for scoring several hundred thousand tag SNPs depends on being able to model the underlying haplotype structure for typed and untyped SNPs. As in the program FASTPHASE, the haplotype structure of the human genome can be modelled as generated by K independent Poisson arrival processes corresponding to K modal haplotype states, with block-like structure represented by allowing arrival rates to vary between intervals. We have adapted an existing program for modelling genetic admixture (ADMIXMAP) to this purpose. The posterior distribution of model parameters, hidden states and missing genotypes are generated by MCMC simulation, and score tests are obtained from this posterior distribution. We demonstrate the approach with HapMap data on 51000 SNPs on chromosome 22 typed in 60 unrelated individuals, and a tag SNP panel based on the SNPs included in the 300K chip. Tests for lack of fit show that a model with K = 6 modal states is sufficient to explain residual LD between adjacent pairs of loci in the HapMap. The efficiency of the tag SNP panel (with other genotypes missing), measured by the ratio of observed to complete information in the score tests, was 91%. Thus given any sample of cases and controls typed for a genome-wide panel of tag SNPs, we can test all loci in the HapMap for association with the disease or trait, and evaluate the adequacy with which the tag SNP panel extracts information about association with a locus or region of interest. We are developing a parallel version that will allow this to be scaled up to large-scale asssociation studies.

Non-parametric linkage analysis incorporating unaffected siblings. *A.G. Matthews*[1,2], *E. Feingold*[1] 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA.

Traditional non-parametric linkage analysis relies on affected individuals, but there are circumstances under which unaffected individuals may add a non-trivial amount of information. We discuss a class of allele-sharing statistics for sibships that incorporate phenotype information from unaffected individuals, and we evaluate the power of several different statistics in this class. We also discuss the portion of the genetic model space for which these statistics might be useful.

Whole-genome association in Alzheimer's disease using high-density SNP genotyping microarrays: A comparison of the Affymetrix DM and BRLMM genotype-calling algorithms. *D.H. Lince[1], K.L. Ohlsen[1], X. Wang[1], K.J. Elliot[1], M. Ryder[1], L. Bertram[1], R.E. Tanzi[2,3], K.D. Becker[1]* 1) TorreyPines Therapeutics, La Jolla, CA; 2) Genetics and Aging Research Unit-Massachusetts General Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA.

We are completing a genome-wide association study in Alzheimers disease (AD) using a family-based approach and 500,000 SNP markers (Affymetrix). Average SNP call rates of accepted high quality data obtained for the Nsp 250 and Sty 250 arrays were 95.8% and 95.4%, respectively, using the Dynamic Modeling genotype-calling algorithm (DM: Di et al, 2005. Bioinfo. 21:1958-63). While genotyping is still in progress, approximately 97% of all samples genotyped to date are above a 93% call rate threshold. Analysis of performance in a test data set demonstrated high reproducibility (~99%) and low error (0.3% inheritance errors). Filtering out poorly performing SNPs based upon missing genotypes, Hardy-Weinberg equilibrium and inheritance errors will further improve the quality of data for genetic analyses. Application of the Bayesian Robust Linear Modeling using Mahalanobis distance algorithm (BRLMM: Rabbee and Speed, 2006. Bioinfo. 22:7-12) increased the average SNP call rates by ~3% (98.8% for Nsp and 98.6% for Sty). We will present an analysis of SNP genotype quality before and after SNP filtering, as well as a comparison of the Affymetrix DM and BRLMM genotype-calling algorithms with respect to genotype reproducibility, call rates, and accuracy.

Case report of Zimmermann-Laband syndrome: patient affected with inter-auricular communications, and severe hand and feet compromise. *Z. Martinez*[1], *F. Suárez*[2] 1) Departamento de Pediatria, Pontificia Universidad Javeriana, Bogotá D.C., Colombia; 2) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogotá D.C., Colombia.

Zimmermann-Laband syndrome is a rare genetic disorder characterized by gingival fibromatosis, abnormalities of soft cartilages of nose and ears, hypoplastic or absent nails and terminal phalanges, joint hypermobility, hepatosplenomegaly, mild hirsutism and learning difficulties. Less than 40 cases have been reported in the literature. We present a 9 years old affected, with severe compromise of distal hand and foot phalanges with absent of all nails, hirsutism mental retardation and congenital heart defect.

Determining Evidence for Association Using an LR: Implications for Multiple Test Adjustments. *S.E. Hodge*[1,2], *L.J. Strug*[2] 1) NYSPI, Unit 24, Columbia Univ, New York, NY; 2) Department of Biostatistics, Columbia Univ, New York, NY.

Recently, we have shown that the likelihood ratio (LR) for two simple hypotheses provides a valid measure of evidence in linkage studies (Strug & Hodge, Hum Hered, In Press). We presented alternative error probabilities to Type I and Type II error rates used for planning linkage studies, and showed how one can *decouple* the error probabilities from the measure of evidence, the LR. This approach yields a more practical way of dealing with the multiple testing problem: two-stage designs of linkage genome screens serve as the adjustment for conducting multiple tests of linkage across the genome. Here we extend these results to association studies. An experimenter can choose to construct the LR from profile likelihoods, conditional likelihoods, etc. As an example, we present the LR for the odds ratio=$\exp(_1{}^*)$ for two independent binomial samples, comparing H_1: $_1 = 0$ and H_2: $_1=_1{}^*$, constructed from conditional likelihoods. Define $A(u)=(n_1Cu)[n_2C(t-u)]$, where nCr is the combinatoric coefficient. Then $LR_c = \exp(_1{}^*t_1)A(u) / [A(u)\exp(_1{}^*u)]$ where n_1 and n_2 are the numbers of individuals with and without the trait of interest, respectively; t_0 is the total number of individuals with the genotype of interest; and t_1 is the number of diseased individuals with the gentoype of interest. The summations are defined over u from $\max(t_0-n_2, 0)$ to $\min(t_0, n_1)$. We show that when one uses this conditional LR as the measure of evidence about association for two simple hypotheses, a replication study or two-stage genome-wide association study itself provides the adjustment for conducting multiple tests of association along the genome.

Simultaneous discovery and testing of small segregating deletions for association with disease in SNP genotyping studies. *J.R. Kohler, D.J. Cutler* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

There are a number of forms of copy number variation (CNV) including aneuploidies, somatic chromosomal changes, duplications and microdeletions that have long been known to play a crucial, causative role in disease such as Down syndrome, cancer, thalassemia and DiGeorge syndrome. Common techniques to detect large-scale CNV are expensive and time-consuming relative to modern SNP genotyping, which we show can be used to detect small CNV. Deletions have at least three signatures detectable in SNP genotype data: departures from Hardy-Weinberg ratios, Mendelian inconsistencies and unusual patterns of missing data. In this study, we show how to use all three forms of information in a single modeling framework, not only to detect the presence of the deletion, but also to accurately estimate the deletion frequency, to infer who carries the deletion in both heterozygous and homozygous states and finally to test the imputed deletion for potential association with disease using standard association tests (TDT).

We have implemented this approach in a freely available computer program (microdel), and demonstrate its effectiveness on both simulated and real data. In realistic coalescent simulations with a 500 K SNP density, containing both genotyping error and missing data, we show that in studies of 100 trios, a 20 kb deletion at frequency 0.05 can be detected with greater than 75 % power. Power increases with increasing sample size, deletion frequency and deletion length. A 100 kb deletion at frequency 0.20 can be found with ~100 % power. We further show that estimated deletion frequencies are highly accurate, and that even with imperfect sensitivity, TDT tests on the imputed deletion maintain nominal false positive rates. Furthermore, false positive deletions are only detected ~1 per 5,000 SNPs and are generally just a single SNP in length. We also report our survey of deletion polymorphism in the HapMap 16c data, where 1882 deletions of length two or more SNPs were inferred, to date 510 of these deletions have been validated by other methods.

Gametic Phase Disequilibrium as a Method to Map Deafness Genes. *W. Nance[1], A. Pandya[1], S.H. Blanton[2], K.M. Dodson[1], X.J. Xia[1], K.O. Welch[3], K.A. Arnos[3]* 1) Virginia Commonwealth University, Richmond, VA; 2) Duke University, NC; 3) Gallaudet University, Washington DC.

By aggregating mutations for non-allelic genocopies within individuals, assortative mating leads to a non-random distribution of genes known as Gametic Phase Disequilibrium (GPD).Each generation, deaf offspring of hearing parents join the deaf mating pool. Similarly, hearing children of deaf adults (CODA) who are frequently carriers of multiple non-allelic genes for recessive deafness carry these genes into the hearing mating pool. We have collected family histories and CX typing on 105 deaf probands with deaf parents and 995 with hearing parents. We assigned each proband an ancestral deafness index score (I) based on the probability each deaf ancestor transmitted a recessive deafness gene to the proband, summed over all deaf ancestors in the pedigree. The frequency of CX26 heterozygotes increased progressively from 7% in probands with hearing parents (I= 1), to 18.6% in those with deaf parents but no other deaf ancestors (I= 2), to 29 & 40% in probands with I= 2-3 and I> 3 respectively. The hearing loss in these subjects must be caused by at least one additional non-allelic gene for deafness. These data therefore provide clear evidence for GPD and its association with the duration and intensity of assortative mating. Probands in the most extreme group had a CX26 carrier frequency that exceeded the 3.5% rate in the general population by an order of magnitude. The striking aggregation of genes for deafness in this mating group offers a unique opportunity to map them either by case control SNP frequency comparisons of high-density genome scans using conditional logistic regression analysis, or by GPD mapping, an iterative, orthogonalized analysis of non-syntenic disequilibrium beginning with known genes for deafness. For the latter we are currently typing SNPs in and around GJB2, to identify the region showing the greatest SNP frequency differences by case-control comparison. This process will be reiterated until all identifiable known deafness genes in the sample have been detected. Remaining sites of disequilibrium represent candidate regions for new deafness loci.

Characterizing genomic rearrangements in oligodendroglioma using whole genome tilepath hrCGH arrays. *N.V. Johnson[1], J.J. Connelly[1], J. Virgadamo[1], R.E. McLendon[2], J.M. Vance[1], D.D. Bigner[2], S.G. Gregory[1]* 1) Duke Center for Human Genetics, Durham, NC; 2) Duke Comprehensive Cancer Center, Durham, NC.

Primary brain tumors account for 1% of the new cancer cases in the US which, given the mortality of 4.1% per 100,000 persons, accounted for 13,100 deaths in 2001 alone. These tumors have a broad histopathology, variable sensitivity to treatment and, therefore, have unpredictable progression and survival times. In general, the molecular mechanisms underlying all these variables are poorly understood. For many years it has been contended that genetic instability leads to cancer development via non-random chromosome losses and gains that contribute to tumor malignancy. To identify these underlying molecular mechanisms we have generated high-resolution comparative genomic hybridization (hrCGH) data using our whole genome tilepath microarrays to identify chromosomal rearrangements associated from 110 oligodendroglioma (OD) tumors. We have generated hrCGH data at 100kb resolution from 45 tumors histopathologically determined to be well differentiated oligodendroglioma (WD); 40 anaplastic oligodendroglioma (AO) tumors; and 25 tumors with only an OD designation. Analysis of the entire tumor set identified characteristic loss of 1p and 19q within 72% of the tumors analyzed. In addition to gross chromosome rearrangements, amplifications or deletions (>4Mb) throughout other regions of the genome, we observed a number of single clone deletions and amplifications within our tumor set. The novel data associated with our analysis therefore represents either novel copy number polymorphisms or, more likely, genomic loci which contain genes associated with the development and progression of oligodendroglioma. Additionally, we observed an accumulation of genomic rearrangements between stage II and III stages. We will present a detailed analysis of genomic intervals that define minimally deleted and amplified regions between all OD tumors. These regions now form the focus of on-going candidate gene analysis.

Gene copy number variation and the limits of detection using Affymetrix GeneChip Human Mapping 100K and 500K arrays. *A.D. Delaney[1], R.A. Holt[1], H. Li[1], T. Nayar[1], A. Baross[1], A. Ally[1], J. Asano[1], D. Bailey[4], P. Birch[2], M. Brown-John[1], M. Cao[4], S. Chan[1], P. Eydoux[3], N. Fernandes[2], S. Flibotte[1], A. Go[1], G. Kennedy[4], S. Langlois[2], J.M. Friedman[2], M.A. Marra[1]* 1) Genome Sciences Centre, British Columbia Cancer Agency, Vancouver, BC, Canada; 2) Dept. of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 3) Dept. of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada; 4) Affymetrix Inc., Santa Clara, CA.

Genomic amplifications and deletions are known to be important in disease and have recently been shown to occur frequently as normal polymorphisms. It has recently been shown that the frequency of such polymorphism increases as the size of the aberration decreases. In our study, we used Affymetrix GeneChip Human Mapping 100K and 500K arrays in combination with new informatics techniques to detect such copy number variation(CNV) in a large set of unaffected parents (214) and their children (107) with mental retardation. This presentation focuses on the large set of newly discovered presumably benign CNVs in the unaffected parents. Detection of CNVs depends on recognition of a set of adjacent SNPs that show a concordant change in copy number. As the minimal number of SNPs chosen to define an amplification or deletion decreases, the rate of false positive discovery rises. We have quantified this dependency and present the lower limit of detection of the Mapping 100K and 500K arrays as a means for CNV discovery. We also present several approaches to data normalization, as well as treatment of non-random variation and noise. This includes comparison of four software packages currently available for normalization and CNV detection from Mapping 100K and 500K array data, as well as novel approaches being developed by our group.

Retrospective association analysis of case-control data using clustered haplotypes. *M.L. Jones[1], M.P. Epstein[2], J.Y. Tzeng[1]* 1) Department of Statistics, North Carolina State Univ, Raleigh, NC; 2) Department of Human Genetics, Emory University, Atlanta, GA.

Many regression-based methods exist for conducting haplotype analysis in case-control studies of disease. Such methods generally are based on either a prospective framework (modeling the probability of disease conditional on haplotypes and covariates) or a retrospective framework (modeling the probability of haplotypes and covariates conditional on disease). For haplotype analysis, both theoretical and simulation work have demonstrated that a retrospective framework can be more efficient than a prospective framework in this context. Given this result, we propose to further improve the performance of the retrospective haplotype framework by allowing for haplotype clustering. Our previous work to enhance the efficacy of haplotype analysis suggested that clustering haplotypes under the prospective framework can increase the power of haplotype-based association analysis. With the aim of seeing an even greater improvement from clustering for case-control data, this work extends the clustering idea to the retrospective framework. Specifically, we construct a retrospective likelihood using a design matrix that does not require pre-specification of the haplotype of interest and derive generalized scores statistics to test for haplotype effects at the global and individual levels. Through simulation, we assess the validity of the retrospective clustering method and compare the power of the method with the power of the full-dimensional analysis. We also examine the power of the retrospective method relative to the prospective clustering method. In addition, we will apply our proposed approach to real data from a genetic study of Type 2 Diabetes.

Evaluating life scientists' and geneticists perceptions and understanding of research ethics. *J. McCormick, A. Boyce, R. Garg, M. Cho* Center for Biomedical Ethics, Stanford University, Palo Alto, CA.

As research on fundamental biological processes and genetics moves forward, significant questions are raised about ethical, legal, social, and policy (ELSP) issues, , as well as how to ethically conduct research. It is important for scientists to have a good understanding of the issues and to be proactive in addressing these concerns. The questions are then, how much do scientists know about ELSP implications related to their research, and how capable and willing are they to participate in addressing these concerns? The goal of this study was to evaluate the perceptions life science and genetics researchers have of the ELSP concerns related to their work and to determine the role they see themselves playing in the policymaking process. In additional, we assessed why and when scientists might use a service providing assistance in resolving ethical and social quandaries related to their research. This service, called the Benchside Ethics Consultation Service (BECS), has recently been established at Stanford University. We conducted interviews (N=20), focus groups (N=28), and surveys of graduate students, postdoctoral fellows, research staff, and faculty at Stanford University (N=500) and 6 other research universities (N=1500) across the United States. Genetics departments at all institutions were included in the sample. Our preliminary findings suggest that researchers do think about ELSP issues but often not in the context of their specific research. The term research ethics conjured up thoughts on scientific misconduct, data falsification, and author recognition. Informed consent issues were also recognized by study participants as important issues. Some researchers using human subjects seem to recognize concerns about reporting research results and incidental findings. Confidentiality and privacy of their own consultations are some of the main concerns for potential users of BECS or a service like it. Our analyses suggest topics about which we should be more proactive in informing the life science community and support the need for a service like BECS.

Association study of 7 ALOX5AP gene polimorphisms in patients with myocardial infarction or coronary artery disease. *G. Malerba[1], U. Cavallari[1], L. Xumerle[1], E. Trabetti[1], M. Biscuola[1], N. Martinelli[2], O. Olivieri[2], D. Girelli[2], R. Corrocher[2], P.F. Pignatti[1]* 1) Department of Mother and Child and of Biology-Genetics, Section of Biology and Genetics, University of Verona, Verona, Italy; 2) Department of Clinical and Experimental Medicine, University of Verona, Verona, Italy.

Recently, variants of the gene ALOX5AP (also known as FLAP) encoding arachidonate 5-lipoxygenase activating protein have been associated with risk of atherosclerosis, myocardial infarction (MI) or stroke. The present study aimed to validate those findings in an Italian sample. To assess the contribution of the ALOX5AP variants to cardiovascular diseases, 7 single-nucleotide polymorphisms (SNPs, rs17222814, rs17216473, rs17222772, rs17216522, rs17222828, rs17222877, rs17222842), tagging the previously reported high risk haplotypes in Icelandic (HapA) and British (HapB) populations (Helgadottir et al., Nat. Genet. 2004), were genotyped from 1171 patients with coronary artery disease (CAD) and 407 CAD-free assessed by coronary angiography. Single marker, 2 or 3 marker SNP haplotype analyses did not show any significant difference in the frequencies between the control and patient groups for any of the investigated phenotypes (CAD and MI). The hypothesis that ALOX5AP contributes to susceptibility for MI was not confirmed in the Italian population.

Chromosome Analysis of Single Cells by High Resolution Comparative Genomic Hybridization after Whole Genome Amplification using A Random Fragmentation Approach. *B. Levy[1], O. Nahum[2], K. Hirschhorn[2]* 1) Dept Pathology, Columbia Univ, New York, NY; 2) Dept Human Genetics & Pediatrics, Mount Sinai School of Medicine, New York, NY.

We used a random fragmentation whole genome amplification (WGA) approach combined with high resolution comparative genomic hybridization (CGH) to detect the chromosomal status of single cells. Single cells were extracted from 32 random specimen cultures that were initially obtained for clinical cytogenetic analysis. All cultures were de-identified and blinded (with respect to the cytogenetic diagnosis) before being transferred from the clinical laboratory to the research laboratory. Single cells were lysed and then subject to WGA using a random fragmentation approach (GenomePlex - Sigma-Aldrich). The resulting DNA was labeled using Nick-translation and high resolution CGH was performed to determine DNA copy number and thus the chromosomal status of the single cells. CGH results were compared to the karyotype as determined by conventional cytogenetic analysis. The study was approved by the IRBs of Columbia University and the Mount Sinai School of Medicine. The specimens analyzed included normal males, normal females, various trisomies (4, 10, 11, 13, 14, 16 and 21), an unbalanced translocation and an iso-22 chromosome. There were no false negatives and the correct diagnosis was made in 32/32 cases at the 99.9% CI and 31/32 cases at the 99.99% CI. Certain artifactual abnormalities were observed in addition to the true abnormality in some cases and the impact of these still needs to be determined in a larger test series. This approach offers significant benefits over current FISH-based preimplantation genetic diagnosis as the entire genome is scanned for chromosomal imbalances. Further assessment of sensitivity and specificity is required before such methods can be targetted for clinical application.

A locus for an autosomal dominant paroxysmal abdominal pain maps to 8q13.2-22.3. *B. Kremeyer[1], N.G. Pineda-Trujillo[1,2], M.W. Burley[1], F. Lopera[2], G. Bedoya[2], A. Ruiz-Linares[1,2]* 1) Department of Biology, University College London, London, United Kingdom; 2) Medical School, Universidad de Antioquia, Medelllin, Colombia.

We identified an extended family in Antioquia (Colombia) with multiple individuals presenting abrupt crises of severe abdominal pain. These episodes occur from infancy and are characterised by very intense spasmodic pain, predominantly in the abdomen, but occasionally generalised. Episodes are associated with stiffness of the abdominal wall, profuse sweating but not loss of consciousness. One episode can last for 30 to 60 min, the pain gradually becoming more severe as the crisis progresses. We carried out a whole genome linkage scan using ~550 microsatellite markers (deCODE Genetics Genotyping Service) with an average spacing of 6 cM. Parametric linkage analysis was carried out using a model of autosomal dominant inheritance with high penetrance (0.985). Two-point LOD scores 2, suggesting genetic linkage, were found on chromosomes 2p, 3p, 8q, 9q, and 13q. A single two-point LOD score 3 was obtained on chromosome 8q12.3, for marker D8S512 (Z=4.18 at =0). Multipoint LOD score analysis of chromosome 8 yielded a maximum LOD score of Z=4.42 in the interval D8S512-D8S279, notably in the same region that had also shown the most significant LOD score in the two-point analysis. Haplotype analysis confirmed the segregation of a candidate region in the family. We therefore conclude that we identified a region on chromosome 8q13.2-22.3 that harbours a predisposing gene for familial paroxysmal abdominal pain. Fine-mapping and sequencing of candidate genes is under way.

Familial Borjeson-Forssman-Lehmann syndrome not associated with PHF6 mutation. *M. Ottaviani[1], A. Zeffiri[1], L. Di Medio[1], L. Carosi[1], S. Toccafondi[1], S. Guarducci[2], L. Giunti[2], E. Lapi[2], M.L. Giovannucci Uzielli[1]* 1) Department of Paediatrics, Genetics, University of Florence, Florence, Italy; 2) Childrens Hospital A. Meyer, Florence, Italy.

Borjeson-Forssman-Lehmann syndrome (BFLS; OMIM 301900) belongs to the syndromic forms of XLMR disorders. BFLS is now best described as a mental deficiency-endocrine disorder. This rare disorder was described for the first time in 1962. It is characterised by moderate to severe intellectual disability, epilepsy, microcephaly, coarse facial features, long ears, short stature, obesity, gynecomastia, hypogonadism, tapering fingers, and shortened toes. Although BFLS is an X chromosomal recessively inherited disorder, it may also be seen in females, perhaps as a consequence of X inactivation skewing as has been confirmed by methylation specific PCR. Four years ago, mutations have been identified in the PHF6 gene, a novel widely expressed zinc-finger [Plant Homeodomain (PHD)-like finger] gene, mapped to the human Xq26 region, by Lower et al., Nat Genet 2002;32:661.5 We report a two-generation family with clinical phenotype of the Borjeson-Forssman-Lehmann syndrome in a 11 years old girl, and in her maternal uncle. Both the phenotype, severely expressed in the uncle and also in the proposita, the natural history, and the X chromosomal mode of inheritance, prompted the diagnosis of BFLS. The differential diagnosis included several rare and less rare disorders. Molecular analysis performed in the proposita, by direct sequencing of the coding exons 2-10 and of the flanking intronic sequences (50 base pairs) of the PHF6 gene, in genomic DNA, revealed no mutations. This study does not rule out a mutation in the uncharacterised gene regulatory elements or in the intronic sequence outside the splice donor and acceptor sites. X inactivation and UPD studies are now in progress as well. However, it seems to us too early to speak about genetic heterogeneity of BFLS.

Exploring the role of maternal age and the location of recombination in chromosome 21 nondisjunction. *T.R. Oliver[1], E. Feingold[2], S.L. Sherman[1], K. Yu[3]* 1) Human Genetics, Emory University, Atlanta, GA; 2) Human Genetics, University of Pittsburg, PA; 3) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD.

Human chromosome nondisjunction (NDJ) occurs at a high frequency in humans and is known to be influenced by maternal age and recombination. We examined the association of these two known risk factors among maternal chromosome 21 NDJ stratified by meiosis I (MI, n=637) and meiosis II (MII, n=278) errors. We found intriguing patterns of association that were specific to the type of NDJ error. For MI errors, the frequency of a single exchange near the telomere of chromosome 21 is highest among young mothers and decreases significantly with age. In fact, the pattern of exchanges amongst our eldest group of women mimics the pattern observed among normally disjoining chromosomes 21. Recombination among MII errors reveals a different relationship with maternal age: single pericentromeric exchanges occur most often among the oldest maternal age group. These results suggest that multiple mechanisms that lead to NDJ. For example, single telomeric exchanges appear to predispose to NDJ irrespective of maternal age. However, for MII errors, recombination-related factors appear to interact with maternal age related factors.

2DE-DIGE proteomic analysis in mesial temporal lobe epilepsy. *M.J. Murai[1], R. Horiuchi[2], D. Martins[2], C.V. Maurer-Morelli[1], J.C. Novello[2], F. Cendes[3], I. Lopes-Cendes[1]* 1) Medical Genetics Department, Unicamp, Campinas, São Paulo, Brazil; 2) Biochemical Department, Unicamp, Campinas, São Paulo, Brazil; 3) Neurological Department, Unicamp, Campinas, São Paulo, Brazil.

Epilepsy affects 1% to 2% of the general population; therefore, it is considered a public health problem by the World Health Organization. Mesial temporal lobe epilepsy (MTLE) is the most common and severe type of partial epilepsy, representing ~50% of all adult epilepsy patients and frequently associated with pharmaco-resistance. The relationship between MTLE and hippocampal sclerosis (HS) is well established. However, the precise pathogenesis of HS and its relationship with MTLE is not completely clarified. Two-dimensional electrophoresis (2DE) is a powerful fractionation method for complex protein mixtures. In difference gel electrophoresis (DIGE) based proteomics, the experimental and control samples are labeled with different fluorophores and are run in the same gel, thereby minimizing gel preparation variation. DIGE is one of the few techniques that is capable to perform quantitative proteomics, generating statistical data to differences in protein abundances. We analyzed the proteome of three hippocampus removed from patients with refratory MTLE who underwent epilepsy surgery. 2DE-DIGE identified 2 up-regulated and 10 down-regulated proteins as determined by Students T-test (p0.01). The observed molecular weight of the spots ranged from 28 to 93 kDa. The identity of these spots will be elucidated by mass spectrometry in order to gain additional information in a global scale about the mechanism of epileptogenesis in MTLE.

Comparison between BAC and oligo array platforms in detecting submicroscopic genomic rearrangements. *P. Hixson[1], E. Laritsky[1], X. Wang[2], T. Jiang[1], S. Cheung[1], I. Van Den Veyver[1,2], W. Cai[1]* 1) Dept of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept of Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX.

Array-based comparative genomic hybridization (array CGH) has emerged as a powerful diagnostic technique for high resolution analysis of the human genome. It is a specific, sensitive and rapid technique enabling detection of genomic arrangements and copy number changes. A variety of array CGH platforms are currently available, both commercially and in academic institutions. The choice of platform may depend on the type of data sought, however, the price, reproducibility and standardization are crucial factors that need to be considered. Our goal was to determine the ability of our in-house prepared BAC array to identify submicroscopic genomic rearrangements. We constructed a 39,000 human whole genome (HWG39K) BAC clone microarray from the RPCI-11 human library with a resolution of approximately 12 BACs/Mb using standard alkaline lysis method. This platform was used, in a masked fashion, to analyze genetic aberrations in five clinical samples showing abnormalities using a targeted array that has been clinically implemented. These samples were also examined using oligo-based platforms in an attempt to compare the performance of our BAC arrays with the oligo arrays. We were able to identify deletions on chromosomes 1 (1 patient) and 22 (2 patients), a deletion/duplication event on chromosome 8 (1 patient) and a duplication on chromosome 12 (1 patient). Our results were consistent with previous cytogenetic and FISH findings and were comparable to those obtained by different oligo array platforms available commercially. The negative rate of detection for our BAC array platform ranges from 0 to 12.4% using 2.5 SD units as the cutoff level. Therefore, this platform provides us with an alternative to characterizing submicroscopic genomic rearrangements on a whole human genome array in a single experiment at an affordable cost.

Characterizing Intronic Sequences by Chromosomal Location: Valleys in the Genomic Terrain. *C.M. Malcom*[1], *G.J. Wyckoff*[2] 1) Department of Anthropology, University of Chicago, Chicago, IL; 2) Department of Molecular Biology and Biochemistry, University of Missouri---Kansas City, Kansas City, Missouri.

Through previous work, we have established that, in mammalian lineages, genes co-located in syntenic blocks (i.e., stretches of coding sequence that have been preserved over evolutionary time and have persisted throughout chromosomal rearrangements) resemble one another in many respects, including length, evolutionary rates, and number and length of domains (Malcom et al., 2003, 2004). This work has allowed us to identify chromosomal families---that is, human chromosomes that cluster together in terms of genic characteristics. These families are relevant to the study and understanding of human disease, as their shared characteristics imply shared ancestry and evolutionary history. Thus, these relationships may give us insight into factors that have worked within biologically bounded units to shape the genome over time. Here, we expand our inquiry into positionally shared characteristics by turning to noncoding sequences. We consider how closely noncoding sequences within a chromosome resemble one another (in terms of length, substitution rates, GC content, and other characteristics) as well as the relationship between coding and noncoding sequences within chromosomes. In keeping with previous research (e.g., Hughes and Yaeger, 1997; Wyckoff et al. 2005; Ko et al., 2006), our work here shows that the relationship between characteristics of coding and noncoding regions is complex and not simply summarized. However, consideration of coding and noncoding regions as two distinct groups that are internally homogenous obscures patterning in the data. Consequently, partitioning both the coding and noncoding parts of the genomes into biologically meaningful subunits (such as syntenic blocks and chromosomes) has considerable potential to enlighten researchers on the mechanisms that control genomic fidelity and change over evolutionary time and the scale on which these mechanisms work. Viewing the genomic terrain from these multiple perspectives may greatly enhance researchers ability to select targets for disease research.

Variants in the Trehalase Gene (TREH) are Associated with Type 2 Diabetes Mellitus and Determine Trehalase Activity in Pima Indians. *Y. Muller, G. Nishimoto, J. Loebel, R. Hanson, S. Kobes, J. Goswami, W. Knowler, C. Bogardus, L. Baier* Epidemiology & Clinical Res, NIDDK/NIH, Phoenix, AZ.

Trehalase is an enzyme which hydrolyzes the disaccharide trehalose into the glucose. Trehalase is encoded by the trehalase gene (TREH) which is located on Chr.11q23, within a region linked to both body mass index (BMI) and type 2 diabetes mellitus (T2DM) in diverse populations including Pima Indians. Association studies of single nucleotide polymorphisms (SNPs) for fine mapping of linkage in the Pima Indians identified several SNPs near/within the TREH gene that were associated with BMI and/or T2DM. The coding region and ~2 kb of the promoter region of the TREH gene was sequenced in 39 Pima Indians, and 12 SNPs were identified. These 12 SNPs, and 14 additional database SNPs were genotyped in 1037 subjects that gave rise to the linkage peak. 21 SNPs were associated with T2DM (p=0.01 to 0.0001), and 5 SNPs were associated with BMI (p=0.01-0.001). These analyses were adjusted for age, sex, birth year, heritage and family membership. In addition, serum trehalase activity was measured in 570 non-diabetic subjects, and trehalase activity was highly associated with a nonsynomous SNP Arg486Trp and a promoter SNP located at -100 bp ($p=10^{-12}$, $p=10^{-15}$, respectively, adjusted for age, sex, heritage and family membership), and several other SNPs that were in perfect LD with these SNPs. Haplotype analysis showed that subjects who were homozygous for 3 variants (Trp486, Ala389 and C at -100 bp) had the lowest trehalase activity, and carried the lowest risk of T2DM. Furthermore, a higher trehalase activity was associated with higher BMI in 564 subjects (r=0.11, p=0.01), where the association was more prominent in 269 male subjects (r=0.24, p<0.0001) than in 295 female subjects. However, mean trehalase activity measured in non-diabetic subjects was not significantly associated with subsequent development of diabetes in 570 subjects (diabetic=250, non-diabetic=320, p=0.57). These results indicate that the genetic variants in the TREH gene highly influence the serum trehalase activity, and a specific haplotype of TREH is associated with both low levels of TREH activity and risk of T2DM.

Novel mutation in *DSPP* underlying DI type II. *S. Hart[1], J. Atkinson[2], S.J. Choi[2], M.D. Ramaswami[2], T.C. Hart[2]* 1) Office of the Clinical Director, NHGRI, Bethesda, MD; 2) Section on Human and Craniofacial Genetics, NIDCR, Bethesda MD.

Dentinogenesis imperfecta (DI) is an autosomal dominant condition characterized by tooth discoloration and by enamel that fractures easily from the underlying dentine. Radiographically, bulbous crowns, narrow roots, and small or obliterated pulp chambers and root canals are seen. Three subtypes have been recognized, with types II and III the non-OI forms. In this report, we report mutational analysis of a 16 year old male from the Brandywine triracial isolate segregating DI and his unaffected mother. A sample on the affected father was not available. Sequencing of the *DSPP* gene revealed that the mother was heterozygous for a T>C transition that is predicted to substitute threonine for isoleucine at position 131, but she did not transmit this alteration to her son The son was heterozygous for two coding alterations, neither of which was present in the mother. The first, a T>C transition predicted to change a highly conserved proline residue to a serine (p.P17S), was not present in Caucasian or African American controls. Mutation of this same residue (p.P17T) was previously reported in a Chinese kindred segregating DI and bilateral high frequency sensorineural hearing loss. The proband in this study nor his father reported any hearing problems. The second coding alteration, p.R68W, was reported as disease-causing in a Swedish kindred. We detected the p.R68W mutation in control individuals and thus this change is most likely a polymorphism. Site directed mutagenesis was used to introduce the mutations into human DSP cDNA, subcloned into the pcDNA3 expression vector that was then transfected into mouse odontoblast cells. Supernatants and cellular extracts were analyzed for DSP protein. The p.P17T mutation was associated with significant decrease in DSP excretion from cells, while the p.R68W alteration displayed normal excretion. The p.P17S alteration is currently being evaluated in this system. Analysis of DI families supports that the term DI type II is appropriate to describe the non-OI forms of DI. In conclusion, we report a novel mutation, p.P17S, that causes DI type II.

Discordance for ovarian dysgenesis in a pair of monozygotic twins. *L. Matyakhina[1], J. Meck[1], A.L.A. Martin[2], M.M. Martin[2]* 1) Obstetrics and Gynecology, Georgetown University Hospital, Washington; 2) Pediatrics, Georgetown University Medical Center, Washington.

An unusual case of monozygotic (MZ) female twins is presented, one normal and one with congenital anomalies including ovarian agenesis. The twins were born at 29 weeks gestation with birth weights and lengths at the 5th percentile. They were monochorionic; monozygosity was confirmed by molecular VNTR analysis. At birth, Twin A had a single umbilical artery (SUA) and a displaced and dysplastic left thumb. She also had a patent ductus which required surgical correction, as well as an ASD and VSD. Elevated serum gonadotropins suggested ovarian dysfunction. Laparoscopy revealed no left ovary and a streak on the right. A biopsy showed fibrovascular connective tissue, but no epithelial cells or follicles. Sonography showed an infantile uterus. At age 12, when twin B entered puberty, estrogen replacement therapy was initiated in twin A with estradiol 20 ng/kg po. This dose was increased over several years guided by clinical, cytological and hormonal findings, using twin B as the model. At age 17, 125 ng/kg po estradiol provided adequate estrogen replacement. Cyclic hormonal therapy was started and regular periods followed. Growth and development proceeded appropriately. Twin A reached an adult height of 156.4 cm, close to twin Bs height of 159.7 cm. Gonadal dysgenesis is associated with X-chromosome anomalies. Karyotype analyses on lymphocytes from both twins and on fibroblasts from twin A were normal 46, XX. FISH on lymphocytes from both twins with X and Y centromere probes showed no sex chromosome mosaicism or Y signals. Discordance associated with SUA is common in MZ twins. 25% of babies with SUA have chromosome anomalies. Somatic anomalies; not genital tract abnormalities, have also been reported. Post zygotic, epigenetic and environmental events are often suggested to explain MZ twin discordance. 20% of MZ twins differ in X chromosome inactivation patterns. Highly skewed X inactivation may explain the findings in Twin A. X-linked mutations may be unmasked in her but not Twin B. X chromosome inactivation testing may assist in understanding their discordance.

Unbiased Evaluation of TagSNP Panels Genetic Coverage. *K. Hao, S. Cawley* Algorithm & Data Analysis, Affymetrix, Inc, Santa Clara, CA.

Common genetic polymorphism explains a portion of the heritable risk for at least some and possibly many common diseases. Because of linkage disequilibrium (LD), it is possible to catalog many polymorphisms by genotyping only a relatively small collection of tag SNPs. Various tag SNP selection algorithms and genotyping panels have been developed, facilitating whole-genome association studies. Genetic coverage and average r2 are often used as benchmarks evaluating the performance and power of whole genome SNP panels and tag SNP selection algorithms. Since SNP panels are typically designed using a specific collection of subjects and SNPs, both independent subjects and SNPs are necessary to provide accurate estimates of genetic coverage. Here, we conduct an unbiased evaluation of the genetic coverage of tag SNP panels on a genome-wide scale. First we apply Affymetrix GeneChip technology and genotype >100K SNPs which are not included in the HapMap project (as of HapMap release 20). We find a sizable over-fitting effect, where the genetic coverage of a 300~500K tag SNP panel is typically overestimated by 10~15% if evaluated on the training SNP set itself (e.g., HapMap SNPs) rather than an independent testing set. This finding is consistent to our simulation studies. Secondly, employing independent subjects, we also observe ~10% overestimation of genetic coverage due to over-fitting on samples (also known as the tag SNP transferability problems). In addition, simulations show the SNP and sample over-fitting effects are additive and our results indicate that caution is necessary in evaluating such tag SNP panels. Furthermore, we propose improvements in tag SNP selection algorithms to reduce sample and SNP over-fitting risks. Keywords: TagSNP, Genetic Coverage, Linkage Disequilibrium (LD), Over-fitting and Independent Validation.

Hereditary colorectal cancer: the French Canadian mutation spectrum. *J. Jarry[1], G. Chong[1,2], I. Thiffault[2], S. McVety[2], S. Winocour[1], P.H. Gordon[1], G. Ouellette[3], I. Gorska[4], D. Farber[1,2], V. Marcus[2], R. Fodde[5], P. Hutter[6], W.D. Foulkes[2]* 1) SMBD-Jewish General Hospital, Montreal, Canada; 2) McGill University, Montreal, Canada; 3) CHUS, Sherbrooke, Canada; 4) CHUM, Montreal, Canada; 5) Dept Pathology, Erasmus Medical Center, Rotterdam, the Netherlands; 6) Institut Central des Hôpitaux Valaisans, Sion, Switzerland.

Colorectal cancer (CRC) ranks amongst the most frequent cancers worldwide and is the second leading cause of cancer-related deaths in the Western world. Inherited forms of CRC include hereditary non-polyposis colorectal cancer (HNPCC), caused by mutations in the mismatch repair genes MLH1, MSH2, MSH6, and PMS2; familial adenomatous polyposis (FAP), caused by mutations in APC; and MYH-associated polyposis (MAP). The CRC mutation spectrum in the French Canadian (FC) population, a recently founded population in which many founder effects have been reported, remains poorly documented. We report our experience on the mutation screening of FC patients with hereditary CRC. Using a multimodal approach that includes testing for both DNA and RNA, we have successfully identified mutations in MLH1, MSH2, and MSH6 in FC families fulfilling the Amsterdam or Bethesda criteria for HNPCC. A total of 22 mutations have been identified of which half were caused by exon deletions. Four of these mutations were detected more than once, but pedigree analysis indicates the families are unrelated. Haplotype analysis indicates the presence of a founder effect for these recurrent mutations. An additional number of FC families were tested for FAP and a total of 16 distinct mutations were identified in the APC gene. Families, in which probands exhibited a phenotype compatible with the attenuated form of FAP but for which no APC mutation could be found, were screened for the two common European mutations in the gene MYH. Four individuals were identified as biallelic carriers of mutations in MYH. While the spectrum of CRC mutations is wide in French Canadians, an abundance of exon deletions and the presence of founder effects for HNPCC patients can be singled out as characteristics of this population at the molecular level.

Chromosome 6q21: Positional candidate genes for psychosis in Alzheimers and Schizophrenia. *V. Kodavali[1], R.A. Sweet[1], M.I. Kamboh[2], V.L. Nimgaonkar[1,2]* 1) Dept Psychiatry, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Psychotic symptoms, i.e., hallucinations and delusions, are common among patients with late onset Alzheimers Disease (LOAD) and Schizophrenia. Our group is working on the genetic causes of psychosis in these patients. We have found LOAD+P (LOAD with Psychosis) to be familial, with a heritability of psychosis during LOAD of 61-70%. We performed linkage analysis among families having two or more first-degree relatives with LOAD+P, using data from the NIMH Alzheimer Disease Genetics Initiative. We found suggestive linkage at chromosome 6q near marker D6S1021 (112.2 cM, MLS = 2.32; p = 0.001) a region that may also harbor psychosis liability genes for schizophrenia and bipolar illness. We conducted follow-up association studies of the chr 6q region in DNA pools of 180 subjects with LOAD+P, 180 unrelated individuals with LOAD-P (LOAD without psychosis), 180 subjects with schizophrenia and 180 unscreened neonatal controls. We conducted our studies in three stages, a) Identification of tagged SNPs, b) Allele-frequency estimations using pooled DNA method and c) Individual genotyping by SNPlex and Illumina assay methods. We analyzed information on 3500 SNPs from the Hapmap project, covering 10Mbp genomic region near DNA marker D6S1021. We obtained 679 tagged SNPs (r2=0.8) generated by using the H-clust method, covering 41 genes in this region. We estimated allele frequencies in these DNA pools for 679 tagged SNPs using DNA pooling method [Chowdari KV et al, Genes, Brain and Behavior, 2006. (In press)]. Thus we selected 75 SNPs, which showed p value of <0.2 by comparing LOAD+P, LOAD-P, schizophrenia and neonatal control pools, for further individual genotyping. We found significant associations at several SNPs from NR2E1, SNX3, ARMC2, SESN1 and c6orf182. We show here that the pooled DNA method is a convenient and rapid method for efficiently screening case-control differences for genetic association studies. We are currently evaluating these findings in additional replication samples.

A High Density SNP Genome Screen For Age Related Macular Degeneration Reveals Novel Loci. *M.A. Hauser[1], S. Schmidt[1], R.R. Allingham[2], P. Gallins[1], W.K. Scott[1], A. Argawal[2], E. Postel[2], K.L. Spencer[3], J.L. Haines[3], M.A. Pericak-Vance[1]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Ophthalmology, Duke Univ Medical Ctr, Durham, NC; 3) Center for Human Genetics Research, Vanderbilt, Nashville, TN.

Age-related macular degeneration (AMD) is the leading cause of blindness in older Americans. Here we report a SNP-based genome-wide screen on a large AMD family dataset. A genome-wide screen was performed on a dataset of 364 individuals from 127 multiplex AMD families. The Illumina Bead Station platform (Linkage Panel IV) was used to genotype 5253 single nucleotide polymorphisms (SNPs). For multipoint analyses a single SNP was selected from each bin of SNPs in linkage disequilibrium (r2 0.16). Both parametric and non parametric analyses were performed. This analysis replicates previous linkages, including the regions on 1q containing the Complement Factor H gene, and on 10q containing the LOC388715 gene, both of which play a major role in the genetic susceptibility to AMD. Linkage to chromosome 9 replicates findings from multiple other groups. We have previously identified linkage to chromosomes 14 and 16 by using ordered subsets analysis (OSA) to stratify a microsatellite genome scan by clinical measures including intraocular pressure, systolic blood pressure and body mass index. Application of OSA to the new linkage data significantly increases the lod score on chromsome 14 from 1.55 to 4.1 in a clinically distinct subset of 61 families (p=0.017). In addition, this new genome scan identifies novel linkage peaks with multipoint lod scores greater than 1.0 on chromosomes 3, 6, 13, and 22. The most interesting novel linkage is on chromosome 20 with a lod 3.0. These linkage regions are being further examined using both family based and case/control association analyses. This work continues the rapid dissection of the genetic underpinnings of AMD, which will lead to new therapeutic interventions to help prevent blindness in millions of AMD patients.

Genome-wide association analysis of obesity using 304,968 SNPs in 869 Finnish normal glucose tolerant individuals. *K.L. Mohlke[1], A.U. Jackson[2], L.J. Scott[2], K.N. Conneely[2], A. Swift[3], K.F. Doheny[4], E.W. Pugh[4], R.M. Watanabe[5], G.R. Abecasis[2], T.T. Valle[6], J. Tuomilehto[6], R.N. Bergman[5], F.S. Collins[3], M. Boehnke[2]* 1) U North Carolina, Chapel Hill, NC; 2) U Michigan, Ann Arbor, MI; 3) NHGRI, Bethesda, MD; 4) CIDR, JHU, Baltimore, MD; 5) U Southern California, Los Angeles, CA; 6) National Public Health Institute, Helsinki, Finland.

Obesity is a major cause of morbidity and mortality in the USA and worldwide. Although obesity shows strong heritability, the underlying genes are not well understood. Waist to hip ratio (WHR) is a measure of fat distribution that strongly predicts cardiovascular disease. In the context of a case-control association study for type 2 diabetes, we performed preliminary association analysis with WHR using the first 869 of a planned 1186 normal glucose tolerant individuals in stage 1 of our 2-stage study. All individuals are participants in the Finland United States Investigation of NIDDM Genetics (FUSION) and/or Finrisk 2002 studies. These 869 individuals have an average WHR of .900 .088 (range .67-1.12) and an average BMI of 27.1 3.7 (range 17.5-39.1). Prior to association analysis the trait values were adjusted for age, gender, and birthplace within Finland. 304,968 SNPs genotyped on the Illumina HumanHap300 BeadChip passed initial quality control using criteria of >95% success, HWE p>.001 and <2 duplicate discrepancies. For each SNP analyzed we calculated p-SNP, an overall p-value for the SNP corrected for 3 genetic models tested. The lowest p-SNP of $2.4x10^{-6}$ was observed for rs966935, a SNP on chromosome 10 located 7.5 kb from a putative processed transcript; the median WHR values for 77 GG, 384 AG, and 407 AA individuals were .918, .906 and .890, respectively. Slightly more p-SNP values exceed the significance threshold of .005 than expected by chance (p=.01). These results suggest that the genetic variants responsible for susceptibility to obesity have modest effects not easily distinguished from chance results in 869 samples. Analysis of all stage 1 samples for WHR, waist circumference, and BMI will further clarify the role of these SNPs in obesity susceptibility.

Prader-Willi syndrome (PWS) in Taiwan. *S.-P. Lin[1, 2, 3], H.-Y. Lin[1], J.-L. Yen[4], M.-C. Chao[5], D.-M. Niu[6], P.-L. Kuo[7]*
1) Department of Pediatrics & Medical Research, Mackay Memorial Hospital, Taipei, Taiwan; 2) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 3) Department of Infant & Child Care, National Taipei College of Nursing, Taipei, Taiwan; 4) Department of Pediatrics, Branch for Women & Children, Taipei City Hospital, Taipei, Taiwan; 5) Department of Pediatrics, Kaohsiung Medical University Chung-Ho Memorial Hospital, Kaohsiung, Taiwan; 6) Department of Pediatrics, Taipei Veterans General Hospital, Taipei, Taiwan; 7) Department of Obstetrics & Gynecology, National Cheng-Kung University Hospital, Tainan, Taiwan.

The information concerning the clinical features of PWS is rather fragmentary in Taiwan. We report retrospective analysis of 70 PWS cases (M:F=39:31; age one month to 23 years) seen in 4 major medical centers in Taiwan from 01/88 to 05/06. All cases were confirmed by methylation-specific PCR. Complete genetic study was performed in 52 patients. The abnormalities found included deletions in 45 (87%), maternal UPD in 5 (10%), and probable imprinting center deletion or imprinting defect in 2 (4%). The average weight at birth was 2588540 gm. Bone age delay > 2 years was detected in 11/40. GH deficiency was noted in 12/20. In 2000, Taiwan instituted Rare Diseases & Orphan Drugs Act and mandated a 3-phase screening protocol for PWS. Of the 41 diagnosed prior to 2000, only 4 (10%) were diagnosed before age of 3 months; in the 29 patients diagnosed after 2000, 15 (52%) were diagnosed before 3 months of age ($p<0.001$). Our finding is in contrast to most of the previous reports that indicated a higher incidence of UPD. It is not clear whether this discrepancy in incidence of UPD arises from under-diagnosis, or because of ethnic differences, or a younger maternal age in our group. This question is worthy of further study. The 3-phase screening program has brought great impact to early diagnosis of PWS in Taiwan. Our Bureau of National Health Insurance agreed to subsidize GH therapy, in May 2005, for all the PWS patients up to the end of puberty. Up to now, 24 patients have received the therapy for more than a year. They all show a remarkable improvement in linear growth, weight control, and quality of life.

Molecular profiling of idiopathic hirsutism for markers of androgenic metabolism and insulin endothelial regulating genes. *D. Minella[1], F. Amati[1], M. Biancolella[1], G. Grassi[1], F. Gullotta[1], A.M. Nardone[1], P. Spitalieri[1], A. Farcomeni[2], S. Bueno[2], G. Chillemi[2], D. Lauro[3], A. Desideri[4], C. Moretti[3], G. Novelli[1]* 1) Dept. of Biopathology and Diagnostic Imagining, Tor Vergata University, Roma, Italy; 2) CASPUR, Roma, Italy; 3) Dept. of Internal Medicine, Tor Vergata University, Roma, Italy; 4) Dept. of Biology, Tor Vergata University, Roma, Italy.

Hirsutism is the presence of terminal hairs in females in a male-like pattern, and affects between 5% and 15% of women surveyed. Hirsutism results from the interaction between the androgen level and the sensitivity of the hair follicle to the androgen. However the severity of hirsutism does not correlate well with the level of androgen, because the response of the androgen-dependent follicle to androgen excess varies considerably within and among persons. In fact some women with excess androgen have no skin manifestations; other women develop hirsutism also with normal androgen levels (idiopathic hirsutism IH). The pathophysiology of IH is presumed to be associated to SRD5A activity, probably both isoenzyme types (SRD5A1 and SRD5A2) and possibly an alteration in androgen receptor function. However, hirsutism is also related to obesity and insulin resistance. With the aim of identify gene involved in the pathogenesis of this disease we have developed a specific oligonucleotide low-density microarray (called AndroChip). We used the microarray technology to study the expression profiles of 204 genes involved in the androgen biosynthesis and metabolism, and other genes coding for products active in the insulin pathway, in skin genital fibroblasts of four idiopathic hirsute women and 4 related controls. Expression level filtering and statistical analysis identified 6 differentially expressed genes, 4 up-regulated and 2 down-regulated. Differentially expressed genes included products involved in the insulin signalling and none was found to be related to the androgen pattern. This result suggests the misregulation of genes related to insulin pathway occur in hirsutism.

Long-term wide-spread somatic correction in MPS II mice using a self-complimentary AAV2 vector. *L.K. Kang*[1], *H.F. Fu*[2], *D.M.M. McCarty*[2], *J.M. Muenzer*[1] 1) Department of Pediatrics, University of North Carolina, Chapel Hill, NC; 2) Center for Gene Therapy, Columbus Childrens Research Institute, Department of Pediatrics, Ohio State University, Columbus, OH.

Mucopolysaccharidosis II (MPS II) is an X-linked lysosomal storage disorder due to the deficiency of the iduronate sulfatase (Id-S). No definite treatment is available for MPS II patients. AAV gene therapy is a promising treatment for MPS disorders. Traditional AAV vectors deliver a single-stranded DNA genome (ssAAV), which must be converted by host-cell-mediated DNA synthesis to double-stranded DNA for active expression. The recently developed self-complementary AAV (scAAV) vector allows more efficient expression by delivering a duplex genome and bypassing second strand DNA synthesis which may be the rate limiting step in AAV transduction. In this study, scAAV2 vector expressing human Id-S was compared to traditional ssAAV in MPS II mice. Both scAAV2 and ssAAV2 were administered to the adult MPS II mice intravenously (5 X 1011 viral particles) and intracisternally (5 X 1010 viral particles) after pretreatment with mannitol (1-2mg/gm body weight). Four scAAV treated MPS II mice were scarified at 20-22 months of age when they developed severe neurological symptoms. Our result demonstrated that complete correction of glycosaminoglycan storage in multiple tissues were observed in the scAAV treatment group, including liver, spleen, kidney, heart, lung, intestine, and muscle, compared to the nontreated mice ($p<0.05$). The ssAAV2 treated MPS II mice group shows complete correction in liver, partial correction in spleen, heart, lung, intestine and muscle and no correction in the kidney. Id-S enzyme activity was > normal levels in liver and spleen of the scAAV2 treated group, and about 10-100% of the normal activity in the kidney. In contrast, Id-S enzyme activity can only be detected in the livers, but not in the spleens or kidneys of the ssAAV2 treatment group. These results suggest scAAV2 mediated gene delivery results in significant wider distribution of Id-S expression compared to ssAAV. These preliminary results suggest that scAAV vector is a promising candidate for the treatment of MPS II.

Identification of multiple-gene associations from SLC6A4, ITGB3 and GABA receptor subunit genes in autism by MDR-Phenomics. *H. Mei[1,2], E. Martin[1], M. Pericak-Vance[1], M. Cuccaro[1]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Bioinformatics Research Center, NCSU, Raleigh, NC.

We present an application of a novel method, MDR-Phenomics, to identify multiple gene effects by analysis of autism (AUT) candidate genesserotonin transporter gene [SLC6A4] and integrin beta 3 [ITGB3] on Chr17 and -aminobutyric acid (GABA) receptor subunit genes (GABRB3, GABRB5 and GABRG3) on Chr15. In complex diseases like AUT, multiple genes may increase disease risk through weak additive effects or gene-gene interactions when only weak single-gene effects exist. Traditional methods based on tests of main gene effects often fail to detect disease-risk genes. While the MDR (Multifactor Dimensionality Reduction) and its extensions, EMDR and MDR-PDT, are designed to detect multiple gene effects, they may not detect joint effects when genetic heterogeneity exists. Genetic heterogeneity may be expressed as phenotypic heterogeneity (different genetic variants may lead to different constellations of clinical characteristics). To improve power in the presence of heterogeneity, we developed MDR-Phenomics, which detects single- or multi-locus associations with disease in families by using phenotypic covariates (PC). AUT is more frequent in males and displays broad variation in core features including social interaction, language, and repetitive behaviors. Using sex and severity of repetitive behaviors as PC for MDR-Phenomics we studied candidate genes in the serotonergic and GABA-ergic systems. We analyzed 3 markers in SLC6A4 and 4 markers in ITGB3 in 489 family triads with AUT using sex of the proband as a PC. We also examined eight markers in GABRB3, GABRB5 and GABRG3 in 148 family triads with severity of repetitive behaviors as a PC. The first analysis showed a significant 4-locus model with two loci from SLC6A4 and two loci from ITGB3. Statistical modeling is ongoing to understand this 4-locus effect. Results from the second analysis showed that a 2-locus model with a locus from GABRB5 and GABRG3 was marginally significant after adjusting for multiple tests. The results suggest that gene-gene interactions may exist between SLC6A4 and ITGB3, and between GABRB5 and GABRG3.

Association of toll-like receptor polymorphisms and pulmonary tuberculosis. *C.D. Hamilton[1], W.F. Hulme[1], J.B. Rimmler[1], S.G. Patillo[1], A.W. Mosher[1], M.E. Stryjewski[2], E.H. Abbate[3], R. Estevan[3], J.R. Gilbert[1], W.K. Scott[1]* 1) Department of Medicine, Duke University Medical Center, Durham, NC; 2) CEMIC, Buenos Aires, Argentina; 3) F.J. Muñiz Hospital, Buenos Aires, Argentina.

Tuberculosis (TB) is a significant cause of premature mortality worldwide. Ten percent of exposed individuals develop pulmonary TB, suggesting that host factors, partly under genetic control, determine development of active TB. Pattern recognition molecules such as the toll-like receptors (TLRs) are important contributors to innate immunity. In particular, TLR2, TLR4, and TLR9 have been shown to play a role in response to infection with *Mycobacterium tuberculosis* in mouse models. We collected samples from 171 African-American and 107 white families with at least one case of pulmonary TB. Individuals older than 14 years with culture-confirmed pulmonary TB and children younger than 14 years with culture- or clinically-confirmed TB were recruited from the North and South Carolina TB control programs and the outpatient population of F.J. Muñiz Hospital, Buenos Aires, Argentina and enrolled along with unaffected sibling or parental controls. We examined tag single nucleotide polymorphisms (tagSNPs) in each of these genes for association with TB in a family-based study. tagSNPs were selected from HapMap Phase II data using the tagger function of HaploView. tagSNPs captured the common variation (minor allele frequency (MAF) 5% in each gene with r^2 0.8. Other coding SNPs (cSNPs) with MAF 1% were genotyped as well. Nine SNPs in TLR2, 25 in TLR4, and 12 in TLR9 were genotyped using TaqMan. The association in the presence of linkage (APL) test was used to analyze marker-disease associations. Families were analyzed stratified by self-reported race to limit confounding by ethnic background. No significant associations were detected in the white family sample. Three SNPs in TLR2 and two SNPs in TLR9 were nominally associated with TB in the African-American sample (0.01p0.05) in single point analysis. These results suggest that genetic susceptibility to TB in individuals of African descent might be influenced by variation in the TLR2 and TLR9 genes.

Direct sequencing quality control: a novel software approach to reducing researcher labor. *K. Hunkapiller, E. Vennemeyer* Applied Biosystems, Foster City, CA.

With the completion of the Human Genome Project, the shift from de novo sequencing to direct sequencing (resequencing) has created the need for more accurate variant detection for medical research and clinical diagnostics. The bottleneck in the workflow (from DNA extraction to result data analysis) has been cited as taking up to 70% of researchers time per project, due to manual review of individual nucleotide bases. This review has been required due to the necessity of having confidence in the variant result. Increasing confidence can come from applying diligent quality control metrics, including use of Quality Values for DNA trace value and confidence values for variant validity. Based on Applied Biosystems experience, this system will both filter out bad data and alert users to potential resequencing problems. The software will then direct users to review only low confidence variants. A flexible workflow based system is being built to enable researchers to obtain their high confidence results in less time. Methods for filtering low quality data based on optimal settings and quality visualization tools will be integrated into the system along with simpler variant review and reporting tools to allow researchers to quickly analyze their data.

Mutations in TMEM76 are associated with N-acetyltransferase deficiency in mucopolysaccharidosis type III C patients. *M. Hrebicek[1], L. Mrazova[1], J. Majewski[3], L. Noskova[1], H. Hartmannova[1], R. Ivanek[2], A. Cizkova[2], H. Poupetova[1], J. Sikora[1], J. Urinovska[1], V. Stranecky[1,2], J. Zeman[1,2], S. Kmoch[1,2]* 1) Institute of Inherited Metabolic Disorders, Charles University, Prague, Czech Republic; 2) Center for Applied Genomics,Charles University, Prague, Czech Republic; 3) Department of Human Genetics and Genome Quebec Innovation Centre, McGill University, Montréal, Canada.

Mucopolysaccharidosis type IIIC (MPS IIIC) is caused by a deficiency of the acetyl-coenzyme A: -glucosaminide N-acetyltransferase (N-acetyltransferase), leading to impaired degradation and lysosomal storage of heparan sulfate. To identify the MPSIIIC gene we assessed 54 individuals from four Czech MPS IIIC families. Measurement of N-acetyltransferase levels in leukocytes unambiguously classified affected, carriers, and non-carriers and allowed us to performed linkage analysis under an autosomal codominant model. We genotyped 18 microsatellite markers located in a recently identified MPS IIIC locus on chromosome 8. In all families we confirmed the linkage to MPS IIIC region with a maximum LOD score of 7.8 at D8S531 and identified several recombination events that narrowed the candidate region between markers D8S1115 and D8S1831 and physical coordinates 42655724-51968859 Mbp of chromosome 8. Bioinformatic search and gene expression analysis of all the genes located within the candidate region on oligonucleotide microarrays pinpointed a single gene *TMEM76* with significantly decreased expression in patient samples. Sequence analysis of the *TMEM76* showed that all five patients from analyzed families are compound heterozygotes for eight different mutant alleles. Five mutations are predicted to result in truncated products (L321X, R384X and R506X, 16 bp deletion I345fs, and splicing mutation IVS9+5G>A). The rest are missense mutations R344H, M482K and P571L affecting the conserved residues. All the mutations completely segregated in the families with the phenotype based on the enzyme assay, which provides support that *TMEM76* is the gene encoding N-acetyltransferase deficient in MPSIIIC patient. Support: NR/8361-3, 1A/8239-3 from IGA MZ-CR.

Activity-dependent PP2A dephosphorylation of FMRP suggests a novel, dynamic and immediate phase of translational regulation in neurons. *U. Narayanan[1], M. Nakamoto[1], D. Pallas[2], S.T. Warren[1,2,3]* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Biochemistry, Emory University, Atlanta, GA; 3) Department of Pediatrics, Emory University, Atlanta, GA.

Fragile X syndrome is a frequently inherited form of cognitive impairment caused by transcriptional silencing of the *FMR1* gene. Thus, there is a functional absence of the encoded protein, FMRP, a selective RNA-binding protein that suppresses translation of target messages when phosphorylated at serine 499. We have identified protein phosphatase 2A (PP2A) as a FMRP phosphatase in both primary neuron cultures and non-neuronal cells. Here, we present biochemical studies demonstrating that PP2A enzymatic activity mediates a rapid (< 1 min) FMRP dephosphorylation following mGluR5 stimulation in primary hippocampal neurons. However, longer mGluR5 stimulation (> 5 min) resulted in FMRP phosphorylation. These activity dependent changes in FMRP phosphorylation correlated with translational changes of a predominantly dendritic target transcript, *SAPAP3*. Thus, these data link mGluR5 activation and PP2A enzymatic activity with FMRP phosphorylation suggesting a novel, temporally restricted phase of local protein synthesis that may represent an immediate effect of synaptic activation.

Population Stratification Adjustment Based on Assessment of "Spurious" Linkage Disequilibrium. *D. Hu, E. Ziv*
Center for Human Genetics, Department of Medicine, University of California San Francisco, San Francisco, CA.

Population substructure or recent admixture may confound the results of genetic association studies among unrelated individuals. Several methods exist for assessing and adjusting for population stratification using additional control loci. These methods can be classified as genomic control and structured association. Both approaches generally work well, but have certain limitations. We have developed a novel approach to assess and adjust for substructure and recent admixture in association studies. The approach is based on the concept that allelic association between physically unlinked markers (spurious linkage disequilibrium) is the basis for the false positive and false negative results. We derive a summary measure of spurious LD (SLD) for each candidate marker with the rest of the genome. The estimate of SLD is then used to weight the association statistic for that particular marker. We simulate the method under a variety of conditions using data on allele frequency from the HapMap. We show that the method works well under a variety of discrete and admixed population scenarios. For example, to eliminate the bias in an association study that includes individuals of both African and European ancestry, approximately 50 random SNP markers are required. In contrast, for a population consisting of groups as similar as Chinese and Japanese approximately 250-500 random SNP markers are required. Our approach is similar to the structured association approach which identifies subpopulations based on (SLD). However, our approach does not require explicit identification of subpopulations and therefore may be more useful in studies where substructure is subtle and the number of subpopulations is difficult to detect.

100 Robust Dosage PCR (RD-PCR) assays: easy to develop and highly accurate dosage assays can robustly detect germline deletion mosaicism at a level of 1.4 copies per genome. *V.Q. Nguyen[1], J. Han[2], C.H. Buzin[2], C. Kasper[3], S.S. Sommer[1,2]* 1) Dept Molecular Genetics, City of Hope Medical Ctr, Duarte, CA 91010; 2) Clinical Molecular Diagnostics Laboratory, City of Hope Medical Ctr, Duarte, CA 91010; 3) Orthopaedic Hospital of Los Angeles, Los Angeles, CA 90007.

Recently, Multiplex Ligation PCR Amplification (MLPA) has become widely used for dosage analyses. Though multiplex dosage analyses can be performed, new assay development can be time consuming and significant false-positive and false-negatives can occur (1-3). In contrast, RD-PCR assays are easy to develop, reproducible and highly accurate, but each region has to be analyzed individually. Wild type male and female samples serve as dosage controls, even in the absence of known deletions. We have developed over 100 RD-PCR assays, which are routinely validated by blinded analyses. To illustrate the accuracy of RD-PCR, we describe a mosaic for a large deletion in hemophilia B. The mother is a heterozygous carrier while the maternal grandmother is mosaic for the deletion (average of 1.4 copies per white blood cell). The average standard deviation across three exons from 48 samples assayed by two individuals for wild type males, wild type females, and the mosaic person are 0.009, 0.016 and 0.012, respectively. RD-PCR assays are flexible and rapidly developed with an accuracy sufficient to detect mosaicism as well as heterozygous deletions and duplications. 1) Walsh et al., (2006) JAMA 295(12):1379-1388; 2) Monfort et al., (2006) J Lab Clin Med, 147:295-300; 3) Warshawsky et al. (2006) Clin Chem 52:7.

Analysis of a de novo complex chromosomal rearrangement: t(4q;9q) with ins(Xq;4q) identified by FISH and defined by array-based comparative genomic hybridization in a patient with dysmorphic features. *K.S. Hwang[1], Y.J. Chen[2], M.H. Tseng[3], D.C. Ding[4], Y.S. Yuh[3], J.S. Chang[5], S.W. Cheung[6]* 1) Department of Obstetrics and Gynecology, Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan; 2) Institute of Genome Sciences, School of Life Sciences, National Yang-Ming University, Taipei, Taiwan; 3) Department of Pediatrics, Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan; 4) Department of Obstetrics and Gynecology, Buddhist Tzu Chi Medical Center, Hualien City, Taiwan; 5) Youthgen Biomedical Laboratory, Taipei, Taiwan; 6) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The development of molecular cytogenetics techniques has made it possible to identify complex and cryptic chromosome rearrangements in mentally retarded and dysmorphic individuals who could not be diagnosed by conventional cytogenetics analysis. We report on a 9-months-old girl who presented with growth deficiency, developmental delay, and dysmorphic features including hypertelorism, low-set ears, simian crease, and low saddle nose. The G-banding analysis revealed a de novo complex chromosomal rearrangement (CCR) involving the distal long arm of one chromosome 4, 9, and X. FISH analysis using whole chromosome painting revealed not only a translocation between the long arms of chromosomes 4 and 9 but also an interstitial deletion from chromosome 4q that became inserted at the translocational breakpoints on derivative chromosome X. Comparative genomic hybridization (CGH) on metaphase chromosomes showed no apparent loss and gain. Subsequent array-based CGH will be performed to identify the abnormality. Molecular cytogenetics characterization of the CCR with these methodologies and follow up studies will be presented. This case further demonstrates the diagnostic usefulness of combining conventional cytogenetics with new molecular chromosome analysis methods for clinical interpretation of complex chromosome abnormalities.

Phenotype-association based ranking of human disease protein complexes. *K. Lage[1], E.O. Karlberg[1], Z.M. Størling[1], P.I. Olasson[1], O. Rigina[1], A. Gorm[1], Z. Tumer[2], F. Poicot[3], N. Tommerup[2], S. Brunak[1]* 1) CBS, DTU, Lyngby,Denmark; 2) WJC, IMBG, University of Copenhagen, København; 3) Steno Diabetes Center, Gentofte.

Efforts are ongoing to search for novel global aspects of human disease and recent studies hint at the general existence of human disease protein complexes. Here we make a systematic analysis of such complexes hereby showing they exist in all categories of human disease. By making a phenotype association based ranking of putative human disease protein complexes, we develop a novel Bayesian predictor which in 298 out of 669 linkage intervals correctly ranks the known disease causing protein as the best candidate, hereby outperforming other computational methods for disease gene identification. Based on this approach we prioritize candidate genes in ~850 linkage intervals, with no identified disease gene, leading to likely novel candidates in disorders such as Alzheimer disease, amyotrophic lateral sclerosis, inflammatory bowel disease and type 2 diabetes. By constructing a quality controlled human protein interaction network and implementing an computational phenotype association scheme, we show here that disease complexes exist in essentially all categories of human disease. We use this approach to identify a large number of potential human protein disease complexes, and train a Bayesian predictor to prioritize candidates in around 850 linkage intervals associated with various specific diseases, based on these complexes. We present a thorough benchmark and a number of case studies to show how the proposed disease complexes can be exploited to generate novel hypotheses which point directly at specific validation experiments and specific patient material. Thus, integrated data underlying these predictions provide a first draft of ~90 potential human disease protein complexes in many different categories of human disease at a level of completeness determined by the current amount of data.

Subclinical orbicularis oris muscle (OO) defects are increased in relatives of individuals with nonsyndromic cleft lip with or without cleft palate (CL/P). *K. Neiswanger[1], S.M. Weinberg[1], C.R. Rogers[1], C.A. Brandon[1], M.E. Cooper[1], K.M. Bardi[1], M.P. Mooney[1], J.M. Resick[1], F.W.B. Deleyiannis[1], A. Bowen[2], J.E. De Salamanca[3], M.L. Marazita[1]* 1) Univ Pittsburgh, Pittsburgh, PA; 2) Ch Hosp, Pittsburgh, PA; 3) Niño Jésus Univ Ch Hosp, Madrid, Spain.

Nonsyndromic CL/P is a common birth defect that occurs more frequently in males than females. We hypothesized that defects in the OO muscle are a subclinical form of cleft lip. To test this, upper lip ultrasound images were taken for 782 people with no overt cleft (525 unaffected relatives of individuals with CL/P and 257 controls). The images were scored and staffed by three independent raters as normal (a continuous OO muscle), affected (discontinuous at some point), or unknown. Study subjects were ascertained from three populations: Guatemalans (285 relatives, 136 controls), U.S. Caucasians (147 relatives, 121 controls), and Spanish Caucasians (93 relatives only). In the overall sample, 10.3% (54/525) of the relatives had an OO defect, significantly higher than the 5.8% (15/257) observed in controls ($p = 0.04$). Although not statistically significant, the same trend was seen in the Caucasian and Guatemalan samples separately. When the sample was stratified by gender, significantly more male relatives had OO defects than male controls [12.0% (28/234) vs 3.2% (3/94); $p = 0.01$]; similarly, more female relatives than female controls had OO defects, but this difference was not statistically significant [8.9% (26/291) vs 7.4% (12/163); $p = 0.56$]. Inclusion of OO data in candidate gene SNP association tests added 29 new affected individuals to the analysis, and increased significance for association with IRF6 from $p = 0.007$ to 0.006, with FGF10 from $p = 0.01$ to 0.003, and for EGFR from $p = 0.006$ to 0.003. Our results suggest that, as with overt clefting, males tend to demonstrate a lower threshold for subclinical forms, such as OO defects, and that OO defects are likely to be part of the phenotypic spectrum of CL/P. Supported by NIH grants R01-DE016148, P50-DE016215, R21-DE016930, M01-RR00084, SNP genotyping: CIDR NIH contract N01-HG-65403.

Initial Discovery and Replication in Whole Genome Association Scans: A Sequential Analysis Approach. *B.S. Maher, R.J. Weyant, T. McHenry, M.L. Marazita* Univ Pittsburgh, PA.

A major issue in whole genome association studies is replication. To address this issue, many two stage designs have been proposed. However, for many investigators, sample splitting will result in a sample size lacking power to detect an initial discovery. Thus, many investigators are faced with the a priori decision of a two-stage design, sacrificing the power of the full sample for initial discovery; or a single stage design, sacrificing the ability to replicate an initial discovery. We propose a sequential analytic design that maintains the power of a single stage design while providing the opportunity for replication in a single sample. The method follows the approach proposed by OBrien and Fleming (1979) for sequential clinical trials. Under the sequential design, samples can be sequentially added in a planned number of interim analyses, while preserving a subset of the sample for replication and maintaining the study-wise type I error rate. To simulate a large scale genetic association study, we simulated 10,000 replicates of 10,000 SNPs (1 disease, 9999 null) in a sample of 1000 case-control (c-c) pairs under a variety of genetic models. The samples were analyzed and compared under three analytic approaches: two-stage (500 initial and 500 replication c-c pairs), the single stage with 1000 c-c pairs, and the sequential design (performing 3 interim analyses while reserving the remaining sample for replication). We demonstrate that the sequential design outperforms the two-stage design and maintains the power of the complete sample (single stage) for initial discovery under every tested model. For example, at an odds ratio of 1.4, the power to detect initial allelic association is 90.3% and 89.8% in the sequential and single stage designs respectively while it is only 19.0% for the two-stage design. The sequential design also has greater study-wise power to detect and replicate an allelic association. At an odds ratio of 1.4, the power to detect and replicate a finding was 57.4% for the sequential design and only 18.8% for the two-stage design. Lastly, we demonstrate that the sequential design maintains the proper study-wise type I error rate.

BAX gene polymorphisms increase risk and severity of multiple sclerosis in Caucasians. *J.D. Hart[1], J.M. van der Walt[1], A.M. Prokop[1], S. Schmidt[1], S.G. Gregory[1], N. Schnetz-Boutaud[2], J.L. McCauley[2], J.L. Haines[2], M.A. Pericak-Vance[1]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Ctr Human Genetics Research and Dept of Molecular Physiology and Biophysics, Vanderbilt Univ Medical Ctr, Nashville, TN.

Multiple sclerosis (MS) is an inflammatory disease of the central nervous system characterized by demyelination and axonal damage. Mechanisms which underlie MS etiology are not well defined; however, disregulation of the apoptotic pathway may play an important role. Therefore, we examined eight polymorphisms within the pro-apoptotic gene, BAX, in a large family-based study including 842 families and 636 discordant sib-pairs for association with MS risk. BAX is located within a region of genetic linkage in MS on chromosome 19q. Family-based tests (PDT, APL) were used to test whether SNPs in BAX influence risk of MS. We observed significant association of markers rs1009316 (p-value=0.007), rs1805419 (p-value=0.013) and rs2387583 (p-value=0.006) with increased risk of MS. All makers are located within intronic regions and are in high linkage disequilibrium. We also calculated Multiple Sclerosis Severity Scores (MSSS) for each affected individual in order to define disease progression (severity). MS severity can be evaluated by comparing a patient's EDSS score (Expanded Disability Status Scale) for a given disease duration against the Global MSSS distribution calculated for a large Caucasian reference population (Roxburgh et al. 2005). Our analysis demonstrated that rs1009316 significantly effects disease severity (p-value = 0.01). Our preliminary results suggest that BAX influences both risk and severity of MS. We are conducting comprehensive resequencing of BAX to identify causal variants that may be associated with MS risk.

Investigating the origins of the BRCA1 mutation c.5385dupC. *N. Hamel[1], L. Foretova[2], S.A. Narod[3], L. Tihomirova[4], V. Zajac[5], S. Ciernikova[5], S. Armaou[6], D. Yannoukakos[6], C. Greenwood[7], W.D. Foulkes[1]* 1) Dept Medicine, McGill Univ Health Ctr, Montreal, Canada; 2) Dept Cancer Epidemiology & Genetics, Masaryk Memorial Cancer Inst, Brno, Czech Republic; 3) Ctr for Research on Women's Health, Univ Toronto, Canada; 4) BMC, Riga LV-1067, Latvia; 5) Dept Cancer Genetics, Cancer Res Inst, Slovak Academy of Sciences, Bratislava, Slovak Republic; 6) Mol Diag Lab, Natl Ctr Scientific Research, Athens, Greece; 7) Prog in Genetics & Genomic Biol, Hospital for Sick Children Res Inst, Toronto, Canada.

The BRCA1 mutation c.5385dupC is a well-known cancer susceptibility founder in the Ashkenazi Jewish (AJ) population, but it is also found in several non Jewish populations throughout Europe and elsewhere. We wanted to know whether the mutation originated from a single common ancestor or whether it arose many times in human history. Since c.5385dupC consists of a C inserted among three consecutive Cs, this site may represent a hotspot for replication error. We collected 135 AJ and non-AJ mutation carriers from Latvian, Greek, Slovak, Czech, Polish, Brazilian and Canadian populations. All carriers were genotyped for 15 microsatellite markers spanning 12 Mb on chr 17 including BRCA1. When available, close relatives of the carriers were also genotyped. Preliminary data showed 100% linkage between the mutation and a rare allele (frequency < 1% in controls) at marker D17S1327, 268 kb from the mutation, suggesting c.5385dupC is identical by descent in all populations studied. Based on our preliminary data, we genotyped 36 additional SNP markers within a 2.9 Mb maximum region of conservation observed around BRCA1. We are currently reconstructing haplotypes from all genotypes using the program PHASE. These haplotypes will be used to estimate the age of the mutation based on progressive decay of linkage disequilibrium as a function of distance from the mutation using the Bayesian linkage analysis program DMLE. Neuhausen et al (1996) previously estimated the age of this mutation to be 36 generations (720 years). Our larger study should refine this preliminary estimate and help us gain insight into the place of origin of c.5385dupC and how it spread to the populations where it is found today.

The medical sequencing pipeline at the Washington University GSC. *Y. Kasai, L. Ding, E. Mardis, R. Wilson, GSC Medical Sequencing Team* Genome Sequencing Center, Washington University School of Medicine, 4444 Forest Park Ave. St. Louis, MO 63108.

With the completion of the reference human genome sequence, researchers have begun to answer questions about individual human genomic variation, both in the context of normal variation and of disease onset, progression and prognosis. Over the past year, the GSC at Washington University has developed a high-throughput pipeline for PCR-based genomic re-sequencing, including infrastructure to design and test primer pairs, automation to achieve 384-well plate-based sample processing, and barcode-based sample tracking. We also have developed robust procedures and QC checks throughout the pipeline. At present, human re-sequencing data is actively being produced with this pipeline for multiple genes using DNA from a variety of patient-derived tissues. Our corresponding sequence analysis pipeline utilizes a suite of informatics tools for mutation detection of the assembled sequence reads. A GBrowse-based viewer that illustrates polymorphisms and somatic mutations in the context of relevant genome annotation are under development. Results from some ongoing projects (including a cancer genomics effort) will be presented.

The relationship between Glucokinase -30 G/A variant, early growth and adult metabolic phenotypes in a Finnish birth cohort. *M-R. Jarvelin[1,5], A.J. Bennett[2], U. Sovio[1], A. Ruokonen[3], H. Martikainen[4], A. Pouta[5], A-L. Hartikainen[4,5], S. Franks[6], P. Elliott[1], M.I. McCarthy[2,7]* 1) Dept of Epidemiology and Public Health, Imperial College London, London, UK; 2) DRL OCDEM, Oxford, UK; 3) Dept of Clinical Chemistry, University of Oulu, Finland; 4) Dept of Obstetrics and Gynaecology, University of Oulu, Finland; 5) Dept of Public Health Science and General Practice, University of Oulu, Finland; 6) Institute of Reproductive and Developmental Biology, Imperial College London, UK; 7) Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

Rare mutations in the glucokinase gene (GCK) have been associated with type-2-diabetes and low birth weight. More common variants, such as the -30 promoter variant (G/A rs1799884) have also been associated with glucose intolerance, reduced beta-cell function and abnormal early growth. To determine the ability to generalize the findings, we genotyped this variant in 5141 subjects from the Northern Finland Birth Cohort of 1966 using an Amplifluor assay. We used linear regression to analyse associations with early growth (e.g. birth weight, ponderal index) and adult metabolic phenotypes (e.g. fasting glucose, BMI, beta-cell function [HOMA%B]) measured at age 31y. Genotype frequencies were in Hardy-Weinberg equilibrium (p=0.62). No significant associations were observed for measures of early growth. However, fasting glucose at age 31 was significantly associated with an increasing number of copies of the minor A allele (p=0.003, adjusted additive model). When the individuals with fasting glucose levels >6mmol/l were excluded (to remove outliers with frank diabetes), the per-allele increase in glucose remained significant (p=0.001). HOMA%B showed non-significant reductions with increasing copies of the A allele (p=0.066). In this large birth cohort, we confirmed that variation in the GCK promoter modifies adult fasting glucose levels, but were unable to confirm associations with early growth measures such as birth weight. This may reflect the competing effects of maternal GCK variation (causing gestational diabetes and macrosomia) and variation in the fetus which compromises insulin secretion and growth.

Genetic and Cellular Factors Influencing the Frequency of Nonallelic Recombination Among Interspersed Repetitive Elements. *D.J. Hedges, P.L. Deininger* Tulane Cancer Center, Tulane University Health Sciences Center, New Orleans, LA.

A substantial fraction of the human genome is comprised of parasitic L1, Alu, and SVA repetitive elements. While a number of genetic diseases have been directly attributed to disruptions caused by mobile element insertions, still more appear to be the consequence of subsequent genetic instability resulting from nonallelic recombinations among interspersed element copies. The various factors governing the relative stability/instability of repetitive elements residing in diverse genetic contexts remain poorly understood. Additional empirical data concerning when and where instability most frequently occurs may aid in predicting regions in the genome that have the highest likelihood to destabilize in the germline or in the soma during an organism's lifespan. Identifying such regions of "cryptic genomic instability" may help in further narrowing candidate regions, not only for specific genetic disorders, but also those related to tumorgenesis, metastatic evolution, and genetic deterioration associated with aging individuals. In order to gain further insight into the influence of various genetic and cellular factors on the propensity for nonallelic recombinations among mobile elements, we have constructed a series of cell culture-based reporter assays. With these assays, we have the ability to place repetitive elements within diverse genetic contexts and cellular conditions in order to observe the resultant impact on nonallelic homologous recombination frequencies. Here we report on our initial results from these experiments. Our preliminary data indicate that increases in the ambient level of mobile element expression itself significantly impacts the observed recombination frequency. This result suggests that, in addition to providing ideal substrates for nonallelic recombinations, mobile element activity also actively instigates these instability events, probably through introduction of DNA double-strand breaks. These results further illustrate the potential epidemiological risks associated with inter-individual variation in human mobile element activity.

GENOME: a rapid coalescent-based whole genome simulator. *L. Liang, S. Zöllner, G.R. Abecasis* Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Computer simulations can provide important information to help plan genome-wide association studies. Nevertheless, present simulation methods do not allow efficient simulation of whole genomes. We present GENOME, a computer program that uses a rapid coalescent approach to sample whole genome data (>3000 Mb) from a population simulated using the Wright-Fisher neutral model. The program assumes an infinite-site mutation model and allows for recombination and migration among subpopulations. Past demographic events such as population bottlenecks or expansion and population merges and splits can also be simulated. In addition to uniform recombination rates, it is possible to allow recombination rates to vary so as to mimic the pattern of hotspots along the genome. Within small regions, we have compared our simulated samples with those generated by other coalescent simulators and theoretical predictions and show that GENOME provides the expected LD patterns and frequency spectra. To simulate 1200 sequences, each 150Megabases long, GENOME requires ~44 minutes, compared to >12 hours for Hudson's ms. The program can be used to study the sampling properties of any statistic for a whole genome study under the neutral model. We evaluate the properties of several statistics that may be useful for genome wide association scans by simulating regions of different lengths.

N-Acetylmannosamine treatment rescues a mouse model of Hereditary Inclusion Body Myopathy. *M. Huizing[1], E. Klootwijk[1], B. Galeano[1], I. Manoli[1], M-S. Sun[1], C. Cicone[1], D. Darvish[2], D. Krasnewich[1], W.A. Gahl[1]* 1) MGB,NHGRI, NIH, Bethesda, MD; 2) HIBM Research Group, Encino, CA.

Hereditary Inclusion Body Myopathy (HIBM) is an adult onset autosomal recessive neuromuscular disorder characterized by slowly progressive distal and proximal muscle atrophy and weakness. This myopathy is caused by deficiency of UDP-GlcNAc 2-epimerase/ManNAc kinase (GNE), the rate-limiting, bifunctional enzyme catalyzing the first two committed steps of sialic acid biosynthesis. Decreases in GNE activity impair sialic acid production and interfere with sialylation of muscle glycoproteins such as -dystroglycan. Levels of polysialic acid on neural cell adhesion molecule (PSA-NCAM) may also be affected. To study the pathogenesis and treatment of HIBM, we created a GNE knock-in mouse mimicking the human Persian-Jewish GNE founder mutation, M712T. Homozygous (-/-) mutant mice were born in a Mendelian distribution, but did not survive beyond postnatal day 3 (P3). GNE enzyme activity in skeletal muscle tissues of -/- mice at age P2 was 20% of normal. However, histological examination did not reveal any muscle pathology. Rather, the kidneys of -/- mice showed petechial hemorrhages, proteinuria, and signs of glomerular disease. As a treatment option, we administered to pregnant females ManNAc (1 g/kg/d), an uncharged sugar intermediate located within the sialic acid pathway after the GNE feedback inhibition step. Upon feeding +/- matings ManNAc in their drinking water, 44% of the -/- pups survived beyond P3. At P2, -/- mice that received ManNAc had less severe kidney hemorrhages, and their muscle GNE activities increased to 50% of normal mouse levels, suggesting that ManNAc might stabilize the mutant enzyme. Surviving -/- mice were smaller than their littermates, but appeared healthy otherwise, even after weaning (P21), when they no longer received ManNAc. It remains to be determined if the surviving -/- mice (now ages 3 and 6 mo) will develop a muscular pathology later in life. Taken together, survival of -/- mice, improved kidney pathology and increased GNE activity after ManNAc administration strongly support consideration of a clinical trial of ManNAc for the myopathy of HIBM.

Genomewide SNP linkage scan of schizophrenia in a large multicenter sample. *D.F. Levinson[1], P.V. Gejman[2], C. Laurent[3], M.J. Owen[4], A.E. Pulver[5], B. Riley[6], D.B. Wildenauer[7], K.S. Kendler[6], J. Mallet[3], B.J. Mowry[8], G. Nestadt[5], M.C. O'Donovan[4], A.R. Sanders[2], S.G. Schwab[7], V.K. Lasseter[5], I. Nikolov[4], R. Segurado[4], P.A. Holmans[4], Schizophrenia Linkage Collaborative Group* 1) Stanford University, Palo Alto, CA; 2) ENH/Northwestern University, Evanston, IL; 3) LGN/CNRS, Paris, France; 4) Cardiff University, Cardiff, UK; 5) Johns Hopkins University, Baltimore, MD; 6) Virginia Commonwealth University, Richmond, VA; 7) University of W. Australia, Perth, Australia; 8) University of Queensland, Brisbane, Australia.

A genomewide linkage scan was carried out in pedigrees from 8 clinical samples, including 971 families with 4,540 genotyped subjects, 2,120 affected under a narrow diagnostic model (schizophrenia or schizoaffective disorder). Of 5,992 autosomal, X and XY SNP markers (Illumina v4 map), 5,903 met quality control criteria. We are analyzing marker-marker linkage disequilibrium (Haploview), constructing maps that maximize marker heterozygosities while constraining marker-marker r2 values to 0.05 or less, and carrying out multipoint linkage analyses (ALLEGRO, exponential model). Analyses of six chromosomes have been completed for the primary analysis of 755 informative European-ancestry pedigrees (3,479 genotyped individuals, 1,727 affected). Suggestive evidence for linkage (pointwise $p < 0.0005$, information content 0.90) was observed on chromosome 8p at 46.8 deCode cM. This peak is consistent with findings in other samples, and it is of interest that the well-known candidate gene NRG1 lies outside the 1-lod support interval (42.6-50.5 cM), but it is not yet known whether NRG1 and/or other loci account for the linkage evidence observed in these studies. Notably, on the chromosomes analyzed so far, 25-30% of SNPs had to be removed to reduce LD, otherwise very large spurious linkage peaks were observed in regions with multiple high-LD marker pairs. Ongoing are analyses of all chromosomes for the European-ancestry families, of all families, of linkage taking cross-site heterogeneity into account, and of the effect of these and other recent results on Genome Scan Meta-Analysis results for schizophrenia.

SCREENING TO FIND LOCI ASSOCIATED WITH CLEFT LIP AND PALATE. *K. Osoegawa[1], G.M. Vessere[1], R. Pfundt[2], E.F.P.M. Schoenmakers[2], J. Staaf[3], A. Borg[3], M.A. Mansilla[4], B.C. Schutte[4], E. Lammer[1], J.C. Murray[4], P.J. de Jong[1]* 1) Children's Hospital Oakland Research Institute, Oakland, CA; 2) Dept. Human Genetics, University Medical Centre Nijmegen, The Netherlands; 3) Dept. Oncology, Lund University, Sweden; 4) Pediatrics and Biological Sciences University of Iowa, IA.

Human bacterial artificial chromosome (BAC) libraries played a critical role for construction of physical maps and genome sequencing. We previously developed a high-resolution overlapping-BAC collection of >32,000 well-characterized clones, spanning the entire human genome. We subsequently used PCR-amplified DNAs from these BACs to create array comparative genomic hybridization (CGH) slides with a detection resolution for copy number variation of about 70 kbp. Cleft lip with or without cleft palate (CL/P) are common structural birth defects. We are surveying the genome for candidate gene regions by searching for micro-deletions/duplications using DNA samples derived from 48 cases of syndromic CL/P (20 of Van der Woude syndrome). The patient and reference DNA samples were labeled with Cy3 and Cy5, respectively, and co-hybridized onto 32k array-CGH slides. We identified several deletions and duplications with sizes exceeding 500 kb. Interestingly we have identified a novel large duplication on 8p21.3-8p12 (8.8 Mb) along with a deletion of 8q23.1-8q24.12 (11.2 Mb) in one of the samples tentatively diagnosed with Kabuki syndrome. We also identified a 2.7 Mb deletion on 22q11.21 from a patient having cleft palate. The region is overlapping with known DiGeorge syndrome region. We also focused on the chromosome 1q32.2 region that includes the interferon regulatory factor 6 (IRF6) gene and found 100 kb - 1Mb deletions for five patients, including two previously reported deletion cases. Mutation in the IRF6 gene has been reported to cause Van der Woude Syndrome, the most common form of syndromic cleft lip and palate. While these 1q32.2 mutations do not indicate a new genetic or congenetic source for CL/P, the findings reveal the sensitivity of our detection approach. We plan to look at parents for evidence of de novo deletions.

Improved long-term survival of the mucopolysaccharidosis II mouse after combined intravenous and intracisternal administration of an AAV2 vector expressing iduronate sulfatase. *J. Muenzer[1], L. Kang[1], S. Moy[2], H. Fu[1,3]* 1) Dept Pediatrics, University North Carolina, Chapel Hill, NC; 2) Dept Psychiatry, University North Carolina, Chapel Hill, NC; 3) Center for Gene Therapy, Columbus Children's Research Institue, Dept of Pediatrics, Ohio State University, Columbus,OH.

Mucopolysaccharidosis II (MPS II) is an X-linked disease due to the deficiency of the lysosomal enzyme iduronate sulfatase (Id-S). Deficiency of Id-S results in lysosomal accumulation of glycosaminoglycans (GAG), with progressive tissue and organ dysfunction, and premature death. No definite treatment is available for MPS II patients. Adeno-associated virus (AAV) mediated gene delivery is a promising treatment for lysosomal storage disorders. We studied the therapeutic effects of combined intravenous (IV) and intracisternal (IC) injections of AAV2 vector expressing the human Id-S cDNA driven by a CMV promoter after pretreatment with mannitol in the MPS II mouse. We injected 2 X 10^{11} viral particles IV and 2 X 10^{10} viral particles IC after 1-2 mg of mannitol/gm body weight in 22 MPS II mice at 4 to 6 weeks of age. AAV2 treated MPS II mice were scarified when they developed severe neurological symptoms between 15 to 23 months of age. The AAV treated mice had complete correction of GAG accumulation in liver ($P<0.01$) and partial correction in spleen, heart, muscle, and lung ($P<0.05$). Id-S enzyme activity was detected in the liver of treated MPS II mice from 50% to 120% of that in normal mice. Histopathology and transmission electron microscopy studies show clearance of lysosomal storage in liver. Decreased CNS lysosomal storage was shown by histopathology in the brain. Id-S enzyme was detected in the brain of the AAV injected mice (1%-7% of normal). MPS II mice after AAV treatment had improved physical features and rotarod performance. The life span of the MPS II mice after the AAV gene therapy was prolonged (means 17.8 months), compared with the life span of the non-treated group (means 13.4 months) ($p<0.01$). These results suggest that IV combined with IC injections of AAV2 vector following mannitol pretreatment is a promising approach for treating both somatic and CNS disease in lysosomal storage disorders.

Acute presentation of beta ketothiolase deficiency- Should PALS take into consideration metabolic disorders? *L. Lukose*[1], *T. Markello*[2] 1) Medical Genetics, National Human Genome Research Institute, Bethesda, MD; 2) Division of Genetics and Metabolism Children's National Medical Center 111 Michigan Avenue NW Washington DC.

We present a case of beta ketothiolase deficiency with significant morbidity. A previously healthy 12-month-old female infant developed malaise from a viral illness. Newborn screening (not extended) was negative. She presented to a rural ER with vomiting, listlessness, fever, poor oral intake, and labored breathing. Arterial blood gas analysis and electrolytes were suggestive of metabolic acidosis with an anion gap. Serum ammonia was minimally elevated. Urinalysis revealed ketones. There was tachycardia, but normal oxygen saturation. The patient was managed for shock by current Pediatric Advanced Life Support (PALS) protocol. Urine organic acid analysis later revealed elevated tiglylglycine levels and elevated 2- methyl 3- hydroxybutyric acid. During initial management, she did not receive glucose in the intravenous fluids. Intravenous bicarbonate was given. She was treated for persistent acidosis with hemodialysis. During dialysis she had a cardiopulmonary arrest and later developed a femoral artery thrombosis. After resuscitation she was transferred to a tertiary care facility where she had an unremarkable clinical course. Beta ketothiolase deficiency was later confirmed by enzyme analysis on skin fibroblasts. This case illustrates a typical presentation of beta ketothiolase deficiency. This patient may have benefited from earlier consideration of metabolic disorders in the differential diagnosis. As expanded newborn screening identifies more infants with metabolic disorders, consideration to include an alternative management in PALS might avoid inappropriate care. PALS guidelines do include a consideration of reversible causes (including metabolic disorders). Subsequent steps in the algorithm, including a recommendation for the co-administration of intravenous glucose will improve the outcome of patients with metabolic disorders. While rapid consultation with metabolic specialists is always desirable, initial training of first responders may also contribute to improved care.

Inter-population linkage disequilibrium (LD) patterns of *GABRA2* and *GABRG1* genes at the GABA cluster locus on human chromosome 4. *C. Ittiwut[1,2,3], J. Listman[4], R. Hirunsatit[1,2,3], A. Mutirangura[1], R. Malison[2], J. Covault[5], H. Kranzler[5], A. Sughondhabirom[6], N. Thavichachart[6], J. Gelernter[2,3]* 1) Inter-Dept. Program of Biomedical Science, Chulalongkorn U., Thailand; 2) Dept. of Psychiatry, Yale School of Medicine, CT; 3) VAMC, West Haven, CT; 4) Dept. of Anthropology, New York U., NY; 5) Dept. of Psychiatry, U. of Connecticut School of Medicine, CT; 6) Dept. of Psychiatry, Chulalongkorn U., Thailand.

The *GABRA2* locus has been found to be associated with alcohol dependence (AD) in several studies, but no functional variant that can account for this association has been identified to date. In order to understand the reported associations, it is important to understand LD patterns and haplotype structure of this gene; extending this understanding to multiple populations would allow further inferences about the evolutionary history of a variant that increases AD risk. The *GABRA2* and *GABRG1* genes, encoding subunits of the GABA-A receptor, are located within the GABA cluster on chromosome 4p. As these genes are close to one another (intergenic distance, ~90 kb), it was anticipated some markers might show LD between them. To study LD architecture in 5 different populations (European American, African American, Chinese (Han and Thai), Thai, and Hmong), we genotyped 13 SNPs, 7 of which map to *GABRA2* and the other 6 of which are located within and flanking *GABRG1*. Haplotype structures were determined by Haploview v3.2 software and compared between populations. Variations in haplotype block structure were observed between populations; the most extreme variation being seen in the Hmong, which showed considerably higher LD than any other population. In Hmong, high LD (D>0.85) extended from rs1497571 in intron 7 of *GABRG1* to rs279837 in intron 3 of *GABRA2*, a 280 kb sequence, whereas in other populations, there were two or more LD blocks across this region. This LD break observed in other populations corresponds to lower D between rs10033451 and rs567926, which are located 89 kb apart in an intergenic region. These findings may aid in understanding genetic association of this locus with alcohol and drug dependence in several populations.

Recurrence of a multiple congenital anomaly syndrome: value of fetal MRI in gaining patient acceptance. *M. McCoy[1], S. Bhatt[1], D. Krakow[2], R. Sinow[3]* 1) Genetics, Genzyme, Orange , California; 2) Cedars-Sinai Medical center, Los Angeles, California; 3) Magella Medical, Torrance, California.

We present a case of a 29 year old G4P2012 female, who was referred for genetic counseling and ultrasound at 17 3/7 because of a prior son with multiple anomalies: developmental delay, seizure disorder, polymicrogyria, agenesis of the corpus callosum, VSD, bilateral hearing loss, GU anomalies, dysmorphic ears, and eleven ribs. Karyotype analysis was normal and no diagnosis had yet been made. 2D and 3D ultrasound of the current pregnancy revealed a male fetus with a VSD, absent cavum septum pellucidum, ventriculomegally (11 mm), small, posteriorly rotated ears, flat nasal bridge, and micrognathia. Amniocentesis was performed and revealed a 46, XY karyotype and normal FISH for 22q11 deletion. Because of the presence of fetal brain abnormality and similar structural malformations observed in this fetus, the family was counseled regarding a recurrence of the syndrome affecting their older child. The couple had difficulty accepting the fetal findings. To confirm the findings, a fetal MRI was then performed and which confirmed dysgenesis of the corpus callosum and ventriculomegaly. After review of the MRI with the parents they were more accepting of the recurrence and chose not to continue the pregnancy. The family elected against fetal autopsy. The experience with this case suggests that fetal MRI can be an important adjunct to ultrasound in helping parents accept the presence of major congenital anomalies and aid in critical decision making.

Genome Wide Association (GWA) Studies: Performance experience with the Illumina HumanHap300 Genotyping Beadchips in a high-throughput setting. *K. Hetrick[1], C. Bark[1], E. Kwasnik[1], J. Gearhart[1], J. Romm[1], M. Zilka[1], C. Ongaco[1], A. Robinson[1], J. Goldstein[1], R. King[1], L. Watkins[1], M. Barnhart[1], B. Craig[1], M. Boehnke[2], E. Pugh[1], K. Doheny[1]* 1) Center for Inherited Disease Research (CIDR), IGM, JHUSOM, Baltimore, MD; 2) Dept. of Biostatistics, Ann Arbor, MI.

CIDR is a centralized facility established to provide genotyping and statistical genetics services for investigators seeking to identify genes that contribute to human disease. Finland-United States Investigation of NIDDM Genetics (FUSION) case-control samples were assayed using Illumina Infinium II HumanHap300 Beadchips as part of our evaluation process for choosing a GWA platform for CIDR. Here we present quality metrics of genotypes generated with NO MANUAL data review using the Illumina-provided cluster definition file and BeadStudio v. 2.3.25. Of the 2,608 samples attempted, 2,576 (99%) were successful (call rate >98%) after an initial attempt. 25 (78%) of the initial failures succeeded when repeated. Average call rate was 99.7%, within-dataset replicate reproducibility rate for 52 independent pairs was 99.994%, and the parent-parent-child Mendelian consistency rate for 15 independent trios was 99.98%. For 41 CEPH samples (17 unique), the concordance rate with HapMap genotypes was 99.83%. Sample processing was tracked with a LIMS developed at CIDR which assured correct pairing of DNA sample to BeadChip and validated workflow and reagent use at each step. In addition to using BeadLab Tecan robots for assay automation, existing Beckman Coulter Biomek 2000 and Perkin Elmer Multiprobe II PLUS robots automated portions of the assay, increasing throughput over currently available Illumina protocols. An Illumina BeadScan software modification resulted in a 38% decreased scan time of version 1.0 BeadChips with a 99.998% reproducibility rate for chips scanned in both modes and a reduction in average call rate of 0.13%. Tools developed for daily data QC include Spotfire DecisionSite 8.1 templates for trend monitoring and a gender check program. This pilot projects success allowed us to offer the Infinium products as a GWA genotyping service to investigators to research the genetic basis of complex human diseases.

Genomic analysis of sentinel lymph nodes: in search of predictive markers of breast cancer metastasis. *B.R. Haddad[1], S.L. Santos[2], E.M. Ribeiro[2], J.D. Rone[1], C.A. Urban[3], R.S. Lima[3], I.J. Cavalli[2], L.R. Cavalli[1]* 1) Georgetown Univ. Medical Ctr., Washington, DC; 2) Federal University of Parana, Curitiba, Brazil; 3) Hospital Nossa Senhora das Gracas, Curitiba, Brazil.

Despite significant improvement in our understanding of the mechanisms of breast cancer development and progression, accurate prediction of the potential for future metastasis of non-metastatic primary tumors remains illusive. We set out to determine new predictive markers to augment the current criteria used to assess prognosis. The sentinel lymph node (SLN) is the first node to harbor malignant cells in breast tumors with metastasis. Because genetic alterations in the SLN lesions are likely to represent early and significant changes in the process of metastasis, characterization of such changes may aid in the discovery of new prognostic markers. Towards this end, we initiated this study to compare genomic alterations between primary breast tumors and their corresponding sentinel lymph node metastatic lesions using CGH analysis. Here, we report our results from the analysis of the 1st fourteen cases (paired samples). Although the number of cases analyzed so far is too small for statistical analysis, an interesting trend emerged: i) chromosomal abnormalities were observed in all 14 cases studied in both the primary tumors and the SLN lesions; ii) despite the diversity in the alterations detected in each case, both the primary and metastatic lesions shared a small number of alterations [gains (+) and losses (-)], specifically: -1p31~p21, +17, +19 and +20; iii) the above four alterations were also the most commonly observed in the whole set; iv) gain on chromosome 20 was more frequently observed in the primary tumors, whereas losses on 1p31~p21 and gains on 17 and 19 were equally observed in both groups. This study will allow assessment of clonal divergence and genetic heterogeneity that characterize the metastatic process and identification of a subset of relevant genetic alterations associated with metastasis. These can potentially be used as additional markers to predict metastasis thus reducing the need for invasive surgical procedures (e.g. axillary lymph node dissection).

Detecting signals of selection on standing variation. *S. Kudaravalli, X. Wen, J.K. Pritchard* Department of Human Genetics, University of Chicago, Chicago, IL.

A benefit of large scale genotyping efforts such as HapMap is that they allow us to explore evolutionary patterns across the entire genome, including recent positive selection. We have identified several regions that are putative targets of natural selection[1]. Several other reports have also explored the human genome for evidence for recent positive selection. An assumption underlying such studies is that an episode of selection is initiated when a selectively advantageous allele arises due to mutation and sweeps to high frequency. Statistics that are currently used to characterize signatures of selection are most powerful when a new allele is immediately advantageous. However, an allele that is already segregating in the population (standing variation) may also be a target of selection [2,3,4,5]. But standard tests for selection do not fare well in detecting such episodes[4,5]. By examining unusual patterns of linkage disequilibrium we aim to identify regions that are targets of selection on standing variation in the human genome. Analysis of simulations shows that our method has appreciable power in detecting such episodes of selection.

Localization of psoriasis susceptibility gene PSORS4 to the LEP/SPRR cluster of genes within the epidermal differentiation complex (EDC) on chromosome 1q21. *C. Helms[1], J. Robarge[1], K. Gold[1], S. Duan[1], R. Donaldson[1], P. Stuart[2], R. Nair[2], J. Elder[2], A. Bowcock[1]* 1) Genetics, Washington Univ Sch Medicine, St Louis, MO; 2) Dermatology, Univ Michigan Med Sch, Ann Arbor, MI.

Psoriasis is a complex inflammatory disease of the skin affecting 1-2% of the Caucasian population. It is accompanied by an increase in epidermal proliferation, recruitment of inflammatory cells to the dermis and epidermis, and a disruption of the cornified envelope; a structure at the surface of the skin that forms a barrier to the environment, preventing water loss and guarding against infection by pathogens. Although a major determinant for psoriasis lies within the histocompatibility locus antigen cluster (HLA) on chromosome 6p21, additional loci have been identified with genome-wide linkage scans. One of these maps to the epidermal differentiation complex (EDC); a cluster of over 80 genes on chromosome 1q21 (PSORS4). We have evaluated 250 psoriasis trios for association to this region, with a set of 136 tag SNPs spanning the interval. Two peaks of association were identified where $p < 0.001$ with both single and multilocus transmission disequilibrium (TDT) analyses. These associations were confirmed in a second sample of 535 psoriasis families of various structures, where $p < 0.01$ was observed for both peaks with single locus pedigree disequilibrium (PDT) analysis. One is in a ~75kb interval harboring the late envelope proteins (LEPs). A second is a ~75kb region harboring the small proline rich proteins (SPRRs). Genes encoding these proteins are expressed late in epidermal differentiation and are involved in the formation of the cornified envelope. Resequencing of the associated intervals in individuals with risk- and non-risk haplotypes revealed variants that are being considered for their role in psoriasis susceptibility. Some variants are those typically seen in clusters of gene family members and include gene deletion and gene conversion events. The mapping of PSORS4 to a genomic interval involved in epidermal barrier formation suggests that an alteration in terminal differentiation of keratinocytes may be triggering increased proliferation in the basal layer.

Mutations in the leucine zipper domain of ORF1p adversely affect L1 reverse transcription. *A.E. Hulme, D.A. Kulpa, J.N. Athanikar, J.V. Moran* Dept. of Human Genetics, University of Michigan, Ann Arbor, MI.

The non-LTR retrotransposon LINE-1 (L1) comprises ~17% of human DNA. A retrotransposition competent L1 contains a 5' UTR, two non-overlapping reading frames (ORF1 and ORF2), and a 3' UTR that ends in a poly (A) tail. ORF2 encodes a protein (ORF2p) with endonuclease (EN) and reverse transcriptase (RT) activities that are required for retrotransposition. ORF1 encodes a protein (p40 or ORF1p) that co-localizes with L1 RNA and ORF2p in cytoplasmic ribonucleoprotein particles (RNPs), which are likely retrotransposition intermediates. The N-terminus of ORF1p mediates multimer formation and contains a predicted coiled coil domain, whereas the C-terminus contains conserved amino acids needed for RNA binding. Human ORF1p also has a putative leucine zipper (LZ) domain near its N-terminus that is required for L1 retrotransposition, but is dispensable for ORF1-ORF1 protein interaction.

Here, we have characterized the LZ domain with respect to L1 RNP formation and function. Mutations in the LZ domain did not affect overall L1 RNA levels, but resulted in less ORF1p in cytoplasmic RNPs when compared to a wild type L1. ORF2p translation was not affected by LZ domain mutation, as assayed in a trans-complementation assay. Therefore, we next examined LZ mutant RNPs for ORF2p RT activity, using a biochemical assay. Surprisingly, mutation of the LZ domain decreased RT activity and seemed to adversely affect the initiation of reverse transcription. This decrease in activity could not be attributed to simply less ORF1p as an ORF1 RNA binding mutant that does not localize to RNPs has robust RT activity. Thus, our data suggest that the LZ domain is needed for proper RNP formation and robust reverse transcription, both of which are critical for L1 retrotransposition.

Gene Expression Profiling in CD4+CD25+high T cells from a recent-onset Type 1 Diabetic subject reveals reduced expression of HLA genes. *P. Jailwala, S. Glisic-Milosavljevic, J. Waukau, S. Jana, J. Rovensky, L. Meyer, M. Hessner, S. Ghosh, V. Magnuson* Department of Pediatrics, Medical College of Wisconsin, Wauwatosa, WI.

Type 1 diabetes (T1D) is a T cell-mediated autoimmune disease leading to the destruction of pancreatic insulin-producing beta cells. Genetic studies suggest T1D is also an oligogenic disease, the major predisposing region mapping to the HLA locus, that harbors over 125 expressed genes. Naturally occurring CD4+CD25+high T cells, which reduce effector CD4+CD25- T cell function both in vitro (known as suppression) and in vivo, may be defective at controlling autoimmunity in T1D. FoxP3, a transcription factor, is highly expressed in CD4+CD25+high T cells. We hypothesized that HLA and other susceptibility genes could act at the level of CD4+CD25+high T cells. We carried out gene expression profiling of CD4+CD25+high cells isolated by Fluorescence Activated Cell Sorting (FACS) from a recent-onset T1D patient and a Control subject, using Affymetrix human genome U133 plus 2.0 GeneChip. Data were filtered and normalized using standard software. The most striking difference was in expression of HLA genes. Of the 30 HLA Class II genes, 24 had reduced expression, while all of the 32 HLA-Class I genes had reduced expression in the T1D subject. The recent-onset T1D subject showed weak CD4+CD25+high T cells suppressive activity (48%) compared to the control subject (78%). Intracellular staining for FoxP3 protein was also reduced (11.8% vs 28.6%). An overall reduction in HLA gene expression along with reduced function of the CD4+CD25+high T cells could potentially implicate abnormal antigen-specific interaction between effector CD4+CD25- and regulatory CD4+CD25+high T cells in the pathogenesis of disease. After confirming gene expression results in 5 more T1D-control pairs, we plan to find a polymorphism in a transcription factor that regulates overall HLA gene expression and is associated with T1D in over 230 families.

Investigating the Role of the Transcription Factor FEV in Response to the Antidepressant Citalopram Utilizing a Large Clinical Sample. *J. Kraft[1], E. Peters[1], S. Slager[2], G. Jenkins[2], M. Reinalda[2], P. McGrath[3], S. Hamilton[1]* 1) Dept Psychiatry/Biopharm Sci, University of California, San Francisco, San Francisco, CA; 2) Division of Biostatistics, Mayo Clinic College of Medicine, Rochester, MN; 3) New York State Psychiatric Institute and Columbia University.

The large inter-individual variability seen in patient response to antidepressant medication is thought to be influenced at least in part by DNA variation. Selective Serotonin Reuptake Inhibitors (SSRIs) act by antagonizing the serotonin transporter; however, the delay in therapeutic response suggests other mechanisms or regulatory events are necessary for a response phenotype to occur. Specifically, we are interested in the role that the transcription factors FEV plays in antidepressant response. Recent studies done on the mouse homolog, Pet-1, suggest this transcription factor plays a large role in the expression of several genes in the serotonin signaling pathway (TPH, MAOA, SERT, etc.).

In order to uncover unknown variants and select tagging SNPs, we resequenced all exons, intron-exon boundaries, and 5 conserved non-coding sequence of the gene FEV in a subset of 95 individuals from our larger dataset. We discovered 5 previously undiscovered SNPs in FEV. Then from all of our identified SNPs, we chose tagging SNPs, which are currently being genotyped in a larger sample (N=1,953) of patients with major depression who took the SSRI citalopram. This sample is a subset of a study investigating treatment options for patients with major depression (Sequenced Treatment Alternatives to Relieve Depression, STARD). Sequencing and association results from our study will be presented.

Association between genes on Chr 4p16 and Nonsyndromic Oral Clefts in 4 Populations. *R.G. Ingersoll[1,2], J.B. Hetmanski[1], J.W. Park[1], M.D. Fallin[1], I. MacIntosh[3], E.W. Jabs[2], C. VanderKolk[2], Y. H. Wu-Chou[4], P.K. Chen[4], V. Yeow[6], S.S. Chong[5], F. Cheah[5], J.W. Sull[7], S.H. Jee[7], A.F. Scott[2], T.H. Beaty[1]* 1) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Johns Hopkins School of Medicine, Baltimore, MD; 3) American University of the Caribbean, St. Maarten, Netherlands Antilles; 4) Chang Gung Memorial Hosp, Taoyuan, Taiwan; 5) KK Women's & Children's Hosp, Singapore, Singapore; 6) National University of Singapore, Singapore, Singapore; 7) Yonsei University, Seoul, Korea.

Isolated cleft lip with/without palate (CL/P) and cleft palate (CP) are among the most common human birth defects. Linkage studies have consistently found a relationship between CL/P and chromosome 4p16. One gene in the region, MSX1, has been found to contain different mutations and may account for a small percentage of non-syndromic CL/P. These mutations, however, cannot explain the strength and consistency of the signal in this region. To map this region, 393 SNPs were selected across a 2 Mb region surrounding MSX1, with an average spacing of 1 SNP per 5 kb. The region spans 18 genes in NCBI genome build 35. These SNPs were genotyped using the Illumina platform, on 383 case-parent trios from 4 populations (Taiwan, Korea, Singapore and Maryland). The 67 cases of CP trios from Taiwan, Singapore and Maryland were analyzed separately. TDT analysis using both individual SNPs and sliding haplotype windows of size 2-5 SNPs each showed 19 genes or intergenic regions yielding suggestive evidence of linkage and disequilibrium among CL/P trios in >1 populations, as defined by empirical p-values. Two genes (STK32B and EVC) and an intergenic region yielded consistent evidence in all 4 populations, while EVC2 and STX18 were statistically significant in 3 of 4 populations. Eighteen genes or intergenic regions gave suggestive evidence from the CP trios in >1 populations. Three genes (STK32B, EVC2 and EVC), 2 putative genes (LOC391613 & LOC402162), and 2 intergenic regions were suggestive in CP trios from all 3 populations. This analysis confirms the etiologic importance of genes in this region, but indicates MSX1 may not be the only influential gene here.

Genetic regulation of vitamin D in a cohort of multiple sclerosis twins. *S. Orton[1], B. Herrera[1], M. Lincoln[1], S. Ramagopolon[1], M. Chao[1], K. Morrison[1], R. Vieth[2], G.C. Ebers[1], Canadian Collaborative Project on Genetic Susceptibility to MS (CCPGSMS)* 1) Clinical Neurology, University of Oxford,UK; 2) Pathology and Laboratory Medicine, University of Toronto, Canada.

Vitamin D deficiency has been implicated in several autoimmune diseases, including multiple sclerosis (MS). Levels of 25-hydroxy-vitaminD (25OHD) are deemed to be the best measure of vitamin D health and are believed to be determined predominantly by environmental factors, primarily UV exposure. However, recent evidence suggests that genetic factors are also important and their effects would be most evident when environmental influence is marginal, such as wintertime. Published studies considering the genetic regulation of vitamin D metabolism are scarce and more systematic studies are needed. Twin study designs offer one route for assessing relative contributions of genetic factors affecting a trait. The first objective was to consider the relative genetic contribution to variance of serum 25OHD levels. Secondly, as our dataset consisted of MS patients, we asked whether a relationship between 25OHD and MS risk could be observed. The sample was drawn from the CCPGSMS and included 39 monozygotic (MZ) and 61 dizygotic (DZ) twin pairs, with a mean age of 53 years and 83 pairs discordant for MS. We collected serum at the end of winter to minimize environmental impact on levels, namely UV exposure, and collected data on use of supplements, tanning beds and recent vacations. Radioimmunoassay was used to measure serum 25OHD (overall mean = 78 nmol/L). Applying logistic regression with robust variance estimators, we did not find any significant association between 25OHD and MS risk. Gender and age were also not associated with levels in our sample. The correlation coefficient for 25OHD in MZ twins ($r=0.72$, $p<0.000$) was significantly higher than that of DZ twins($r=0.34$, $p=0.003$) and heritability was estimated at 0.77. Although there was no significant association between 25OHD levels and MS status observed, we can not rule out the possibility that such a relationship exists. The findings suggest that 25OHD levels are under genetic regulation and further investigation in family-based datasets is warranted.

Single Cell Aneuploidy Analysis by High Resolution Comparative Genomic Hybridization (CGH) after Whole Genome Amplification reveals Maternal Cell Contamination in the Original Products of Conception Culture. *O. Nahum[1], V. Jobanputra[2], K. Hirschhorn[1], B. Levy[2]* 1) Depts of Human Genetics and Pediatrics, Mount Sinai School of Medicine, New York, NY; 2) Dept of Pathology, Columbia University Medical Center, New York, NY.

We performed high resolution CGH analysis on a single cell extracted from a culture set up from tissue obtained from the products of conception (POC) of a spontaneously aborted pregnancy. Whole genome amplification (WGA) using a random fragmentation approach (GenomePlex - Sigma-Aldrich) was utilized in order to obtain a sufficient amount of DNA for the CGH analysis. The culture was de-identified and blinded (with respect to the cytogenetic diagnosis) before being transferred from the clinical laboratory to the research laboratory. The POC culture was part of a larger IRB approved study assessing aneuploidy analysis of single cells. Single cells were lysed and then subject to WGA. The resulting DNA was labeled using nick-translation and high resolution CGH was performed to determine the chromosomal status of the single cells. CGH results were compared to the karyotype as determined by conventional cytogenetic analysis. Following CGH analysis, a normal female karyotype was predicted. However, when compared back to the original karyotype (47,XY,+16), both the sex and diagnosis were incorrect. Our recent experience with single cell aneuploidy analysis has been very favorable and we therefore considered maternal cell contamination as a feasible explanation for the discrepancy. Interphase FISH using probes specific for the X and Y chromosomes was performed on the original POC culture and, in addition to a small number of XY cells, revealed a high number of XX cells consistent with our hypothesis. Also, DNA extracted from the original culture confirmed the presence of maternal cell contamination. This case illustrates the potential of single cell aneuploidy analysis but highlights the dangers of a diagnosis based on a single cell. This is particularly applicable to preimplantation genetic diagnosis where mosaicism is an issue and fetal cells from maternal circulation where maternal cell contamination is a problem.

Null evidence for linkage of familial breast and colon cancer to CHEK2. *H. Ochs-Balcom[1,2], D. Daley[1, 3], R. Elston[1,2], G. Wiesner[2,4]* 1) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH, USA; 2) Ireland Comprehensive Cancer Center at University Hospitals of Cleveland and CWRU, Cleveland, OH, USA; 3) The James Hogg-iCAPTURE Centre for Cardiovascular and Pulmonary Research, University of British Columbia, St. Pauls Hospital, Vancouver, British Columbia, Canada; 4) Department of Genetics and Center for Human Genetics, CWRU, Cleveland, OH, USA.

CHEK2, a gene important in the cell cycle and DNA repair, is hypothesized to be important in breast cancer etiology and perhaps also in other cancers. Families with both breast and colon cancer have been reported to have mutations in the CHEK2 gene, leading to the hypothesis that this gene may be a susceptibility factor for both of these cancers. A total of 159 sibling pairs in 33 nuclear families, each containing two cases of advanced polyps or colon cancer and at least one primary breast cancer in a sibling or mother, were genotyped for 6 markers on chromosome 22. Model-free linkage analysis was performed to determine whether the CHEK2 region is linked to familial breast and colon cancer. Allele sharing identical by descent for concordantly affected sibling pairs at D22S689, 0.02 cM centromeric of CHEK2, was 0.47 (SE 0.05; p=0.76), and at D22S685, 3.74 cM telomeric of CHEK2, was 0.46 (SE 0.05; p=0.77). Similarly, there was no statistically significant evidence for linkage using Haseman-Elston regression. The study had 90% power at the 5% level to detect a locus-specific sibling relative recurrence risk of 1.4 and therefore suggests that CHEK2 is an unlikely susceptibility locus in kindreds with breast and colon neoplasia. We further plan to investigate epistatic interaction of CHEK2 with BRCA1 and 2 because both are candidate genes for breast cancer that may jointly influence risk.

Feasibility of neonatal screening of lysosomal tripeptidyl peptidase 1 (TPP1) for classical late-infantile neuronal ceroid lipofuscinosis (NCL2). *Y. Huang[1,2], W. Ju[1], N. Zhong[1,2]* 1) New York State Institute for Basic Research , Staten Island , NY; 2) Peking University Center of Medical Gnetics.

Neuronal ceroid lipofuscinosis (NCL) affects 1 per 20,000 to 100,000 in the general population with an incidence of 1 per 12,500 births in homogenous population. About 35% of NCL are late-infantile neuronal ceroid lipofuscinosis (LINCL). Among which, about 80% of LINCL are caused by a deficiency of the lysosomal tripeptidyl peptidase I (TPP I) that is encoded by CLN2 gene. Presently, little is known about the frequency of the affected and carriers in newborn children worldwide. To carry out a large neonatal screening for TPP1 deficiency, we have investigated the feasibility of existing approach of analyzing TPP1 activity. We analyzed a capillary electrophoresis (CE) procedure for TPP1 by using Ala-Ala-Phe-NA as a substrate. We optimized the pH condition to 4.5 and found that the maximal absorption is at wavelength of 380 nm, at which higher product peak with almost no nonspecific noise background can be obtained. The enzyme reaction volume can be scaled down to 25-50 ul, and only 0.5-1.0 ug cellular total protein is needed. Although this procedure is reliable and can be robotic, it is time consuming (at least 2.5 hours for each sample including 2 repeat and 1 blank) and frequently capillary can be easily got clogged by air bubbles. Using the same substrate, we also analyzed TPP1 activity with a microplate reader at 405 nm. Although this approach is efficient and economical, it is less sensitive and less reliable. In our case, the absorption of the digested NA product is quite low. Fluorescent method is much sensitive and reliable, more and more enzyme assays are using fluorescent substrate. We are currently optimizing the conditions using a fluorescent substrate of TPP1, which has been indicated to be suitable for large-scale screening, espacially when bloodspots, which have been used for other neonatal screening, are applied.

Profiling Segmental Polymorphisms in the Human Genome Using High Resolution Fosmid Arrays. *T.J. Jiang[1], W.L. Liu[1], S.S. Scherer[1,2], R.G. Gibbs[1,2], J.B. Belmont[1], P.H. Hixon[1], WW.C Cai[1]* 1) MH Genetics, Baylor college medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College Medicine, Houston, Texas.

Segmental copy number variations have been found to be a common type of genome polymorphisms in humans since the introduction of Array-based Comparative Genomic Hybridization (aCGH) in profiling human genomes. Previous studies about segmental polymorphisms have been incomplete and preliminary because of limitations in aCGH resolution, data quality and sample size. Currently, the platforms for aCGH are mainly BAC arrays and oligo arrays. Large scale whole genome oligo arrays usually can only be obtained from commercial sources. The costs of these commercial arrays are still too high for large-scale applications. Whole genome tiling BAC arrays are relatively easier to make in an academic lab. The resolution (about 100-200kb) of BAC tiling path arrays is determined by the size of BAC clones and these arrays cover all euchromatic sequences in the genome. Drawing on our extensive experiences in fabricating whole genome human and mouse BAC arrays, we have developed whole genome human fosmid tiling arrays. Briefly, 85,062 clones were picked from human fosmid library WIBR-2 to form a tiling path human fosmid clone set. Clones were cultured in 96-well blocks, and DNA was extracted by protease-SDS lysis. Fosmid DNAs were chemically modified and spotted onto hydrophobic glass slides using high-precision silicon pins, which can uniformly print high density arrays with each spot size of 50 um in diameter. These whole genome human fosmid arrays contain 85,062 fosmid DNA clones printed on a single slide, with resolution of 40kb based on cloned insert size. We have used this high resolution fosmid array in analysis of 180 human samples from different populations. Novel and concordant segmental copy number variations (SCNV) have been found. More samples will be studied using this fosmid array to establish a more complete database on SCNV in the human genome.

Chromosomal deletion syndrome 1q22-25. *R.R. Lebel*[1, 2], *B.J. Shutt*[2] 1) Greenwood Genetic Center, Greenwood, SC; 2) Clemson University, Clemson, SC.

Prenatal ultrasonographic findings revealed major abnormalities, including apparent schizencephaly and cleft lip/palate. Amniocentesis was performed, and the karyotype reported by a reference laboratory as 46,XY. Multidisciplinary conference was convened for planning delivery and neonatal interventions (genetics, neonatology, neurosurgery, nursing, obstetrics, pastoral care, parents). The newborn was stable in the special care nursery. Dysmorphology examination revealed low birth length, microcephaly, bilateral facial clefting, malformed and low-set ears, cryptorchidism with inguinal hernia, small hands and feet, clinodactyly, hypotonia. These findings did not connote an apparently identifiable hereditary syndrome. Lymphocytes sent to a different reference laboratory revealed an interstitial deletion: del(1q22-q25). Review of the literature showed very few published cases of similar deletions, and that there is a consistent phenotypic pattern of dysmorphic features associated with poor prenatal and postnatal growth, and psychomotor developmental delays. The present case illustrates useful information about long-term survival with this syndrome.

Multi-SNP Genetic Risk Scores Increase Power to Predict Clinical Disease Phenotypes. *B.D. Horne[1,2], J.L. Anderson[1,3], J.F. Carlquist[1,3], J.B. Muhlestein[1,3], N.J. Camp[2]* 1) Cardiovascular Dept, LDS Hospital, Intermountain Medical Center, SLC, UT; 2) Genetic Epidemiology, Univ Utah, SLC, UT; 3) Cardiology, Univ Utah, SLC, UT.

Genetic association studies of common, complex diseases such as coronary artery disease (CAD) and myocardial infarction (MI) have produced unreliable results for both single nucleotide polymorphisms (SNPs) and SNP haplotypes, perhaps due to allelic and locus heterogeneity. We have described a genetic risk score (GRS) method that integrates SNP data with intermediate phenotypes (IPs) to derive a multi-SNP score for association testing with clinical phenotypes. In this study, the GRS method was applied to two data sets: 11 tagging (t) SNPs in the cholesteryl ester transfer protein (CETP) gene, with high-density lipoprotein cholesterol (HDL-C) as the IP, for association with CAD; and 8 SNPs in matrix metalloproteinase (MMP) and MMP inhibitor genes, with high-sensitivity C-reactive protein (hsCRP) as the IP, for association with MI. Association of SNPs with an IP used linear regression and the GRS was calculated from regression coefficients. In 6,285 patients with CETP tSNPs, the CETP-HDL GRS was associated with CAD (OR=1.32 [p=0.033], 1.44 [p=0.008], 1.05 [p=0.69], 1.20 [p=0.17], 1.24 [p=0.10], 1.32 [p=0.034], 1.20 [p=0.17], 1.35 [p=0.023], 1.16 [p=0.27] for deciles 1-9, respectively, vs. decile 10). Individually only a few tSNPs were nominally associated with CAD. Adjustment for age, sex, HDL-C, and CAD risk factors gave similar results. In 3,304 patients with MMP SNPs, the MMP-hsCRP GRS was associated with MI (OR=0.85 [p=0.17], 0.78 [p=0.029], 0.80 [0.061], 0.76 [p=0.017] for quintiles 2-5, respectively, vs. quintile 1). Analyzed individually, only MMP-9 predicted MI. Adjustment (including for hsCRP) marginally improved significance. The GRS method is multi-locus, allowing for sensible combination of SNPs in a single metric based on relevant IPs. In two different data sets the GRS approach increased power to detect association with clinical endpoints, confirming its potential in genomic risk evaluation. Further extension of the GRS approach to the genome-wide association study setting is suggested.

Novel assay for detecting integrated HPV. *P. McGrath, P. Moen, D. Hochberg, E. O'Lear* One Cell Systems, Inc., Cambridge, MA.

There is increasing consensus that integration of oncogenic HPV DNA into the host genome is the primary cause of cervical cancer and an assay that specifically detects viral integration would have high clinical utility. We are developing a method to detect integrated viral DNA after removing interfering episomal DNA. Using a model HPV cell line containing both episomal and integrated HPV-16 DNA, we developed experimental conditions for selectively removing episomal viral DNA without releasing integrated viral or cellular DNAs. Using in situ hybridization, the diffuse HPV DNA signal generated by episomal DNA present in control cells was absent in extracted cells. Conversely, hybridization signal from integrated viral DNA and an endogenous gene remained, indicating that the extraction conditions specifically removed protein-bound episomal DNA. Using a more sensitive PCR assay, we confirmed that, after extraction, the level of HPV DNA decreased in a cell line containing both episomal and integrated virus and remained essentially unchanged in two integrated cell lines. Successful application of this assay format to clinical samples will lead to precise detection of integrated HPV DNA and identification of patients who are likely to develop cervical cancer.

Delineation of a *de novo* 3q deletion in a newborn girl using Comparative Genomic Hybridization (CGH). *M.J. Macera[1], G. Kupchik[2], S. Krinshpun[2], D. Sulllivan[2], A. Babu[1]* 1) Div Molec Medicine & Genetics, Dept of Medicine, Wyckoff Heights Medical Ctr, Brooklyn, NY; 2) Dept Pediatrics, Maimonides Medical Ctr, Brooklyn, NY.

A newborn female was evaluated due to dysmorphic features. The family was known because of an older sibling with Trisomy 21. Amniotic fluid analysis performed elsewhere reported an apparently normal female karyotype. Fetal ultrasound at 17 weeks gestation was within normal limits. A follow-up fetal ultrasound at 32 weeks gestation revealed polyhydramnios, single umbilical artery and dilated ventricles. On physical exam after birth, her head circumference measured above the 90th percentile and she had widely spaced sutures, soft fontanels, hirsutism, a prominent occiput, bulbous nose, low set ears, triangular facies, down slanting palpebral fissures and prominent big toes. Cranial ultrasound indicated ventriculomegaly with extra axial space prominence in the frontoparietal areas. Renal ultrasound and echocardiogram disclosed bilateral hydronephrosis and atrial septal defect, respectively. Because of dysmorphic features, a high resolution chromosome analysis and FISH were preformed on peripheral blood that revealed a karyotype of 46,XX, del(3)(q22q25.1).ish del(3)(wcp3+). No hybridization signal was seen using whole chromosome paint 3 (wcp3), over any other chromosome besides homologues 3. Both parents had normal karyotypes. Comparative genomic hybridization (CGH) analysis revealed that the deleted segment is more distal than that originally designated by GTG-banding. The proximal breakpoint is at band q24 while the distal breakpoint is at the proximal end of band q26.1, therefore the patient is monosomic for 3q24q26.1. A 7-Mb critical region for the Dandy-Walker malformation has been mapped to 3q24 to q25.1. Initial MRI on our patient was not consistent with Dandy-Walker malformation. The 7-Mb Dandy-Walker associated region in our case only accounts for a small portion of the material missing. Accurate delineation of the breakpoints of deletion 3q is important to correlate segmental monosomies with clinical presentation. Such cases are rare in the literature and worth reporting.

Performance of Random Forests in Identifying SNPs Predictive of Phenotype when SNPs are in Linkage Disequilibrium. *Y. Meng[1], L.A. Cupples[1], C.T. Baldwin[1], R. Inzelberg[2], R.P. Friedland[3], L.A. Farrer[1], K.L. Lunetta[1]* 1) Boston University, Boston, MA; 2) Hillel Yaffe Medical Center, Israel; 3) Case Western Reserve University, Cleveland, OH.

Association studies for complex phenotypes produce genotypes on 100s-1000s of single nucleotide polymorphisms (SNPs). One approach to dealing with large numbers of SNPs is to screen the data using some criterion to rank SNPs for follow-up. Random Forests produce a single importance measure (IM) for each SNP that takes into account a SNPs main and interaction effects on an outcome without requiring model specification. Random Forests have been shown to be powerful for detecting independent interacting risk susceptibility SNPs (rSNPs). However, correlation between noise SNPs that do not affect disease risk (nSNPs) and risk SNPs may decrease IM for the rSNPs. We explore the performance of Random Forests in the presence of nSNPs correlated with the rSNPs.

Using simulation under several complex disease models with sib recurrence risk 2 and up to 32 interacting risk-associated SNPs (rSNPs), we show that in general, the Random Forest importance measure IM for rSNPs decreases with increasing number of nSNPs in LD with the rSNPs. The IM for rSNPs also decreases with increasing numbers of nSNPs in LD with each other, but at a slower rate. The ratios of IM(rSNP) to $\max_{nSNP}$ IM(nSNP) also decrease with increasing number of nSNPs in LD with the rSNPs. The probability that IM(rSNPs) exceeds the maximum of independent nSNPs shows a similar trend. The probability that all rSNPs are among the top-ranking SNPs decreases with increasing number of nSNPs in LD with the rSNPs.

We conclude that performance of the Random Forest method in assigning higher ranks to all rSNPs than to independent nSNPs decreases when nSNPs are in LD with the rSNPs. Importantly, the inclusion of nSNPs in LD with the rSNPs actually increases the probability that all rSNPs will be retained for further analysis. We illustrate the application of Random Forests with a data set of Alzheimer cases and unaffected controls genotyped at about 300 SNPs in candidate genes.

A novel bioloop strategy for labeling synthetic oligonucleotide probes. *E. O'Lear, P. Moen, D. Hochberg, J. Trnovsky, P. McGrath* One Cell Systems, Inc., Cambridge, MA.

We have developed a new strategy for labeling synthetic oligonucleotide fluorescence in situ hybridization (FISH) probes. This procedure, termed Bio-Loop labeling, involves synthesizing oligonucleotides (ODNs) to contain multiple labels in a region of the probe not involved in hybridization to a target sequence. Our experimental data shows that BioLoop labeled ODNs generate a 2-fold higher signal to noise ratio than conventional end-labeled oligonucleotide probes and hybridization specificity is identical. Here we present assessment of the optimum BioLoop construct and results using BioLoop labeled ODN probes for several infectious diseases, including HPV, HIV and EBV. This labeling strategy overcomes blocking DNA labeling intellectual property and provides a new approach for FISH as well as other molecular biology technologies that rely on nucleic acid labeling and probing.

Comparison of linkage disequilibrium patterns between a cohort from Cebu, Philippines and the four populations genotyped by HapMap. *A.F. Nave, L.A. Lange, E.M. Lange, Y. Wang, L.S. Adair, K.L. Mohlke* U. North Carolina, Chapel Hill, NC.

Patterns of linkage disequilibrium (LD) differ between populations. Although the International HapMap Project has identified patterns of LD within the human genome in four populations, the similarity of these patterns to other unstudied populations is not fully known. In the current study, we assessed the value of HapMap data to select tag SNPs for a cohort from Metro Cebu, in the central Philippines. We first re-sequenced 800 nucelotides from each of the ten HapMap ENCODE regions in 24 individuals to determine whether common SNPs in Filipinos from Cebu are under-represented in SNP databases. We identified only one new SNP (minor allele frequency (MAF)= .05) not already present in dbSNP or HapMap, suggesting that SNP discovery will not be critical prior to future SNP selection. We then selected polymorphic SNPs from the CHB, JPT, and CEU HapMap data in 40 kilobase regions within each of the ten HapMap ENCODE regions. We successfully genotyped 501 polymorphic SNPs in 80 individuals using the Illumina GoldenGate genotyping assay. Of these, 467 SNPs were also present in the HapMap CHB, JPT, and CHB+JPT samples with an average of 47 SNPs in each ENCODE region (range 26 to 77); 480 and 465 SNPs were also present in the HapMap CEU and YRI samples, respectively. We compared allele frequencies between Filipinos from Cebu and the HapMap samples for SNPs in all ten ENCODE regions and observed average Pearsons correlations of .91, .90, .86, .72, and .60 in CHB, CHB+JPT, JPT, CEU, and YRI, respectively. Differences were observed across the ten regions, however no obvious patterns were detected. We evaluated LD patterns by comparing pairwise r^2 values between Filipinos from Cebu and HapMap samples for SNPs with MAF .1. We observed Spearmans correlations of .81, .82, .81, .66, and .54 in CHB, CHB+JPT, JPT, CEU, and YRI, respectively. The strong correlations between the Filipinos from Cebu, CHB and CHB+JPT analysis panels suggest that using HapMap data will be appropriate and useful for selecting tag SNPs in the Cebu cohort.

Genetic analysis of hypertrophic cardiomyopathy genes in noncompaction cardiomyopathy patients: could NCCM be a phenotypic variant of HCM? *Y.M. Hoedemaekers[1,2], K. Kaliskan[2], F.J. ten Cate[2], D.F. Majoor - Krakauer[1], D. Dooijes[1]* 1) Dept Clinical Genetics, Erasmus Medical Ctr, Rotterdam, Netherlands; 2) Thoraxcenter, Erasmus Medical Ctr, Rotterdam, Netherlands.

Background: Noncompaction cardiomyopathy (NCCM) is characterized by abnormal segmental thickening of the left ventricular wall with deep, prominent intertrabecular recesses, as visualised by two dimensional echocardiography or MRI. Clinical manifestations include heart failure, lethal arrhythmias and/or thrombo-embolic complications, mostly affecting patients at a relatively young age. It is a major cause of paediatric cardiomyopathies. NCCM is genetically heterogeneous and can be inherited as an autosomal dominant (AD) or X-linked disorder in familial cases. DNA variants in familial AD NCCM have been identified in genes coding for cytoskeletal or cell junction proteins: LMNA/C, -dystrobrevin and Cypher/ZASP. In families with X-linked NCCM an association was found with mutations in the G4.5 gene, which is allelic with Barth syndrome. Due to a similarity in morphology, the aetiology of NCCM is thought to be caused by an arrest of normal intrauterine endomyocardial development and a lack of compaction of the loose myocardial meshwork. **Hypothesis:** NCCM may be a phenotypic variant of hypertrophic cardiomyopathy (HCM) in some cases. To investigate this, we performed a genetic analysis of known HCM genes in a group of 23 isolated and familial adult NCCM patients. We report one NCCM family with a mutation in the Myosin Binding Protein C (MYBPC3) gene and one family where NCCM is associated with the -Myosin Heavy Chain (MYH7) gene. Mutations in the MYH7 and the MYBPC3 genes are a well known cause of AD HCM. **Results:** In three patients with NCCM in one family, we identified a D545N/D955N double missense mutation, in cis, in the MYH7 gene. The second family revealed the 2373insG mutation in the MYBPC3 gene, which is a founder mutation in the Dutch population, in a patient with NCCM and in her father, who was diagnosed with dilated HCM. **Conclusion:** Sarcomeric genetic defects in NCCM and the co-occurrence of NCCM and HCM within one family suggest, at least in some cases, a common aetiology.

A novel 300bp Alu insertion in MSH2 causes Lynch Syndrome. *M. Hegde, L.H. Chin, P. Ward, B. Roa, C. Eng* DNA Diagnostic Laboratory,Medical Genetics Laboratories, Baylor Col Medicine, Houston, TX.

Lynch syndrome or hereditary nonpolyposis colorectal cancer (HNPCC) is the most common hereditary cause of colorectal cancer. HNPCC is caused by mutations in DNA mismatch repair genes, with majority of mutations found in the MLH1 and MSH2 genes. Approximately 25% of these mutations can be identified by dosage-sensitive methods for large deletions or duplications, and the remainder are detectable by DNA sequencing. We describe a novel insertion mutation of ~300 bp with Alu repeat homology (1676_1677ins~300bp) in exon 11 of the MSH2 gene. This insertion was detected by PCR and sequencing analysis on a 52 year old Caucasian male with sebaceous adenomas and a family history of gynecological cancer. He was referred to our laboratory for MSH2 gene sequencing and deletion/duplication analysis, subsequent to immunohistochemistry analysis that showed absent MSH2 and MSH6 expression. MSH2 dosage analysis by quantitative Real-Time PCR did not detect any gross gene rearrangements. Concurrently, PCR-based sequence analysis of all 16 coding exons of MSH2 was performed; PCR amplification of exon 11 showed a novel product of ~ 600bp in addition to the 291bp wild type product, which suggested a heterozygous insertion. These bands were individually gel purified and sequenced. The smaller product showed the wild type sequence. The larger product showed an insertion of ~300bp with Alu repeat homology, with 15bp of MSH2 exon 11 flanking the insertion. Our data is consistent with the proposed mechanism for Alu repeats, wherein reverse transcription of an Alu element is followed by insertion at a new site. This process is associated with duplication of 7-21 bp flanking the insertion site. This MSH2 mutation predicts an altered and truncated gene product, and exemplifies an Alu-mediated mutation associated with Lynch syndrome.

Apoptosis as a mechanism for caudal truncation in adrenocortical dysplasia (*acd*) mice. *C.E. Keegan, A.S. Krause, M.J. Morley, T. Else, B.C. O'Connor, G.D. Hammer, D.O. Ferguson* Univ Michigan, Ann Arbor, MI.

Adrenocortical dysplasia (*acd*) is a spontaneous autosomal recessive mouse mutant with developmental defects in organs derived from the urogenital ridge: the kidneys, gonads, and adrenals. In addition, the *acd* mutation exhibits embryonic lethality on certain genetic strains, and analysis of *acd* mutant embryos reveals a striking embryologic phenotype that includes caudal truncation and axial skeletal patterning defects. We have previously characterized the *acd* mutation as a splicing defect in a gene (*Acd*), which encodes a novel component of the telomere cap complex that functions to maintain telomere integrity and regulate telomerase activity. Here, we report widespread expression of *Acd* mRNA in mouse embryos. We observed increased expression in the developing limb buds, tail, and neural tube, which resembles the embryonic expression pattern of the telomerase RNA component (*Terc*) gene and corresponds to the structural defects observed in *acd* mutant embryos. We have also shown that *acd* mouse embryonic fibroblasts exhibit evidence of telomere dysfunction with an increased number of chromosomal end-to-end fusions compared to wildtype cells. To further explore the relationship between telomere dysfunction and caudal dysgenesis, we have investigated potential mechanisms leading to caudal truncation in *acd* mutant embryos. Based on the proposed function of ACD as a telomeric protein, we hypothesized that the loss of cells in the caudal region might be due to apoptosis or cell cycle arrest via activation of p53. We have observed a significant increase number of apoptotic cells in the caudal region of *acd* embryos using TUNEL staining and cleaved caspase-3 immunohistochemistry, but no gross differences in proliferation, suggesting that apoptosis is the predominant mechanism leading to caudal truncation in *acd* mice. We are currently crossing *acd* mice to p53 null mice to determine whether p53 deficiency rescues the caudal dysgenesis phenotype. This work will shed important insights on the role of telomere stability during development. This work was supported by NIH K08-HD42487 and the March of Dimes.

High-throughput genotyping of International HapMap Project Populations with Applied Biosystems TaqMan Drug Metabolism Genotyping Assays: an automated laboratory and analysis pipeline. *K.A. Haque[1], K.D. Lazaruk[2], J.S. Ziegle[2], L.M. Wronka[1], M.B. Beerman[1], R.A. Welch[1]* 1) Core Genotyping Facility, SAIC-Frederick, Inc., NCI-Frederick, Gaithersburg, MD; 2) Applied Biosystems, Foster City, CA.

Although high-density whole genome SNP scans are available for association studies, the tagging SNP approach used to design many of these panels from International HapMap Project data may miss a substantial number of coding functional variation of drug metabolism enzymes (DME). In fact, 40+ DME genes are not covered by the HapMap Project, probably due to the difficulties in assay design for these highly homologous gene families. Additionally, many of these technologies do not provide detection in a high number of known DME genes, leading to further gaps in whole genome scans. Of the polymorphic putative functional DME variants not typed in the HapMap, a large proportion is untagged by any combination of HapMap SNPs. Therefore, to correlate phenotypes to putative functional DME variations in pharmacogenomic drug efficacy and toxicology studies, direct genotyping of these functional SNPs will be necessary. Applied Biosystems has developed a panel of 2,394 TaqMan Drug Metabolism Genotyping Assays to interrogate putative functional variations in 217 DME genes. At the National Cancer Institutes Core Genotyping Facility, an automated, high-throughput pipeline has been created to genotype these assays on the International HapMap Project population. DNA sample preparation and handling, assay set-up, genotype analysis, and data publishing at SNP500 Cancer Database (http://snp500cancer.nci.nih.gov), have all been automated. Using a series of custom-designed methods on two Beckman Coulter Biomek FXs, a Laboratory Information Management System, and analysis software, >650K genotypes have been obtained and analyzed by a single person in ~ 8 weeks. Using this pipeline, a completion rate of >99% and no Mendelian inheritance errors were observed. With this robust set-up for high-throughput genotyping of functional DME variants, we are embarking in larger studies of pharmacogenetics cohorts with similarly high success. Funded by NCI Contract N01-CO-12400.

Current status of thalassemia in minority populations in Guangxi, China. *T. Huang[1,4], H. Pan[1,2], G. Long[3], Q. Li[2], Y. Feng[2], Z. Lei[2], H. Wei[2], Y. Huang[2], J. Huang[2], N. Lin[2], Q. Xu[2], S. Ling[2], X. Chen[2]* 1) Div Human Genetics, Univ California, Irvine, Irvine, CA; 2) Affiliate Hospital of Youjiang Medical College for Nationality, Baise City, Guangxi, 533000, China; 3) Guangxi Medical University, Nanning City, China; 4) Department of Developmental and Cell Biology, University of California, Irvine, CA, USA.

Thalassemia is one of the most common monogenic disorders in the world. A community-based prevention program could be effective. In order to establish a successful prevention program, it is necessary to investigate the genetic status in the endemic area, including the prevalence of the mutation spectrum as well as the available resources. In this study, we screened 12,900 samples for - and -thalassemia in Baise City, Guanxi China with hematological methods and molecular assays. We found that the frequency of carriers in this area for -thalassemia is 15%;. -thalassemia carriers comprise 4.8%; of the population. The majority of - thalassemia carriers in this area have deletion mutationsfive of them account for 98% of -thalassemia. The most common mutations for -thalassemia are the missense mutation. Seven mutations in the -globin gene account for 99%; mutations in this region. The most of -thalassemia major die in the uterus or shortly after birth. We have followed 106 patients with -thalassemia major in our clinic. In general, the patients with -thalassemia major develop clinical symptoms at 3-6 months of age and the majority of them die before 5 years of age. Knowledge surveys about - and -thalassemia were conducted in both the general and medical populations in Baise City. Our results show a severe deficiency in knowledge of thalassemia in both the medical professions and in the general populations. We conclude from our study that thalassemia is a very severe public health issue in minority populations in Baise City, China. Identification of the common mutations will allow us to design cost-effective molecular tests. However, we have a long way to go to educate the general population and the medical community for a successful community-based prevention program.

Identification of regulatory regions nearby COL18A1 gene. *E. Kague[1], L. Armelin-Correa[1], O.T. Suzuki[1], M.C. Sogayar[2], M.R. Passos-Bueno[1]* 1) CEGH-IBUSP, Brazil; 2) IQ-USP, Brazil.

COL18A1 gene contains 43 exons and is transcribed in 3 distinct isoforms using two promoters and an alternative splicing of the third exon. Although collagen is found in all vascular and epithelial basement membranes each of the variants show a characteristic expression pattern, with the highest levels of RNA in liver, kidney and lung. Mutations that lead to inactivation of both the long and short isoforms of COL18A1 gene cause Knobloch syndrome, an autossomal recessive disorder. The collagen XVIII is also involved in other processes through a proteolytic fragment of this collagen called endostatin, an important inhibitor of angiogenesis involved in some pathological processes, such as cancer progression. High sequence conservation among species allows the identification of important gene regulatory regions. Distant regulatory regions of COL18A1 are not yet known. Therefore, the aim of this work is the identification of regulatory regions in the vicinity of the COL18A1 gene (100kb upstream of the first exon, introns and 3UTR). Using available bioinformatics tools (VISTA browser- http://genome.lbl.gov/vista/index.shtml, UCSC browser- http://genome.ucsc.edu/ and, http://enhancer.lbl.gov) we selected 13 conserved noncoding sequence blocks greater than 100pb in length and 75% of sequence identity from orthologous regions of the human and mouse genomes nearby Col18A1. After the *in silico* analysis, we cloned each region in a reporter PGL3-promoter vector (Promega) that carries a luciferase reporter system and transfected these constructs into HEK293T and HeLa cells. These two cell lines were chosen for transfection assays, as we observed through Real-Time quantitative RT-PCR that they have the highest and lowest COL18A1 expression levels, respectively, among five cell lineages tested (HEK293T, SHSY, HeLa, HUVEC, h-FOB). Until now, we observed that two out of 6 tested regions changed the luciferase transcription levels in HEK293T (p0,05). The regions with a positive functional result *in vitro* assay will also be tested *in vivo* models. CEPID / FAPESP erikakague@yahoo.com.br.

Comparisons of genome coverage can be misleading as indicators of the power of SNP sets or chips for association studies. *J. Marchini, C. Spencer, Z. Su, P. Donnelly* Department of Statistics, Oxford University, Oxford, United Kingdom.

When comparing sets of SNPs for use in genome-wide association studies, such as those offered on commercially available chips, it has become standard to compare them on the basis of genome coverage. For example, coverage is often measured by estimating the proportion of common SNPs in the genome which are well correlated (say $r^2$0.8) with at least one SNP on the chip, or sometimes (via multi-marker tagging) with combinations of SNPs on the chip. With the availability of the HapMap data, coverage is straightforward to estimate. Further, coverage is often taken as a surrogate for what really matters, but is much harder to estimate, namely the power to detect causative SNPs in an association study. Here we describe new methods to estimate power and present results which compare the power of different SNP sets for large genome-wide association studies, and contrast these with comparisons of coverage for the same sets. Strikingly, marked differences in genome coverage may well not translate into appreciable differences in power in association studies. As one example, supplementing a commercially available chip with an additional 130K markers specifically chosen to maximise coverage increased coverage (measured pairwise) from 65% to 81%, but resulted in only a slight increase in power, over a range of common allele frequencies and effect sizes. With hindsight, there are several reasons why coverage comparisons can be misleading indicators of relative power.

Role of cytoplasmic DNA in other disease. *M. Houshmand* Medical Genetics Unit, National Institute for Genetic Engineering and Biotechnology, Tehran, Iran.

The hypothesis that mitochondrial DNA (mtDNA) may be implicated in susceptibility to MS is supported by an increasing number of reports. We studied the mitochondrial possible point mutations background for both diseases. In 56 Iranian MS patients we couldn't find any primary LHON point mutations. We also investigated the same mitochondrial haplogroup (J, K) in Iranian patients. We studied 70 MS patients and 149 healthy controls for Haplogroup J and K with PCR RFLP method. Our result showed that 14 out of 70 positive (20%) in MS group and 14/149 (9.4%) in control group for J ($P < 0.05$); and 9/70 (13%) in MS group and 5 out of 70 (7%) in control group positive for Haplogroup K ($P=0.4$). Association between haplogroup J and Optic Neuritis showed; significant ($P< 0.005$). Our haplogroup investigation (J, M, BM and N) in LHON patients normal control group (149 controls for haplogroup J. and 246 controls for haplogroups M, BM and N, from different regions of Iran) showed any relation between LHON and the haplogroups J, M and N. However the results showed a slight relatedness between haplogroup BM and LHON. Conclusion: 1) LHON and MS had not the same haplogroups background as well as point mutations 2) This study showed that haplogroups J may be a risk factor for MS diseases special for MS patient with Optic neuritis but genetic susceptibility factors for these disorders vary between different populations, 3) there is a slight relatedness between haplogroup BM and LHON. Our analysis revealed high proportion of haplogroup W in infertile men (14.2%) compared to normal controls (0%). ($P= 0.02$) Therefore, we hypothesize that mtDNA haplogroup W might constitute a risk factor for infertility and might act as predisposing haplotypes, increasing the risk for infertility.

Long term implications of genetic diagnosis and genetic counseling for families with chromosomal abnormalities.
T. Narumanchi, D. Wesley, J. Thoene, M. Li Hayward Genetics Center, Tulane School of Medicine, New Orleans, LA.

We report a case of a three generation family with a balanced translocation in two unaffected females, an affected female with a marker chromosome and an affected male with an unbalanced translocation. The proband was a female infant with microopthalmia, congenital heart defects, and severe dysmorphic features as a result of a maternally inherited marker chromosome [47,XX,+mar.ish der(22)t(17;22)(q25.3;q13.1) (TUPLE1+,ARSA-)mat]. During our interview we discovered that the maternal family had previously had an extensive cytogenetic workup and genetic counseling due to an affected half-uncle. The patients mother was aware that the grandmother was a balanced carrier, but believed that she herself had a normal karyotype. The discovery that she was a carrier of a balanced translocation, and the subsequent feelings of guilt were traumatic for the mother, and were compounded by her daughters subsequent demise. This case reinforces several important concepts: 1.Balanced translocation carriers diagnosed as children may not understand the implications of a balanced translocation, especially as it applies to their own future pregnancies; 2. Follow-up with balanced translocation carriers, especially those who may have children at a later date is vital; 3. Patient memories can become erroneous or faded as time passes. They may also lose their laboratory reports or other clinical documents. Genetic centers must therefore consider the need to maintain records for decades.

Genotype-Phenotype Analysis of the *MGC1203* C430T Mutation in an Ethnically Diverse BBS Cohort. *C. Mok*[1], *J. Bin*[1], *N. Noordeh*[1], *E. Héon*[1,2] 1) Dept. Genetics & Genomic Biol., Sick Kids Hospital, Toronto, ON, Canada; 2) Dept. of Ophthalmology and Vision Sciences, Sick Kids Hospital, Toronto, ON, Canada.

Bardet-Biedl syndrome (BBS) is characterized by features such as retinal degeneration with eventual vision loss, obesity, renal anomalies, frequent digit anomalies and learning disabilities among other less common features. BBS is a genetically heterogeneous, autosomal recessive disease with well-documented cases of inter and intrafamilial phenotypic variability. It has been proposed that genetic modifier(s) may play a role in determining phenotype severity. The C430T change in *MGC1203* (*BBSIP1*) was recently suggested to have such a modifying effect in worsening the phenotype. This C430T mutation causes an increase in aberrant splicing leading to a premature termination codon and therefore a loss of mRNA transcript. We investigated the role of this BBS genetic modifier in 36 unrelated patients affected with BBS. Assessment of phenotype severity included parameters such as the primary BBS mutation, visual acuity, rod and cone function assessed by electroretinography as well as systemic changes (obesity, kidney and liver function, hearing, smell, etc.). A heterozygous C430T sequence change was confirmed using an ARMS assay and direct sequencing in 3 probands (8%). Two of these probands had affected siblings who were also heterozygous for this change. The sequence variant did not explain the intrafamilial phenotype variability of these pedigrees. This study does not support the role of MGC1203 as a major modifier of phenotype severity in the cohort of patients studied.

Toward identification of molecular pathways in dyslexia and related disorders. *J. Kere[1,2,3], M. Peyrard-Janvid[1], I. Tapia-Paez[1], H. Anthoni[1], N. Kaminen[3], S. Massinen[3], M. Zucchelli[1], H. Matsson[1], P.J. Lindsberg[3,4], E. Castren[3], K. Hannula-Jouppi[3]* 1) Karolinska Institutet, Stockholm, Sweden; 2) Karolinska University Hospital, Huddinge, Sweden; 3) University of Helsinki, Finland; 4) Helsinki University Central Hospital, Finland.

Developmental dyslexia (specific reading disability) affects the capacity to learn reading and writing in the presence of normal senses, intelligence and educational opportunity. Specific genes for developmental dyslexia have been identified by genetic studies in recent years, and the first implications for neurodevelopmental processes involved in dyslexia arose from the identification of the axon and dendrite guidance receptor gene ROBO1 and the neuronal migration gene DCDC2 as dyslexia susceptibility genes. The product of the first suggested dyslexia gene, DYX1C1, has been identified as a CHIP-associating protein involved in ubiquitination, and the fourth dyslexia candidate gene KIAA0319 can regulate neuronal migration. Additional candidate genes at the DYX3 locus are being characterized (H. Anthoni et al. this meeting). We are identifying the molecular pathways and interactions of these genes and proteins. We show that DYX1C1 is regulated by SNPs in its promoter region by a transcription factor complex, identified by EMSA and protein sequencing (Tapia-Paez et al. this meeting), and that DYX1C1 protein is rapidly regulated by heat shock to translocate to cytoplasm, interacting there with CHIP and ubiquitin (Kaminen et al. unpublished). Preliminary data suggest that DCDC2 and ROBO1 may be linked in a common pathway, and confirmation of this regulatory pathway may define the first biochemical mechanism involved in dyslexia. We conclude that genes involved in neurodevelopmental processes underlie specific reading disability, and characterization of the biochemical and regulatory pathways may offer first clues to explain dyslexia on the molecular level.

Phenotypic characterisation of alveolar macrophages from atopic asthmatic subjects. *A.-M. Madore[1,2], V. Turmel[3], M. Laviolette[2,3], E. Bissonnette[2,3], C. Laprise[1,4]* 1) University of Montreal Community Genomic Medicine Centre, Saguenay, Canada; 2) Laval University, Quebec, Canada; 3) Institut universitaire de cardiologie et de pneumologie de l'Université Laval, Quebec, Canada; 4) Université du Québec à Chicoutimi, Saguenay, Canada.

Rationale: Environmental and genetic factors play an important role in asthma, particularly with regard to its specific inflammatory process. The alveolar macrophages (AM) are regarded as the major line of defence of lungs. At this time, the literature reports only few genetic determinants and biological ways, which permit to partially define the implication of AM in asthma. **Objectives:** To identify biomarkers specific to the activity of AM in asthma and atopy particularly related to the inflammatory process. The specific objectives are: 1) to study the AM transcriptome using HG-U133A Affymetrix DNA chips, 2) to target new candidate genes for atopic asthma and 3) to select certain genes and carry out a validation by real time RT-PCR. **Methods:** The sample consists of 5 atopic asthmatic individuals and 5 control individuals (without asthma nor allergy). The extraction of AM RNA was followed upon their isolation starting from bronchoalveolar lavages. The analysis of the results of the DNA chips was carried out in order to draw up a list of new candidate genes specific to the activity of AM in atopic asthma. Thereafter, the RNA was used to validate by real time RT-PCR the differences in expression for 5 selected genes. **Preliminary results:** The analysis of chips showed 36 genes, classified in 9 clusters related to inflammation, differently expressed in AM of atopic asthmatic and control subjects. To date, 3 of 5 selected genes were tested by real time RT-PCR of which 2 were validated, the development for other genes being in hand. **Perspectives:** The validation by real time RT-PCR will be completed and the characterization of the protein expression of 5 genes will be done by immunocytochemistry and western blot. Thereafter, functional studies will be carried out for one of the 5 genes starting from cell lines, in order to better characterize the biological way in which it is integrated.

Screening of Nuclear Genes Encoding Proteins Critical For Mitochondrial Genome Replication and Maintenance, and Physiological Function: Retrospective Analysis of Clinical Samples Manifesting Mitochondrial Disorder Phenotypes Without Known Pathogenic Mutations Or Deletions In Mitochondrial DNA. *M. Koul[1], J. Hempel[1], S. Edstrom[1], J. Stoddard[1], B-L. Wu[1,2], S. Lilleberg[1]* 1) Transgenomic Labs, Omaha, NE, United States; 2) Childrens Hospital, Harvard Medical School, Boston, MA, United States.

Disorders associated with mitochondrial respiratory chain dysfunction affect at least 1 in 8000 of the general population. Known defects of mtDNA account for approximately one-half of all primary mitochondrial respiratory disorders. Heterogeneous mitochondrial disorders are caused by gene defects in the either mitochondrial DNA or the nuclear DNA or both. Also, distinct mutations in a single gene may cause strikingly different phenotypes, or conversely, patients with different respiratory chain disorders can have a similar phenotype (phenocopies). To further understand these more complex genotype-phenotype relationships, we initially analyzed the whole mitochondrial genome from 25 clinical samples from patients with various clinical presentations of mitochondrial disorders. For this purpose, we utilized our validated in-depth screening strategy for the detection of mitochondrial DNA alterations by an optimized PCR protocol to cover the entire mtDNA with 40 overlapping amplicons designed specifically for our accurate and sensitive scanning techniques of WAVE DHPLC, SURVEYOR with double stranded DNA cycle sequencing for the detection of both heteroplasmic and homoplasmic variants in mtDNA. Samples with the absence of any known pathogenic mitochondrial DNA alterations, were further analyzed for mutations in the nuclear genes encoding factors needed for mt DNA replication (DNA POLG), followed by genes involved in maintaining the mitochondrial nucleotide pool (DGUOK, TK2), and respiratory function (COXIV assembly genes; SURF1, COX10, SCO1, and SCO2) as part of a tiered screening approach for efficient analysis in a clinical laboratory. Results from this comprehensive analysis of nuclear and mitochondrial genes will be presented with relevant functional information on the mutations/polymorphisms that were detected.

Distribution of clinical data in prostate cancer affected men with early age at onset. *D.M. Mandal*[1], *S.L. Halton*[2], *J.E. Bailey-Wilson*[3], *W. Rayford*[4] 1) Genetics, Louisiana State University Health Sciences Center, New Orleans, LA; 2) Baylor Clinic, Houston, TX; 3) NHGRI/NIH, Baltimore, MD; 4) Department of Preventive Medicine, University of Tennessee, Memphis,TN.

Several risk factors have been identified in prostate cancer, including age, race and family history. In general, incidence rate of prostate cancer in African-American men is twice as high as the Caucasian males. Earlier studies in literature show that African-American men are often diagnosed with advanced stages of prostate cancer and their age-specific PSA is higher than their Caucasian counterparts. We have identified 125 individuals in our prostate cancer study with early age at onset (65 years) from Southern Louisiana. There are 60 African-Americans and 65 Caucasians. Family history was verified for all of them and pathological reports were reviewed. Data were analyzed to observe the distribution of age, PSA and Gleason Scores in two races. A significant difference ($p = 0.0008$) in the age at onset values was observed between African-American (range 38-65 years with median age of 57.5 years) and Caucasian (range 44-65 years with median age of 61 years) males. No statistical significance was observed in PSA and Gleason Score values in two races. In further analyses, data were stratified with respect to sporadic cases and cases with family history of prostate cancer. African-American and Caucasian cases with family history produced a significant difference of $p < 0.01$ in the age at onset values. This result enables us to observe clinical characteristics of prostate cancer in different races in Louisiana males, which may contribute significantly in prostate cancer screening strategies.

New Autosomal Recessive Multiple Congenital Anomalies/Mental Retardation (MCA/MR) Syndrome Consisting of Fronto-Nasal Dysplasia, Hypertelorism, Short Stature, Brachydactily and Speculated Irises. *M. Haimi[1], R. Gershoni-Baruch[1,2]* 1) medical genetics, Rambam medical center, Haifa, Israel; 2) The Ruth and Bruce Rapport Faculty of Medicine, Technion-Israel Institute of Technology, Haifa, Israel.

Fronto-nasal dysplasia is a developmental field complex associated with variable degrees of midline facial clefting and singled by wide variability of expression. The clinical findings consist of ocular hypertelorism, median facial clefts, broad nasal root, lack of formation of nasal tip, anterior cranium bifidum occultum and widow's peak hair anomaly. We describe two female sibs born to a consanguineous Arab Muslim couple in northern Israel. Among other clinical findings, both have moderate mental retardation, short stature, leonine facies with hypertelorism, broad nasal root, long philtrum, fronto-nasal dysplasia, speculated irises, brachy-clinodactily, low-set posteriorly rotated ears and a webbed neck. Fronto-nasal dysplasia constitute a salient manifestation of cranio-fronto-nasal dysplasia (CFND) or cranio-fronto-nasal syndrome (CFNS) which is characterized by hypertelorism, coronal synostosis with brachycephaly, downslanting palpebral fissures, clefting of the nasal tip, joint anomalies, longitudinally grooved fingernails and other digital anomalies. Otherwise, the combination of hypertelorism, brachydactyly, ligamentous laxity, pectus excavatum and peculiar penoscrotal relations (shawl scrotum) was reported as an X-linked disorder termed faciogenital dysplasia for which sex-influenced autosomal dominant inheritance was also suggested. This association of anomalies differs from previously reported entities characterized by mid-face clefting and defines a new MCA/MR syndrome. Parental consanguinity and familial occurrence in two sisters suggest autosomal recessive inheritance.

A locus for familial mesial temporal lobe epilepsy mapped on chromosome 18p. *C.V. Maurer-Morelli[1], R. Secolin[1], R.R. Domingues[1], R.B. Marchesini[1], N.F. Santos[1], E. Kobayashi[2], F. Cendes[2], I. Lopes-Cendes[1]* 1) Department of Medical Genetics, FCM/UNICAMP, Campinas, São Paulo, Brazil; 2) Department of Neurology, FCM/UNICAMP, Campinas, São Paulo.

We have reported a large group of families with mesial temporal lobe epilepsy (FMTLE) associated with hippocampal atrophy (HA) and other signs indicative of hippocampal sclerosis (HS) detected by magnetic resonance imaging techniques. Previous pedigree and complex segregation analyses provided evidence for the presence of a major gene predisposing to HA in FMTLE. The aim of this study was to identify the region harboring the main gene associated with HA in FMTLE by linkage analysis. Genome-wide scan was performed using a total of 332 microsatellite markers with a polymorphism information content 0.75% at approximately 12cM intervals. An additional 14 markers were genotyped to fine mapping in the candidate region. Two-point and multipoint LOD scores were calculated with the LINKAGE computer package. We assumed an autosomal dominant inheritance with incomplete penetrance. A locus for FMTLE was identified at chromosome 18p11.3-11.2 with a maximum LOD score of 3.60 at = 0.0 for the D18S976 marker in a single family with 11 affected individuals with HA. Multipoint and haplotype analyses localized the locus within a 6 cM interval flanked by markers D18S976 and D18S452. No other significantly positive LOD score was detected for this family in the entire genome. This is the first conclusive evidence that HA may be caused by genetic factors, which can have major implications in the study of the pathophysiological mechanisms underlying HS and its relationship with temporal lobe epilepsy. Supported by FAPESP.

Pathogenic duplication or variant: Molecular cytogenetic discrimination of proximal 15q and 8p23.1 as models.

J. Lee, B. Bunke, D. Saxe, D.H. Ledbetter, C.L. Martin Department of Human Genetics, Emory University, Atlanta, GA.

G-banding analysis often reveals structural chromosome variations in regions such as 8p23.1, 9p12, 15q11.2 and 16p11.2, which have been referred to as euchromatic variants. However, as more is learned about the underlying genomic structure, it has become evident that apparently identical imbalances at the G-banding level are not equivalent at the molecular level. Targeted molecular cytogenetic analysis has enabled clarification of these findings to differentiate between copy number variations and pathogenic imbalances. Here, we present data from two such regions, proximal 15q11.2 and 8p23.1, using FISH with genomic clones. The amplification of pseudogenes in proximal 15q has been reported as a normal euchromatic variant, however duplications of unique genes just distal to this region can cause autism. To discriminate this polymorphic variant from clinically significant duplications, we utilized clones corresponding to the NF1 pseudogene and the unique region (SNRPN) of proximal 15q in 6 cases that showed a possible duplication by G-banding. All 6 cases showed an amplification of the pseudogene region on one homolog compared to the other, classifying these cases as polymorphic variants. Likewise, a duplication of 8p23.1 is frequently identified by G-banding. In some cases, this duplication is associated with a normal phenotype, while in others it is associated with congenital anomalies. We have studied two cases with 8p23.1 duplications that look identical by G-banding using FISH with clones mapped to the olfactory receptor (OR) gene cluster and unique genes located between the two OR gene clusters in 8p23.1. In Case 1, one of the homologs showed an amplified hybridization signal for the OR cluster and a normal hybridization pattern for the unique genes. Therefore, this dup(8)(p23.1) is most likely a normal variant. In Case 2, the probes for the unique gene region are duplicated, demonstrating that the dup(8p)(p23.1) is pathogenic. Our data from 8p and 15q demonstrate that molecular cytogenetic characterization of cytogenetically identical imbalances such as these is necessary for an accurate clinical interpretation.

Spurious Evidence for Two Neighboring Disease Loci can be Caused by Different Patterns of Linkage Disequilibrium. *I. Ionita[1], L.J. Strug[2], J. Zhang[2], D.A. Greenberg[2,3]* 1) New York University, New York, NY; 2) Div Stat Genetics, Depts. Biostatistics & Psychiatry, Columbia U; 3) NY State Psychiatric Institute.

Statistical methods exist to detect whether more than one locus in a region is involved with disease susceptibility. We present a situation in which linkage disequilibrium patterns lead to a false conclusion of multiple loci. Linkage analysis of Idiopathic Generalized Epilepsy (IGE) identified a disease-linked region on chromosome 18(Durner et al. 2001) and single-nucleotide polymorphism (SNP) case-control and family-based analysis in that region revealed alleles at several loci strongly associated with disease (Greenberg et al 2005). In the case-control analysis there were two distinct peaks. The first peak was in the malic enzyme 2 (ME2) gene; the second, just telomeric to ME2, could be a second disease locus or perhaps a shadow peak, caused by the pattern of LD in the region. In order to determine the nature of the second peak, we performed a stepwise regression procedure (Cordell & Clayton 2002) to evaluate the relative importance of the SNPs. The puzzling results showed that the case-control analysis did not exclude the possibility of two disease loci, while the family-based data, in a conditional logistic regression, supported the one disease locus model. We performed a simulation study to determine the frequency with which two distinct association peaks would be observed when only one disease locus exists. We simulated both case-control data and family-based data with a single disease locus. We created a pattern of low LD in the disease locus region, followed by a high LD region, a pattern similar to the real data. We observed that the frequency of two significant peaks in the case-control data was 20%. In contrast, in the family-based data, the frequency was less, approx. 6%. The simulation results show that observing two association peaks in the same region can arise by a combination of chance and the fine-grain LD structure of the region. The pattern of LD we used was but one of many possible LD patterns. We anticipate other LD patterns could lead to other types of misleading results in association studies.

Investigating the methylation status of genes which are responsible for the formation of conventional renal cell carcinoma. *H. Onay[1], S. Pehlivan[2], M. Koyuncuoglu[3], Z. Kirkali[4], F. Ozkinay[5]* 1) Medical Genetics, Ege University Faculty of Medicine, Izmir, Turkey; 2) Biology, Ege University Faculty of Science, Izmir, Turkey; 3) Pathology, Dokuz Eylul University, Izmir, Turkey; 4) Urology, Dokuz Eylul University, Izmir, Turkey; 5) Pediatrics,Ege University Faculty of Medicine, Izmir, Turkey.

Renal cell carcinoma (RCC) is the most common malignancy of the kidney. At initial diagnosis of RCC 30% of patients have metastatic disease. Metastatic disease does not respond to most treatment regimes and median survival rate for such patients is less than one year. For this reason early diagnosis of RCC is crucial. Changes in the methylation pattern of the promotor region of tumor supressor genes are important in the development of the cancer. These changes may occur before the clinical manifestations of the disease are recognised. Methylation Specific Polymerase Chain Reaction (MSP) which is frequently used in methylation studies is a sensitive and rapid technique and has a high throughput. In this study, 7 tumor suppressor genes (RASSF1A, ECAD, TIMP3, APC, MGMT, p16, RARB2) which are thouhgt to have a role in the development of RCC were investigated for the methylation status in their promoter region in three different tissue samples (normal, premalign and malign) of 21 conventional RCC patients using MSP technique. The aim of the study was to form a methylation based early detection test comprising of the genes which are detected to be important in the development of RCC. High methylation rates for the genes RASSF1A (76%), p16 (80%), ECAD (42%), TIMP3 (33%) and MGMT (33%) were observed in the patients with RCC. The APC (14%) and RARB2 (19%) genes showed respectively low methylation rates. In conclusion a methylation based early diagnosis gene test which consists of the tumor suppressor genes RASSF1A, ECAD, TIMP3, MGMT and p16 may be used in patients with RCC.

An X;Y translocation in a fertile, phenotypically normal female with a normal daughter and fatal fetal anomaly in a son. *L.C. Layman[1], J.D. Bell[1], S.P.T. Tho[1], A. Kulharya[2], P.G. McDonough[1]* 1) Dept OB/GYN, Sect Reprod Endocrinol, Infertil, & Genet, IMMAG, Medical Colleg of Georgia, Augusta, GA; 2) Dept Pediatrics, Medical Gollege of Georgia, Augusta, GA.

Human X;Y translocations are uncommon and produce considerable variability in progeny outcome. We present the case of a mother with a balanced X;Y translocation ascertained through the analysis of a stillborn male. She is a 25 year-old WF G2P1101 with regular menses who conceived spontaneously without medical intervention. On physical exam, she is 49 but is otherwise phenotypically normal with a normal cycle day #2 FSH level. Her first pregnancy resulted in the birth of a healthy girl who is normal except for short stature (<2.5%), but her second pregnancy ended at 20 weeks with the delivery of a stillborn male with hydrocephalus. The maternal serum unconjugated estriol level was unmeasurable. A karyotype revealed a 46,Y,der(X)t(X;Y)(p?22.3;q?11.2). FISH demonstrated ish der(X)t(X;Y)(wcpY+,wcpX+), with the presence of the KAL1 region and deletion of the steroid sulfatase (STS) locus, defining the breakpoint on the X chromosome. In addition, interphase FISH studies on the probands peripheral lymphocytes demonstrated the the X centromere (DXZ1+) and Yq12 (DYZ1+), but not the Y centromere (DYZ3-), indicating the presence of only Yq on the X;Y derivative chromosome. Both the proband and her daughter carry the 46,X,der(X)t(X;Y)(p22.3;q11.23) balanced translocation with the derivative X lacking p22.3 to the telomere and containing Yq11.2 to the telomere. The patient was counseled to have a cardiac echo to exclude potential aortic abnormalities. Currently, the breakpoints are being determined using STS markers on Yq11.2. Issues of concern for the patient with this translocation include: future fertility, meiotic behavior of the translocation and the risk for congenital anomalies, the risk for gonadoblastoma and aortic root abnormalities, and the challenge of pre-implantation diagnosis.

Can Lmx1a and Lbx1 genes be genetic risk factors for Neural Tube Defects? *T. Jafarov, L. Mehltretter, D. Siegel, T. George, D. Enterline, J. Gilbert, M. Speer, NTD Collaborative Team* Center For Human Genetics, Duke University Medical Center, Durham, NC.

Introduction:Recently published studies on dreher (carrying mutated homeobox gene Lmx1) and Lbx-1- mouse models have demonstrated their important roles in the development of CNS, heart, extremities, roof plate and the rostral part of neural tube. Disruption of normal function of these genes theoretically could lead to complex conditions like neural tube defects (NTDs). Despite of the significant roles these genes can play, there have been no studies of these genes in human NTD patients. We have screened 105 DNA samples of patients with different types of NTDs for mutations in the human homologues of these genes, Lmx1a and Lbx1, with partial 3UTR regions. Materials and methods: Genomic DNA from NTD patients was extracted from blood and was used to amplify the exons and fluorescent direct sequencing was performed afterwards. Sequence data were blasted against the Human Genome Database and were analyzed with different bioinformatics programs. Results: We have found no non-synonymous mutations in coding sequences of Lmx1a and Lbx1 among the studied samples. A number of synonymous mutations were detected in both genes and among them novel ones were: Ser13Ser, Thr344Thr for Lmx1a. Altogether 13 known SNPs and 21 novel SNPs were detected in Lmx1a and Lbx1 genes. SNPs IVS1-35 C>T, IVS4-3 C>T,IVS7-37 G>A, IVS8-30 C>A in Lmx1a gene and SNPs IVS2-38 G>C, IVS2-41 C>A, IVS2-18 A>G and IVS2-21 G>C in Lbx1 gene could be of particular interests due to their position or frequencies. Discussion: Despite extensive search for genetic and environmental factors predisposing to neural tube defects, the progress in understanding the molecular mechanisms in humans has been slow. Although we have not found any mutations altering the protein sequence of Lbx1a and Lmx1a genes among the studied DNA samples, the SNPs found within close proximity to exon-intron boundaries could affect splicing and therefore change their mRNA profiles. The future case-control and mRNA profiles studies could provide supporting evidence for association between these genes and neural tube defects.

Dementia and relatedness in the mid-western Amish. *J.L. McCauley[1], A.E. Crunk[1], J.M. van der Walt[2], L.L. McFarland[1], P.C. Gaskell[2], L. Jiang[1], P.J. Gallins[2], K.A. Welsh-Bohmer[3], W.K. Scott[2], C.E. Jackson[4], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetics Research and Dept of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Human Genetics and Dept of Medicine, Duke University Medical Center, Durham, NC; 3) Joseph & Kathleen Bryan ADRC/Division of Neurology, Duke University Medical Center, Durham, NC; 4) Scott & White, Temple, TX.

The genetics of Alzheimers disease (AD) have proven to be quite difficult to understand and elucidate. Although a role for the APOE gene in late-onset AD is apparent, it accounts for less than half of the susceptibility and thus other genetic factors are likely to be involved. Genetic heterogeneity is a major complicating factor hindering further gene identification. To minimize heterogeneity, we have been collecting individuals with dementia from the genetically isolated Amish populations of both Ohio and Indiana. To date we have assessed over 1200 individuals who have consented to participate in our studies (97 of whom have probable or possible AD). Through use of the Anabaptist Genealogy Database (AGDB) and its query software PedHunter, we can interrogate the complete family structure of our sample through the examination of kinship coefficients and the construction of pedigrees based on those coefficients. The average kinship coefficient for our entire sample is 0.012, which is similar to that described for other Amish community samples. These kinship coefficients also demonstrate that the individuals ascertained within Adams County, Indiana are distinctly more related to each other (k.c.=0.041) than to individuals ascertained in the other regions (k.c.=0.0051). The vast majority (>90%) of our sample can be traced back at least 10 generations to a single founding couple. Furthermore, we are tracing both maternal and paternal lineages (using mitochondrial and Y-chromosome markers) to better estimate the number of founders in our sample. These data indicate that the Amish of Adams County, Indiana may represent a separate subsample of the Amish genome, and have helped us to develop 13 complex yet analytically tractable subpedigrees for analysis of dementia.

Preliminary Pharmacogenetic Analysis of Gene Expression in Patients with Major Depressive Disorder Treated with Citalopram. *F. Mamdani[1], P.A. Sequeira[1], J. ffrench-Mullen[2], M. M. Beaulieu[1], G. Turecki[1]* 1) McGill Group for Suicide Studies, Douglas Hospital Research Centre, McGill University, Montréal, Quebec, Canada; 2) GeneLogic Inc., Gaithersburg, Maryland, USA.

Major depression (MD) is a psychiatric disorder that affects 5-10% of the population and is considered the second leading cause of disability by the World Health Organization. Several studies have indicated the involvement of genetic factors in MD, which may also play a role in a patients response to antidepressant treatment. In order to identify gene targets that may mediate response to Citalopram (Cit) treatment, a commonly used SSRI (selective serotonin reuptake inhibitor) antidepressant, we are conducting a large-scale gene expression study of patients being administered CIT for 8 weeks, with Affymetrix U-133 Plus2 microarrays being performed pre- and post-treatment. We are presenting preliminary results on 28 cases. Outlier detection was performed using several quality control variables and principal component analysis. Differential expression analysis resulted in 42 genes having altered expression between responder and non-responder samples and 208 genes showing differential expression in relation to gender. The findings of our preliminary analyses are interesting in that they suggest an interaction between response and gender, not surprisingly given gender differences in MD prevalence rates. Gene ontology analysis of differentially expressed genes revealed several biological processes being affected by treatment; these include regulation, transcription, response to stress, as well as, biosynthesis and metabolism of macromolecules and proteins. Our results suggest that there appears to be differential expression following Cit treatment and these differences may be correlated to treatment response.

Genome-wide linkage study in the NIMH Bipolar data sets of alcohol dependence and correlation with loci significant for psychosis. *B. Kerner, D.L. Brugman, N.B. Freimer* Ctr Neurobehavioral Genetics, Department of Psychiatry and Biobehavioral Sciences, Univ California, Los Angeles, Los Angeles, CA.

Purpose: Alcohol dependence has a high co-morbidity with bipolar disorder and has been shown to be genetically influenced. Linkage signals with this trait have been found on chromosomal regions overlapping with those for schizophrenia or bipolar disorder. In our previous analysis of the NIMH Bipolar data sets a significant linkage signal for psychotic bipolar disorder was found to be located on chromosome 5q33-34. Families in this linkage scan had significant co-morbidity with alcohol dependence. Since this chromosomal region has also been implicated in genome scans for alcohol dependence we performed a linkage scan in the NIMH data sets Waves 1, 2, 3, and 4 and compared the obtained linkage signals with those in our previous linkage scan for psychotic bipolar disorder. Methods: DSMII-R or DSM-IV alcohol dependence was used in this study as the phenotype definition for a whole genome scan of the NIMH Bipolar Genetics Initiative data sets. Wave 1 and 2, as well as Waves 3 and 4 combined, were analyzed using non-parametric linkage analysis in MENDEL. Results: This analysis showed a suggestive linkage signal on chromosome 1q21-1q22 in Wave 1 and 2 in the vicinity of the markers D1S534/D1S1595. This locus has been previously implicated in scans for schizophrenia. A signal in this region was also detected in Wave 3 and 4 near the marker D1S1589. Other interesting results included signals on chromosome 15q15-q21 in Waves 1 and 2 and on chromosome 8q11 and 11q21-q22 in Waves 3 and 4 combined. Conclusion: The phenotype of alcohol dependence in families ascertained for bipolar disorder revealed a suggestive linkage signal on chromosome 1q. The linkage signals were distinct from those that were obtained in a linkage scan for psychotic symptoms in bipolar disorder. The co-morbidity of alcohol dependence should be taken into account when linkage scans for psychiatric disorders are performed since genetic interactions with this trait are likely.

3q29 microduplication: a novel syndrome in a three-generation family. *E. Lisi[1], A. Hamosh[1], B. Jackson[2], R. Galczynski[2], D. Batista[2,3]* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD; 3) Department of Pathology, Johns Hopkins University, Baltimore, MD.

We describe four affected individuals in a three-generation family with a subtle 3q29 microduplication. The proband is an 11 month old male with developmental delay, severe microcephaly, and dysmorphic facies. His affected mother and maternal aunt have mild to moderate mental retardation, microcephaly, dysmorphic facies, and obesity. The affected maternal grandfather has mild mental retardation, obesity and type II diabetes. Previous reports of dup(3q) syndrome, associated with growth retardation, microcephaly, dysmorphic facies, and mental retardation, have mapped the critical region to 3q26.3-27. Additionally, a newly described 3q29 microdeletion syndrome is associated with mental retardation and variable dysmorphic features, but only 1 of 6 patients has microcephaly. Using a combination of microarray CGH and FISH with several BAC clones, we mapped the proximal breakpoint in our family to be between RP11-352G9 and RP11-252K11. The distal breakpoint lies telomeric to RP11-496H1. The maximum size of the microduplication is estimated to be about 2-2.5 Mb. The microdeletion 3q29 syndrome seems to be associated with low-copy repeats that flank the breakpoints and might predispose to nonallelic homologous recombination. In our family with microduplication, the proximal breakpoint lies within the same region as on the microdeletion syndrome, however the distal breakpoint is telomeric. The distal breakpoint in our family is more distal than previously reported. Thus, we postulate that an additional low copy repeat may be present on chromosome 3q, causing a propensity for variable deletions and duplications of this region. Additionally, our family gives evidence that the critical region for phenotypic expression of mental retardation and microcephaly may be more distal than previously described, or additional genes critical to brain growth and development may map to 3q29.

Evaluation of the Risk for Tay-Sachs Disease in Individuals of French Canadian Ancestry Living in New England. *M.R. Natowicz[1], D.C. Martin[2], B.L. Mark[3], B.L. Triggs-Raine[2]* 1) Genomic Medicine Instititute, Cleveland Clinic, Cleveland, OH; 2) Department of Biochemistry and Medical Genetics, University of Manitoba; 3) Department of Microbiology, University of Manitoba.

Background: The assessment of risk for Tay-Sachs disease (TSD) in individuals of French Canadian background living in New England is an important health issue. In preliminary studies of the enzyme-defined carrier frequency for TSD among Franco-Americans in New England, we found frequencies (1:53) higher than predicted from the incidence of infantile TSD in this region. We have now further evaluated the risk for TSD in the Franco-American population of New England.

Methods: The carrier frequencies for TSD in 2783 Franco-Americans were determined using a fluorescence-based assay for -hexosaminidase activity. DNA analysis was used to identify mutations causing enzyme deficiency in TSD carriers.

Results: We determined the enzyme-defined carrier frequency for TSD as 1:65 (95%CI 1:49 to 1:90). DNA-based analysis of 24 of the enzyme-defined carriers revealed 21 with sequence changes: 9 disease-causing, 4 benign, and 8 of unknown significance. Six of the unknowns were identified as c.748G>A p.G250S, a mutation we show by expression analysis to behave similarly to the previously described c.805G>A p.G269S adult-onset TSD mutation. This putative adult-onset TSD c.748G>A p.G250S mutation has a population frequency similar to the common 7.6 Kb deletion mutation that occurs in persons of French Canadian ancestry.

Conclusions: We estimate the frequency of deleterious TSD alleles in Franco-Americans to be 1:73 (95%CI 1:55 to 1:107). These data provide a more complete evidence base from which to formulate policy recommendations regarding TSD heterozygosity screening in individuals of French Canadian background.

A Phase 3 study of the efficacy of sapropterin dihydrochloride (tetrahydrobiopterin, 6R-BH_4) in reducing phe levels in subjects with phenylketonuria. *H. Levy[1], A. Milanowski[2], A. Chakrapani[3], M. Cleary[4], F. Trefz[5], C. Whitley[6], F. Feillet[7], A. Feigenbaum[8], J. Bebchuk[9], H. Christ-Schmidt[9], A. Dorenbaum[10]* 1) Dept Medicine, Children's Hosp, Boston, Boston, MA; 2) Instytut Matki i Dziecka, Warszawa, Poland; 3) Birmingham Childrens Hospital, Birmingham, UK; 4) Great Ormond Street Hospital, London, UK; 5) Klinik fur Kinder und Jugendmedizin Reutlingen, Reutlingen, Germany; 6) University of Minnesota, Minneapolis, MN; 7) Hopital dEnfants - CHU Brabois, Vandoeuvre les Nancy, France; 8) Hospital for Sick Children, Toronto, Ontario, Canada; 9) Statistics Collaborative, Inc, Washington, DC; 10) BioMarin Pharmaceutical,Inc. Novato, CA.

Strict dietary management of Phenylketonuria (PKU) is the only option to prevent mental retardation. Major challenges remain to achieve optimal outcomes. We studied Sapropterin, a synthetic form of BH_4, as a new treatment for PKU that could potentially improve long-term care. Patients previously screened for BH_4 response enrolled in a Phase 3, multicenter, randomized, double-blind, placebo controlled trial. Safety and efficacy in reducing blood phenylalanine (Phe) were compared in PKU patients treated with oral sapropterin 10 mg/kg, or placebo, once daily for 6 weeks. Of the 89 subjects enrolled, 87 completed treatment. Age ranged from 8 to 49 years (mean 209.7). At baseline, mean (SE) blood Phe was 843 (47) M and 888 (47) M in the sapropterin and placebo groups, respectively. After 6 weeks of treatment, sapropterin-treated patients achieved a mean blood Phe decrease of 236 (40) M (-29%) compared with a 3 (35) M (+3%) increase in the placebo group (p0.0001). At week 6, the percentages of subjects with blood Phe levels 600 M were 54% and 23% for the sapropterin and placebo groups, respectively (versus 17% and 19% at baseline). There was a consistent reduction over time in the average mean change in weekly blood Phe levels in the sapropterin group compared to the placebo group (p0.001). The type and incidence of adverse events were similar in the two study arms. Sapropterin was well tolerated and effective in significantly reducing blood Phe levels in PKU patients previously screened for BH4 responsiveness.

SNP-based microarray for the detection of submicroscopic chromosomal abnormalities. *J.M. Kogan, T.A. Smolarek, M. Keddache, H.M. Saal, G.A. Grabowski* Division of Human Genetics, Cincinnati Childrens Hospital Medical Center, Cincinnati, OH.

Aberrations in genomic copy number play a significant part in mental retardation and congenital malformations as well as cancer and infertility. Conventional cytogenetic techniques such as karyotyping and fluorescence in situ hybridization can be useful for diagnosis for these conditions, but they suffer from limitations in resolution and are labor intensive. In addition, they cannot detect copy-neutral abnormalities such as uniparental isodisomy. Recent advances in single-nucleotide polymorphism (SNP) arrays allow high-density genome analysis to be conducted in a relatively short amount of time. SNP-based chromosomal analysis also offers several advantages to other genome-wide analyses such as comparative genomic hybridization including ease of use. Also, with the manufacture of newer high density chips up to 1,000,000 SNPs, greater sensitivity can be achieved.

We used the Illumina Golden Gate assay containing 5,850 SNPs spaced at an average of 0.5 MB across the human genome to detect DNA dosage changes in nine patient samples with known losses or gains of chromosomal material and four samples with no identifiable chromosomal abnormality. Chromosomal abnormalities included trisomies, microdeletions, duplications, and unbalanced translocations. Abnormalities were easily detectable using BeadStudio Genotyping software. Of the chromosomally normal samples, one copy number polymorphism was found.

High resolution SNP-based chromosomal analysis will likely become essential for identifying copy number changes not detectable by conventional cytogenetic methods. Patients with mental retardation and/or having two or more congenital anomalies of unknown etiology are most likely to benefit. One caveat is that an increasing number of large-scale copy number polymorphisms are being identified in the population, and care must be taken when assigning diagnoses. Lack of identification of a similar abnormality in the parents chromosomes increases the likelihood, but does not guarantee that the chromosomal abnormality is causative for the patients phenotype.

Confirmation of Association between Variations in NOS1AP and the QT Interval in a Community-based U.S. Cohort. *W.H.L. Kao[1], D.E. Arking[1], W. Post[1], P.M. Spooner[1], G.F. Tomaselli[1], E. Marban[1], N. Sotoodehnia[2], E. Boerwinkle[3], A. Chakravarti[1]* 1) Johns Hopkins University,Baltimore, MD; 2) University of Washington, Seattle, WA; 3) University of Texas, Houston, TX.

The QT interval is a measure of cardiac repolarization. Through a genome-wide association scan, we previously identified SNPs in the upstream region of NOS1AP to be associated with the QT interval. The association for one of these SNPs, rs10494366, was subsequently replicated in three independent Caucasian cohorts. We now test the importance of genetic variations in NOS1AP in the Atherosclerosis Risk in Communities (ARIC) study, a prospective study of adults aged 45-64 years in 1989-92. Using data from HapMap, a total of 22 SNPs were selected to tag the block containing rs10494366 and rs4657139 (the most significant SNP from fine mapping in our initial study) and its neighboring blocks (criteria of r2>0.65 and MAF>0.05 using Tagger). No putatively functional SNPs were tested. General linear models were constructed to correct for age, sex, heart rate, and history of myocardial infarction. A three-means model was assumed. All analyses were stratified by race. Here, we present results from 3,564 African Americans. Several SNPs were associated with the QT interval in ARIC African Americans. While rs10494366 was marginally associated (p=0.09), an additional SNP, rs7539281, was significantly associated with the QT interval in this group (p=0.04). Genotyping in ~12,000 Caucasians is ongoing. Preliminary results in ~40% of the Caucasians indicate that the magnitude and direction of associations to be similar in the two groups. In summary, variations in NOS1AP are associated with the QT interval in a large cohort of middle-aged African Americans. Differences between findings of this study and our previous findings may be due to differences in populations and potentially inadequate selection of informative tagging SNPs in African Americans. Results from the present study, taken with our previous findings, demonstrate sequence variation in or around NOS1AP influences QT interval in the general population and that additional experiments are needed to identify the causal variant.

Genetic Profiling of Tay Sachs neuroglia cells and delineation of events associated with disease mechanism. *S.A. Igdoura[1,2], B. Trigatti[3], J.P. King[1]* 1) Dept Biology, McMaster Univ, Hamilton, ON, Canada; 2) Dept Pathology & Molecular Medicine, McMaster Univ, Hamilton, ON, Canada; 3) Dept Biochemistry, McMaster Univ, Hamilton, ON, Canada.

Tay Sachs disease is a lysosomal storage disorder characterized by lysosomal accumulations of GM2 ganglioside. The events that follow the initial increase of ganglioside storage and eventually lead to disease pathogenesis in this disorder remain largely undetermined. In order to examine the impact of GM2 accumulation on gene expression in Tay Sachs disease, we characterized global gene expression in cultured human cerebellum neuroglia cells isolated from normal and Tay Sachs embryos using the CodeLink microarray technology (GE-Healthcare). We report that several classes of genes involved in inflammation, apoptosis, interleukin signaling, potassium balance, and WNT signaling were altered in the Tay Sachs cerebellum cells. To confirm and validate our observations, we used Quantitative Real Time PCR (qRT-PCR) and Western blot analysis. Our studies confirmed the up regulation of Caspase 1, Interleukin 6, Potassium Channel, Eotaxin, Phospholipase C, and Prostaglandin Synthase, and down regulation of Heme Oxygenease, Histone Deacetlyase, Sphingomyelin Phosphodiesterase, Calpain, and Inositol 1,4,5-Triphosphate Receptor. To establish a link between the altered genetic profile and the disease status of Tay Sach neuroglia cells, we treated cells with n-butyldeoxynojirimycin (NBDNJ) to prevent and alleviate GM2 storage. Using qRT-PCR to determine gene expression, we discovered that NDBNJ reversed to normal levels the expression of several of these genes. Genetic profiling of expression pointed to mediators of apoptosis and potassium-deprivation induced depolarization as the most responsive genes to GM2 accumulations. These mediators therefore may be the main players in the disease mechanisms associated with Tay Sachs phenotype.

Hypophosphatasia: c.1133A>T, p.D378V is the most common American *TNSALP* mutation. *S. Mumm[1,2], D. Wenkert[2], X. Zhang[1], M. Geimer[1], J. Zerega[2], M.P. Whyte[1,2]* 1) Div Bone & Min Dis, Wash Univ Sch Med, St Louis, MO; 2) Cntr Metab Bone Dis & Mol Res, Shriners Hosp, St Louis, MO.

Hypophosphatasia (HPP) is a rare, heritable, inborn-error-of-metabolism featuring defective skeletal mineralization caused by loss-of-function mutation in the tissue non-specific alkaline phosphatase gene (*TNSALP*). Severity ranges greatly from neonatal lethal disease to asymptomatic carrier. HPP can be inherited as an autosomal dominant or recessive trait. Generally, recessive disease is more severe. To better understand the molecular basis and inheritance of HPP, we performed mutation analysis of the *TNSALP* gene for approximately 155 HPP probands, primarily from North America. One particular missense mutation, the transversion c.1133A>T, p.D378V (previous nomenclature: D361V), was found in 22 probands, making this defect the most common *TNSALP* mutation in our cohort of patients. In all but one individual, a second *TNSALP* mutation was not detected, supporting autosomal dominant inheritance for the HPP in these kindreds. Genealogy has thus far not disclosed a common ancestor among these families, which all seem to have early American heritage. The clinical phenotype for these patients is generally mild (odonto-, childhood, or adult HPP), however, 3 probands had infantile HPP. An exon deletion of the other *TNSALP* allele has not been ruled out for these 3 cases. Thus, they could represent heterozygous, recessively inherited, HPP. Where investigated (20 of 22 kindreds), common *TNSALP* polymorphisms in exons 7, 8, and 9 were invariably found along with the D378V mutation. In cases where parental DNA was also studied, these polymorphisms cosegregated with the D378V mutation. We therefore propose that the D378V mutation in our North American cohort is due to a common founder, and when dominantly inherited usually causes a mild phenotype. Nevertheless, a surprisingly broad clinical expression of HPP manifests in these 22 families with this identical heterozygous *TNSALP* mutation. Hence, patients with c.1133A>T, p.D378V and relatively severe HPP bone disease likely have additional genetic or environmental factors that contribute to their HPP phenotype.

Myocilin and Optineurin Sequence Variants in Primary Open Angle Glaucoma in a Hispanic Population of Mexican Descent. *K. LaRocque-Abramson[1], X. Yin[1], C. Santiago-Turla[1], A. Ventura-Viray[1], L. Ramirez[2], M. Alvarez[2], A. Beltran[3], M. Pericak-Vance[1], M. Hauser[1], R.R. Allingham[1]* 1) Duke Univ Medical Ctr, Durham, NC; 2) Oftalmologos Associados, Nogales, Mexico; 3) Clinica Oftalmologica, Hermosillo, Mexico.

Glaucoma is a major cause of blindness and is characterized by progressive loss of retinal ganglion cells and optic neuropathy. Population-based studies demonstrate that the prevalence of primary open-angle glaucoma (POAG) is high in Hispanic persons of Mexican descent. Although POAG is often accompanied by elevated intraocular pressure (IOP) over 80% of patients in this population have a variant of POAG with IOP in the normal range. Variations in myocilin(MYOC) and optineurin(OPTN) have previously been reported to cause POAG. The goal of this study is to determine the contribution of disease-associated variants of MYOC and OPTN in POAG in Hispanic patients of Mexican descent. Patients were ascertained from 2 ophthalmology clinics in the Mexican state of Sonora. Criteria for inclusion included: glaucomatous optic nerve damage in both eyes, visual field defects in at least one eye, and age of diagnosis 40 years. Elevated intraocular pressure(IOP) was not used as a criterion for affected status. The MYOC and OPTN genes were PCR amplified from genomic DNA and sequenced. Sequences were assembled into contigs and analyzed using Sequencher. Three non-synonymous coding variants were found in MYOC. Arg7His and Lys398Arg were each found in 1% of cases. The non-pathogenic Arg76Lys variant was found in 19% of cases. Only the Lys98Met variant was found in OPTN, in 5% of cases. Both genes also show multiple synonymous coding and intronic variations. MYOC mutations account for 4% of POAG cases in other populations, so the 2% found here reflects a relatively low contribution of MYOC to disease in this population. The Lys98Met OPTN variant has been variably associated with glaucoma in some populations. Age- and ethnicity-matched controls are currently being analyzed to complete the assessment of POAG risk in this population. In conclusion, the role of MYOC and OPTN in POAG appears to be limited in Hispanics of Mexican descent.

Differential Alu retrotransposition in HeLa cells. *H.C. Kopera, J.L. Garcia-Perez, J.V. Moran* Human Genetics, University of Michigan, Ann Arbor, MI.

Long Interspersed Element-1 (LINE-1 or L1) is a non-long terminal repeat (non-LTR) retrotransposon that comprises ~17% of the human genome. A retrotransposition competent human L1 (RC-L1) is ~6 kb and contains a 5 UTR, two non-overlapping reading frames (ORF1 and ORF2), and a 3 UTR that ends in a poly (A) tail. Both the ORF1 and ORF2 encoded proteins (ORF1p and ORF2p) are required for retrotransposition, which likely occurs by a mechanism termed target site primed reverse transcription (TPRT). The proteins encoded by RC-L1s also are responsible for the mobilization of Alu elements and the formation of processed pseudogenes, which together comprise at least 10% of human DNA. Unlike L1 retrotransposition, Alu mobility only requires ORF2p, suggesting that other host factors functionally substitute for ORF1p. However, little is known about these host factors.

Here, we report two different HeLa cell lines that differ in their ability to support Alu retrotransposition in a cultured cell retrotransposition assay. Experiments conducted with engineered L1s demonstrate that the first cell line (HeLa-HA) supports L1 retrotransposition, ORF1p-dependent pseudogene formation, and Alu retrotransposition. By comparison, the second cell line (HeLa-JVM) supports L1 retrotransposition and ORF1p-dependent pseudogene formation at similar levels as HeLa-HA, but shows a 2-3 fold order of magnitude reduction in Alu retrotransposition. One possibility for this difference is that HeLa-JVM has lost a factor required for Alu retrotransposition. Here, we describe our efforts to functionally complement the defect in HeLa-JVM cells using a cDNA library constructed from HeLa-HA. These studies will further our understanding of Alu mobilization as well as the retrotransposon-host dynamic.

The Hunter Outcome Survey (HOS): A registry of mucopolysaccharidosis II (MPS II) patients. *R. Martin[1], M. Beck[2], E. Wraith[3], R. Giugliani[4], J. Clarke[5], J. Muenzer[6]* 1) St. Louis Children's Hospital, St Louis, MO; 2) Children's Hospital, University of Mainz, Mainz, Germany; 3) Willink Biochemical Genetics Unit, Manchester, UK; 4) Hospital de Clinicas de Porto Alegre, Porto Alegre, Brazil; 5) Hospital for Sick Children, Toronto, ON, Canada; 6) University of North Carolina at Chapel Hill, Chapel Hill, NC.

Mucopolysaccharidosis II (MPS II, Hunter syndrome) is a rare, progressive X-linked disorder of glycosaminoglycan (GAG) metabolism that results in progressive GAG accumulation within multiple tissues and organs, due to a deficiency of iduronate-2-sulfatase (I2S). The clinical features of MPS II include hepatosplenomegaly, central nervous system and skeletal involvement, upper airway and cardiac disease, decreased joint range of motion, and short stature. Currently there is no approved therapy for MPS II. Idursulfase, a recombinant human I2S, is being developed as a treatment for MPS II. The Hunter Outcome Survey (HOS) is a global patient registry of MPS II patients regardless of treatment status. The objectives of HOS are to enhance our understanding of the natural history of MPS II, to monitor the safety and efficacy of enzyme replacement therapy, and to provide the basis for the development of clinical management guidelines. The HOS database will include clinical information obtained during the routine follow-up of MPS II patients. All data will be captured and transmitted to the central database electronically. This registry is sponsored and supported by Shire Human Genetic Therapies, Inc., Cambridge, MA. HOS will benefit participating physicians by providing them with the opportunity to contribute to the study of the management of MPS II and by giving them the ability to review data on a larger population of MPS II patients. As of May 2006, fifty patients have been enrolled into HOS, from 15 sites across 7 countries. As enrollment increases, HOS will improve our understanding of MPS II, the long-term impact of enzyme replacement therapy and allow the development of evidence based clinical management guidelines.

Spastic paraplegia 5: locus refinement, candidate gene analysis and extension of the phenotype. *S. Klebe[1], A. Durr[1,2], N. Bouslam[1,3], D. Grid[4], C. Paternotte[5], A. Bouhouche[3], N. Elleuch[1], H. Azzedine[1], J. Hazan[5,6], A. Brice[1,2], G. Stevanin[1,2]* 1) IFR Neurosciences, INSERM U679-NEB, Paris, France; 2) APHP, Salpetriere hospital, Dept of Genetics, Paris, France; 3) Neurology B and Neurogenetics unit, Specialties hospital, Rabat, Morocco; 4) Généthon, Evry, France; 5) Genoscope, CNS, Evry, France; 6) Centre for Developmental Neurobiology, Kings College London, Guys Hospital Campus, UK.

Thirty-two different loci for hereditary spastic paraplegias (HSP) have been mapped, and 14 responsible genes have been identified. Autosomal recessive HSP (ARHSPs) usually have clinically complex phenotypes but the SPG5, SPG24 and SPG28 loci are considered to be associated with pure forms of the disease. Up to now, 10 families have been mapped to the SPG5 locus on chromosome 8q12. After exclusion of known ARHSP loci, a genome-wide screen performed in a French kindred provided evidence of linkage with a maximal multipoint lod score of 2.6 in the D8S1113-D8S1694 interval. This interval partially overlapped SPG5 and reduced it to a 5.9 megabase (Mb)-region between D8S1113 and D8S544. In a family of Algerian origin from a series of 17 other ARHSP kindreds, linkage to the SPG5 locus was supported by a multipoint lod score of 2.3 over the entire restricted interval. The direct sequencing of 5 candidate genes (RAB2, ASPH, TTPA, Q8NB32 and BHLHB5) did not detect mutations/polymorphisms in the index cases of both linked families. The phenotype of the two SPG5-linked families consisted of early onset spastic paraparesis associated with deep sensory loss. In several patients with long disease durations, there were also mild cerebellar signs suggesting that this genetic entity might also account for complex HSP. In conclusion, the frequency of SPG5 was ~10% (2/18) in our series of ARHSP families with pure or complex forms. In addition we have refined the SPG5 locus to a 3.8 cM interval on chromosome 8q12 and extended the phenotype of this form of ARHSP to include cerebellar signs.

Investigation of PARK10 gene for Parkinson disease. *Y.J. Li, J. Deng, G.M. Mayhew, X. Huo, J. Grimsley, J.M. Vance* Ctr Human Genetics, Duke Univ Medical Ctr.

Chromosome 1p was previously mapped to Parkinson disease (PD) by two independent studies including our linkage screen for age-at-onset (AAO) of PD (Li et al. 2000) and Hicks et al.s (2000) screen on Icelandic families, where they designated this locus as PARK10. Interestingly, these two linkage regions were almost identical regardless of different phenotypes used. We followed up this region by using a genomic convergence approach and an iterative association mapping across a 19.2 megabase region under the AAO linkage peak (Oliveria et al. 2005). The two most significant genes were: EIF2B3 for AAO (min P= 0.0004) and HIVEP3 for risk of developing PD (P0.006 for rs648178 and rs661225). Recently, Maragnore et al. (2005) conducted a whole genome association (WGA) study using 248,535 SNPs and reported LOC200008 as the potential PARK10 with two significant SNPs. Importantly, their study also found two moderate significant SNPs in HIVEP3 in the Tier 1 dataset (P0.008) and Tier 2 dataset (P=0.03). To further investigate the potential PARK10 gene, we revisited HIVEP3 and LOC200008 with an expanded PD family dataset (293 multiplex and 467 singleton families). Recently, other authors have not been able to replicate the LOC200008 findings, but none has tested it in a family dataset of equivalent size to ours. We have genotyped most available HapMap tagSNPs as well as additional SNPs, while maintaining an equal spacing within the gene (in total, six SNPs in LOC200008 and 36 in HIVEP3). We used the PDT and APL methods for testing association with PD risk, and the QTDT program for AAO. No significant results were found for any of the six SNPs in LOC200008. Significant association with PD was found in six SNPs in HIVEP3 including two our previously reported SNPs (min P=0.007). However, the two WGA SNPs in HIVEP3 were not significant. Our failure to replicate the LOC20008 findings supports the negative results of three recent replicate studies for this gene. It is encouraging that HIVEP3 was found to be significantly associated with PD in two independent studies, implying HIVEP3 as a strong candidate for PARK10. Further testing of HIVEP3 by other groups is encouraged.

HER-2/neu amplification, hyperdiploidy, and ERBB2 expression by IHC in breast cancers: A FISH analyses study of 165 cases. *T.J. Jodlowski, D.T. Walsh, L.A. Cannizzaro, K.H. Ramesh* Department of Pathology, Montefiore Medical Center, Bronx, NY. 10461.

Patients with a positive HER-2/neu gene amplification result by immunohistochemistry (IHC) and fluorescence in situ hybridization (FISH) may undergo further treatment with Herceptin (Trastuzumab) in combination with paclitaxel for a better prognosis. However, limitations in the FISH scoring criteria, including the relationship between hyperdiploidy and amplification, may rule out potential patients from receiving this or other beneficial treatments. By FISH, HER-2/neu amplification status is determined by the number of copies of the HER-2/neu gene localized to 17q11.2-q12, divided by the number of chromosome 17 centromeres present in infiltrating or invasive breast tumor cells. A ratio of 2.2 or greater for HER-2/neu is considered positive for amplification. In our study, cases with a ratio of centromere 17 signals to the number of cells analyzed, greater than 2.5 were considered hyperdiploid. By IHC, 1+ is considered negative for over expression of ERBB2, 2+ is weakly positive, and 3+ is positive. Of the 165 cases that we studied, a significant number were hyperdiploid for centromere 17 and negative for amplification (31%). Although multiple copies of HER-2/neu were indeed present in the hyperdiploid cases in our study, the scoring criteria for amplification dictates these cases to be reported as negative for HER-2/neu amplification. Of our 165 cases, 24% were 2+ by IHC, hyperdiploid and reported as negative for amplification by FISH. Additionally, 4% of our 165 cases were 3+ by IHC, hyperdiploid, and negative for amplification by FISH. Conversely, 5% of our 165 cases that were 3+ by IHC and hyperdiploid were amplified. Based on this study further evaluation of the FISH scoring criteria for HER-2/neu amplification and reporting of hyperdiploidy with or without HER-2/neu gene amplification in breast cancer is strongly suggested. Hyperdiploidy results, with or without HER-2/neu gene amplification obtained from studies on a larger cohort may provide valuable information that could be vital in the treatment and prognoses of patients with aggressive breast tumors.

DNA methylation analysis of the GABRB3 promoter in monozygotic twin pairs discordant for Non-syndromic Cleft lip and/or Palate. *J.W. Kimani, J.C. Murray* Department of Pediatrics, University of Iowa, Iowa City, IA.

Non-syndromic cleft lip with or without cleft palate (CL/P) and cleft palate only (CPO) are common birth defects of multifactorial etiology, involving both genetic and environmental factors. The gamma-aminobutyric acid (GABA-A) receptor, subunit beta 3 (GABRB3) gene is a clefting candidate gene: mouse knockouts of GABRB3 or its ligand result in a cleft palate, and one study has reported linkage disequilibrium between GABRB3 and CL/P. GABRB3 is located in the Prader-Willi and Angelman Syndromes 15q11-12 imprinted region, and is expressed specifically from the paternal allele, which is hypermethylated in the promoter region. As part of an ongoing twin study, we are testing the hypothesis that aberrant methylation in the GABRB3 promoter region may underlie discordance for clefting in a set of monozygotic (MZ) twins. Our samples include 3 pairs of control (unaffected) and 6 pairs of discordant twins. Using bisulfite sequencing, we have examined cytosine methylation at 114 CpGs in a 0.8kb region located within a CpG island immediately 5 of the GABRB3 gene. PCR products were gel extracted, cloned and sequenced. Analysis of at least 10 clones per individual showed varied methylation from clone to clone. The two chromosomes could not be distinguished due to lack of informative polymorphisms in the region, but some clones showing higher levels of methylation were suspected to be of paternal origin. Overall methylation profiles between pairs of twins (both control and discordant) were similar. Our current results do not provide support for the hypothesis that epigenetic differences between MZ twins who generally share an identical genotype may result in phenotypic discordance. Future studies include extension of the region studied, expansion of our sample size and examination of methylation differences at a global level.

Clinical Complications in Adults with Congenital Disorders of Glycosylation type Ia (CDG-Ia). *D. Krasnewich, K. O'Brien, S. Sparks* Medical Genetics Branch, NIH, Bethesda, MD.

Congenital Disorders of Glycosylation are a group of metabolic disorders resulting from defective synthesis of N-linked oligosaccharides. CDG-Ia is the most common of the sixteen known types defined by defects in different steps of the pathway. An increasing number of American adults with CDG-Ia are being recognized, but little is documented on the morbidity and mortality in this population. The clinical issues and management strategies for these affected adults will be discussed. We follow 4 adults with CDG-Ia, ages 19-36 years old. All are active, dysarthric conversant adults with moderate cognitive impairment. Although they are ataxic and wheelchair dependent, only the oldest man shows significant muscle atrophy. Three of four remain on anticonvulsants with only occasional seizures and none have had stroke-like episodes since their teen years. Their skeletal issues include severe kyphoscoliosis, joint contractures and osteopenia. Retinitis pigmentosa and myopia complicate their functional vision. The women do not menstruate and the men have small testes resulting from hypogonadotropic hypogonadism. A 33-year-old woman with CDG-Ia recently presented to NIH with a history of lower extremity deep vein thrombosis (DVT) and subsequent multiple pulmonary emboli. She was treated initially with heparin and Lovenox, required the placement of an inferior vena caval filter and is chronically anticoagulated on Coumadin. She developed immobilizing lower extremity pain and muscle contractions. Chronic muscle relaxant medication and physical therapy were necessary to regain her previous functional level. Hematologic evaluation revealed protein C, protein S, and antithrombin III deficiency, consistent with her diagnosis of CDG. Hematologic abnormalities have been described in CDG, including factor XI, antithrombin III, protein C and protein S deficiencies. DVTs have been published in three patients with CDG (ages 8, 17, and 18 years). Documentation of clinical complications and successful management strategies in adults with CDG will improve their quality of life and allow more informed prognostic discussions with families of younger affected individuals.

Prevalence of A69S in LOC38771, a gene associated with Age-Related Macular Degeneration, in a US population. *M. Mikula, A. Buller, W. Sun, C. Strom* Molecular Genetics, Quest Diagnostics Nichols Institute, San Juan Capist, CA.

Age-related macular degeneration (AMD) is a major cause of visual loss in developed countries with as much as 30 percent of the elderly population succumbing to some degree of impairment due to AMD. AMD is incurable although early treatment may prevent the more severe forms of the disease. Recent genome wide linkage studies have implicated two major AMD susceptibility loci, CFH on chromosome 1 and, more recently, LOC387715 on chromosome 10. Studies have determined the major AMD-susceptibility allele in LOC387715 to be a missense variant in exon 1, A69S. Data shows that this variant is responsible for a 2.85 increased risk of AMD in heterozygotes and an 8-fold increased risk in a German population where the frequency of the risk allele was 31.3% and 4.7% for heterozygotes and homozygotes respectively. (Hum Mol Gen 2005, 14(21)). There is a paucity of published frequency data for the A69S polymorphism in the general U.S. population. Based on the high prevalence of AMD and the A69S susceptibility allele determined thus far, additional frequency data in various susceptible populations is warranted. A single-nucleotide primer extension assay (SNaPshot) was used to screen anonymized samples previously characterized for Cystic Fibrosis and Factor V Leiden DNA analyses. The assay detects the A69S mutation by single-nucleotide extension of a primer next to the mutation, followed by capillary electrophoresis and fluorescent detection. 1219 samples were genotyped. 476 heterozygotes (39%) and 64 homozygotes (5.2%) for the risk allele were observed, similar to that of German population. The ability of the assay to detect the genotype at this locus has been confirmed by DNA sequencing.

TENR gene mutations in infertile males who display oligospermia or azoospermia. *T.D. Brown, L.P. Chorich, L.C. Layman* Dept of Ob/Gyn, Section of Reproductive Endocrinology, Infertility, & Genetics, Developmental Neurobiology Program, Institute of Molecular Medicine & Genetics, Medical College of Georgia, Augusta, GA.

The successful differentiation of male spermatids into mature spermatozoa is vital for normal fertility in the final stages of spermiogenesis. Tenr, an RNA binding protein, is exclusively expressed in the testis and appears to be involved in spermiogenesis. Disruption of this gene is predicted to interfere with male fertility. Homozygous male Tenr knockout mice exhibited infertility and no litters due to a 6-fold lower number of sperm in the epididymis, a 3-fold reduction in motility, and a 4.5-fold increase in abnormal sperm morphology. The purpose of the present study was to determine if TENR mutations occur in infertile human males who display oligospermia or azoospermia and to demonstrate TENR expression in human sperm. The TENR protein coding region (exons 3-13) and splice junctions from the genomic DNA of 66 infertile males (13 with azoospermia and 53 with oligospermia) and controls were subjected to PCR, agarose gel electrophoresis, and DNA sequencing. A silent mutation (Tyr338Tyr) c.270 C>T in exon 4 was identified; it was homozygous mutant in 2/64, heterozygous in 12/64, and homozygous wild type in 50 /64. To date, it has not been identified in controls. In addition, another potential mutation was identified in an intron (IVS12+20A>G); it was heterozygous mutant in 2/43 patients analyzed. We are currently determining if these mutations affect splicing of mRNA. Human TENR expression was demonstrated by RT-PCR in a control male with the presence of a predicted 2kb fragment using TENR-specific primers. The TENR gene represents a reasonable candidate gene for mutations in infertile males with abnormal semen analyses. However it appears that TENR gene mutations may not be a common cause of infertility in oligospermic or azoospermic males.

C677T and A1298C polymorphisms of the methylenetetrahydrofolate reductase gene and elevation of transaminases in Mexican patients with rheumatoid arthritis treated with methotrexate. *J. Mena[1], IP. Dávalos[1], L. González[2], J. Gamez-Nava[2], L. Sandoval[1], LE. Figuera[1], J. Sánchez[2], A. Celis-de la Rosa[1], M. Salazar-Páramo[2]* 1) División de Genética,CIBO, IMSS y CUCS, Universidad de Guadalajara; 2) División de Investigación, UMAE,HGZ 110, HE,CMNO, IMSS.

INTRODUCTION: The variants C677T and A1298C in the 5,10-methylenetetrahydrofolate reductase gene, has been involved in homocysteine metabolism and considered as a genetic risk factor in the increase of transaminases levels in Rheumatoid Arthritis patients treated with methotrexate (RA-MTX). **OBJETIVE:**To determine the genotype (GF) and allele frequencies (AF) of the C677T and A1298C variants of the MTHFR gene in mexican RA-MTX patients and the association with transaminasemia. **METHODS:**71 patients with RA (ACR 1987 criteria) and treated with MTX were included. Demographic, clinical laboratory and therapeutic data were obtained using a structured questionnaire. Molecular analysis was performed by PCR/RFLP method with the restriction enzymes *Hinf*I and *Mbo*II, for C677T and A1298C, respectively. For statistical analysis, chi square test with GDA and OR with de Finetti programs were used. **RESULTS:**From 71 patients, 13 (18%) had an increase in the serum transaminases levels. The 677T AF in RA-MTX patients with transaminasemia was slightly less (42.3% *vs* 44.7%)than in RA-MTX without transaminasemia. Otherwise the A1298C AF was greater in the RA-MTX with transaminasemia group (42.3%*vs* 21%), showing a p=0.02193 and OR=2.75. **CONCLUSIONS:** The A1298C polymorphism is associated with elevation of transaminases in RA-MTX patients. The identification of MTHFR A1298C in mexican patients with RA-MTX could be associated with elevation of transaminases. It allow to identify at risk patients and to give a treatment more individualized.

A novel autosomal dominant Hereditary Spastic Paraplegia with generalized dystonia: linkage to 2q34-2q31. *E. Leslie[1,2], D. Gilbert[1,2], M. Keddache[1,2], N. Leslie[1,2]* 1) Human Genetics, Cincinnati Children's Hospital Research Foundation, Cincinnati, OH; 2) University of Cincinnati.

The Hereditary Spastic Paraplegias (HSPs) are neurodegenerative disorders characterized by pyramidal tract disease and progressive spasticity and weakness of the legs and feet. In contrast, the dystonias are movement disorders characterized by extrapyramidal dysfunction and abnormal posturing. An extended family has been identified that spans 4 generations, with a novel combination of HSP, apparent anticipation, and generalized dystonia. Family members were considered affected if verified by neurological examination and unaffected if the exam was normal at age >40. All others, including those with increased reflexes, were considered uncertain. Initial whole genome linkage analysis of 42 pedigree members was performed using microsatellite markers from ABI linkage mapping set v2.5. Regions on chromosomes 2q and 4q showed maximum nonparametric mutlipoint lod scores above 4. To confirm and refine the region, SNP genotyping using the Illumina Linkage Array was performed on a limited set of 9 clearly affected individuals including those with uncomplicated HSP as well as more severely affected individuals with early onset and dystonic features. This approach identified a single critical region of 12 Mb on 2q (2q24-2q31) with a maximum nonparametric lod score of 17.4 (p value=0.0097). The multipoint parametric lod score with an AD model and 99% penetrance was 2.71 across a haplotype between rs2058996 and rs2007326. This region excludes the known HSP and Dystonia genes, including SPG 13, located telomeric to the identified region. A number of genes located in the region show expression in the brain and spinal cord and serve as attractive candidate genes for identification of the disease gene.

Towards Noninvasive Prenatal Diagnosis of Trisomy 21 Down Syndrome. *M. Hulten, F. Crea, W. Puszyk, R. Old*
Dept Biological Sci, Univ Warwick, Coventry, United Kingdom.

Currently many women delay childbearing until after the age of 35 years, leading to a dilemma caused by the combination of age-related reduced fertility and increased risk of fetal aneuploidy, in particular Trisomy 21 Down Syndrome. This dilemma is aggravated by the fact that traditional prenatal diagnosis, based on invasive procedures, such as chorionic villus sampling and amniocentesis, is associated with a procedure-related fetal loss rate in around 1-2 % of these (precious) pregnancies. It has been known for many decades that fetal cells enter the maternal circulation, and since 1997 that a relatively large proportion of free-floating DNA in maternal blood samples are of fetal origin, around 1-3 %. Thus it is now possible to use maternal blood samples for Noninvasive Prenatal Diagnosis (NIPD) based on the identification of fetal-specific, paternal DNA sequences, i.e. sex-linked and paternal dominant conditions. In this presentation we will review these advances and in particular highlight our own work on the development of epigenetic biomarkers for NIPD of common chromosome disorders, the majority of which are of maternal origin. We have developed a new assay for simple and rapid screening of epigenetic biomarkers in general and applied this method for identification of a number of chromosome 21-specific DNA sequences that show differential methylation patterns. These novel biomarkers are expected to allow specific identification and quantification of free-floating fetal DNA against a large background of maternal DNA- with the potential for NIPD of Trisomy 21 Down Syndrome in the first trimester of pregnancy. A large-scale clinical evaluation of this new NIPD assay is underway, using blood samples collected from pregnant women at high risk as ascertained by a combination of maternal serum screening and ultrasound (nuchal translucency) followed by QF-PCR aneuploidy diagnosis (and karyotyping) using chorionic villus samples. Any biomarker assessing the amount of free fetal DNA in maternal plasma may also be used for assessing risk of pregnancy-related disorders, such as pre-ecplampsia, premature labor and fetal intrauterine growth restriction.

Supernumerary marker chromosome 17: new case report, delineation of the phenotype, and comparison with other segmental 17p duplications. *R. McGoey[1], F. Tsien[2], M. Leake[2], M. Marble[3]* 1) Pathology, Louisiana State University, New Orleans, LA; 2) Genetics, Louisiana State University, New Orleans, LA; 3) Genetics, Children's Hospital of New Orleans, New Orleans, LA.

Trisomy 17p due to a supernumerary marker chromosome (SMC) is a rare and typically mosaic cytogenetic rearrangement. Ten patients with SMC(17) have been described but the molecular delineation is published in only four. A consistent genotype-phenotype correlation has not been established. We report a new patient with SMC(17) thus and extend the phenotypic spectrum associated with SMC(17).

Our patient is a 3 week old with cleft palate, hypotonia and a ventricular septal defect. She had hypertelorism, midface hypoplasia and micrognathia. Digits 2/4 were overriding the 3rd. Renal ultrasound and cranial CT were normal. Cytogenetics revealed a SMC which by FISH was from centromeric chromosome 17. This SMC(17) was identified in 60% of cells. Parental karyotypes were normal. At 2 months of age, she had reflux and was feeding via a gastrostomy tube. Her weight was 3.0kg (<3%), height 55cm (5-10%) and head circumference 36cm (2%).

To date, a consistent clinical pattern associated with SMC(17) has not been established. This may be due to the variable size and gene content of the SMC, the extent of mosaicism, and the fact that only four cases have been molecularly analyzed, all of which involved region 17p11.2. Among these cases, the more common clinical features included developmental delay, poor feeding, hypotonia and a triangular facies. Our patient shares these features but also has cleft palate and a heart defect. This combination of a facial cleft and heart defect has been reported in two SMC(17) patients, one with trisomy 17ptercen and another with trisomy 17pterp11. This may suggest potential clefting or cardiac genes in regions distal to 17p11.2. We will review the previously reported patients with SMC(17) emphasizing those cases with molecular refinement and those with clefting and heart defects. Follow-up molecular studies of our patient will also be presented.

Isolation of the t(1;19)(q10;p10) associated with human oligodendrogliomas using Conversion Technology. *R.B. Jenkins, H. Flynn, H. Blair, K. Meyer, P. Schneider, V. Marley, K. Schowalter, W.E. Highsmith* Div Laboratory Genetics, Mayo Clinic, Rochester, MN.

One of the goals of cancer cytogenetics is to isolate and clone chromosomal anomalies/breakpoints associated with malignancies. However, the isolation of these anomalies/breakpoints can be difficult because the amount of tissue may be limited and/or the tumor cells do not proliferate *in vitro*. Conversion Technology is a technique for the separation of human homologues in mouse-human somatic cell hybrids. For conversion, *msh2* deficient, embryonic mouse fibroblasts (E2) and human cells are fused and cultured with HAT selection. The hybrids are genotyped for the chromosome(s) of interest to determine which haplotype is present. Once hybrids containing the isolated homologues are identified, individual cell lines can be expanded. Here we report the use of Conversion Technology to isolate the t(1;19)(q10;p10) associated with human oligodendrogliomas that have combined 1p and 19q deletion. Cells from 3 different fresh glioma specimens were dispersed, washed and fused with mouse E2 cells. After 18 days of HAT selection, hybrid clones from each tumor were plucked into 96-well plates and cultured for an additional 10 days. DNA from replica plates was genotyped using 5 STR markers for both chromosomes 1 and 19. Based on the distribution of the STR markers, we were able to predict the genotypes of hybrids that contained the normal chromosome 1, the normal chromosome 19 and the derived t(1;19). We were able to isolate all three chromosomes from 2 gliomas with combined 1p and 19q deletion and all four chromosomes 1 and 19 from a glioma without combined deletion. FISH analysis of cells derived from passages 2 to 4 of the expanded hybrids confirmed the STR genotyping results. This study demonstrates that Conversion Technology can be used to isolate and clone normal and derived chromosomes 1 and 19 from fresh, uncultured, primary glioma specimens. Our results suggest that Conversion Technology can be applied to other primary malignancies for the isolation of normal and abnormal chromosomes. The isolation of such chromosomes may faciliate analyses of the human cancer genome.

***CCM2* deletions are a common cause of cerebral cavernous malformations.** *D.A. Marchuk[1], C.L. Liquori[1], M.J. Berg[2], F. Squitieri[3], T.P. Leedom[1], L. Ptacek[4], E.W. Johnson[5]* 1) Mol Genet & Microbiol, Duke Univ Medical Ctr, Durham, NC; 2) Strong Epilepsy Center, Dept of Neurology, Univ of Rochester Medical Ctr, Rochester, NY; 3) Neurogenetics Unit, Istituto di Ricovero e Cura a Carattere Scientifico, Neuromed, Pozzilli, Italy; 4) Dept of Neurology, Univ of California San Francisco, San Francisco, CA; 5) Molec Diagnostics and Biobanking, Prevention Genetics, Marchfield, WI.

Cerebral cavernous malformations (CCMs) are vascular abnormalities of the brain that can result in a variety of neurological disabilities, including stroke and seizures. Mutations in the gene *Krit1* are responsible for CCM1, mutations in the gene *MGC4607* are responsible for CCM2, and mutations in the gene *PDCD10* are responsible for CCM3. Over several years, we have collected 64 CCM probands with family history and/or multiple lesions, and sequence analysis showed that a high proportion (41%) of these probands lacked any identifiable mutation. We now report that large genomic CCM2 deletions represent a major component of this disease which are missed by routine mutation screens. We used multiplex ligation-dependent probe analysis (MLPA) to screen 26 non-CCM1, non-CCM2, and non-CCM3 probands for potential deletions or duplications within all three CCM genes. We identified a total of 14 deletions - 1 in the CCM1 gene, 13 in the CCM2 gene, and none in the CCM3 gene. Interestingly, 50% of the identified CCM2 deletions span exons 2-10. Sequence and deletion analysis of our 64 probands gave a frequency ratio of 39% (25/64) CCM1, 36% (23/64) CCM2, 6% (4/64) CCM3, and 19% (12/64) unknown. These data indicate that the prevalence of CCM2 is much higher than previously suspected and that the frequency of CCM1 mutations and CCM2 mutations are approximately equal. With respect to CCM2, we highly recommend that deletion screening should be performed to avoid missing over half of the responsible mutations. The fact that 19% of CCM mutations still remain unidentified suggests either that the remaining mutations cannot be identified by sequence or deletion analysis or that there may be an additional CCM gene(s).

A novel autosomal recessive degenerative phenotype of cerebellar atrophy : homozygosity mapping to a 1.5cM locus on chromosome 22. *Sh. Khateeb[1], O. Birk[1,2], R. Ofir[1], H. Flusser[3]* 1) The Morris Kahn Laboratory of Human Genetics Dept. of Development Genetics , Ben-Gurion University, Beer-Sheva Israel; 2) The Institute of Genetics,Beer-Sheva,Israel; 3) Soroka Medical Center,Beer-Sheva,Israel.

We describe a novel autosomal recessive syndrome of progressive cerebellar atrophy, affecting 6 members of 3 related families of a single Bedouin Israeli inbred kindred. Affected individuals, born to consanguineous marriages, were normal at birth. At age ~18 months began gradual psychomotor retardation with regression in cognitive and motor abilities, progressing to death of asphyxia at age 7-10 years. Clinical hallmarks were hypotonia of the trunk with enhanced tonus in the limbs, augmented tendon reflexes and pyramidal signs. Combined vertical and horizontal nystagmus and pallor of the optic discs were evident. There was no dysmorphism and no defects or phenotypic stigmata other than the neurological phenotype. Computerized tomography and MRI demonstrated cerebellar atrophy, with widened cerebellar folds and atrophy of the vermis. The fourth ventricle and the cysterna magna were enlarged, with normal lateral ventricles and no evidence of cortical brain atrophy. Genomic DNA samples of 22 family members including 6 affected individuals were tested: linkage analysis studies ruled out association with any of the known loci associated with phenotypes involving cerebellar atrophy. Genome-wide linkage analysis using 400 polymorphic markers failed to identify a locus associated with the disease. Genome-wide linkage analysis using Affymetrix 10K SNP microarrays identified a 1.5cM region of homozygosity on chromosome 22, with a maximum LOD score of [Zmax] = 4.7 at recombination fraction [q] = 0.0. Analysis of candidate genes within the defined interval is underway.

Investigations of the effect of CTCF on the promoters of the anti-apoptotic Bcl-2 gene. *A. Molouki*[1], *E. Klenova*[2], *H. Najmabadi*[1] 1) Genetics Department, University of Welfare Science & Rehabilitation, Tehran, Iran; 2) Department of Biological Sciences, University of Essex, Colchester, UK.

The highly conserved, ubiquitously expressed 11-Zn finger nuclear protein CTCF is involved in the mechanisms through which this transcription factor acts at various levels of gene regulation. This experiment is a follow-up to a series of recent investigations performed by Dr. Elena Klenova and colleagues on how Bcl-2 protein can overcome the effects of lowering CTCF levels and alternatively, how CTCF can overcome the effects of the pro-apoptotic protein, Bax in the cell. The main attention was focused on the role of CTCF in regulation of the promoters of the Bcl-2 gene in breast and non-breast cancer cell lines. Co-transfection assays using LB322 Bcl-2-Luc promoter-reporter constructs showed that CTCF protein strongly activates the expression of Bcl-2 in 293T and slightly in MCF-7 and CAMA-1 cancer cell lines. Further experiments revealed that CTCF can both repress and activate the promoter by binding to different regions of the promoter. Co-transfections of LB124, LB334 and LB556 with CTCF into the same cell lines showed to repress the expression while LB335 combined with CTCF resulted in activation of expression suggesting that CTCF can only activate the Bcl-2 expression and protect cells from apoptosis by binding to a sequence located between bases -170 and -1281 of the promoter. Furthermore these experiments demonstrate that CTCF anti-sense inhibits the CTCF transcription in MCF-7 cells resulting in a reduction of Bcl-2 expression. This result was not confirmed in 293T co-transfections.

KELVIN: A 2nd generation distributed multiprocessor linkage and linkage disequilibrium analysis program. *Y. Huang[1], A. Segre[2], J. OConnell[3], H. Wang[2], V. Vieland[1]* 1) Columbus Children's Research Institute , Columbus, OH; 2) University of Iowa, Iowa City, IA; 3) University of Maryland, Baltimore, MD.

Genetic analysis software has been widely used to map disease genes. This success is largely due to the development of statistical genetic analysis techniques and methodologies over the last few decades. Each method, and its software implementation, has specific strengths and weaknesses. LIPED, introduced in 1974, was the first model-based linkage analysis program. MLIP (Multiprocessor LIPed), developed at the University of Iowa, extends LIPED's core algorithm to calculate two-point LOD scores over a multi-dimensional trait parameter space using a cluster of computers. MLIP's parallel processing has greatly enhanced our ability to analyze complex traits. However, since LIPED is limited to two-point analyses, we are now implementing a new extended version of VITESSE into MLIP. VITESSE uses novel algorithms such as set-recoding and fuzzy inheritance algorithms to accelerate the likelihood calculation. Our new implementation, called KELVIN, uses data structures and software engineering techniques to allow for future expansion. The KELVIN design supports both two-point and multipoint linkage, dichotomous, quantitative, and mixed traits, linkage and linkage disequilibrium mapping, heterogeneity and other complications such as covariate dependent penetrances, and uses Bayesian sequential updating to accumulate evidence across multiple data sets. KELVIN will also, like MLIP but unlike VITESSE, employ large clusters of computers for distributed computing for improved speed of calculation. Moreover, we have also prototyped another innovative approach to exploit symbolic computation to reduce likelihood calculation costs significantly (see also abstract entitled "Fast Computation of Large Numbers of LOD Scores for Genetic Linkage Analysis"; by Wang et al.). The software firepower represented by KELVIN will support computationally-intensive calculations, like the PPL, over higher-dimensional spaces than are possible today.

The OpenArray Platform: Enabling high-throughput SNP genotyping applications in nanoliter volumes. *S. Liu-Cordero, K.D. Munnelly, J. Garcia, K. Yoder, J. Cho, A. Katz, T. Kanigan, T. Morrison, C. Brenan, D.G.W. Roberts*
BioTrove Inc, Woburn, MA.

Single nucleotide polymorphism (SNP) genotyping has become increasingly important in both pharmaceutical and agricultural biotechnology as a means of identifying biologically important genetic variations. Examples include understanding genetic variations associated with drug metabolism, association of polymorphisms and diseases, and marker assisted breeding. BioTrove has developed a SNP genotyping platform based on through-hole technology, a broadly applicable nanoliter fluidics technology for parallel and low-volume solution phase reactions. The OpenArray chip consists of 3072 through-holes that can be loaded with reagents to perform individual 33 nL reactions for use in endpoint genotyping applications. The unique configuration of the through-holes enables the researcher to interrogate a large number of nucleic acid samples against a large number of assays in a flexible, configurable format. By altering the number of assays or the number of samples the researcher can easily customize the OpenArray to meet their changing needs. Researchers using this technology benefit from the parallelism of microarrays and the data quality of solution phase reactions. Performance characteristics of the OpenArray platform will be presented and implications to genomic research will be discussed.

Validation of SNP Oligonucleotide Microarray Analysis (SOMA) for Clinical Cytogenetic Diagnosis. *V. Jobanputra[1], O. Nahum[2], K. Anyane-Yeboa[1], W. Chung[1], Y. Sun[2], E. Bottinger[2], W. Zhang[2], D. Warburton[1], B. Levy[1]*
1) Depts Genetics & Development, Obstetrics & Gynecology, Pathology and Pediatrics, Columbia University Medical Center, New York, NY; 2) Depts Medicine and Pediatrics, Mount Sinai School of Medicine, New York, NY.

SNP arrays are high-density oligonucleotide-based arrays that can identify both loss of heterozygosity (LOH) at individual nucleotides and copy number alterations. In contrast to the CGH array approaches, in SNP arrays only one genomic sample is hybridized to the array, so copy number changes are identified by comparison with independent control hybridizations. In the current study, copy number gains and losses were determined by means of the Circular Binary Segmentation method. We are currently validating the Affymetrix 500K SNP Oligonucleotide microarray for clinical cytogenetic analysis (SOMA) and report on our first 18 cases. Cases were chosen to contain a variety of known cytogenetic aberrations, including whole chromosome aneuploidy, unbalanced rearrangements, marker chromosomes and microdeletions. All aberrations except one subtelomeric deletion were correctly identified by segmentation analysis of the SOMA data. With over half a million SNPs and a mean spacing of 5.8 kb, the 500K SNP array offers a comprehensive whole genome scan and has the potential to provide the highest resolution of copy number detection currently available. Since deletions and duplications can be precisely defined by using the SNP positions on the genome browser, SOMA will useful for the clinical interpretation of both visible and submicroscopic cytogenetic imbalances. Another advantage of using a SNP-based array lies in the concurrent availability of genotype information that would allow simultaneous DNA-based studies such as uniparental disomy (UPD), zygosity and maternal cell contamination. Further studies of normal populations are currently underway and these will be critical for delineating benign copy number variants. In addition, our ongoing study will also assess whether the coverage of the SNPs is adequate for most clinical cytogenetic diagnoses, including all known microdeletions and cryptic sub-telomeric gains and losses.

Evidence for FOXE1 Having an Etiologic Role in Nonsyndromic Cleft Lip With or Without Cleft Palate (CL/P).

L. M. Moreno[1], S. A. Bullard[1], J. Martin[1], M. A. Mansilla[1], M. Johnson[1], M. Arcos-Burgos[2], H. Mishima[1], B. S. Maher[3], T.H. Goldstein McHenry[3], M.E. Cooper[3], C. Valencia-Ramirez[4], A. Hing[5], E.J. Lammer[6], M. Jones[7], A. Jugessur[1], N. H. Robin[8], P. Chines[2], J. C. Murray[1], M. L. Marazita[3], A. C. Lidral[1] 1) Univ Iowa, Iowa City, IA; 2) NHGRI, NIH, Bethesda, MD; 3) Craniofacial and Dental Genetics, U. of Pittsburgh, Pittsburgh, PA; 4) Odontologia, U de Antioquia., Medellín, Colombia; 5) Univ Washington, Seattle, WA; 6) Children's Hospital Oakland Research Institute, Oakland, CA; 7) Children's Hospital, San Diego, CA; 8) Univ Alabama, Birmingham, AL.

Nonsyndromic (CL/P) is caused by failure of fusion between the nasal and maxillary prominences. Genes expressed in facial prominences during primary palatogenesis or in which mutations cause a clefting phenotype are good candidates for CL/P. FOXE1 is a transcription factor expressed in cranio-pharyngeal ectoderm and thyroid, yet Foxe1 expression has not been described during primary palatogenesis. Only two FOXE1 mutations are known, both causing Bamforth-Lazarous syndrome, which includes cleft palate and thyroid dysgenesis. FOXE1 maps within a major CL/P locus: human 9q22-q33 (Marazita et al., 2004). The goal of this study is to determine if it has a role in primary palate formation. Whole mount and section in situ hybridization were performed using a digoxygenin labeled Foxe1 RNA probe in C57BL/6J mouse embryos at E9.5, E10.5 and E11.5. Foxe1 expression was observed at E10.5 and E11.5 particularly in the epithelium involved in the fusion of the medial nasal and maxillary processes. These data are consistent with FOXE1 playing a role in lip development. Also, Foxe1 expression is similar to that of Shh which is known to regulate Foxe1 transcription (Brancaccio et al. 2004). Altering Shh function in chick embryos results in cleft lip (Hu & Helms 1999), suggesting that Foxe1 and Shh are in a pathway involved in lip formation. This is supported by human studies (Marazita et al. & Mansilla et al. this meeting) showing highly significant association between FOXE1 and CL/P. Grant Support: NIH RO1DE14677 (ACL, MAB, MLM), KO2DE015291 (ACL), NIH P60 DE13076 (JCM), MOD Grant #6-FY01-616 (ACL, MAB) and P50-DEO16215.

A principal components-derived psychosocial phenotype reflecting Type A Behavior and Ambition is linked to chromosome 11q in Mexican Americans. *J.W. Kent Jr.[1], S.P. Fowler[2], H.P. Hazuda[2], R. Arya[2], M.P. Stern[2], J. Blangero[1], R. Duggirala[1]* 1) Dept. of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Div. of Clinical Epidemiology, Dept. of Medicine, University of Texas Health Science Center, San Antonio, TX.

Measures of mental state can be challenging phenotypes for quantitative genetic analysis, as they are not expected to map one-on-one with the underlying biochemical pathways regulated by genes. Such measures may be intercorrelated and represent effects of multiple underlying processes. The San Antonio Family Diabetes/Gallbladder Study (SAFDGS) is a large, extended family-based study of the genetics of diabetes and its comorbidities in Mexican Americans. We assessed by questionnaire 8 psychosocial measures (Ambition, Trait anger, Self esteem, Emotional lability, Mastery, Non-easygoingness, Perceived daily stress, and Type A behavior) in 450 participants (176 males and 274 females) in SAFDGS. Variance components-based quantitative genetic analyses were performed in SOLAR. All of the measures except Anger were heritable (range 0.23-0.41) and most exhibited significant genetic and/or environmental correlations in bivariate analyses. Genome-wide linkage scans of the individual traits yielded suggestive evidence of linkage but none at genome-wide significance (LOD ? 3). To maximize the information available from the correlations among traits, we performed a principal components analysis on the standardized traits. The first 3 principal components accounted for 69% of the total variance. Each of these components was heritable: PC1 (weighted on Mastery, Esteem, Anger, and Lability), 0.29; PC2 (Type A, Ambition), 0.38; PC3 (Non-easygoingness), 0.40 (all significant at $P<0.001$). PC1 showed suggestive linkage (LOD = 2.2) on Chr. 20. PC3 showed a suggestive LOD = 2.4 on Chr. 16. PC2 showed significant linkage (LOD = 3.2) on Chr. 11q. Several previous studies, including linkage analysis and analysis of chromosomal rearrangements, have associated this region with bipolar disorder. These results provide a preliminary glimpse at the genetic architecture of normal variation in personality and mood in this study population.

Chromosome 15q telomere imbalances: Association of *IGF1R* with growth abnormalities. *Z. Nawaz, D.H. Ledbetter, C.L. Martin* Department of Human Genetics, Emory University, Atlanta, GA.

Patients with cytogenetically visible deletions of the distal part of 15q have intrauterine growth retardation (IUGR), postnatal growth delay and variable mental retardation. In contrast, patients with duplication of distal 15q have macrosomia at birth, overgrowth, macrocephaly and mild developmental delay (DD). It has previously been shown that deletions, duplications or mutations of the insulin-like growth factor 1 receptor gene (*IGF1R*), which maps to 15q26.3 and codes for a kinase receptor-containing transmembrane protein, disrupts normal growth. Using genome-wide telomere FISH analysis, we identified three patients with *de novo* deletions of the 15q telomere region: one patient had a terminal deletion while the other two had unbalanced translocations with X/Yq and 3q, respectively. All three patients had IUGR, postnatal growth retardation and significant DD. To delineate the size of the deleted material on chromosome 15q and determine if the *IGF1R* gene was included in these deletions, a combination of array comparative genomic hybridization (aCGH) with a homebrew chromosome 15 BAC array and FISH analysis were utilized. The 15q deletion in the patient with an unbalanced translocation between 15q and X/Yq was determined to be ~4.6-5.5 Mb while the 15q deletion in the patient with the unbalanced translocation with 3q was ~4.3-4.6 Mb. The patient with the pure terminal deletion had a deletion ~7.5-8.0 Mb in size. The deleted region in all three patients includes *IGF1R*, indicating that they are hemizygous for this gene, which is believed to be responsible for their growth delays. We also identified a patient with overgrowth and a cytogenetically visible duplication of the 15q telomere region resulting from an unbalanced translocation with 14p. FISH analysis revealed that the duplicated portion of 15q includes *IGF1R*. Our data and the published data on 15q imbalances suggest that this cytogenetic rearrangement should be considered in patients with growth abnormalities. In addition, since three of our cases had normal G-banded chromosome analysis, targeted molecular cytogenetic analysis for *IGF1R* is warranted if routine G-banding is normal.

The role of Wnt9b during primary palatogenesis. *H. Mishima[1], S.A. Bullard[1], L.M. Moreno[1], T. Busch[1], M. Arcos-Burgos[8], C. Valencia[3], A. Hing[4], E.J. Lammer[5], M. Jones[6], N. Robin[7], B.S. Maher[2], M.E. Cooper[2], T. McHenry[2], M.L. Marazita[2], A.C. Lidral[1]* 1) Univ Iowa, IA; 2) Univ Pittsburgh, PA; 3) Univ Antioquia, Colombia; 4) Children's Hosp., Seattle, WA; 5) Children's Hosp., Oakland, CA; 6) Children's Hosp., San Diego, CA; 7) Univ Alabama, AL; 8) NIH, MD.

Cleft lip with or without cleft palate (CL/P) is a common human birth defect. Studies using a mouse strain with spontaneous CL/P have identified 2 epistatically interacting loci, including the *clf1* locus containing the Wnt9b and Wnt3 genes. A retrotransposon insertion has been discovered downstream of Wnt9b (Juriloff et al. 2005), suggesting Wnt9b is involved in primary palate development, which is corroborated by incompletely penetrant CL/P occurring in Wnt9b null mice (Carroll et al. 2005). This study aims to characterize the role of Wnt9b during primary palatogenesis. Mouse embryos from heterozygous Wnt9b null matings were observed at E16.5 to determine frequency of CL/P. Eleven of 22 Wnt9b null embryos had clefts, whereas no clefts occurred in 25 wildtype embryos, and 1 of 35 Wnt9b null heterozygous embryos had cleft palate. In situ hybridization showed both Wnt9b and Wnt3 are expressed in the facial ectoderm during primary palatogenesis. However, Wnt9b is expressed in the ectoderm between the fusing medial and lateral nasal process whereas Wnt3 is not. Expression of potential downstream genes, Bmp4, Cux1, Cux2, Msx1 and Fgf8 revealed incomplete penetrance with reduced Fgf8 expression in the lateral nasal processes. Crabp1, a neural crest cell marker, showed reduced expression at E11.5 in Wnt9b null embryos. No reduction in Axin2, Dkk1, and Fath, which are Wnt canonical pathway markers, was observed. The Crabp1 data suggests normal NCC migration at earlier stages, but loss of Crabp1 induction or decreased NCC survival at E11.5. Persistent Wnt canonical signaling suggests functional redundancy or Wnt9b acts through a non-canonical pathway in the face. Reduced Fgf8 expression connects the Wnt and Fgf signaling pathways during facial development. The syntenic region for *clf1* is on human 17q, and has been implicated in human multifactorial CL/P. We hope to report results evaluating this region in humans.

Candidate gene analysis at 16q12-13 for SLE susceptibility. *S.K. Nath[1], X. Kim-Howard[1], F. Ota[1], M. Gains[1], P. Viswanathan[1], R. Vijayaraghavan[1], D. Mandhyan[1], J. Kelly[1], K. Kaufman[1], J.B. Harley[1,2]* 1) Arthritis & Immunology, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) US Department of Veterans Affairs Medical Center, Oklahoma City, OK, USA.

Systemic lupus erythematosus (SLE) is a multi-system autoimmune disease with high morbidity and mortality morbidity and mortality with an etiology and pathogenesis that are largely unknown. Genetic susceptibility plays an important role in the development of SLE. SLE susceptibility at 16q12-13 was demonstrated previously by multiple independent research groups. We confirmed this linkage in two independent data sets. Additionally, our recent meta-analysis based on 9 published whole-genome scans has further identified this genomic region as one of the most promising regions that may harbor a SLE susceptibility gene. Therefore, repeated evidence for linkage in several independent reports, together with our two individual reports and a meta-analysis, provide strong evidence for a SLE susceptibility gene at 16q12-13. In this study we examined the role of 30 SNPs from 4 plausible candidate genes using the LD based association mapping approach. We have assessed the genotypic as well as allelic association on 1490 cases and 1965 controls, which consisted of 4 separate groups. These are European-American (n=2043), African-American (n=1144), Hispanic (n = 418) and Gullah (n= 240). The Gullah are an African-American population living in the Sea Islands and the nearby coastal low country region of South Carolina. Most of the SNPs were in Hardy-Weinberg Equilibrium for the controls; only 2 SNPs from African-American controls were not in HWE. Using single SNP at a time as well as moving-window haplotype-based analyses, we have found significant evidence of statistical association (p-value ranges from 0.01 to 0.001) between multiple SNPs and SLE phenotype in multiple ethnic groups. The estimated odds ratio per SNP ranges from 1.2 to 2.4. We also tested the association between a subset (lupus nephritis) from the SLE cases and normal controls. We discuss the implication of these associations and the involvement of the candidate genes in the pathogenesis of SLE.

Exploiting genetic model information to identify homogenous pedigrees. *M.W. Logue[1], J.W. Park[2], J.F. Cremer[2], A.M. Segre[1,2], V.J. Vieland[1,3]* 1) Center for Statistical Genetics Research, University of Iowa, Iowa City, IA; 2) Department of Computer Science, University of Iowa, Iowa City, IA; 3) Department of Psychiatry, University of Iowa, Iowa City, IA.

After a linkage peak has been identified based on a set of pedigrees it is often necessary to identify a homogeneous subset of those pedigrees for use in follow-up molecular work with the goal of localizing the putative susceptibility gene. In the absence of relevant covariate information (e.g., age of onset), this is usually done by selecting the pedigrees that individually yield a suitably positive LOD score in the region of the peak. Here we propose selecting a subset with a clustering algorithm that includes pedigrees based on their ability to contribute to the total integrated linkage likelihood (TILL), defined as an expected LOD score, with the expectation taken with respect to the genetic model and . Pedigrees are greedily added to the cluster in descending order of contribution until the percentage TILL increase associated with a newly added pedigree falls below a certain threshold. This method exploits additional information implicit in the shape of the likelihood surface, and only adds pedigrees to the cluster which are compatible in terms of inheritance models. In a series of preliminary simulations, we show that using the genetic model information to identify pedigrees linked to a particular locus has the potential to greatly increase accuracy and reliability when compared to a simple maximum LOD score selection criteria.

Construction and analysis of a novel database of human neutral polymorphisms. *M.F. Hammer[1], M. P. Cox[1], D.W. Garrigan[1], A. Woerner[1], T. Severson[1], J.D. Wall[2]* 1) ARL Division of Biotechnology, University of Arizona, Tucson, AZ; 2) University of Southern California, Los Angeles, CA.

The accurate characterization of human demographic history requires the analysis of neutral polymorphisms from a large number of independently evolving loci. Towards this goal we are re-sequencing 15-20 kb segments from 90 regions of the genome in 90 humans from six geographically diverse human populations (e.g., three from sub-Saharan Africa and three from Eurasia) and 4 great apes. While several larger-scale publicly available re-sequencing databases exist, none of these focuses entirely on re-sequencing non-coding DNA from genomic regions with moderately high recombination and low gene density. Hence, we are in a position to make inferences about human demographic history that are minimally confounded by the effects of natural selection. Statistical approaches are being developed for explicitly testing a number of hypotheses pertaining to the structure of the ancestral population giving rise to *H. sapiens* and the extent of admixture with archaic humans. We have also been working on new quantitative methods for estimating population parameters for a basic model of recent human population history. This model includes several factors known to be important in recent human demography: population divergence between different continental groups, migration between different continental groups, recent population growth and a bottleneck in non-African populations.

Comparison Gene Expression Micro-Array Analysis Between a Term Pregnant Mother and Her Infant Identifies Unique Fetal Biomarkers in Maternal Whole Blood. *J.L. Maron[1], K. Johnson[1], C. Lai[2], M. Ramoni[3], D. Slonim[4], Z. Jarrah[1], D.W. Bianchi[1]* 1) Division of Genetics, Tufts-NEMC, Boston, MA; 2) Nutrition and Genomics Lab, JM-USDA HNRC, Boston, MA; 3) Partners Center for Genomics, Boston, MA; 4) Tufts University, Medford, MA.

Background: The discovery of fetal mRNA transcripts in the maternal circulation holds great promise for noninvasive prenatal diagnosis. Previous studies have been limited in their scope by identifying only placental-derived or Y chromosome gene transcripts. Here, we suggest that mRNA extracted from maternal and umbilical cord whole blood samples, and analyzed with the use of comparative oligonucleotide microarrays, identifies unique fetal transcripts representing broad biological functions. Methods: Comparison HGU133A microarray analyses were performed using extracted and amplified mRNA from whole blood samples. Gene transcripts present in both the womans blood prior to delivery and her infants umbilical cord blood, but absent from the woman within 1 day of delivery were identified as potential fetal biomarkers. Results: Of 14,500 genes on the microarray, 253 genes were identified. Of these, 60 appear to be fetal specific. These include 34 genes involved in embryonic or fetal development including a predominance of neural developmental genes, and embryonic regulatory genes such as *HOXA7*, *SHOX*, and *AMN*. Interestingly, 10 sensory genes involved in auditory, visual and olfactory perception are upregulated in the fetus and detected in the antepartum mother. 16 candidate genes of physiological interest were identified including *KLF1*, which facilitates transition of fetal to adult hemoglobin, and atrionatriuretic peptide receptors, *NPR1* and *NPR2*. Conclusions: Microarray analysis of mRNA gene transcripts in maternal whole blood is feasible, and can identify novel fetal genes in the maternal circulation. The use of whole blood, as compared to prior reports using plasma, identifies a unique subset of fetal genes not previously recognized, which represent a diverse group of biological functions and may allow noninvasive monitoring of fetal development.

Lack of association of two SNPs on chromosome 10 (*rs498055* and *rs4417206*) with Alzheimers Disease. *R.L. Minster*[1], *S.T. DeKosky*[2], *M.I. Kamboh*[1] 1) Department of Human Genetics; 2) Department of Neurology, University of Pittsburgh, Pittsburgh, PA.

Only association between sequence variation in *APOE* and late-onset Alzheimers disease (LOAD) has been consistently replicated, but that variation is estimated to explain only part of the genetic variation in the risk of developing LOAD. Several groups have reported evidence of linkage on chromosome 10 to LOAD. A recent scan of single nucleotide polymorphisms (SNPs) on the long arm of chromosome 10 reported significant associations between *rs498055* and *rs4417206* and risk of LOAD (Grupe et al. *Am J Hum Genet* 78). We examined the two SNPs in up to 1,060 Caucasian Americans with LOAD and up to 810 age-matched healthy Caucasian Americans. Both SNPs were genotyped by template-directed dye terminator incorporation assays detected with fluorescence polarization. Measures of linkage disequilibrium between the two SNPs (D' = 0.881, r^2 = 0.445) in our sample were similar to those calculated in Grupe and colleagues. Genotype frequencies in both SNPs did not deviate significantly from those expected under Hardy-Weinberg equilibrium. We observed no statistically significant differences in allele frequencies between the cases and controls at either locus. The frequency of the minor allele of the *rs498055* SNP was 0.462 in cases and 0.464 in controls (p = 0.884), and for the *rs4417206* SNP it was 0.343 and 0.314 (p = 0.139). We also examined the impact of genotypes at these loci on age-at-onset and found no significant association. As has too often been the case with initial association studies, we were unable to replicate previous results in our relatively large case-control cohort, and a definitive source for the chromosome 10 linkage peaks remains elusive.

Clinical Presentation and Diagnosis of Patients with Hutchinson-Gilford Progeria Syndrome. *M.A. Merideth[1], W.J. Introne[1], L.B. Gordon[2], A.C.M. Smith[1], W.A. Gahl[1]* 1) SHBG, MGB, ORD, NHGRI/NIH, Bethesda, MD; 2) Brown University, Providence, RI.

Hutchinson-Gilford Progeria Syndrome (HGPS) is a sporadic autosomal dominant segmental premature aging syndrome with an incidence of 1 in 4-8 million. The basic defect involves an abnormal lamin A that disrupts the inner nuclear membrane, with protean, multisystemic manifestations. Since February of 2005 we have studied 15 patients with HGPS at the NIH under an IRB-approved natural history protocol. The clinical presentations of children with HGPS at the time of diagnosis have been remarkably consistent, confirming DeBusks description of the HGPS phenotype as so constant that patients with the condition bear an uncanny resemblance to one another (DeBusk, FL. The Hutchinson-Gilford progeria syndrome, J. Pediatr 80:697, 1972). The 15 patients seen at the NIH were diagnosed at a median age of 19 months (range 3.5 months to 4 years). The diagnosis was made most frequently by geneticists (7 of 15 patients), followed by dermatologists (5 of 15 patients), and a gastroenterologist in 1 case. The diagnosing physicians specialty was unclear in 2 patients. At the time of diagnosis, all of the children had skin findings, generally described as sclerosis, and all had been diagnosed with failure to thrive. Alopecia was present in 87% (13 of 15 patients) at the time of diagnosis, and 73% (11 of 15 patients) were described by their parents as sleeping with their eyes partially open. Circumoral cyanosis was observed in 60% (9 of 15 patients) and prominent scalp veins were observed in 53% (8 of 15 patients). Joint contractures were present at the time of diagnosis in 33% (5 of 15 patients), with decreased joint range of motion observed in an additional 2 patients. Our clinical natural history protocol will provide detail to the phenotypic description of patients with HGPS. In addition, therapies addressing the basic defect in HGPS are now being considered. Recognition of the earliest features of HGPS will prompt more rapid diagnosis and may hasten the implementation of salutary interventions.

A novel program for allele- and genotype-based association tests on quantitative traits. *Y.W. Li*[1], *L. Zhang*[2], *E.R. Martin*[2], *Y.J. Li*[2] 1) Stat Dept,NC State Univ; 2) Ctr for Human Genetics, Duke Univ Med Ctr.

The QTDT program (Abecasis et al. 2000) is a frequent used tool for association study for quantitative traits. QTDT includes five association methods, which are all allelic-based tests and applicable to nuclear families. Since genotype of a marker is a direct observation for an individual, it is desirable to assess association at the genotypic level. In some cases, family data includes extended pedigrees, but the current methods, such as the method proposed by Monks and Kaplan (2000) (MK method), use only partial information from the general pedigree, which may result in the loss of statistical power. In this study, we extended the MK method and developed a novel program that could perform both allele- and genotype- based association tests in any pedigree structures. The new genotype-based MK method provides test statistic for each genotype and a global test for combined genotypes. We evaluated the power and type I error rates of our genotype-based MK method through a series of simulation studies. Nuclear families with sibship sizes of one to six were simulated under various genetic parameters including different QTL heritability, allele frequencies of marker and QTL, degree of linkage disequilibrium between marker and QTL, and different genetic models. To evaluate the performance of the new program, we utilized simulated two generations pedigree data and real data. The simulation results demonstrate that our proposed genotype-based MK method has correct type I error and comparable statistical power with the allele-based MK method. Interestingly, genotype-based MK method shows higher power than the allele-based MK method under the overdominate model where the dominant effect exceeds additive effect at the QTL (max difference: 83.1%). The modified version of allele-based MK method in program showed correct type I error for general pedigree. We also demonstrate the utility of the program applied to real data to test association between GSTO1 and age-at-onset data of Alzheimer disease (P=0.025 for the CC genotype of rs4925). From the overall testing, we proved that the program is a robust tool to analyze the quantitative trait data in general pedigrees.

Identifying Genetic variants in Urea Cycle Enzymes. *S. Mitchell, M. Neill, L. Hall, M. Summar* Human Genetics, Vanderbilt Univ, Nashville, TN.

Our lab is carrying out a comprehensive screen of the genes encoding urea cycle enzymes to identify genetic variants. The urea cycle functions to remove nitrogen waste from the body and to generate intermediate products necessary for other metabolic functions. A number of inherited metabolic disorders are associated with the urea cycle.

There are five key enzymes within the urea cycle: carbamoyl phosphate synthetase I(CPSI), ornithine carbamoyltransferase(OTC), argininosuccinate synthase(ASS), argininosuccinate lyase(ASL), and arginase 1(ARG1). Additionally, a sixth enzyme, N-acetyl glutamate synthase (NAGS) is necessary for formation of N-acetyl glutamate which is an allosteric activator of CPSI, the first enzyme in the cycle. Deficiencies in any of these enzymes result in hyperammonemia; which is characterized by high levels of blood ammonia. Ammonia is a toxic compound and has detrimental effects when its levels are elevated, including central nervous system dysfunction, brain damage, coma and death. We hypothesize that functional polymorphisms exist within these enzymes which may confer susceptibility for disease or dysfunction particularly when this system is stressed.

Although some polymorphisms have been described, a comprehensive screen of all the urea cycle enzymes has not been performed. Variants are identified via single stranded conformational polymorphism (SSCP) analysis and sequencing. We have identified a number of polymorphisms in the CPSI gene, and functional characterization of the T1405N substitution is underway. Kinetic enzyme assays are being performed for functional characterization of the T1405N CPSI polymorphism. Preliminary results obtained from enzyme assays reveal differential activity of CPSI. Screening of NAGS, OTC and ARG1 is ongoing. In a preliminary screen of NAGS, polymorphisms were observed in exon 4 and intron 6. Once these screens are complete we will focus on the final two enzymes, ASS and ASL. Through these studies we will gain a better understanding of how genetic variants contribute to urea cycle deficiencies and influence other metabolic processes.

Cell-Free Fetal DNA in Amniotic Fluid: Unique Fragmentation Signatures in Euploid and Aneuploid Fetuses. *O. Lapaire[1], D.W. Bianchi[2], I. Peter[3], B. O'Brien[2], H. Stroh[2], J.M. Cowan[2], U. Tantravahi[4], K.L. Johnson[2]* 1) Univ Womens Hospital, Univ of Basel, Switzerland; 2) Div Genetics, Dept Pediatrics, Tufts-New England Med Ctr, Boston, MA; 3) Inst for Clinical Research and Health Policy Studies, Tufts-New England Med Ctr, Boston, MA; 4) Dept of Pathology, Women and Infants Hospital, Providence, RI.

Background. Circulating cell-free fetal deoxyribonucleic acids (cffDNA) are novel biomarkers with many clinical applications. Amniotic fluid (AF) is a rich source of cffDNA. Our objective was to investigate the biophysical characteristics of cffDNA in AF. **Methods.** Ten mL of fresh AF supernatant, taken for clinical indications, were obtained from women carrying euploid fetuses (n=39) and aneuploid fetuses (n=4). To test the effects of storage and karyotype, samples frozen at -80C were also obtained from euploid fetuses (n=19) and aneuploid fetuses with trisomies 21 (n=16), 18 (n=9), 13 (n=3), triploidy (n=4), and monosomy X (n=2). AF cffDNA was characterized by real-time PCR amplification of *GAPDH*, gel electrophoresis, and analysis of the DNA fragmentation signature. **Results.** The amount of fresh AF cffDNA from euploid fetuses correlates significantly with gestational age ($R2=0.77$, $p<0.0001$), but frozen cffDNA does not ($p=0.63$). The median amount of cffDNA in frozen euploid samples was significantly lower than in fresh samples ($p<0.0001$). Compared to frozen euploid samples, a statistically significant decrease in the median amount of cffDNA was observed in frozen aneuploid samples, when adjusted for gestational age ($p=0.0005$). Analysis of the cffDNA size distribution showed statistically significantly different and qualitatively unique patterns for each karyotype. **Conclusions.** Our data suggest that gestational age, karyotype, and sample storage time affect quantitative levels and fragment size in AF cff DNA. This may be due to fundamental differences in tissue sources, excretion modes, or kinetic pathways. Characteristic fragmentation signature patterns, unique for each common aneuploidy, may offer the possibility of using DNA fragmentation analysis as a rapid and cost-effective means of triaging amniotic fluid samples.

Hierarchical Bayes Prioritization of Marker Associations from a Genome-Wide Association Scan for Further Investigation. *J.P. Lewinger, D.C. Thomas, D.V. Conti, J. Baurley, T. Triche* University of Southern California, Los Angeles, CA.

We describe a hierarchical regression modeling approach to selection of a subset of markers from the first stage of a genomewide association scan to carry forward to subsequent stages for testing on an independent set of subjects. Rather than simply selecting a subset of most significant marker-disease associations at some cutoff chosen to maximize the cost-efficiency of a multistage design, we propose a prior model for the true noncentrality parameters of these associations comprised of a large mass at zero and a continuous distribution of nonzero values. The prior probability of nonzero values and their prior means can be functions of various covariates characterizing each marker, such as their location relative to genes or evolutionary conserved regions, or prior linkage or association data. We propose to take the top ranked SNPs based on either the posterior probability that the noncentrality parameter is not zero or the posterior expectation of the noncentrality parameter for confirmation in later stages of a genomewide scan. The statistical performance of this approach is compared with the traditional p-value ranking by simulation studies. The method is applied to data from a recent genomewide scan for age-related macular degeneration.

The effect of heterogeneity on the chromosome 10 risk in late-onset Alzheimer Disease. *X. Liang[1], E.R. Martin[2], N. Schnetz-Boutaud[1], J. Bartlett[1], B.M. Anderson[1], S. Zuchner[2], H. Gwirtsman[1], D. Schmechel[2], R. Carney[2], J. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics, Duke University, Durham, NC.

Late-onset Alzheimer disease (LOAD) is a complex neurodegenerative disorder with a strong genetic component. However, with the exception of APOE, no universally accepted genetic association has been identified. A broad region of chromosome 10 has engendered continued interest generated from both preliminary genetic linkage and candidate gene studies. To better examine this region, we combined unbiased genetic linkage with candidate gene association studies. We examined five functional candidate genes (VR22, LRRTM3, PLAU, TNFRSF6, IDE) that also fell within the broad area of linkage. 50 SNPs were genotyped across the genes in a case-control dataset containing 745 cases and 998 controls and an independent family-based dataset containing 1337 discordant sib pairs in 567 multiplex families. Simultaneously we attempted to narrow the peak region of linkage by analyzing the family-based dataset using both covariate and subset analyses. We genotyped an additional 36 SNPs evenly spaced across 80.2 Mb. 24/50 SNPs in the five candidate genes gave nominally positive association results in at least one dataset, with at least one positive SNP in each gene. SNPs rs2441718 and rs2456737 in VR22 (67.8 Mb) and SNP rs203162 in TNFRSF6 (90.7 Mb) showed association in both family-based and case-control datasets, with odds ratios (ORs) of 1.29 (95% CI=1.02-1.62, p=0.03), 0.75 (95% CI=0.59-0.94, p=0.01) and 1.23 (95% CI=1.04-1.46, p=0.02), respectively. A two point LOD score of 2.69 was obtained at SNP rs1890739 (45.1 Mb, p=0.03 in 21% families) when the families were ordered from low to high by ApoE LOD score using Ordered Subset Analysis (OSA). These data continue to support a role for chr 10 loci in AD. However, the candidate gene and linkage analysis results did not converge, suggesting that there is more extensive heterogeneity on chromosome 10 than previously appreciated.

A Preliminary Study on X-ray Repair Cross Complementing (XRCC) Gene Polymorphisms as Possible Biomarkers of Breast Cancer Susceptibility among Cypriot Women. *A. Hadjisavvas[1], M. Loizidou[1], M. Daniel[2], E. Kakouri[2], S. Malas[3], Y. Marcou[2], K. Kyriacou[1]* 1) EM and Molecular pathology, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 2) Bank of Cyprus Oncology Centre, Nicosia, Cyprus; 3) Department of Oncology, Limassol General Hospital, Limassol, Cyprus.

Population-based molecular epidemiology studies on genetic variations of genes have shown associations between specific genetic polymorphisms and breast cancer susceptibility. A number of studies have demonstrated that common variants of genes involved in the DNA Double-Strand Break pathway can act as low penetrance breast cancer susceptibility alleles. This preliminary molecular epidemiology study which is carried out for the first time on a Cypriot cohort of patients/controls, aims to investigate the role of polymorphisms in DNA repair genes XRCC1, XRCC2 and XRCC3 in breast cancer. We analysed the XRCC1 Arg194Trp, Arg280His and Arg399Gln variants as well as the XRCC2 Arg188His and XRCC3 Thr241Met gene polymorphisms. To identify these polymorphisms PCR and restriction enzyme digest were performed on DNA obtained from 500 Cypriot breast cancer patients age between 40-70 and 600 age-matched normal controls. Extensive demographic, epidemiological and pathological data were also recorded. Using the Chi-square analysis, we identified a statistically significant ($p = 0.05$) difference between the case group and the control group for the XRCC1 Arg280His polymorphism. Evaluation of potential underlying gene-gene or gene-environment interactions, which might magnify the effect of the variants under study, will require even larger sample sizes. We are currently expanding our analysis to include a greater number of subjects to determine the importance of these initial findings and improve our knowledge on the effect of XRCC gene polymorphisms, on breast cancer susceptibility in Cypriot women.

Determination of mitochondrial sequence variants in familial heart disease using resequencing arrays. *M.K. Halushka[1,4], J. Albertus[2,4], B.R. Bishe[2,4], A. Chakravarti[2,4], R.D. Cohn[2,4], D.J. Cutler[2,4], N. Johnson[3,4], D.P. Judge[3,4], J. Lu[1,4], D.E. Arking[2,4]* 1) Department of Pathology; 2) McKusick-Nathans Institute of Genetic Medicine; 3) Division of Cardiology; 4) Johns Hopkins Medical Institutions, Baltimore, MD.

Despite recent gains in identifying genes responsible for familial forms of heart disease, there is still a significant group of individuals whose underlying genetic mutations remain unknown. This study investigated sequence variation in mitochondrial DNA (mtDNA) as a source of unexplained familial cardiomyopathies. Eight patients from 6 families with familial heart disease (hypertrophic cardiomyopathy, dilated cardiomyopathy (DCM), restrictive cardiomyopathy or exercise intolerance (EI)) were selected based on both the inability to exclude matrilinear inheritance and other phenotypes suggestive of mitochondrial disease. A subset of individuals had prior limited genomic sequencing which failed to identify a cause of disease. mtDNA analysis was performed using the Affymetrix GeneChip Human Mitochondrial Resequencing Array 2.0 on lymphocyte DNA. The ABACUS algorithm assuming homozygosity at each nucleotide was used to scan the chips for variation. The overall nucleotide call rate on the chips was 97% (range 95-98%). Ninety-five variant sites were identified, of which 75 were common variants and 18 were rare variants. Two novel sequence variants, not described in over 2,400 previous human mtDNA sequences were detected. One novel variant was located in the D-loop. The second, in a patient with EI, caused a mutation in a highly conserved threonine in the NADH dehydrogenase 2 (ND2) gene. Three family members with DCM shared a rare variant (frequency ~ 1/800 individuals) located in the 16s rRNA. Mutations in 16s rRNA and ND2 have been shown to cause DCM and a syndrome including EI respectively. Functional testing remains to be performed to confer function on these variants. We have identified two entirely novel sequence variants and one known rare variant which may contribute to the familial cardiomyopathies observed. We found the Mitochip to be a robust, inexpensive and high throughput mechanism to investigate mtDNA.

Reduced MeCP2 expression is frequent in autism frontal cortex and correlates with aberrant *MECP2* promoter methylation. *R.P. Nagarajan[1,2,3,4], A.R. Hogart[1,2,3,4], M.R. Martin[1,3,4], Y. Gwye[1,3,4], J.M. LaSalle[1,2,3,4]* 1) Dept of Med Microbiology and Immunology; 2) Genetics Graduate Group; 3) Univ of California Davis; 4) Rowe Program in Human Genetics.

Mutations in *MECP2*, encoding methyl CpG binding protein 2, cause Rett syndrome, an X-linked neurodevelopmental disorder. Both Rett and autism are pervasive developmental disorders and share many clinical features. Although *MECP2* coding mutations are a rare cause of autism, MeCP2 expression defects were frequently found in brain samples from autism and autism spectrum disorders. MeCP2 immunofluorescence was quantified by laser scanning cytometry on a large tissue microarray containing autism, autism-spectrum, and control postmortem cerebral cortex samples. A significant reduction in MeCP2 expression compared to age-matched controls was found in 11/14 autism, 10/10 Rett, 4/4 Angelman, 3/4 Prader-Willi, 3/5 Down, and 2/2 attention deficit hyperactivity disorder frontal cortex samples. We then tested the hypotheses that *MECP2* promoter mutations or aberrant promoter methylation cause reduced expression in cases of idiopathic autism. One autism female was heterozygous for a rare *MECP2* promoter variant that correlated with reduced MeCP2 expression. A more frequent occurrence was significantly increased *MECP2* promoter methylation in autism male frontal cortex compared to controls. Furthermore, percent methylation of *MECP2* significantly correlated with reduced MeCP2 protein expression. These results demonstrate that both genetic and epigenetic defects lead to reduced MeCP2 expression and may be important in the complex etiology of autism.

Altered expression of lipid-metabolism genes in the frontal cortex of suicide completers: validation of microarray data using real-time PCR. *A. Lalovic[1], A. Sequeira[1], L. Canetti[1], J. ffrench-Mullen[2], T. Klempan[1], G. Turecki[1]* 1) McGill Group for Suicide Studies, Douglas Hosp Research Centre, Verdun, QC, Canada; 2) Gene Logic Inc., Gaithersburg, MD, USA.

An association between low levels of serum cholesterol and suicidal behavior has frequently been reported. Studies investigating this association have generated data to suggest that lipid metabolism and cytokines may play interacting roles in suicidal behavior. We performed large-scale microarray gene expression analysis using the Affymetrix HG-U133 chipset and investigated the expression profile of genes related to lipid metabolism in post-mortem brains from suicide completers and controls. We used tissue from three regions of the frontal cortex (BA 8/9, 11, and 47) from 13 psychiatrically normal male controls and 22 male suicide completers, 15 of whom were diagnosed with major depressive disorder. Of the 196 lipid metabolism genes differentially expressed (fold-change (FC) 1.3 and p 0.05) in the three regions in total, a number of genes were selected for validation using real-time PCR, given their consistency across all three brain regions examined. Stearoyl-CoA desaturase (SCD) was found to be down-regulated in suicides with major depression in all regions (BA 8/9: FC=-1.47, p=0.002; BA 11: FC=-1.74, p=0.009; BA 47: FC=-1.67, p=0.01). Leptin receptor (LEPR) was also down-regulated in suicides in all three brain areas (BA 8/9: FC=-2.26, p=0.002; BA 11: FC=-2.02, p=0.01; BA 47: FC=-1.4, p=0.05). Good correlations were found between our microarray and real-time PCR data for these genes (LEPR: BA 8/9: r=0.49, p=0.02; BA 11: r=0.53, p=0.02, BA 47: r=0.65, p=0.0001). Western blotting experiments are underway to investigate alterations at the protein level. The possible functional roles of these proteins in the context of suicidal behavior will be considered, taken together with previous findings suggesting that leptin may play a role in regulating SCD expression.

Identification of genes involved in tooth development by differential microarray gene expression. *F. Li[1], T.J. Pemberton[1], G.A. Mendoza[1], Y. Hsu[1], M.L. Snead[2], R. Mehrian-Shai[1], P.I. Patel[1,2]* 1) Institute for Genetic Medicine, University of Southern California, Los Angeles, CA; 2) Center for Craniofacial Molecular Biology, University of Southern California, Los Angeles, CA.

Anomalies involving tooth number, such as hypodontia or supernumerary teeth, anomalies of tooth shape and size, and defects involving mineralization are common developmental dental abnormalities. Positional cloning approaches and knock-out mice have identified a number of genes critical in tooth development. As an alternative approach to identifying novel genes in the process, we have used the Affymetrix MGE 430 2.0 microarray to examine gene expression within developing mouse molar teeth between post-natal days 1 to 10. Analysis of the top-100 genes identified as up-regulated in the tooth RNA when compared with 16 control tissues found that they were enriched for membrane-associated, structural, and nuclear genes, and that the protein product of 16% is present in the extracellular matrix. Their functions were greatly enriched for integrin binding, extracellular matrix structural components conferring compression resistance and tensile strength, and for genes involved in biomineral formation, tissue remodelling, skeletal development, osteoblast differentiation, organ morphogenesis, and signal transduction regulation. Twenty-four of these genes have been previously reported to be involved in tooth development, mutations within which are known to cause the tooth developmental anomalies amelogenesis imperfecta, dentinogenesis imperfecta, and trichodentoosseous syndrome. Sixteen genes of unknown function were also identified. RT-QPCR has confirmed the up-regulation of 25 of these genes within the tooth RNA. However, further work is required to confirm the localization of expression within the developing tooth and to determine their role in tooth development. We conclude that microarray and RT-QPCR expression analyses of the developing tooth can facilitate the identification of novel genes involved in the process, which can aid future candidate gene selection during the investigation of the genetic aetiology of dental anomalies.

Parallel Selection on TRPV6 in Human Populations via Soft Sweeps. *D.A. Hughes[1], K. Tang[1], R. Strotmann[2], T. Schöneberg[2], B. Nilius[3], M.A. Stoneking[1]* 1) Dept. of Evolutionary Genetics, Max-Plank Institute for Evolutionary Anthropology, Leipzig, Germany; 2) Institute of Biochemistry, Molecular Biochemistry, University of Leipzig, Leipzig, Germany; 3) Laboratory of Physiology, Catholic University of Leuven, Leuven, Belgium.

To identify and characterize genes under local selection we screened the SeattleSNPs data set using two summary statistics molecular Fst and lnRHap. This screen identified TRPV6, as others have, as a candidate gene for local directional selection in Europeans. We further characterized selection at this locus with a modification of the extended haplotype homozygosity test in order to test the EHH for the same allele between two different populations. With this test TRPV6 in Europeans violates neutral expectations determined from both empirical and simulated distributions. Three tagging SNPs, which are also non-synonymous mutations, were then genotyped in the CEPH diversity panel to determine if this pattern may be limited to Europeans. In contrast to Africans, we discovered that all non-African populations were fixed, or nearly so, for the derived haplotype. Approximately 4kb of non-consecutive sequence in the TRPV6 region was then re-sequenced in 92 individuals from four global populations. We again performed the REHHB test and found that all of these populations have EHH values equal to or greater than that found in Europeans, suggesting that all non-African populations have experienced selection at this locus. We then dated the time since fixation of the European allele to ~12,000ybp, a date too young for there to have been a single selection event for all populations outside of Africa. Moreover, the signature of selection is not limited to non-Africans, for we also find a signature of selection in African-Americans on the same haplotype, suggesting multiple independent selective events for the same haplotype. To determine if there is a functional difference between the two protein alleles we performed multiple functional assays including patch-clamp analyses. These assays show no measurable functional differences between the alleles, suggesting that selection may be on expression differences or alternative isoforms.

Analysis of the C-reactive protein gene in sibling pairs extremely discordant for neovascular age-related macular degeneration. *I.K. Kim[1], F. Ji[2], S. Adams[1], A. Capone[3], J.W. Miller[1], J. Ott[2], T.P. Dryja[1], M.M. DeAngelis[1]* 1) Dept of Ophthalmology, Harvard Medical School, Mass Eye & Ear Infirmary, Boston, MA; 2) Laboratory of Statistical Genetics, Rockefeller University, New York, NY; 3) Associated Retinal Consultants, PC, William Beaumont Hospital, Royal Oak, MI.

Purpose: Inflammation appears to play a role in the pathogenesis of age-related macular degeneration (AMD). Some studies have suggested a correlation between circulating C-reactive protein (CRP) levels and AMD. Genetic variations in CRP partially influence plasma CRP levels. We sought to examine whether genetic variants in the CRP gene were associated with risk of neovascular AMD. **Methods:** We ascertained 144 extremely discordant sibpairs where at least one member had neovascular AMD and another had normal maculae and was past the age at which the affected sibling was diagnosed with neovascular AMD. Disease status for each participant was confirmed by grading of fundus photos by at least two of the investigators, or a home visit. Genotypes were determined by sequencing 9 single nucleotide polymorphisms (SNPs) in the CRP gene. Statistical analyses were performed by McNemars test or conditional logistic regression. **Results:** No significant association between any of the CRP SNPs and risk of neovascular AMD was detected. Stratification of the sibpairs according to complement factor H (CFH) genotypes (Y402H) demonstrated no association between any of the CRP SNPs and risk of neovascular AMD. However, with stratification by smoking status (index patient 10 pack-years vs. normal sibling <10 pack-years), the presence of one or two minor alleles of SNP rs3091244 (-286C > T/A) was found to be negatively associated with neovascular AMD (p = .04; OR: 0.125; CI: .003 - .932). **Conclusions:** No statistically significant association was detected between any of the 9 SNPs in the CRP gene and neovascular AMD when considering disease status alone or with stratification by CFH genotype. Among sibling pairs extremely discordant for smoking history as well as AMD, the minor alleles at SNP rs3091244 may be protective for neovascular AMD. However, this finding is of modest significance and may be due to the effect of smoking alone.

Macrocephaly on Fetal Ultrasound as a sign for Congenital Myotonic Dystrophy. *N. Martin[1], M. Thomas[1], D. Chitayat[1,2]* 1) Dept. of Obstetrics and Gynecology, The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital; 2) Division of Clinical and Metabolic genetics, Dept. of Pediatrics, Hospital for Sick Children; University of Toronto, Toronto, Ontario, Canada.

Myotonic Dystrophy Type 1 (DM1) is an autsomal dominant condition associated with expansion of a CTG trinucleotide repeat and has variable clinical manifestations ranging from mild (late onset) to severe (congenital onset). Congenital DM1 has a high rate of morbidity and mortality and is characterized by severe hypotonia, respiratory insufficiency and mental retardation. We report two cases that presented with a fetal ultrasound finding of macrocephaly among other findings and were later found to have congenital DM1. **Case 1:** A 21- year-old woman presented at 35 weeks gestation with polyhydramnios, mild unilateral cerebral ventriculomegaly, prominent 3rd ventricle and macrocephaly. The biparietal diameter measured 100 mm, which is equivalent to 42 weeks gestation. Delivery was by caesarean section at 38 weeks gestation. The newborn was severely hypotonic, macrocephalic and DNA analysis of the *DMPK* gene showed 1500 CTG repeats, which is consistent with congenital DM1. Subsequently, the mother was found to carry a CTG repeat expansion of 700. **Case 2:** Fetal ultrasound done at 20 and 28 weeks gestation showed mild bilateral ventriculomegaly and mild polyhydramnios and at 30 weeks gestation a distended abdomen, polyhydramnios and macrocephaly were noted. Delivery was at 33 weeks gestation and the baby died 10 minutes after birth. On autopsy, no significant abnormalities were identified apart from megalencephaly (OFC of 38 GA). The mother had features of DMI not noted before and on DNA analysis of the *DMPK* gene had 100 CTG repeats. The baby had 3800 CTG repeats. Macrocephaly has only been reported in one other case series in association with congenital DM1. We would suggest that congenital myotonic dystrophy should be considered when fetal ultrasound shows macrocephaly. Further investigations may be required such as physical examination of the mother and possible DNA analysis for DM1.

New CFTR gene variants in Cystic Fibrosis and Chronic Rhinosinusitis Chilean patients. *G. Molina[1], C. Musri[1], M. González[1], A. Vera[1], F. Vásquez[1], F. Krause[1], A. Milinarsky[2], V. Lezana[2]* 1) Laboratorio de Biología y Genética Molecular. Escuela de Medicina. Universidad de Valparaíso, Valparaíso. Chile; 2) Departamento de Pediatría. Escuela de Medicina. Universidad de Valparaíso,Valparaíso. Chile.

Cystic Fibrosis (CF) is the most prevalent autosomal recessive disease in the Caucasian population (1/2000 newborns). Its prevalence in Chile could vary between 1/4000 to 1/2000 newborns in different regions. CF is caused by mutations in the cystic fibrosis transmembrane regulator (CFTR) gene, which encodes a protein that functions as a chloride channel. This protein regulates electrolytes and water transport through secretory cells. The failure of this protein produces a greater viscosity of mucus and other secretions. Chronic Rhinosinositis (RC) is a CFTR related disease, since greater viscosity of mucus is one of its causes. More than 1000 CFTR gene mutations have been described. We have searched for new mutations in 20 CF patients, using SSCA and sequencing of exon4, exon7, exon10, exon 11, exon12, and exon17b. We have already found two variants (p.T351S, p.G528G). We have not detected the p.T351S variant in 100 chromosomes of individuals from Valparaisos general population, thus it could be a CF causative mutation. Conversely, p.G528G is a common polymorphism. Furthermore, we have determined that homozygous individuals for this variant have an exon 10 normal splicing, despite the fact that it modifies the last base of exon 10. In RC patients we have performed a complete screening of CFTR coding sequencing using RT-PCR of peripheral lymphocytes RNA. We have found splicing variants causing exon 5, 14a, 17a skipping. This approach could lead us to discover new mutations responsible for the unknown 50% of CF causative mutations in our CF patients and to clarify the relationship between CF and RC. DIPUV 39/2004.

Assessing copy number variation in individuals with autism spectrum disorder using Affymetrix 500K SNP arrays. *C.R. Marshall[1], L. Feuk[1], L. He[1], T. Miller[1], J. Skaug[1], P. Szatmari[2], L. Zwaigenbaum[2], B. Fernandez[3], W. Roberts[1], S.W. Scherer[1]* 1) The Hospital for Sick Children, Toronto, Canada; 2) McMaster University, Hamilton, Canada; 3) Memorial University, St. John's, Canada.

Autism is a neurodevelopmental disorder characterized by impairments in social-communication and by a preference for repetitive activities. Twin studies suggest autism is mainly a genetic condition of complex etiology, but the major susceptibility genes are not known. Our studies have shown that 7% of autistic patients have chromosomal anomalies detectable upon karyotyping. We propose that sub-microscopic copy number variation (CNV) in the human genome may also contribute to autism. For detection of sub-microscopic unbalanced rearrangements in autism we are now using the Affymetrix 500K SNP array to (1) characterize all samples having cytogenetically detectable rearrangements and (2) assess the genome in 500 probands with normal karyotypes. We have already mapped 67 cytogenetically-visible breakpoints in 36 patients and will use this for comparison to CNV data. For aim 2, we have inferred copy number changes in 200 samples using a highly stringent Markov Model built into DNA-Chip Analyzer (dChip) software. On average, we detect ~5 CNVs/sample and so far our data does not indicate prevalence for sub-microscopic changes in autism compared to controls. The majority of the variants found in multiple patients are found at similar frequency in controls, indicating that these are common copy-number polymorphisms. For those CNVs that are not found in controls we are prioritizing characterization of regions based on: (1) Recurrent intervals in unrelated samples that contain genes and (2) Large single CNVs that contain candidate gene(s). We then assess these intervals in the larger autism collection and controls. Our combined cytogenetic and microarray data identifies (microscopic and sub-microscopic) potentially phenotype-associated loci on chromosome 1p21.3, 3p14, 7q31.2, 7q31.3, 7q34, 9p22, 15q11.2-15q13.3, 17q12, 22q11.21 and at other regions. Approximately 10% of cases have at least one de novo large CNV that may be associated with the disease providing critical information for clinical diagnostics.

Molecular analysis of *MCCC1* and *MCCC2* genes of infants whose newborn screening results are suggestive of 3MCCD. *P.B. McWhorter, J.D. Cogan, R. Hamid, M.T. Weingartner, J.A. Phillips III* Pediatrics, Vanderbilt University School of Medicine, Nashville, TN.

Introduction: MS/MS newborn screening (NBS) detects elevated 3-hydroxyisovaleryl carnitine (C5OH) which is associated with 3-Methylcrotonyl CoA Carboxylase Deficiency (3MCCD). While often asymptomatic, some infants with 3MCCD present with hypotonia or a Reye-like illness. Reported incidence is about 1:50,000 with no known high risk populations. Products of the *MCCC1* and *2* genes comprise the subunits of 3MCC. **Hypothesis:** Variations in the *MCCC1* and/or *2* genes are associated with elevated C5OHs on NBS in middle TN, especially among Hispanics and Kurds. **Methods:** *MCCC1* and *2* transcripts were sequenced for those with repeated C5OH elevations on NBS and frequencies of variations were determined in controls. **Results:** From July 2004 to present 107 neonates had C5OH elevations on their NBS. Of these 16% were evaluated because they also had 3-OH-isovaleric acid (3OHIA) elevations suggestive of 3MCCD. Ethnicity was 53% European, 18% Hispanic, 18% African American, and 12% Kurdish (all consanguineous). Sequencing *MCCC1* and *2* RT-PCR products from lymphoblastoids treated with puromycin to prevent NMD identified novel mutations in each. Case 1 was heterozygous for a single G deletion (1073delG) that is predicted to cause a frameshift starting with codon 358 of *MCCC1*. Case 2 was heterozygous for a 2bp deletion (640-641delGG) that also causes a frameshift and results in NMD of *MCCC1* transcripts. Case 3 was homozygous for a G to A transition (G1015A) encoding a Val339Met substitution in the *MCCC2* gene. Val339 is highly conserved in all mammalian species. No *MCCC1* 1073delG or *MCCC2* Met339 alleles were detected in 200 control alleles. **Conclusions:** 1) Elevated C5OH and 3OHIA were seen in ~1:3,800 births, 2) Hispanics and Kurds comprise 30% of our cases but less than 3.1% of our population, 3) all of our first three samples analyzed showed rare allelic variants in *MCCC1* or *2* that are plausible causes of perturbed 3MCC function, and 4) determining the mechanisms by which these variations perturb 3MCC expression or function will require further studies.

SNP microarray analysis in an apparently balanced complex chromosome rearrangement. *B. Hay[1], P. Minehart Miron[2,3], P. Crowley-Larsen[2], M. Ito[4], S. Ramakrishnan[2], X-L. Huang[4], J.M. Milunsky[4,5,6]* 1) Dept Pediatrics, Univ Massachusetts Med Ctr, Worcester, MA; 2) Dept Hospital Labs, UMass Med Ctr, Worcester, MA; 3) Dept Pathology, UMass Med Ctr, Worcester, MA; 4) Center for Human Genetics, BU School of Medicine, Boston, MA; 5) Dept Pediatrics, BU School of Medicine, Boston, MA; 6) Dept Genetics & Genomics, BU School of Medicine, Boston, MA.

Complex chromosomal rearrangements are rare events, typically reported in association with abnormalities in a proband. Parental concern regarding prenatal ventriculomegaly and pyelectasis led to chromosome analysis in a phenotypically normal infant that revealed a de novo structural rearrangement involving chromosomes 2, 3, 4 and 9. These rearrangements appeared balanced by initial cytogenetic studies, including analysis of GTG-banded metaphase chromosomes at the 500 band level and metaphase FISH with whole chromosome paints for chromosomes 2, 3 and 4 plus centromere probes for chromosomes 2 and 9. This yielded the following karyotype: 46,XY,der(2)del(2)(p16)ins(2;3)(p16;p13p24.2),del(3)(p13p24.2),der(4)t(2;4)(p16;q28),ins(9;4)(q31;q35q28). Subtelomere probes for 2p, 3p, 4q and 9q revealed disomy for each and localization consistent with the described karyotype. High resolution metaphase comparative genomic hybridization (resolution ~2.5Mb) was performed and was normal. Further investigation using the Affymetrix 250K SNP microarray revealed deletions at 3p24.3 (~2Mb with at least 7 genes) and 4q26 (~200kb with at least 1 gene). To our knowledge, a rearrangement involving these four chromosomes has not been reported. At 1 year of age, this child is exhibiting mild developmental delays and a few minor anomalies. Utilization of the SNP microarray provides more precise data regarding areas of cryptic unbalanced rearrangements, which may be beneficial for clinical management and prognosis.

Cornelia de Lange Syndrome and the Cohesinopathies. *I. Krantz[1], D. Yaeger[1], M. Kaur[1], L. Jackson[2], M. Deardorff[1]* 1) Division of Human Genetics and Molecular Biology, The Childrens Hospital of Philadelphia, Philadelphia, PA; 2) Division of Obstetrics and Gynecology, Drexel University School of Medicine, Philadelphia, PA.

Disorders affecting the sister chromatic cohesion complex likely represent an underappreciated class of clinical disorders. A major component of this complex, Cohesin, consists of the subunits Smc1, Smc3, Stromalin and Rad21. The former two comprise a ring that encircles sister chromatids and the latter two fasten the structure. NIPBL is believed to play a major role in loading Cohesin onto chromosomes. A number of other proteins have also been implicated in the proper regulation of Cohesin. Of these, Eco1 regulates maintenance of Cohesin on chromosomes. The essential function of the Cohesin complex suggests that its disruption would be lethal, however several alterations lead to specific patterns of developmental defects.

The Cornelia de Lange syndrome (CdLS) is a multisystem developmental disorder characterized by facial dysmorphia, hirsutism, growth and cognitive retardation, gastrointestinal abnormalities and limb deficiencies. We have demonstrated that mutations in NIPBL cause CdLS, associating disruption of the Cohesin complex with a developmental disorder. Despite extensive screening, we have found NIPBL mutations in only 50% of patients with CdLS. In the past year, several other members of the sister chromatid cohesion complex have been implicated in human congenital disease. The human homolog of Eco1 (ESCO2), has been found to be mutated in patients with Roberts syndrome/SC phocomelia, which have phenotypic overlap with CdLS. Most recently, mutations in a human Smc1 homolog (SMC1L1) have been found in patients with an X-linked variant of CdLS. We have screened a cohort of 95 NIPBL mutation-negative patients with CdLS and have identified SMC1L1 mutations in 8. These individuals represent mild variants of CdLS. This work confirms that mutations in the Cohesin complex result in CdLS and suggests that mental retardation-associated phenotypes due disruption of this complex may be more common than appreciated.

Large scale case-control, family-based and cohort studies of diabetes-susceptibility variants in the *TCF7L2* gene.

M.I. McCarthy[1,2], C.J. Groves[1], A. Bennett[1], E. Zeggini[2], T.M. Frayling[3], M.N. Weedon[3], G.A. Hitman[4], M. Walker[5], A.T. Hattersley[3], M-R. Järvelin[6,7] 1) OCDEM, University of Oxford, UK; 2) Wellcome Trust Centre for Human Genetics, Oxford, UK; 3) Peninsula Medical School, Exeter, UK; 4) Barts and The London, QMSMD, London, UK; 5) University of Newcastle, UK; 6) Imperial College, London, UK; 7) University of Oulu, Finland.

Evidence is accumulating that common variants in *TCF7L2* represent the most important genetic determinants of type 2 diabetes (T2D) susceptibility yet uncovered. To explore the physiological mechanisms involved, we genotyped four *TCF7L2* SNPs (the two most-associated in Icelandic subjects [rs12255372, rs7903146] plus two well-correlated Hapmap proxies [rs4506565, rs12243326]), in diverse European samples. A case-control analysis in 2158 UK T2D subjects and 2574 controls demonstrated powerful T2D associations at all SNPs, with the strongest effect at rs7903146 (allele-wise RR 1.36 95% CI 1.24-1.48) ($P=1.3x10^{-11}$). Data suggested a multiplicative model, and a population attributable risk between 15-20%. Independent replication was seen in 388 parent-offspring trios (eg rs4506565: 62% transmission, $P=8x10^{-5}$) generating a combined association signal of $P=4.4x10^{-14}$. Overall, T2D-associated *TCF7L2* genotypes were more frequent in cases selected for family history and early onset (rs4506565, P=0.02). Consistent with effects on insulin secretion, diabetes-associated genotypes were, in cases, associated with lower BMI (rs7903146, P=0.0002). In the population-based N Finland Birth Cohort of 1966 (n=5646), we found no association with BMI at age 31, but *TCF7L2* variants were associated with increased fasting glucose (rs12255372 homozygotes differ by 0.06mmol/l, p~0.01) and reduced insulin secretion (HOMA%B, p=0.015). There was a significant but weak effect of the T2D-risk allele at rs12255372 to increase birth weight (62g difference between homozygotes, P=0.028). Our data provide powerful replication of the association between *TCF7L2* and T2D and support an effect mediated through reduced beta-cell function. However, the birth weight association suggests that, in those with the risk variant, insulin secretion may be increased during the prenatal period.

Redundant function of Smad1 and Smad5 during chondrogenesis. *B. Keller[1], P. Hermanns[2], B. Zabel[2], B. Lee[1]* 1) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Center of Pediatrics & Adolescent Medicine, University of Freiburg, Germany.

Bone morphogenetic proteins (BMPs), members of the TGF- superfamily, play a pivotal role in the development of the vertebrate skeleton. The BMP-Receptor BMPR-1B (ALK-6) is expressed in all types of cartilage and expression of a dominant-negative form of BMPR-1B is able to block chondrogenesis and osteogenic differentiation. Smad1, Smad5 and Smad8 are the mediators of the BMP signaling pathway. Binding of BMP to the receptor leads to the phosphorylation of the Smads. They undergo a conformational change and are able to bind the common-partner Smad (co-Smad) Smad4. This complex translocates into the nucleus and activates or represses the transcription of target genes. *Smad1* and *Smad5* are expressed in proliferating and maturating chondrocytes, whereas *Smad1* and *Smad8* are shown to be expressed in mesenchymal cells. We examined the role of Smad1 and Smad5 in chondrogenesis by knocking out *Smad1* in proliferating chondrocytes using the cre-loxP-system. P1 mutant mice skeletons stained with alcian blue and alizarin red appeared to be normal and no obvious patterning defect has been observed. It has been discussed that *Smad5* might compensate for *Smad1* function. To address this issue we crossed mice with a *Smad1* loss of function in proliferating chondrocytes onto a *Smad5*+/- background. While there is no obvious difference in P1 mice, we could observe a weight difference in 8 week old mutants compared to their wt-littermates as well as a subtle disorganization of the growth plate.

Effects of microsatellite marker choice on measures of human interpopulation genetic relatedness and inferred phylogenies. *J. Listman[1], R.T. Malison[2,3], B.Z. Yang[2], A. Sughondhabirom[4], N. Thavichachart[4], H.R. Kranzler[5], S. Tangwonchai[4], A. Mutirangura[4], T. Disotell[1], J. Gelernter[2,3]* 1) Dept Anthropology, New York Univ, New York, NY; 2) Dept Psychiatry, Yale Univ Sch of Med, New Haven, CT; 3) VA CT, West Haven, CT; 4) Chulalongkorn Faculty of Med, Bangkok, Thailand; 5) Dept Psychiatry, Univ CT Sch of Med, Farmington, CT.

Short Tandem Repeats (STRs) are highly polymorphic in contrast to diallelic markers. This is thought to make them useful for human population genetic studies. STRs are used to measure interpopulation genetic distances and genetic diversity, identify first-degree relatives, infer population phylogenies, and assign individuals to a population. The usefulness of STR markers for interpopulation comparisons has been questioned, due to the supposed confounding effects of homoplasy. We used a panel of 35 unlinked autosomal STRs (15 tetranucleotide and 20 dinucleotide repeats) to examine the effects of marker choice and possible homoplasy on inferences of interpopulation genetic distances and phylogenetic relationships for 5 populations. Comparisons were made between 6 measures of genetic distance (D, R_{ST}, D_{SW}, D_a, D_m, D_S, and delta ()). Self-identified Thai (N=45), Thai-Chinese (N=28), Hmong (N=44), European Americans (N=91), and African Americans (N=54) were genotyped for all 35 STRs (4.8% missing data). Marker panels were created based on alleles per marker, repeat size, or semi-random selection to calculate distance measures which were then used to infer neighbor-joining trees. For all distance measures and resultant NJ trees, correlations were lowest between tetranucleotide and dinucleotide marker panels (.49 to .84). For each marker panel, correlations were lowest between R_{ST} or D and other measures. This indicates that design of STR panels can affect relative measures of genetic distance between populations, requiring interpretation of phylogenies within the context of marker properties and chosen distance measure. STRs may be more reliable for population differentiation, identification of close relatives, and population assignment, than for inferring population phylogenies, particularly when only a small number of markers is available.

Losartan modifies the predisposition for dissection in a mouse model of Marfan syndrome. *J.P. Habashi[1], M. Gamradt[1], M. Awad[1], E. Klein[1], D. Bedja[1], H.C. Dietz[1,2]* 1) Johns Hopkins University, Baltimore, MD; 2) HHMI, Baltimore, MD.

Marfan syndrome(MFS)is an autosomal dominant connective tissue disorder with a predisposition for aortic dilation and rupture. blocker therapy has been used to decrease the rate of aortic dilation but has not been shown to prevent the need for aortic root replacement or the risk of sudden death. Many manifestations of MFS, including aortic enlargement, have been shown to be mediated by excess activation of and signaling by the TGF family of cytokines. We demonstrated that losartan, an angiotensin II type 1(AT1)receptor blocker known to antagonize TGF, decreases the rate of aortic root enlargement and improves the architecture of the aortic media in a mouse model of MFS. This model(C1039G/+) shows histologic manifestations of failed aortic wall homeostasis, but fails to progress to dissection or death. While aortic size remains the best predictor of risk of dissection in people, the utility of this parameter has not been tested in mouse models. To determine if losartan therapy modifies the pathogenetic events culminating in dissection, we performed a clinical trial of losartan in mice homozygous for a hypomorphic Fbn1 mutation, (mgR/mgR)that show early aortic dissection. We randomized mgR/mgR mice to receive placebo(n=8),propranolol(50 mg/kg,n=8)or losartan(30 mg/kg, n=19)starting at 7 weeks, with propranolol and losartan doses titrated to achieve comparable hemodynamic effects. Echocardiograms were performed at baseline and monthly until death. While ongoing, the mice have been followed for 7 months and are necropsied on the day of death. At baseline, there was no significant difference in aortic root or ascending aortic size between the placebo, propranolol and losartan groups. Losartan significantly increased survival to 7 months of age(13/19 mice) as compared to placebo(1/7 mice; $p<0.02$) and propranolol(1/8 mice; $p<0.01$). Of the long-term survivors in the losartan treatment group, 3/13(23%) showed stable aortic dimensions while 7/13(54%) showed regression in aneurysm size. These data document that losartan has the capacity to modify the predisposition for aortic dissection in MFS, even in a mouse model with an artificially severe genotype.

Refinement of the FEVE locus and candidates. *B.A. Johannes[1], B.G. Elyas[1], M. Hicks[1], S.M. Haase[1], J.S. Bamforth[1,2], H.F. Pabst[2], M.A. Walter[1], K.A. Sprysak[1], L.M. Vicen-Wyhony[1], M.J. Somerville[1,2]* 1) Dept Medical Genetics, University of Alberta, Edmonton, AB, Canada; 2) Dept Pediatrics, University of Alberta, Edmonton, AB, Canada.

Familial Enteropathy with Villous Edema (FEVE; OMIM 600351) is an autosomal dominant disorder with variable penetrance that typically manifests in childhood as a recurrent acute, life-threatening secretory diarrhea associated with distinctive jejunal histologic changes and IgG2 subclass deficiency. We previously used a genome-wide microsatellite screen on a Mennonite kindred to define linkage of FEVE to D11S908 on chromosome 11q23 with a LOD score of 6.2 at theta = 0. Subsequent work using a higher density microsatellite marker array has refined the critical interval to a 2 Mb interval between D11S4142 and D11S1364.

Six genes from the candidate region have been sequenced: Interleukin 10 Receptor Alpha (IL10RA), Platelet-Activating Factor Acetylhydrolase Beta (PAFAH1B2), Sodium Channel Beta 2 subunit (SCN2B), Epithelial V-like Antigen 1 (EVA1), the delta subunit of CD3 antigen (CD3D), and Adhesion Molecule Interacting with CXADR Antigen 1 (AMICA1). IL10 down-regulates the inflammatory response, and protects against the lethality of intra-abdominal infection and sepsis. PAFAH1B2 is a catalytic subunit that inactivates the Platelet Activating Factor (PAF), where PAF is responsible for reducing inflammation. SCN2B modifies voltage-gated sodium ion channel function. EVA1 is involved mediating homophilic cell-cell adhesion. CD3D antigen has been associated with intestinal malabsorption. AMICA1 is an adhesion molecule in the immunoglobulin super-family. SNPs were found in several of these genes, but no causative mutations have been identified.

Serine proteases are involved in a wide variety of biological processes, including immune response and inflammation. Transmembrane Protease Serine 4 (TMPRSS4) maps to the FEVE critical region, is expressed in the gastrointestinal tract, and is currently being sequenced. Identification of the gene responsible for FEVE is expected to have relevance to other gastrointestinal and/or inflammatory disorders.

Allelic Variability and Tests for Natural Selection at the Human *ALDH2* Locus. *J. Long*[1], *C. Lewis*[1], *J. Li*[1], *R. Malhi*[2], *K. Hunley*[3] 1) Dept Human Genetics, Univ Michigan Medical Sch, Ann Arbor, MI; 2) Dept Anthropology, University of Illinois, Urbana, IL; 3) Dept Anthropology, University of New Mexico, Albuquerque, NM.

This research tests the hypothesis that natural selection has influenced variation at the human *ALDH2* gene locus. The enzyme product of this locus catalyzes the oxidation of aldehydes and is important in alcohol metabolism. *ALDH2* shows unusually high allelic differentiation among human populations. There is a deficiency variant, *ALDH2-2*, that is common in East Asians but absent in other places. This observation implicates the action of natural selection, but other processes can produce similar results. In this study, the null hypothesis of selective neutrality is tested by comparing the *ALDH2-2* allele frequency to the extent of intraallelic variability. In our tests of neutrality, we allow for a structured population. We have sequenced 5 kb of DNA surrounding the functional substitution at the *ALDH2* locus in a total of 134 people. These people represent sixteen populations, including four indigenous populations from each of four continental regions: Africa, Europe, East Asia, and the Americas. As expected, the *ALDH2-2* allele is present in all four East Asian populations, but not in populations from any other continental region. Also as expected, nucleotide diversity is highest in the four African populations and lowest in the four American populations. An old age for the *ALDH2-2* allele is suggested by background substitutions (i.e., intraallelic variability). This is consistent with its high frequency in Asians. However, it is important to examine variability at the locus in the context of the geographic structure of our species. To do this, we established neutral baselines for *ALDH2* sequence diversity in the geographically structured world-wide sample by fitting nested population structure models to the CEPH microsatellite diversity data. When the world-wide population structure was considered, the presence of intraallelic variability and a high allele frequency was inconsistent with the restriction of the *ALDH2-2* allele to the Asian continental region.

Correction of Fasting Hypoglycemia in a Rodent Model of Very Long-Chain Acyl-CoA Dehydrogenase Deficiency (VLCADD) by AAV8 Mediated Gene Transfer. *J.L. Merritt[1,2], T.V. Nguyen[1], D. Matern[1,2], J. Daniels[1], D.B. Schowalter[1]* 1) Dept. of Medical Genetics, Mayo Clinic, Rochester, MN; 2) Dept. of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

VLCADD is a disorder of fatty acid beta-oxidation with clinical presentations ranging from severe neonatal-onset with cardiomyopathy, recurrent episodes of hypoketotic hypoglycemia, and adult-onset skeletal myopathy and rhadbomyolysis. Treatment aims to prevent metabolic decompensation by avoidance of fasting, a diet low in long-chain fatty acids, and vitamin supplementation. The variable phenotype and intracellular expression of the VLCAD protein within multiple tissues makes VLCADD a challenging disorder to treat by gene therapy. We prepared an AAV2/8 based gene delivery system able to correct the metabolic block seen in VLCADD. Six to eight week old VLCAD deficient mice were injected with $1x10^{12}$ genome particles of AAV8-CMV-hVLCAD. Ten days post-injection acylcarnitine analysis in blood demonstrated a significant improvement of C14 and C16 saturated and unsaturated acylcarnitine species of treated mice to levels comparable to wild-type levels. Consistent with these findings, immunohistochemical hepatocyte staining revealed VLCAD expression and Western blot demonstrated the 70 kDa hVLCAD band. Western analysis of liver, muscle and heart tissue demonstrates the majority of gene expression occurs in the liver. Measurement of fasting serum glucose levels pre-treatment (average 43.3 mg/dL +/- 3.3) revealed glucose levels at more physiological levels by day eleven (average 100.3 mg/dL +/- 6.1). Ten weeks post-injection acylcarnitine analysis demonstrated an elevation of acylcarnitine species to near normal pre-treatment levels. These findings demonstrate the short term correction of the biochemical phenotype of VLCADD in mice and provide the basis for further development of a human gene replacement strategy for VLCADD. The short duration of expression most likely is related to CMV promoter down regulation in the liver which has previously been seen with this promoter in other gene delivery systems. Further studies looking at tissue distribution of protein expression over time are in progress.

Prenatal cytogenetic study and molecular genetic characterization of a *de novo* monosomy 1q42-qter. *K. Krabchi[1], M. Ferland[1], A. Demers[2], A.L. Rougemont[3], H. Sartelet[3], R. Drouin[1]* 1) Dept Pediatrics & Genetics, Sherbrooke Univ, Sherbrooke, Qc; 2) Dept of Obstetrics & Gynecology, CHUS, Sherbrooke, Qc; 3) Dept of Pathology, Ste justine hospital, Montreal, Qc, Canada.

High levels of integrated serum markers suggested an amniocentesis be performed in a 33 year old woman. The standard cytogenetic analysis of amniocytes showed a terminal long-arm deletion of chromosome 1. FISH performed on amniocytes, using chromosome 1 specific subtelomeric probes confirmed the distal deletion. The G-banding karyotypes of parents performed on lymphocytes were normal suggesting that the fetal monosomy 1q42-qter had occurred de novo. Hybridization of the same subtelomeric probes on interphasic nuclei from 1 milliliter of maternal peripheral blood enabled us to quantify the total number of fetal nucleated cells (FNCs) in maternal circulation (20 FNCs/mL). Following this diagnostic, a medical termination of pregnancy was decided at the 23rd week of gestation. The fetal autopsy showed dysmorphic findings represented by microretrognathia, hypertelorism, posterior cleft palate, widened and short neck, single transverse palmar crease on the left hand, agenesis of the right kidney and glomerulomegaly of left kidney. The examination of muscular tissues revealed an anisomorphism of cardiac and muscular striated fibers. The severe and extensive autolysis of cerebral tissues didnt allow an analysis of specific nervous structures. The analysis of fetal fibroblasts-DNA and parental blood-DNA by PCR using a panel of polymorphic microsatellite markers showed an allelic distribution with deleted markers localized in the chromosomal segment 1q42-1qter. The deleted markers (D1S2847, D1S103, D1S2709, D1S2800, D1S446, D1S235, D1S2785, D1S2811, D1S2682) were confirmed to be of paternal origin. Moreover, this analysis allowed us to exactly localize the breakpoints on chromosome 1q42.12 sub-band distal to the D1S479 marker. The combined clinical phenotype and cytogenetic features along with literature involving similar cases suggest a novel syndrome involving 1q42-qter and phenotypic features. Our study localizes the genetic defect to 1q42.12-qter and provides specific DNA markers for the syndrome.

Human experimental treatment: report of an ethical dilemma. *V. Muñoz, M. Raymundo, T.A. Vieira, L.L.C. Pinto, A.C.M. Azevedo, A.C.S. Puga, I.V. Schwartz, L. Kalakun, R. Giugliani* Medical Genetics Service and Bioethics Commitee, Hospital de Clínicas de Porto Alegre, Porto Alegre, RS, Brazil.

Medical Genetics Service of HCPA consulted Institutional Bioethics Committee (IBC), searching for an alternative for an adult male patient with attenuated mucopolysaccharidosis Type I (MPS I) and cord compression due to glycosaminoglican deposits. Clinical manifestation included important and progressive gait disturbance, difficulty holding objects, paresia and paresthesia on four limbs. After complete evaluation, laminectomy was recommended. Nevertheless, patient did not agree on blood transfusion (BT) in case of need, due to religious beliefs (Jeovah witness) and neurosurgery team did not agree with surgical procedure under such circumstances. Management, considering that BT authorization would be refused, became a main issue and options were discussed with genetics medical team and IBC. A recent experimental study, on canine model for MPS I, using enzyme replacement therapy (ERT) with laronidase through intra thecal (IT) approach, had presented positive results. Symptomatic cord compression was rapidly progressive on this patient and clinical complications that could result in permanent disabilities or even death could not be ruled out. In such conditions, IT ERT was considered the only existing option for this patient refusing any possibility of BT, in a compassionate manner. After literature review, IBC suggestion was of recommending a compassionate use of IT ERT only for this patient. The most striking peculiarity on this case was the fact that the patient is a Jeovah witness, refusing any chance of BT on one hand and, on the other, the fact that neurosurgery team would not submit the patient to a surgical procedure without a signed informed consent for BT in case of extreme need. From ethics point of view the main purpose was to offer the best option available considering religious beliefs freedom. Compassionate protocols need not to be submitted to Research Ethics Committees in Brazil, albeit this compassionate treatment was submitted to, and approved by, Institutional Research Ethics Committee. Patient underwent IT ERT protocol.

Increased power of within study adjustment of standardized quantitative phenotypes in family-based genetic association analysis. *M.G. Naylor[1], B. Raby[2], S.T. Weiss[2], C. Lange[1, 2]* 1) Department of Biostatistics, Harvard School of Public Health, Boston, Massachusetts, USA; 2) Channing Laboratory, Harvard Medical School, Boston, Massachusetts, USA.

Many genetic association studies of complex traits rely on standardized quantitative phenotypes. For instance, forced expiratory volume in one second (FEV1) is a measurement of lung function commonly used in asthma studies. Body Mass Index has also been used as phenotype data in genetic association studies (Herbert, 2006). Such standardized quantitative phenotypes are appealing because they provide a simple way of comparing people in terms of the trait of interest. However, they may not be the most accurate way to assess subjects within a study. In 2005, Naylor, et al. suggested that using the residuals of predicted FEV1 regressed on the relevant covariates within the study population rather than indirect adjustment using percent of predicted FEV1 is the most useful measurement of FEV1 for large scale asthma studies. Here we use the Childhood Asthma Management Program (CAMP) data to show that this method of assessing complex traits by comparing residuals after within study adjustment yields greater power in family-based association tests. Simulations in which FEV1 is generated by equations derived from the CAMP data by Naylor, et al. result in increased power for family-based association tests when FEV1 is adjusted using this method rather than using percent of predicted FEV1. Power is the same or better even in simulations where FEV1 is generated using standard prediction equations. An application of family-based association analysis of FEV1 and obesity on CAMP data illustrates that more meaningful associations are found when adjusted phenotype residuals are used as opposed to typical standardized quantitative phenotypes.

Characteration of chlorambucil induced chromosome deletions in mice using BAC array CGH. *W. Liu, WW. Cai*
Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza Room T936,Houston, TX. 77030.

Chlorambucil(CHL) is a biofunctional alkylating agent used in cancer chemotherapy. CHL has been reported to be a very efficient mutagen in mouse germ cells, causing primarily chromosomal deletion. We are reevaluating the CHL deletion efficiency in mouse germ cells under different dose conditions in an attempt to develop an efficient strategy for generating mapped mouse deletion mutant resources. We administered intraperitoneally to C57BL/6J and 129 males at a dosage of 0.75, 1.5, 3 or 6 mg/kg body weight. At the 3rd week after treatment, each 129 male was mated to two virgin C57BL/6J females and each C57BL/6J male was mated to two virgin 129 females. We then used 21,382 clone BAC whole genome tiling arrays to analyze chromosome deletions. Among 59 Mice, 29 deletions were detected and verified with PCR using polymorphic microsatellite markers in the respective regions. The size of deletions ranged from 640 kb to 36420kb. Until now, 4 deletions were found transmissible to the next generation. Thus far, we found no obvious phenotype in the heterozygous deletion mutants. We have bred 2 deletions to homozygosity and found no obvious phenotype. These results suggest that all the genes in these homozygous deletion regions are not essential for development.

Automated Identification of Rare Fetal Cells in Maternal Circulation. *M.W. Kilpatrick, T. Tafas, I. Ichetovkin, A. Seppo, Y. Kim, Y. Zhu, P. Tsipouras* Ikonisys Inc., New Haven, CT.

The presence of rare fetal cells in the maternal circulation is generally accepted but their number and the best approach for their enrichment remains unclear. Fetal cells can be indisputably identified through detection of Y FISH signals. We therefore developed an automated system to identify and enumerate cells bearing X and Y FISH signals. Ikonisys fastFISH is a fully robotic fluorescence microscopy platform. Target cells are screened at 10X magnification then verified at 100X. More than 4,000 optical fields per slide can be analysed. To minimize the false positive detection of XY cells, two independent Y-chromosome probes; one centromeric and one telomeric, were used. Putative fetal cells are identified at 10X magnification based on the presence of the X and telomeric-Y signals, and verified at 100X magnification based on the presence of a single X-signal and single signals for each of the Y-probes. Implementation of this approach produced a false positive rate for detection of XY nuclei below 0.00005%. Analysis of 26 maternal samples, 6 first trimester and 20 second trimester, identified fetal cells in 21 of the 23 samples from pregnancies with male fetuses. Samples were analysed both as whole blood, to determine a baseline for the number of detectable circulating fetal cells, and following simple density gradient centrifugation. For whole blood, analysis of a total of 103.4 million nuclei on 161 slides from pregnancies with male fetuses, identified 52 XY nuclei (0.5 XY nuclei per million, 0.3 per slide). Following simple density gradient enrichment, analysis of 64.7 million nuclei on 104 slides from pregnancies with male fetuses, identified 135 XY nuclei (2.1 XY nuclei per million, 1.3 per slide). A single XY nucleus was found in 13.3 million nuclei in samples from female fetus pregnancies. Use of embryonal globin specific antibody for initial identification of fetal cells in first trimester samples could allow analysis of both male and female fetus pregnancies. Our preliminary data suggests such an approach, integrating ICC and FISH, might facilitate non-invasive prenatal diagnosis of chromosomal aneuploidies.

Telomere length in the Amish: heritability and association with age and sex-specific parental effects. *O.T. Njajou[1], R.M. Cawthon[2], C.M. Damcott[3], S-H. Wu[1], S. Ott[3], E.H. Blackburn[1], A.R. Shuldiner[3], B.D. Mitchell[3], W-C. Hsueh[1]* 1) University of California, San Francisco, CA; 2) University of Utah, Salt Lake City, UT; 3) University of Maryland, Baltimore, MD.

Telomere length (TL) is a biomarker for aging and survival. Previous reports have indicated that TL is substantially heritable, and may be influenced through sex-chromosome effects. To further evaluate factors influencing this trait, we measured leukocyte TL in a large homogeneous Amish population. We estimated the heritability (h^2) of TL, and tested for the presence of parental effect on TL variation. Our sample included 954 healthy Amish who were connected within a 5-generation pedigree (378 men and 576 women, aged 18 - 100 yrs with a mean of 51 18 yrs). TL in leukocytes was measured by quantitative PCR (value range: 0.61 - 4.29 units, mean: 1.49 0.49). Information on parental lifespan was obtained from genealogical records maintained by the Amish community. The h^2 estimate of TL in this sample was 0.50 0.06 (p 0.001), after adjusting for age at blood draw, sex and plate batches. As expected, TL was negatively correlated with age (r = -0.40, p 0.001). There was no significant difference in TL between men and women, consistent with our previous findings that Amish men live just as long as Amish women. These findings are in contrast to other populations in which TL was reported to be longer in women than men, consistent with a longer lifespan in women than men. We also observed a positive correlation (r = 0.12, p = 0.06) and association (= 1.0, P = 0.04) between TL and paternal lifespan, but not with maternal lifespan (n = 276). Furthermore, there was a strong correlation between TL in the offspring and paternal TL (r = 0.46), which was even stronger between fathers and sons (r = 0.61) than between fathers and daughters (r = 0.36) (all p 0.001). We did not observe any correlation between TL in offspring and maternal TL. Our analyses were based on one of the largest samples for genetic studies of human TL. Our observations support a link between TL and paternal aging/lifespan, and provide motivation for efforts to map autosomal and sex-linked genetic determinants of TL variation.

High Density SNP Analysis of Ashkenazi Jews. *K. Offit[1], A. Olshen[1], B. Gold[2], J. Struewing[3], J. Satagopan[1], E. Eskin[4], T. Kirchhoff[1], J.A. Lautenberger[2], S. Stefanov[2], D. Goldgar[5], E. Friedman[6], L. Norton[1], N. Ellis[7], A. Viale[1], P. Borgen[1], K. Lohmueller[8], A. Clark[8], J. Boyd[1]* 1) Memorial Sloan-Kettering Cancer Center, NY; 2) Laboratory of Genomic Diversity, NCI; 3) Laboratory of Population Genetics, NCI; 4) University of California, San Diego; 5) University of Utah; 6) Sheba Medical Center, Israel; 7) University of Chicago; 8) Dept of Molecular Biology and Genetics, Cornell University, NY.

To analyze patterns of linkage disequilibrium (LD) in Ashkenazi Jews (AJ), we compared genotypes of 101 healthy New York AJ and 60 Utah CEPH (CEU) samples. 435,632 markers on the Early Access Version 3 (EAv3) 500k SNP array (Affymetrix) were matched to SNPs in the 500k genechip analysis of the CEU samples compiled by Affymetrix. Call rates were 98% for the CEU samples and 93-95% for the AJ samples. Screening out markers with <85% call rate, 379,401 SNPs were evaluable. The proportion of SNPs out of Hardy-Weinberg equilibrium (at $P < 0.05$, FET) was 5% in the CEU and 6-7% in the AJ set. A small but significant global difference in allele frequencies between AJ and CEU was demonstrated by a derived FST of 0.008 ($p<0.001$). Analysis of local LD decay revealed no global differences, but found some regions (e.g. HLA region on chromosome 6) with different decay rates by both D' and R^2 analysis. Haplotype blocks inferred from pairwise LD statistics (Haploview) as well as by EM haplotype phase inference (HAP) showed a greater number of haplotype blocks in the AJ; 41,913 in AJ vs 37,421 in CEU by Haploview, and 52,696 in AJ vs 49,996 in CEU by HAP. Haplotype blocks were smaller in AJ by both measures (e.g. average length 40,354 bp in AJ vs 42,899 bp in the CEU by HAP). These data would suggest that the LD structure of AJ may not provide any global advantage for whole-genome association mapping. On the other hand, a likelihood ratio approach showed that runs of homozygous SNPs were approximately 25% longer in AJ. These data support an emerging picture of the AJ that suggests lower measures of LD than expected by some measures, but also distinctive differences from northern European populations that remain to be fully resolved.

In silico analysis of histone deacetylases. *S. Khuri, G. Dimicco, L.J. Elsas* Center for Medical Genetics, University of Miami , Miami, FL.

Human histone deacetylases (HDACs) remove acetyl groups from histone tails and repress transcription. The 11 known HDACs differ in size, domain organization, and function. They are evolutionarily classified into four groups which do not correlate well with HDAC function nor regulation. HDACs have some tissue- and temporal- specificity, that have not been fully characterized, and little is known about the regulation of HDAC expression. We approached these problems using three in silico strategies. 1.Nucleosome positioning: HDAC promoter sequences were analyzed using the NXSensor software, which predicts nucleosome positioning, and which we had used to demonstrate a difference in nucleosome position between promoters of housekeeping genes and those of tissue-specific genes. The promoter sequence of HDAC4 is predicted to be free of nucleosomes, whereas that of HDAC9 can have several nucleosomes on it. This has important implications for the types of transcription factors that may regulate HDAC genes. 2.Transcription factor binding sites (TFBSs): TFBSs that are conserved (cTFBSs) between human, mouse and rat were collected from the UCSC Genome Browser. cTFBSs are more likely to be functional than the numerous sequence motifs detected by pattern recognition software. However, motif detection is useful for identifying unique TFBSs that may play a role in the tissue- or temporal- specificity of a gene; for this we used the AliBaba2 (TRANSFAC) program. The HDAC4 promoter has the highest number of potentially active TFBSs, but only one cTFBS. There were hardly any cTFBSs that were common among the HDACs. A number of unique TFBSs were found through motif detection, and these merit further investigation. 3.Alternative transcripts (AlTs): NCBIs AceView was data mined for records of HDAC AlTs, and we compared the transcripts against the functional domains of HDAC proteins. The majority of transcripts did not include enough of the catalytic domain to be functional as deacetylases, but they may have a regulatory role. In conclusion, there is a significant variation in the stringency of regulation among the 11 HDACs. Integrated bioinformatics analyses such as this are vital for future experimental analyses of human gene regulation.

***Tbx1*, a 22q11 deletion syndrome candidate gene, is a selector for myocardial cell fate specification in the secondary heart field.** *J. Liao, S. Nowotschin, B.E. Morrow* Department of Molecular Genetics, Albert Einstein College of Medicine, Bronx, NY.

Tbx1 is a member of the T-Box family of dosage sensitive transcription factors and implicated in the etiology of 22q11 deletion syndrome (22q11DS; velo-cardio-facial/DiGeorge syndrome). The 22q11DS patients and *Tbx1*-/- null mice have characteristic cardiac outflow tract (OFT) defects. Tbx1 in the secondary heart field (SHF), a cardiac progenitor population contributing to the anterior part of the heart, is required for OFT development. To determine the molecular pathogenesis of OFT defects, we performed Affymetrix gene expression profiling of the SHF in wildtype and *Tbx1*-/- embryos from E8.75 to E10.75. Surprisingly, except for *Nkx2-6* and *Hod*, two genes involved in myocardial differentiation, which were downregulated, most genes were upregulated in the SHF of *Tbx1*-/- embryos, suggesting Tbx1 may work as a transcriptional repressor. Expression changes of selected genes were validated by real-time RT-PCR and *in situ* hybridization. Among these genes, *Aldh1a2* (*Raldh2*), *Gata4* and *Tbx5* have been reported to play a role in the determination of anteroposterior patterning of the heart. More importantly, expression of cardiac atrial markers *Myh6* (*MHC*) and *Myl7* (*MLC2a*) were significantly increased in the SHF of the null mutants. However, ventricular markers, *Myh7* (*MHC*) and *Myl2* (*MLC2v*) were unchanged, indicating inhibition of the atrial-specific differentiation of SHF cells by Tbx1 is required for normal OFT development. This study shows that *Tbx1* is a selector gene for myocardial cell fate specification in the SHF. These genes we found here are good candidates for genetic modifiers for OFT defects in patients with 22q11DS.

Origin of IVS6-1g>t Allele in Fumarylacetoacetate Hydrolase Gene among Hispanic Patients with Tyrosinemia Type I. *J.-Y. Huang, D. Xu, C.R. Scott* Pediatrics Department, 359320, University of Washington, Seattle, WA.

Hereditary tyrosinemia type I (HT1) is an autosomal recessive disorder characterized by a deficiency in fumarylacetoacetate hydrolase (FAH) activity. At least over 40 different mutations within the FAH gene have been identified with several common mutations having specific geographical origins. IVS12+5g>a is the most common mutation in Northwestern Europe, whereas IVS6-1g>t occurs more frequently in Spain and other Mediterranean counties. We recently screened FAH gene mutations in forty-three U.S. HT1 patients and found at least one copy of IVS6-1g>t mutation in 7 out of 10 patients of Latin American ancestry. To determine whether the IVS6-1g>t allele in Hispanic patients was identical to its European counterpart, we performed single-nucleotide polymorphism (SNP) analysis. We genotyped a panel of 10 SNPs spanning over a 48 kb genomic region at the FAH locus in a total of 12 patients (7 of Hispanic, 4 of European, and one of unknown background) carrying at least one copy of IVS6-1g>t mutation and 12 normal controls of Hispanic ancestry. We found that the allele frequency of each SNP in the Hispanic HT1 patients is significantly different from that of the Hispanic controls due to strong linkage disequilibrium (LD). Pairwise LD analysis of the SNPs demonstrates complete linkage disequilibrium within this region in the patients. One common haplotype backbone projecting the single haplotype block can be defined using maximum likelihood algorithm for each patient. The three patients homozygous for IVS6-1g>t mutation (two Mexican, one European) are also homozygous for this common haplotype. This indicates that the IVS6-1g>t mutation co-segregates with the common SNP haplotype shared by each patient and is independent of their ethnic background. A total of three LD blocks are observed which is consistent with the LD data reported in the HapMap database. The data implies that the IVS6-1g>t mutation was most likely introduced into the Latin American population during the Spanish Conquest of the 16th century.

Cytoplasmic FANCC is not Required for a Normal Response to Interstrand Crosslink Damage. *A. Hemphill, L. Lucas, M. Al-Dhalimy, Y. Akkari, S. Olson, R. Moses* Dept Molecular & Medical Gen, Oregon Health & Science Univ, Portland, OR.

Fanconi anemia (FA) is a recessive disorder characterized by increased cellular sensitivity to interstrand crosslinking (ICL) agents. A core complex of FA proteins (A, B, C, E, F, G, L, M) forms in the nucleus following ICL damage, and is required for normal repair of ICLs. The complex acts to the modify FANCD2 by monoubiquitination. Patient-derived cells deficient in any of the FANC proteins show decreased survival after ICL damage and increased radial formation. Several FA proteins, including FANCC and FANCE, also exist in the cytoplasm of cells before and after DNA damage. We find that depletion of FANCC by siRNA results in loss of cytoplasmic FANCC, but not nuclear FANCC. The nuclear fraction persists for over 96 hours following siRNA transfection, whereas the cytoplasmic fraction is depleted in 24 hours, with recovery apparent at 72 hours. The nuclear fraction confers normal resistance to damage caused by ICLs, as measured by cell survival or radial formation. The persistence of the nuclear FANCC protein may be due to association with other specific FANC proteins. To test this, FANCE, which is known to complex directly with FANCC, was depleted. The depletion of FANCE leads to overall decreased stability of the FANCC protein, allowing nearly complete depletion of nuclear FANCC. We conclude that cytoplasmic FANCC is not required for a normal response to ICLs, and that nuclear complex formation is the basis of stability for nuclear FANCC protein.

First trimester nuchal translucency and maternal ethnicity. *T. Huang[1], C. Meier[1], K. Boucher[1], F. Wang[2], A.M. Summers[1]* 1) Genetics Prog, North York Hosp, Toronto, ON, Canada; 2) Health Surveillance, Alberta Health and Wellness, Edmonton, Alberta, Canada.

Nuchal translucency (NT) is a first trimester ultrasound marker used in the prenatal screening for Down syndrome. Recent studies suggested there were possible ethnic related variations in the measurement of NT. We conducted a study among women who had the Integrated Prenatal Screening (IPS) in North York General Hospital (NYGH) to assess the influence of maternal ethnicity on NT. Between 11/1999 and 8/2004, 27,365 non-diabetic women who had an unaffected singleton pregnancy were screened at NYGH - 15,804 Caucasian, 4,305 Chinese, 4,178 Asian, and 1,286 Black women. Chinese women were identified from the ethnicity category of Asian using a published Chinese surname list. NT was measured between 10 and 14 weeks of gestation and was expressed as multiple of median levels (MoM) of unaffected pregnancies at the same gestational age based on sonographer specific NT curves. The sonographer specific NT curves were established after the initial assessment of 50 NT images from each sonographer before they can enroll in the program and subject for ongoing review. During the study period, 173 sonographers were enrolled in the screening program. Since the NT curves were based on all screened women rather than Caucasian and the proportions of non-Caucasian women each sonographer screened varied substantially, an adjusted NT MoM (Observed NT MoM/sonograper specific median NT MoM for Caucasian) was calculated for this study to reset the median NT MoM for Caucasian to 1.0 MoM. Compared with the median NT MoM for Caucasian, the median NT MoM for Chinese is 4% higher, for other Asian is 1% higher and for Black is 2% lower (p0.05). The differences were similar across most of the weight groups and consistent during the gestational weeks when NT is measured. Although ethnic differences in NT were small, NT is an influential marker in risk estimation. Screening programs may choose whether to made adjustment based on local requirements and the ethnic composition of screening population. The results of this study also provided useful information for genetic counseling.

Prenatal testing and screening in Northern British Columbia: Question of access or personal preference? *J. Nuk[1], J. Atkinson[2], M. Pearson[1], K. Kelly[3], L. Arbour[1]* 1) UBC Medical Genetics, Children's and Women's Health Centre, Vancouver, BC; 2) IWK Health Centre, Halifax, NS; 3) University of Northern BC, Prince George, BC.

BACKGROUND Access to specialty services is challenged in rural and northern areas. As prenatal testing and screening options are often considered standard of care, access is an issue for women in rural and northern Canada. In BC, a discrepancy in the uptake of the triple marker screen (TMS) is seen between the more densely populated Vancouver Coastal Health Authority (69%) and the less densely populated Northern Health Authority (NHA) (20%). To determine if the discrepancy results from difficulty in accessing screening and follow-up services, or reflects informed personal choices, an exploratory survey was distributed in the NHA to pregnant and postpartum women. **STUDY DESIGN** Surveys were distributed at hospital registration and at prenatal and neonatal classes. The survey collected demographic information, explored health care practices and documented experiences and beliefs related to prenatal testing and screening, community beliefs and telemedicine. Quantitative and qualitative data were collected. The majority of questions were categorical and analyzed using the ^{2} statistic. Trends were noted as the proportion of women who chose each multiple choice option. **RESULTS** From a total of 92 respondents, over 75% were offered TMS with 36% electing to be tested. The most influential factors on decision making were understanding of the test and the amount and quality of information available. Most felt well informed of their options (p0.001). Of least importance were culture and ethnicity (p0.035) and the cost and inconvenience of travel for follow-up services. **CONCLUSIONS** Our results suggest the lower uptake of TMS in the NHA is primarily based on informed personal choices. Though considered inconvenient, women in this northern community did not indicate that access to follow-up services influenced their decisions. This exploration may have relevance for health care planners concerned with access to genetic services. Further research is underway exploring the same questions in a high uptake region.

A novel g.-1285C>T substitution in a conserved putative regulatory element of *PAX9* is associated with autosomal dominant molar hypodontia. *G.A. Mendoza[1], J.M. Gee[1,2], C. Gonzalez-Quevedo[1], K. Lee[3], J. Hartiala[1], S.M. Leal[3], H. Allayee[1], P.I. Patel[1,2,4]* 1) Institute for Genetic Medicine, University of Southern California, Los Angeles, CA; 2) School of Dentistry, University of Southern California, Los Angeles, CA; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Center for Craniofacial Molecular Biology, University of Southern California, Los Angeles, CA.

The transcription factor PAX9 plays a critical role in the switch of odontogenic potential from the epithelium to the mesenchyme during tooth development. Twelve mutations in the coding region of *PAX9* have been previously reported to cause non-syndromic autosomal dominant hypodontia. We ascertained a family of European American descent that segregated a non-syndromic autosomal dominant form of hypodontia involving primarily molar teeth. Three microsatellite markers, D14S1462, D14S1463, and D14S1464 located 39, 49 and 72 kb, respectively upstream of the *PAX9* gene and a SNP within exon 3 of *PAX9*, were tested for linkage. A maximum multipoint LOD score of 3.6 was obtained with all four markers demonstrating linkage between the disease locus and the marker loci within and flanking the *PAX9* gene. There were no recombination events identified between these markers and the disease locus, and all affected individuals shared the same marker haplotype. Every exon of the *PAX9* gene was sequenced twice and no mutation was found in the coding or 5- and 3- untranslated regions. A novel g.-1285C>T sequence variant within a multiple species conserved sequence element upstream of the *PAX9* promoter, was identified in all affected family members, but not in the unaffecteds or within 3088 control chromosomes (95% confidence interval 0 - 0.0012) of the same ethnic background. The impact of the variant on *PAX9* expression is being examined. We have previously shown that haploinsufficiency for PAX9 is the underlying basis for molar hypodontia. The present data in conjunction with these earlier findings suggests that the g.-1285C>T variant may be located within a putative regulatory element that causes reduced *PAX9* expression leading to the hypodontia phenotype in this family.

A new model for South American origins inferred from hierarchical modeling of mtDNA variation. *C. Lewis, J. Long* Dept. Human Genetics, U. of Michigan, Ann Arbor, MI.

Genetic diversity in native South Americans forms a complex pattern at continental and local levels. Western populations have higher diversity within groups and smaller genetic distances among groups when compared to eastern populations. From this pattern, it was proposed that a larger, more genetically diverse, founding population entered the West than the East. After the initial settlement, the West harbored a larger effective size with higher gene flow. Here, we question the pattern and interpretation of South American genetic diversity because regional diversity was previously inferred from diversity within local populations without considering the diversity among local populations within regions. This potentially biased the continental pattern by underestimating eastern diversity. We analyzed mtDNA sequences from positions 16040-16361 for 892 people which represent 27 populations from North (2), Central (3), and South America (22). A series of nested models were fit to diversity estimates within and between all pairs of local populations. Each model added a level of nesting to the previous model. We tested three hypotheses: i) that diversity is patterned into West and East regional populations ii) that there is more genetic diversity in the West iii) that a single source population is sufficient to explain the continental pattern of diversity. By considering the diversity within and between populations, we found that i) the diversity in the East is not reduced relative to diversity on the continent as a whole, ii) that the West possesses a subset of the diversity on the South American continent, and iii) that diversity in the South American populations is reduced relative to the total for North, Central and South America. These findings suggest that South America forms a single meta-population with only one regional cluster, the West. This leads us to propose a new scenario for the peopling of South America: The continent was peopled from a single source population that became subdivided; the western region was founded by one subpopulation, while many subpopulations characterized by frequent fissions and bottlenecks persist in the eastern region.

Mathematical Methods for Analysis of Protein Arrays. *A. Pirozhenko[1], B. Love[3], G. Michaud[4], K.P. Clancy[2]* 1) Bioinformatic Sciences, Invitrogen Corp, 1600 Faraday Ave, Carlsbad CA; 2) Bioinformatic Sciences, Invitrogen Corp, 7305 Executive Way, Frederick MD; 3) Corporate Research Laboratory, Invitrogen Corp, 7305 Executive Way, Frederick MD; 4) Microarray R&D Protometrix, Invitrogen Corp, 688 E. Main St. Branford CT.

Microarray technologies permit investigators to investigate genes of interest in a global fashion. Performing such experiments with protein arrays provides investigators with a much broader understanding of the function of their protein of interest than is possible with conventional technologies. The Protoarray chip provides more than 5000 biochemically active proteins as well as appropriate negative and positive controls. These arrays provide analysis support for a number of proteomics based methodologies, including the global profiling of kinase or other enzymatic activities; identification of protein-protein interactions (PPI) between arrayed proteins and a protein of interest, and; profiling of serum antisera for reactivity to the arrayed proteins. Although the Protoarray has several similarities to more conventional microarray strategies, the more complex biological nature of proteomics applications means that different statistical methods for array analysis have had to be devised and tested. For instance, Protoarrays may be probed using either fluorometric or radiometric labelled analyses, so different statistical approaches were utiliized to discern signal from array background. Z-scores, representing the deviation of the signal for a given protein feature from the mean of the signal of all other protein features were found to maximize signals while minimizing Type I and Type II errors. Serum profiling was best analysed using a combination of quantile normalization and M-statistics to maximize signal while reducing errors. Sharing and reproduction of protein array experiments will require the development of suitable standards for data analysis and exchange. Changes to the oligo microarray stadard, MIAME, will be necessary to manage the more complex analyses of protein arrays.

Power loss in structured populations. *Y.G. He[1], R.H. Jiang[1], G.E. Swan[1], L. Jin[2,3]* 1) Health Center, SRI International, Menlo Park, CA; 2) School of Life Sciences, Fudan University, Shanghai, China; 3) CAS-MPG Partner Institute for Computational Biology, Shanghai, China.

Large scale association study holds promise to disclose genetic mechanisms for complex traits. However, loss of statistic power was still not well known for population-based association study with population stratification. Further investigation in this power loss would help us to figure more powerful approach for association studies.
We generalized an existed genetic model, which was proposed by Devlin et al in 2001, to more common genetic scenarios. The generalized model provides us a powerful tool to look into the power loss in structured populations. Our result shows that correlation between disease prevalence and suspect allele frequency among subpopulations plays critical roles in power change of statistic in association study. While there is a negative correlation between them, statistic power will reduce with an increase in genetic divergence. The power loss would be very severe in structured populations with moderate genetic divergence, Fst0.001. The change could be more than 20% if prevalence was obviously different among subpopulations. Power loss became more serious to the suspect loci with lower relative risk or lower allele frequency. Parts of suspect loci could be undetectable, even with extremely large sample size. Due to severe bias in estimation for relative risk of suspect loci, genetic contribution from these loci would be difficult to be evaluated accurately. Statistic power will increase with enhance of genetic divergence when disease prevalence and suspect allele frequency is correlated positively among subpopulations. However, the improvement in power disappeared under circumstance where false positive rate was well controlled.
All of the results indicated that control for false negative result is as important as control for false positive result in population-based association study for complex trait.

Novel mutations in the *MFN2* gene causing familial and sporadic axonal Charcot-Marie-Tooth disease type 2 (CMT2). *M. Milani, D. Pareyson, V. Seveso, C. Gellera, F. Taroni* Division of Biochemistry and Genetics, IRCCS Istituto Neurologico Carlo Besta, Milan, Italy.

Axonal CMT (CMT2) is genetically highly heterogenous, with at least 14 loci and 10 genes identified thus far. Mutations in the gene encoding the mitochondrial protein mitofusin-2 (*MFN2*) have been shown to be responsible for autosomal dominant CMT2 type A2 (CMT2A2). The *MFN2* gene maps to chromosome 1p36.2 and encodes a 757-amino acid protein which is an essential component of mitochondrial fusion in mammalian cells. The CMT2A2 phenotype is largely indistinguishable from that of CMT2A1 (*KIF1B*), CMT2E (*NEFL*), and CMT2F (*HSPB1*). However, in a subset of CMT2A2 patients, pyramidal involvement and visual impairment have been reported. The disease exhibits reduced penetrance: studies in large families have shown that individuals with *MFN2* mutations may present no signs of disease even at the electrophysiological examination. We studied 99 unrelated CMT2 index patients, including 82 isolated cases and 17 familial cases. Nine heterozygous mutations (8 novel) were detected in 10 unrelated patients but in none of >200 control chromosomes. Mutations were found in 6/82 (7.3%) sporadic cases and in 4/17 (23.5%) familial cases. Similar to previous reports, the majority (7/9) of the mutations cause an amino acid change. Two mutations were unusual: a frameshift mutation predicted to cause an early truncation of the protein and a synonymous mutation predicted to abolish an exon splicing enhancer (ESE). Onset in infancy was reported in 3 cases (1 sporadic and 2 familial). Pyramidal involvement was present in 2 cases. Optic atrophy was observed in 2 cases. In one family, CMT2 was associated with tremor. In conclusion, our results indicate that: 1) *MFN2* mutations are not rare causes of axonal CMT; 2) genetic testing for CMT2 should begin from the *MFN2* gene; and 3) *MFN2* mutation analysis should be performed in both familial and sporadic cases. Familial Translocation with Partial trisomy 21 and Partial trisomy 18, manifesteing as ADHD. *C. Trujillo[1], N.M. Erfan[2], S.B. El Badawi[3], A. Hasanat[1]* 1) Genetics Unit, Dr. Erfan & Bagedo Hospital, Jeddah, Saudi Arabia; 2) Jeddah Child and Adolescent Psychiatric Services, Jeddah; 3) Laboratory Department, Dr. Erfan & Bagedo Hospital, Jeddah, Saudi Arabia.

We report a case of a partial trisomy 21 and partial trisomy 18, in a 5 year old boy, referred to us with the clinical diagnosis of Atention Deficit Hyperactive Disorder (ADHD). The patient does not have mental retardation, with IQ in the normal range; initially presented speech and language delay, but now is normal. He had no major malformations, but have mild dysmorphic features.

G and R banding, coupled with FISH using probes WCP 21, WCP 18 and TelVysion 21q (Vysis), revealed a karyotype 47,XY,der(21),t(18;21)(18q22qter::21q2121pter). His mother and aunt had a balanced translocation 46,XX,t(18;21)(q22;q21)that was absent in all other family members. The aunt had 4 previous miscarriages but cytogenetic analysis was only performed as a consequence of proband findings.

The extra derivate chromosome of the proband is clearly missing the DSCR (Down Syndrome Critical Region) located between 21q22.1 to 21q22.3 explaining the absence of phenotypic features of Down Syndrome.

Major features of trisomy 18, such as congenital heart disease, early death, and external malformations, appear to be consistently related to the trisomic state of 18q12 to 18q21 but, in this case, partial trisomy 18 starts at 18q22, which may explain the mild phenotype.

Our results seems to confirm previous findings, that the smallest extra region causing serious anomalies of trisomy 18 appears to be 18q12.1-q12.2 segment being the "critical" zone.

The mild manifestations of our patient are probably due to the absence of critical regions on translocated segments of the 21 and 18 chromosome.

The genes associated so far with ADHD lie outside chromosome 21 and 18. We suggested that a third copy of a gene or genes in 18q22qter::21q2121pter regions, may be associated with ADHD.

Simvastatin lowers plasma 24S-hydroxycholesterol in Smith-Lemli-Opitz syndrome. *L.S. Merkens[1], J. Jordan[2], J. Penfield[1], D. Lutjohann[3], K. von Bergmann[3], W.E. Connor[2], R.D. Steiner[1,4]* 1) Dept Pediatrics, Oregon Health & Science Univ (OHSU), Portland, OR; 2) Dept Medicine, OHSU, Portland, OR; 3) Dept Clin Pharm Rheinische Fredrick-Wilhelms, Univ Bonn, Bonn, Germany; 4) Dept Mol & Med Genetics, OHSU, Portland, OR.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive disorder caused by a defect of the enzyme in the final step of cholesterol (CH) synthesis. Mental retardation is a nearly universal feature. CH deficiency and accumulation of potentially toxic CH precursors such as 7- and 8-dehydrocholesterol (7- and 8-DHC) may be causative. One treatment objective of SLOS is to raise CH concentrations and lower 7- and 8-DHC. Dietary CH is widely used a potential treatment, but it does not cross the blood brain barrier (BBB), so it is unlikely to impact neurological development in affected children. Statins, inhibitors of a key regulatory enzyme of CH synthesis (HMG CoA reductase), have been shown to reduce plasma and cerebral spinal fluid 7- and 8-DHC in SLOS. Lipophyllic statins, like simvastatin (simv), cross the BBB and may be effective in reducing 7- and 8-DHC in the brain. 24S-hydroxcholesterol (24S) is formed from CH in the brain, and it is able to cross the BBB. Almost all of the 24S in plasma originates from the brain and is therefore a marker of brain CH turnover. We investigated the effect of simv on brain CH turnover as measured by plasma 24S in children with SLOS. Most of the children without simv treatment consumed a high CH diet (n=18,samples=27), a few were on a low CH diet (n=6,samples=6). All of the children receiving simv (0.2 to 0.5 mg/kg/d) consumed a high CH diet (n=5,samples=16). We measured plasma CH by GC and plasma 24S by GCMS. Plasma 24S was corrected for CH (g/mg) and analyzed on the natural logarithmic scale by multiple linear regression. Simv was estimated to lower 24S relative to CH by approximately 25%(P0.001). The decreased plasma 24S in response to simv may reflect decreased CH turnover and flux through the CH synthetic pathway in the brain. This could have a beneficial clinical effect by reducing brain 7-and 8-DHC.

The Prdm8 transcription factor is essential for the development of rod bipolar cells in the mammalian retina. *C. Jung*[1,2], *R.R. McInnes*[1,2] 1) Prog. in Developmental Biology, Hosp. for Sick Children; 2) Dept. of Molecular & Medical Genetics, Univ. of Toronto, Toronto, ON, Canada.

In mammals, disruptions of over 25 retinal transcription factor genes are associated with developmental eye defects or retinal degeneration. In a screen for retinal developmental regulators, we identified PRDM8 as a zinc finger putative transcription factor likely to be important for retinal formation, since at least 5 of the 17 predicted mammalian PRDM proteins are essential regulators of cell fate or maintenance. *Prdm8* mRNA is expressed broadly in the developing nervous system. In adults, expression is most prominent in hippocampus, cerebellum and retina; retinal Prdm8 protein is most abundant in the interneurons of the inner nuclear layer (INL) and in ganglion cells, with lower expression in photoreceptors. To define the roles of *Prdm8* in the developing and mature brain, we generated a mouse *Prdm8* protein null allele, replacing part of the ORF with an *eGFPnls* (nuclear localized eGFP) knock-in. Homozygous *Prdm8* null mutants are viable and express eGFP in retina, hippocampus and cerebellum. *Prdm8* null retinas have specific morphological defects: there is striking INL hypocellularity, with a complete absence of rod bipolar cells, while cone bipolar cells and other major retinal cell types appear normal. The regions of interneuron synaptic contacts are abnormal: the inner plexiform layer is thin, and the outer plexiform layer is disorganized. *Prdm8* null mice also groom excessively, leading to skin lesions in the groin and chest in 80% of outbred *Prdm8* null mice, with 20% displaying no increased grooming. We conclude that i) *Prdm8* is critical for the formation or maintenance of rod bipolar cells, a major class of retinal interneurons; ii) the loss of *Prdm8* function is associated with an unusual and specific behavioural phenotype that is influenced by the genetic background; iii) given the strong conservation of the Prdm8 protein sequence (90%) and of rod bipolar cell function between human and mouse, *PRDM8* (chr. 4q21) is a candidate gene for congenital stationary night blindness, a condition associated with disordered rod signaling in humans.

Rare missense polymorphisms: the good, the bad and the ugly. *G.V. Kryukov, S.R. Sunyaev* Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, MA.

Several recent reports showed that common complex phenotypes can be caused by multiple rare non-synonymous variants, and proposed association studies based on complete re-sequencing of candidate genes. In a study of this design, a cumulative frequency of rare deleterious mutations in a candidate gene, rather than individual SNPs frequencies, is compared between disease and control cohorts. The success of such approach critically depends on the proportion of deleterious mutations among all detected missense polymorphisms and on our ability to distinguish deleterious amino acid substitutions from neutral ones. If the majority of amino acid substituions detected in the study are neutral, then, the power of the method will be low because of the low signal to noise ratio.

It is not known what fraction of missense substitutions among *de novo* mutations and polymorphisms are strongly detrimental, mildly deleterious or effectively neutral. We estimated these values by comparing expected and observed numbers of nonsense, missense and synonymous changes among disease mutations, human SNPs identified by systematic re-sequencing projects and substitutions fixed in the human lineage after divergence from chimpanzee. As expected, fraction of deleterious mutations among common polymorphism was extremely low. However, despite commonly held belief that even among rare missense SNPs most are effectively neutral, our results indicate that the majority of human missense polymorphisms with detected frequency below 1% are, in fact, deleterious. This suggests that allele frequency alone can serve as a strong predictor of functional significance of missense polymorphic variants. We estimated that, on average, each human genome has approximately 600 deleterious missense SNPs associated with selection coefficients in the range of 10^{-2}-10^{-3}.

Our results suggest that association studies aimed to detect enrichment in rare non-synonymous variants might be efficient tool to study genetics of complex diseases and our work serves as a theoretical foundation for this approach.

Individualized Bayesian updating of genetic risk prediction models. *E. Iversen[1], Y. Tao[2], G. Parmigiani[3]* 1) Dept Biostatistics & Bioinformatics, Duke University; 2) Dept Biostatistics, Johns Hopkins University; 3) The Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins University.

Individuals at high familial risk of disease are frequently counseled on basis of predictions from a genetic model for the suspected syndrome. For example, an individual with a family history of breast cancer may be given BRCA1/2 mutation carrier probability estimates from a prediction model that makes a specific set of assumptions about the genetic model and related parameters that describe the syndrome. Given the inherent difficulty in characterizing allelic and other sources of family-specific heterogeneity in penetrance, the assumed penetrance models tend to characterize a typical mutation carrier.
We describe modifications to standard genetic models to address familial heterogeneity in penetrance of a disease gene or family of disease genes. The approach uses Bayesian model averaging, a technique that incorporates uncertainty in parameters of the genetic model and, to the extent possible, learning of family--specific values of those parameters. Bayesian model averaging has been shown to improve predictions over assuming a fixed model; we show that this result applies to carrier probability and disease risk prediction. We review Bayesian model averaging and what is necessary to adapt genetic models for family data to the approach and describe a method for updating model weights and making weighted predictions in light of family data. We restrict the collection of possible models to a discrete set with each representing a distinct penetrance scenario and describe an approach for estimating its members given a training dataset of family data on individuals genotyped at the gene(s) involved. We report on an analysis of family data from a multi-center study of familial breast and ovarian cancer. The data set includes results of genetic assays at BRCA1 and BRCA2 and detailed family histories. Using this data, we demonstrate that a typical family history collected in a high risk clinic carries enough information to tailor the genetic model to the individual's family history and that this approach results in more accurate predictions.

Methylation-dependent fragment separation: Direct detection of DNA-methylation by capillary electrophoresis of PCR products from bisulfite-converted genomic DNA. *A.E. Karger[1], B. Finkelnburg[2], A. Rico[3], K.I. Moody[1], K.J. Livak[1], G. Zon[1], V.L. Boyd[1]* 1) Applied Biosystems, MB-Genetic Analysis R&D, Foster City, CA; 2) Applera Deutschland GmbH, Darmstadt, Germany; 3) Applera France S.A., Courtaboeuf Cedex, France.

We report a novel method for methylation detection by denaturing capillary electrophoresis (CE) using standard fragment analysis conditions. Bisulfite treatment of gDNA will selectively deaminate C but not 5-methylcytosine (5mC). Amplicons generated from bisulfite-converted gDNA are analyzed immediately after PCR using a 6-carboxy fluorescein (6-FAM) dye-labeled primer. The amplicons from methylated and unmethylated gDNA separate based solely on base composition due to the presence of multiple C versus thymine (T) differences. By direct detection of PCR amplicons following PCR using primers that anneal independent of methylation status, the overall workflow from gDNA sample input to data analysis is relatively simple. Furthermore, the same PCR product is suitable for additional analyses such as direct sequencing, cloning and sequencing, single-base extension, and post-PCR incorporation of a modified dCTP, the latter of which allows resolution of amplicons with as little as a single C/T difference. We show the utility of this novel CE detection assay by analyzing the hypermethylated region of the fragile-X FMR1 locus.

A comprehensive analysis of LRRK2 gene in patients with Parkinsons disease (PD). *Y. Liu, K.M. Bond, G. Mayhew, J. Gibson, D. Daniel, M. Noureddine, M.A. Hauser, J.M. Vance* Center for Human Genetics, Duke University Medical Center, Durham, NC.

Genetic studies of PD have contributed significantly to our understanding of the pathogenesis of neurodegeneration. Leucine-rich repeat kinase 2 (LRRK2) gene has been identified as a cause of the late-onset PD. Due to the size of LRRK2 gene, most studies have only investigated a few primary exons. However, through our ongoing autopsy program for PD, we were able to sequence the cDNA of LRRK2 (NM_198578) from 35 brain autopsy samples with Parkinsonism, identifying 18 coding variants. Two variants were novel, but led to synonymous changes. Eight non-synonymous SNPs were previously reported, but in small studies that precluded a determination whether they were mutations or polymorphisms. Therefore, we genotyped these and the one novel SNP in 760 PD families to determine their frequency. Preliminary results demonstrate that at least seven are in fact polymorphisms, with two still in progress. As LRRK2 becomes increasingly screened, it is important to test all variations in large, well characterized populations to determine their value in diagnosis of PD.

Initial results from a Phase II clinical trial of migalastat hydrochloride in patients with Fabry disease. *P. Huertas[1], R. Schiffmann[2], G. Pastores[3], W. Wilcox[4], D. Palling[1], B. Wustman[1]* 1) Amicus Therapeutics, Cranbury, NJ; 2) National Inst. of Neurological Disorders and Stroke, Bethesda, MD; 3) NYU School of Medicine, New York, NY; 4) Cedars-Sinai Medical Center, Los Angeles, CA.

We report initial results from a Phase II clinical trial of migalastat hydrochloride (Amigal; Amicus Therapeutics, Inc.) in patients with Fabry disease. The trial is designed to enroll Fabry patients with a missense mutation, greater than 3% residual -galactosidase A (-GAL) activity, and an in-vitro increase of -GAL activity in lymphocytes treated with migalastat hydrochloride of more than 20%. Patients enrolled in the trial receive migalastat hydrochloride 25 mg PO BID, 100 mg PO BID and 250 mg PO BID in an ascending fashion every two weeks, followed by an additional 6 weeks of 25 mg PO BID. At the beginning of the trial and during each escalation, safety parameters, -GAL activity in white cells, globotriaosylceramide (GL-3) in plasma and urine, and migalastat hydrochloride pharmacokinetics are determined. Additionally, at the beginning of the trial and at the conclusion of 12 weeks of treatment, a skin biopsy is collected for analysis of -GAL activity, GL-3 levels, EM scoring of lysosomal inclusions, and IHC determination of -GAL and GL-3 localization. The initial data from the first four patients enrolled in the trial showed that migalastat hydrochloride was well-tolerated with no reported serious adverse events, and that the -GAL enzyme activity in patient white blood cells after six weeks of treatment was on average more than five-fold higher than before treatment. After 12 weeks of treatment, enzyme activity in skin was increased in two out of two patients with assessable biopsies. GL-3 levels in patient plasma, urine and skin were in the normal range of healthy individuals both before and after 12 weeks of treatment. Migalastat hydrochloride belongs to a new class of drugs known as pharmacological chaperones, which selectively bind to a target protein, increasing stability and trafficking to the proper location, thereby increasing activity and improving biological function. We will present an update on all available interim data from our ongoing Phase II clinical trials.

Sodium phenylbutyrate decreases steady-state plasma concentration of branched-chain amino acids without altering their appearance rate or protein turnover as measured by stable isotope tracers in healthy human subjects. *B. Lanpher[1], J. Marini[2,3], F. Scaglia[1], S. Carter[1], P.J. Garlick[2], F. Jahoor[3], B. Lee[1,4]* 1) Baylor College of Medicine, Houston, TX; 2) University of Illinois at Urbana-Champaign; 3) Children's Nutrition Research Center, Houston, TX; 4) Howard Hughes Medical Insitute.

Sodium phenylbutyrate (Buphenyl) is used commonly in the pharmacologic management of urea cycle disorders. The primary active metabolite, phenylacetate, conjugates glutamine to form phenylacetylglutamine which is readily excreted in the urine. We have observed that patients taking sodium phenylbutyrate have decreased circulating levels of branched chain amino acids. To examine this further, 7 healthy controls were studied using a multiple primed-constant infusion of stable-isotope tracers at baseline and after 2 days of sodium phenylbutyrate treatment. In each case, after two days of dietary stabilization (0.6 g protein/kg/day), infusions were conducted over 10 hours. Blood, urine, and breath samples were collected just prior to and during the infusions. Urea synthesis decreased by 247 mol/kg/hr($p<0.05$) in treated subjects, while glutamine flux increased by 409 mol/kg/hr($p<0.05$). Also, BCAA levels decreased in subjects on phenylbutyrate. Fasting leucine levels dropped from 10633 to 6418 mol/L($p<0.01$). Isoleucine dropped from 549 to 3310 mol/L($p<0.01$). Valine dropped from 20424 to 13932 mol/L($p<0.01$). There were no significant changes in the concentration of other amino acids, including threonine, serine, methionine, phenylalanine, and lysine. There was no change in the appearance rate of leucine (104.94 mol/kg/hr at baseline, 110.021 mol/kg/hr on treatment, $p=0.53$). There was no change in whole-body protein oxidation as measured by leucine oxidation($p=0.27$). Hence, at this level of protein intake in control subjects, sodium phenybutyrate achieves its desired effect on urea synthesis, while the decrease in BCAA does not appear to adversely affect total body protein catabolism. An important question will be whether this will similarly hold true in UCD patients who may have less capacity for adaptation to a nitrogen load.

Human neocentromere formation at a large variable-copy number tandem array in 8q21. *D. Hasson[1], A.L. Alonso[1], F. Cheung[1], J.H. Tepperberg[2], P.R. Papenhausen[2], J.J. Engelen[3], P.E. Warburton[1]* 1) Human Genetics, Mount Sinai School of Medicine, NYC, NY; 2) Laboratory Corporation of America, Research Triangle Park NC; 3) Clinical Genetics, Academic Hospital, Maastricht, the Netherlands.

Neocentromeres are variant centromeres that have arisen epigenetically in ectopic chromosomal locations. Neocentromere are devoid of alpha satellite DNA found at endogenous centromeres, and therefore permit analysis of the underlying DNA and chromatin structure important for centromere formation and function. We have investigated two independent neocentromeres from band 8q21, 1) a neodicentric chromosome 8 with an 8q21 neocentromere and an inactivated endogenous centromere and 2) an ~10Mbp neocentric ring chromosome largely derived from band 8q21. We have used FISH with ordered BACs from 8q21/q22 to localize the constriction on the neodicentric chromosome to an ~5Mbp region and CENP-C immunofluorescence to localize the kinetochore to ~1Mbp within this constriction. At the proximal edge of the CENP-C domain, the human genome sequence (hg18) showed a large tandem array, consisting of ~6 copies of a 12kb repeat which spanned an 87kb unbridged gap. Each repeat contains an mRNA that includes the Gor1 RNA exonuclease-like gene and an L1PA5 line element. Arrays were sized by pulsed field gel electrophoresis of genomic DNA digested with restriction enzymes that do not cut within the repeat unit. 13 independent arrays, from both the neocentromere lines and two families, ranged in size from ~700kb to ~1500kb (mean = ~950kb). Thus, this gap contains ~60 to ~125 additional copies of the 12kb repeat units in a large variable copy tandem repeat and represents a significant portion of genomic DNA. The arrays in the neocentromere lines were among the smallest observed (~700 to ~900kb), but similar sized arrays were also seen in non-neocentric lines. The neocentric ring chromosome contains an intact array with the 8q21 breakpoint mapping just a few kb proximal to it. We are investigating the hypothesis that these tandem arrays may provide good substrates for cis-transcribed RNA-based heterochromatin and neocentromere formation, analogous to alpha satellite DNA at endogenous centromeres.

Common leukemia-associated genetic alterations are present in healthy individuals: Silent micro-mosaicism or latent predisposition? *D. Mercer*[1], *M.M. Li*[1, 2] 1) Human Genetics Program,; 2) Dept Pediatrics, Tulane Univ Medical Sch, New Orleans, LA.

Leukemia-associated genetic alterations, such as the t(9;22) BCR/ABL fusion gene in CML and ALL, play important roles in leukemogenesis. However, recent studies have indicated that some leukemia-associated genetic alterations may present in up to 100% of healthy individuals when evaluated with nested RT-PCR. To further delineate these genetic alterations in healthy individuals and their significances, we studied MLL partial tandem duplications (PTDs) in 44 healthy individuals aged from newborn to 55 years old and BCR/ABL p190, BCR/ABL p210, AML1/ETO, and MLL/AF4 in 22 healthy individuals aged from newborn to 27 years old. Among the 44 individuals studied for MLL PTD, 24 showed positive (55%). Sequencing studies demonstrated that the MLL PTD is characterized by an in-frame repetition of MLL exons in a 5 to 3 direction. The most common duplication was PTD e9/e3, followed by e11/e3. Other duplications observed were e9/e4, e10/e3, and e10/e4. The MLL PTDs were also detected in genomic DNA samples. Among the 22 patients studied for BCR/ABL p190, BCR/ABL p210, AML1/ETO, and MLL/AF4, 13 were positive for BCR/ABL p190 (59%), 20 positive for BCR/ABL p210 (91%), 6 positive for MLL/AF4(27%), and none positive for AML1/ETO. These data demonstrated that many leukemia-associated genetic alterations are commonly present in healthy individuals. Since the frequency of healthy carriers is a few magnitudes higher than the incidence of the diseases, most healthy carriers will never suffer from the leukemia corresponding to their mutation, maintaining their silent micro-mosaic status for life. However, previous studies did show that some leukemia-associated fusion genes were detected in neonatal blood spots of children who developed related leukemia with more than 10 years latency, indicating a higher risk in at least some positive individuals. Carefully designed long term follow-up studies of positive individuals may help to determine criteria for subgroups that may be at a higher risk and to identify genetic or environmental factors that may promote malignant transformations.

Array-CGH analysis of cell-free fetal DNA in amniotic fluid detects human aneuploidies. *K.L. Johnson[1], O. Lapaire[2], X.Y. Lu[3], H. Stroh[1], J.M. Cowan[1], U. Tantravahi[4], D.W. Bianchi[1]* 1) Division of Genetics, Department of Pediatrics, Tufts-New England Medical Center, Boston, MA; 2) University Womens Hospital, University of Basel, Switzerland; 3) Spectral Genomics, Inc., Houston, TX; 4) Department of Pathology, Women and Infants Hospital, Providence, RI.

Background. Previously we showed that comparative genomic hybridization (CGH) analysis of cell-free fetal (cff) DNA isolated from amniotic fluid (AF) allows for prenatal molecular karyotyping and fetal gender identification (Am J Hum Genet 75:485-91). Subsequent technical advances have increased the yield of extracted cffDNA to permit CGH analysis of 10 mL of AF (Clin Chem 52:156-7). Here we aimed to determine whether a variety of fetal aneuploidies can be identified thorough the analysis of cffDNA from AF by array-CGH.

Methods. CffDNA was extracted from 10 mL of residual AF supernatant using AVL buffer and maxi columns (Qiagen, Valencia, CA). In all cases, test cffDNA and reference DNA were labeled with different fluorescent dyes and applied to Spectral Constitutional Chip 2.0. The following fetal abnormalities were analyzed: trisomies 13 (n=1), 18 (n=3) and 21 (n=2), as well as cases of mosaicism (47,XX,+9[18]/46,XX[2]) and triploidy (69,XXY).

Results. CffDNA isolated from aneuploid fetuses showed increased hybridization signals on the majority of the affected chromosome markers compared to euploid reference DNA. Aneuploid fetuses were correctly identified in all cases.

Conclusions. These results indicate that cffDNA extracted from 10 mL can be analyzed using array-CGH to correctly identify human autosomal and sex chromosome aneuploidies. In conjunction with previous work, we show that this technology allows for rapid screening of AF samples for whole chromosomal changes without interfering with current standard of care and may augment standard karyotyping techniques by providing additional molecular information.

Tumor marker in the serum proteins of Xiphophorus. *A.I. Islam* Ophthalmology, MEEI, Harvard Medical School, Boston, MA.

Xiphophorus serum proteins were investigated for the establishment of tumor marker in human being. Serum proteins of tumor free and tumor bearing Xiphophorus were conducted in 5% native-PAAG (Polyacrylamide Gel Electrophoresis). Serum proteins of tumor free (Xtf) and tumor bearing (Xtb) Xiphophorus were compared. Both of the strains have 48 chromosomes with similar genetic backgrounds. There have revealed polymorphism in the serum proteins of normal (Xtf) and tumor effected (Xtb) animals. Albumin peaks (molecular wt. - 65 kDa) of tumor free species have high peaks and concentration than Xtb. Lipoproteids peaks (molecular wt. - 24-25 kDa) were more or less similar in patterns in both of the strains. Transferrin peaks and globulin spectra were declining in tumor bearing Xiphophorus. Acute Xtb bear low peaks and contents of lipoproteids than the Xtf fish. Globulin and albumin spectra were more distinct in Xtf than tumor bearing offspring. The quantity of albumin patterns changes in relation to the globulin patterns. Globulin peaks were depressed in the normal and more declining in the acute and tumor-bearing melanoma formed baby Xiphophorus. The tumor free species have the up-rising peaks of globulin and transferrin spectra in comparison to Xtb. From the different patterns of serum proteins, different polymorphic structures were revealed in both Xtf and Xtb strains. This could be an ideal marker for human cancer research.

Restricted DNA Copy Number Variation in CNS Versus Lymphocyte Derived DNA. *R.A. Holt*[1,2], *G. Turecki*[3], *G.M. Wilson*[2] 1) Department of Psychiatry, University of British Columbia, Vancouver, British Columbia (BC), Canada; 2) Canada's Michael Smith Genome Sciences Centre, BC Cancer Agency, Vancouver, BC, Canada; 3) McGill Group for Suicide Studies, Douglas Hospital, McGill University, Montreal, Quebec, Canada.

DNA copy number differences are now recognized as an important source of genetic variation, and have been implicated in both mendelian and complex genetic disorders. However, the extent of somatic copy number variation remains unexplored. In the present study we used Quantitative Real Time PCR (Taqman, ABI) to screen a small cohort of 16 subjects (8 suicide, 8 control) for copy number differences. DNA was derived from both post mortem brain tissue (Brodmans Area 10) and peripheral blood lymphocyte (PBL) from each subject. We interrogated three genes involved in glutamate transmission in the CNS that had previously demonstrated DNA copy number aberrations in post mortem brain; GRIK3, AKAP5, and CACNG2. DNA copy number aberrations were observed at all three loci in the present study, with mean copy number variation significantly restricted in brain derived DNA relative to lymphocyte DNA (GRIK3, P=0.001; AKAP5, P=0.002; CACNG2, P=0.0001 (two-tail, paired t-test, n=16)). No significant difference was observed between diagnostic groups (suicide versus control). Observations at these three loci suggest that copy number variants may be less common in post mitotic cells (e.g. CNS) where fewer cell divisions means fewer chances for an aberration to arise. Further, genes with important roles in a given tissue (e.g. glutamate transmission in the CNS) may have restricted copy number variation due to functional constraint. We are currently estimating the genome-wide copy number variation in these same samples using microarray methods.

Cytochrome P450 CYP3A4 expression as a diagnostic biomarker in breast cancer. *D. McDaniel[1], A. Lewis[1], C. Berry[1], W. Barber[1], P. Smith[2], S. Bigler[3]* 1) Dept Surgery/Neurology, Univ Mississippi Medical Ctr, Jackson, MS; 2) Medicine; 3) Pathology.

This study is to identify variants of the Cytochrome P450 (CYP) 3A4 gene that might be used as diagnostic biomarkers in studies of breast cancer susceptibility. CYP3A4 plays an important role in cell regulation via its involvement in the metabolism of a wide variety of endogenous metabolites active in cellular signaling. Biochemical pathways involved in hormone metabolism have been implicated in the etiology of breast cancer and the CYP 3A enzymes are involved in such metabolisms. To date biopsy results are the most useful means of determination of clinical outcome of breast cancer. There is an urgent need for identification of patients who will benefit from early diagnosis and less aggressive postoperative therapy. Multiple SNPs have been identified in the regulatory region of the CYP 3A4 gene that has been associated with disease conditions. We sought to determine the frequency distribution of the CYP3A4 variant and its effect on gene expression in breast cancer. Clinical conditions including tumor stage, receptor status, previous breast cancer and family history were evaluated for genotype and phenotype association. The homozygous AA allele was present with higher frequency (71.0%) in Caucasian (Cau) group as compared with African American (Af Am) (29%) patients and controls (15%). Homozygous GG alleles were absence in Cau patients and the frequency was increased 4.8-fold in cancer patients as compared with controls ($p<0.05$). A vs. G genotypes were inversely associated with tumor staging in Af Am patients. Patients with stage 0 tumors 50% carry the AA alleles as compared with 33% in stage II, whereas patients with stage III and IV, 67 to 100% carry AG or GG alleles. Expression levels of CYP 3A4 transcript was higher in PBMCs of patients with benign tumors as compared with malignant tumors ($p<0.03$). In summary, Af Am patients with homozygous CYP3A4 GG genotype were at higher risk of developing cancer as compared with Cau and controls. In addition, expression levels of CYP3A4 gene may have implications for both the development and the therapy of breast cancer.

Copy Number Variation Analysis on the HapMap DNA Samples Using TaqMan Assays for CYP2D6, CYP2E1, CYP2A6, GSTM1 and GSTT1. *K. Li[1], K.A. Haque[2], R.A. Welch[2], K. Lazaruk[1]* 1) Applied Biosystems, Foster City, CA; 2) SAIC-Frederick Core Genotyping Facility (CGF), NCI/Advanced Technology Center, Bethesda, MD.

Gene copy number variation is now recognized as an important type of polymorphism in the human genome. Gene duplication/deletion can have a significant impact on phenotype. Copy number polymorphisms have been associated with genetic diseases such as cancer, immunological and neurological disorders, and also associated with variations in drug response as previously demonstrated. Measuring copy number variation in these genes is an important complement to genotyping for two reasons. First, falsely assuming diploidy can lead to inaccuracy in determining the genotype. Second, copy number can interact with genotype to influence phenotype of a variant. The availability of robust and validated genotyping and copy number variation assays allows for full characterization and understanding of genotypes of the genes of interest. Accurate detection of copy number changes is critical for understanding how gene copy number variation plays a role in disease or drug response. Here we report the development of an application using real-time PCR assays to quantify gene copy number and the results of copy number for 5 important drug metabolism genes (CYP2D6, CYP2E1, CYP2A6, GSTM1 and GSTT1) using DNA samples from the International HapMap Project. The gene copy number data is useful in understanding the SNP genotype data from the HapMap samples. For example, our copy number analysis showed high percentage of individuals from the HapMap panel had the null allele(s) for GSTM1 and GSTT1 genes. These observations suggest why many of the SNPs in GSTM1 and GSTT1 SNPs failed QC (were qc-) as reported by the HapMap Project, as they failed due to a low pass rate <80%, a low Hardy-Weinberg p-value, or to Mendelian inconsistencies. All of these inconsistencies within the SNP genotyping data can be explained when the gene dosage data are factored into the analysis, since departures from diploidy can cause apparent genotyping failure, a high proportion of outliers, departures from expected genotype frequencies and aberrant inheritance.

Neural crest derived osteochondroprogenitor cells predominantly contribute to cranial skeletal repair. *P. Leucht, J.-B. Kim, J.A. Helms* Department of Surgery, Stanford University, Stanford, CA.

The cranial skeleton has a complex developmental history. Whereas the appendicular skeleton is derived solely from mesoderm, the cranial skeleton is a patchwork of bony elements, derived from paraxial mesoderm as well as from the cranial neural crest (NC). These differences in embryonic origin raise the possibility that NC-derived and mesoderm-derived skeletal tissues may regenerate using distinct pathways. Since bone repair can accurately recapitulate skeletogenesis, we began to investigate the differences in cranial versus appendicular skeletal repair by creating a mouse model of mandibular/tibial defect healing. By using genetically engineered mice whose NC cells are indelibly labeled with Green Fluorescent Protein (GFP) and whose mesodermal cells are permanently labeled with LacZ (Wnt1Cre::Z/EG mice), we were able to understand the origin of the cells that contribute to the skeletal healing process. In addition, by transplanting cells from one origin into a skeletal element of a different origin, we were able to analyze to what extent adult NC-derived cells contribute to mesoderm bone (tibial) repair, and conversely, whether mesoderm-derived cells participate in NC bone (mandibular) healing. We found that, at a histological level, cranial skeletal repair is indistinguishable from appendicular skeletal repair. When the NC-derived mandible was injured, the callus was composed entirely of NC-derived cells. In contrast, the tibial defect site was occupied entirely by mesoderm-derived cells. These data suggest that injured skeletal elements apparently use cells of their own embryonic origin for repair. The potential clinical impact from this finding is significant, because if bones preferentially heal using cells that share the same embryonic origin then reparative strategies may also have to take this variable into account.

A screen for novel microdeletions/duplications in fetal samples with multiple congenital anomalies. *H.C. Mefford[1,2], A.J. Sharp[1], R.P. Kapur[3], D.G. Albertson[4,5], D. Pinkel[4], E.E. Eichler[1,6]* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Medical Genetics, University of Washington, Seattle, WA; 3) Pathology, Children's Hospital and Regional Medical Center, Seattle, WA; 4) Comprehensive Cancer Center, UCSF, San Francisco, CA; 5) Cancer Research Institute, UCSF, San Francisco, CA; 6) Howard Hughes Medical Institute, Seattle, WA.

The estimated incidence of genomic disorders due to recurrent chromosomal structural rearrangements is 1/1000 live births. We have identified 130 regions in the genome flanked by large blocks of highly homologous segmental duplications whose structure predicts a susceptibility to rearrangements resulting in microdeletion/duplication (Sharp et al., Am J Hum Genet 77:78). Despite an architecture that predisposes to rearrangement, some regions show no evidence of copy number variation in 316 controls or 330 children with mental retardation and dysmorphic features. We hypothesize that these regions contain genes that are critical for normal development and that *de novo* deletion or duplication events will be found in individuals with multiple congenital anomalies (MCA). Using a custom BAC microarray targeted specifically to the 130 regions, we are analyzing 200 individuals with MCA who underwent autopsy after intrauterine demise or therapeutic termination for anomalies; autopsy reports provide detailed phenotypic information. Analysis of the first 38 samples identified two individuals with a potential duplication of approximately 2.5 Mb on 16q24. We are currently performing validation and further characterization of these findings and will report additional findings on the first 100 individuals in our series. Our previous studies and preliminary results of this study suggest that the regions we have targeted undergo recurrent rearrangement and that our strategy provides a powerful tool for identifying novel genomic disorders and genes that are critical in normal human embryonic development.

Agenesis of lateral superior incisors: novel and reappraised evidence for familial aggregation. *P. Maciel*[1], *C. Lemos*[2,3], *T. Pinho*[4], *A. Sousa*[2,3] 1) Life and Health Sciences Res. Inst.(ICVS), School of Health Sciences, Univ. of Minho, Braga, Portugal; 2) UnIGENe-IBMC, Univ. of Porto, Portugal; 3) Dept. Pop. Genet., ICBAS, Univ. of Porto, Portugal; 4) ISCS-Norte, Paredes, Portugal.

The first evidence for a genetic cause for hypodontia came from the identification of significant familial aggregation of congenitally missing teeth in the Swedish population, in the study by Grahnen (1956). The identification of phenotypes of tooth absence in several mutant mice, together with the identification of mutations that cause non-syndromic hypodontia in human families, confirmed the relevance of the genetic determination of tooth development. However, the role of genes in sporadic and less severe forms of hypodontia is not clarified, and there is evidence for an extensive clinical and genetic heterogeneity within the hypodontia phenotype. Further definition of clinical and genetic subtypes within hypodontia is thus warranted, and familial aggregation studies are needed in order to establish a measure of the genetic contribution in each subtype. In this study, we investigated the familial aggregation of the non-syndromic agenesis of lateral superior incisors (LSIA). For this, we obtained novel data in the Portuguese population, and re-assessed data within the Grahnen study, focussing only on LSIA. In the Portuguese sample, we performed a clinical evaluation of all available first and second degree relatives(n=698)of 111 probands, 62 with and 49 without LSIA. The risk for a relative of a proband with LSIA to have the same kind of agenesis was about 13 times greater than that for a relative of a proband without that agenesis. Interestingly, the relative risk (RR)of LSIA increased with the degree of kinship: RR was 8.5 for parents, 7.7 for sibs and 4.7 for cousins. When using the estimated prevalence of LSIA in the Portuguese population (1.3%), the RR for any relative of an affected proband was 15. Parents and sibs had a RR of 14. Analysis of data from the Swedish study, using the estimated prevalence of the trait in the Swedish population (1,6%), revealed a RR of 24 for parents and 15 for sibs. The results obtained with both data sets support a significant familial aggregation of LSIA.

Integrating Gene Arrays, Breast Cancer Families, and Evolutionary Genomics to Identify New Disease Genes for Risk Assessment. *G. Larson[1], D. Smith[2], O. Snove[3], C. Lundberg[1], G. Rivas[1], J. Weitzel[1], C. Glackin[1], T. Krontiris[1]* 1) Div Molecular Medicine, Beckman Res Inst City of Hope, Duarte, CA; 2) Div Information Sciences, Beckman Res Inst City of Hope, Duarte, CA; 3) Div Molecular Biology, Beckman Res Inst City of Hope, Duarte, CA.

Gene expression microarrays provide a quantitative tool (e-QTL) to measure differences in RNA expression patterns in breast tumors versus normal tissue. Specific target genes from these expression signatures are emerging as useful clinical tools in diagnosing the likelihood of disease recurrence. We believe array studies also offer the opportunity to identify a new class of heritable mutations in genes that lead to their abnormal expression. These variants may provide diagnostic value allowing one to identify both women predisposed to disease and those demonstrating altered response to therapy. To find these mutations we are adopting a three-part strategy. First, we employ meta-analysis to compensate for the frequent variability seen in gene expression portraits from multiple studies to identify a set of consistently dysregulated candidate genes in breast tumors. Second, a subset of these candidates, guided by bioinformatics, are being tested for linkages in a cohort of affected sibling pair families with breast cancer. Third, we are comparing orthologous genes from the genomes of primates and mammals to identify putative control elements phylogeneticially conserved through evolution that occasionally contain putative disease SNPs in humans. To date, data indicate that the mutations modulating gene expression in combination with expression profiles may provide a more specialized risk profile for patients and lead to a more detailed understanding of epistatic interactions in the genome.

Human SNM1 protein is a single-strand 5'-3' exonuclease acting in DNA crosslink repair. *J. Hejna, S. Philip, C. Faulkner, A. Hemphill, J. Ott, R. Moses* Molec & Med Genetics, L103, Oregon Health Sciences Univ, Portland, OR.

DNA interstrand crosslinking agents are particularly potent DNA damaging agents because they constrain DNA topology, impeding replication and transcription. Interstrand crosslinks (ICLs) must be removed by a multi-step process, and in yeast three independent pathways are required for optimal repair of ICLs. The yeast SNM1 protein is a 5'-3' exonuclease, operates in the Rad3 pathway, and is needed for normal ICL repair. In human cells, five SNM1 homologs (SNM1, SNM1B, SNM1C/Artemis, ELAC2, and CPSF73) have been identified, raising the question of whether the enzymological function of the protein has been conserved, or whether different homologs have acquired specialized functions. In order to characterize hSNM1 activity, recombinant protein was expressed and purifed from KC167 insect cells. It possesses a strong 5'-3' exonuclease activity, using a single-stranded DNA oligonucleotide substrate. A 5'-phosphate was strictly required for the hSNM1 exonuclease. Gel filtration indicated that hSNM1, like ySNM1, functions as a monomer. Mutation of a conserved aspartate residue (D736 and D252, in hSNM1 and ySNM1, respectively) within the -CASP domain abrogated the activity in both proteins. Whereas ySNM1 efficiently digests both single-stranded and double-stranded substrates, hSNM1 shows a marked preference for single-stranded substrates. Depletion of hSNM1 by siRNA leads to increased chromosomal breaks and radial formations, and decreased cell survival after treatment with mitomycin C. We conclude that hSNM1 is a 5'-3' exonuclease required for normal ICL repair.

Results from a study evaluating the ex vivo effect of AT2101 in blood cells derived from Gaucher patients and phase 1 results of AT2101 in healthy volunteers. *K. Ludwig[1], G. Grabowski[2]* 1) Amicus Therapeutics, Inc. 6 Cedar Brook Drive Cranbury, NJ; 2) Children's Hospital Research Foundation Division and Program in Human Genetics Cincinnati, Ohio.

AT2101 (isofagomine; Amicus Therapeutics, Inc.) is an investigational, orally administered small molecule for the treatment of Gaucher disease (GD). In most GD patients, missense mutations result in the production of beta-glucocerebrosidase (GCase) with reduced stability that may not be properly trafficked from the ER to the lysosome. AT2101 belongs to a new class of drugs known as pharmacological chaperones, which selectively bind to a target protein increasing stability and trafficking to the proper location, thereby increasing cellular activity. We are conducting a non-interventional survey study to characterize the ex vivo effects of AT2101 on lymphoblast and macrophage cells derived from GD patients. Different effects of AT2101 on the mutant GCase protein will be evaluated, including enzymatic activity, protein half-life and trafficking. In addition, effects of AT2101 on cellular physiology will be examined, including changes in substrate levels and cellular stress associated with retention of misfolded GCase in the ER. A variety of mutations associated with types I, II and III GD will be studied. Clinical data will be collected retrospectively from patient medical records. We are also conducting Phase I studies of AT2101 in healthy volunteers to assess safety and pharmacokinetics. In addition, we are studying the ability of AT2101 to enhance GCase activity in white blood cells in healthy volunteers. In a previous study of migalastat hydrochloride, a pharmacological chaperone in development for the treatment of Fabry disease, significant enhancement of -galactosidase activity was observed in a Phase I trial. These data showed that pharmacological chaperones can enhance enzyme activity even for wild-type enzyme in healthy volunteers. We will present data from the ex vivo survey study and results from the AT2101 Phase I studies in healthy volunteers.

Pathogenicity of Lrrk2 R1514Q variation in Parkinsons disease. *K. Haugarvoll[1, 2], M. Toft[2], I.F. Mata[1], O. Ross[1], M.J. Farrer[1]* 1) Neuroscience, Mayo Clinic Jacksonville, Jacksonville, FL; 2) Department of Neuroscience, NTNU, Norway.

Pathogenic evidence for Lrrk2 R1514Q remains equivocal after it was identified in an affected pair of Norwegian concordant twins. To clarify the role of this variant we performed a screening of sixty-six dominant families and three case-control series from Norway, Ireland and Spain. We identified a large kindred harboring the R1514Q, however the variant did not segregate fully with disease. The relatively high frequency in elderly controls in two of the series also supports the hypothesis that this non-synonymous substitution is not pathogenic. These findings highlight the importance of using family-based studies and large multiple population screenings when examining the association of polymorphic variants in LRRK2 with Parkinsons disease.

Increased Expression of a Neuron-Specific Isoform of the *TAF1* Gene with Mouse Development and aging. *S. Makino, G. Tamiya* Division of Human Molecular Genetics, Dept of Neurology and Neuroscience, Tokushima University Graduate School of Medicine, Japan.

The *TAF1* (TATA-binding protein-associated factor 1) gene encodes the largest component of the TFIID complex involved in RNA polymerase II-mediated expression of genes related to cell division and proliferation. We found the limited expression of an isoform of the *TAF1* gene in human brain and neuronal cell line, SH-SY5Y, but not in glial cell line. We cloned the full length of the neuron-specific isoform of the *TAF1* gene, named *N-TAF1*, from human CapSite cDNA library. We also cloned mouse and rat homologues of the *N-TAF1* and found the limited expression in murine brains as well as the human *N-TAF1*. To investigate the detailed expression of the *N-TAF1* gene, we carried out probe-based quantitative RT-PCR analysis in mouse embryo (10.5 and 17.5 dpc), newborn and adult brain (8, 15 and 43 weeks). The *TAF1* mRNA was gradually decreased with mouse development and aging, whereas the *N-TAF1* was rapidly increased after birth and stable until 43 weeks. Our result suggests that the *N-TAF1* gene has an important role in non-dividing neuronal cell after birth rather than in cell division and proliferation during neurogenesis.

Genotyping by Whole Genome Hybridization. *K.W. Jones, P.-H. Wang, J. Yang, J. Huang, G. Fu* Affymetrix, Inc, 3420 Central Expressway, Santa Clara, CA.

Recent technological advances in genotyping methodologies have led to the ability to genotype hundreds of thousands of SNPs in a rapid and cost-effective manner. This in turn has led to fixed marker panels which have successfully been used in whole genome association studies. Recent studies have shown that commercially available panels capture the majority of common SNPs in the HapMap collection either directly or through linkage disequilibrium. However, methods which have based their SNP selection criteria on maximizing genetic information within the HapMap dataset have been shown to overestimate their ability to extract information from hidden SNPs (the estimated 5.3M common SNPs that are not part of the HapMap dataset). In contrast, methods that use an unbiased approach to SNP selection (i.e., Affymetrix GeneChip Human Mapping 500K arrays) have balanced coverage among hidden and non-hidden SNPs. As a means to generate a generic target preparation which maximizes the number of SNPs interrogated and does not bias the genetic information content of the SNP panel, we enabled whole genome hybridizations (WGH) in which unprocessed genomic DNA is fragmented and hybridized directly to arrays containing hundreds of thousands of SNPs. Samples with limited amounts of DNA can also be Whole Genome Amplified prior to hybridization. The WGH assay was tested on 49 HapMap samples using arrays containing greater than 113,000 SNPs that were not preselected based on their performance on other platforms or their presence in the HapMap collection. Genotypes for greater than 50% of the tiled SNPs were called with high consistency and accuracy across the 49 samples. For instance, SNPs with a minor allele frequency >2% were 99.5% concordant with HapMap reference genotypes. Additional data on the ability to extract information from hidden SNPs will also be presented. The simplicity of the WGH assay and its ability to accurately genotype vast numbers of SNPs should prove useful for developing whole-genome genotyping tools and other high complexity DNA hybridization assays.

Population genetics of EWSR1, a highly conserved chromosome 22 breakpoint region. *N. Orr[1], S. Savage[2], G. Thomas[2,3], S. Chanock[1,2,3]* 1) Pediatric Oncology Branch, NCI, Bethesda, MD; 2) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 3) Core Genotyping Facility, NCI, Gaithersburg, MD.

Ewings Sarcoma (ES) is characterised by the presence of a small number of highly specific somatic translocations resulting in fusion of the transactivation domain of the *EWS* gene with the RNA binding domain from one of five members of the ETS gene family. Distributions of *EWS* breakpoint junctions are confined to a 6 kb region termed EWSR1. The incidence of ES is significantly higher in Caucasians than in African Americans suggesting that population specific susceptibility and/or protective factors are implicated. We present a detailed population genetics analysis of EWSR1 as a step towards understanding the ethnic bias of the genetic lesion driving these pathogenic translocations.

We detected a 3.7 kb region of EWSR1 whose evolutionary conservation between 17 species was estimated at 0.752 using the phastCons17way algorithm, suggesting an area of functional or structural significance. We characterised common genetic variation within the EWSR1 region by resequencing in the SNP500 Cancer population (32 Caucasians, 24 African Americans, 23 admixed/Hispanic and 23 Pacific Rim individuals). A total of 16 SNPs were detected; of these, 14 were population private, 11 were singletons, only three had a minor allele frequency of greater than 5% and all were intronic. Nucleotide diversity, as calculated using the pi statistic, was $4x10^{-5}$ and the population mutation frequency, theta, was $42x10^{-5}$. We observed the same predominant ancestral haplotype in all populations accompanied by a low number of singletons. Tajimas D statistic was marginally significant ($p<0.05$) in the African American (-1.866) and admixed (-1.820) populations, suggesting recent selection. Fst, a measure of genetic distance between populations was unremarkable (0.019). Comparison of HapMap phase II data indicates that there may be a region of high recombination in *EWS* in the Yoruba which is not present in Caucasians. These data form the foundation for further genetic studies of ES in order to investigate the marked population bias of this early onset malignancy.

Identifying and comparing sequence determinants of mammalian recombination hotspots. *S.R. Myers[1], A. Kirby[3], C. Wade[1,2], G.A.T. McVean[4], M.J. Daly[1,2,3], P.J. Donnelly[4]* 1) Broad Institute of MIT and Harvard, Cambridge, MA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 3) Department of Medicine, Harvard Medical School, Boston, MA; 4) Department of Statistics, Oxford University, Oxford, UK.

It is now well understood that most human recombination is concentrated into narrow hotspots, of width one to two kilobases, and there is substantial evidence for a similar pattern in other mammalian species. However, the nature of the relationship between the location of such hotspots, and primary DNA sequence, has remained mysterious. We employ new variation datasets to investigate this relationship, and to compare results between humans and other species. A new set of more than 25,000 human hotspots, identified using variation data, provides overwhelming evidence that DNA sequence has a strong local effect, that certain short, specific sequence motifs influence human hotspot activity, and that the same motifs are active in many different genomic contexts. Using mouse polymorphism data, we identify a second new set of potential hotspot locations, within the mouse genome, and use these to compare the two species. As in humans, mouse recombination shows a strong dependence on specific local sequence features - but although some associations are in the same direction as in humans, there are also some intriguing differences. Such cross-species comparisons should help to answer important evolutionary and biological questions relating to recombination and hotspots.

Combined ancestral linkage analysis and whole genome association analysis of migraine with vertigo and aura.

H. Lee[1], J.C. Jen[2], Y.H. Cha[2], B. Merriman[1], R.W. Baloh[2,3], S.F. Nelson[1,4] 1) Dept. Human Genetics, UCLA, Los Angeles, CA; 2) Dept. Neurology, UCLA, Los Angeles, CA; 3) Dept. Surgery, UCLA, Los Angeles, CA; 4) Dept. Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA.

Migraine is a common disorder affecting at least 15% of the adult population world-wide. Several linkage studies and population based family studies demonstrate that migraine is a genetically complex disorder involving multiple genetic factors as well as environmental factors. The International Headache Society (IHS) classifies migraine into the most common forms of migraine without aura (MO) and migraine with aura (MA). However, in order to generate a potentially more homogeneous case group, we have restricted the migraine phenotype to include only individuals who manifest recurrent migrainous headaches, recurrent visual aura and episodic vertigo (MAV). In total 96 samples with MAV were included within the case group and 104 genetically matched samples were selected for the control group. Affymetrix Mapping 250K NspI arrays were used for the genotyping, and 170K snps passed our quality control check. 258 SNPs are associated with MAV in the initial screening set at a $p0.001$, and 4 SNPs are associated with individual $p10^{-5}$. Although none of the SNPs is significant if a conservative Bonferroni correction is applied, several candidate genes are identified. We overlay this association information with the identification of identical by descent intervals between the affected individuals to search for families that share the same ancestral haplotypes at the associated loci.

Cytokine SNPs and Preterm Birth. *M.V. Hollegaard[1,2], J. Grove[2], P. Thorsen[2], D.M. Hougaard[1]* 1) Department of Clinical Biochemistry, Statens Serum Institut, Copenhagen, Denmark; 2) NANEA at Department of Epidemiology, Institute of Public Health, University of Aarhus, Aarhus, Denmark.

Several observations support the idea of a genetic influence on the risk of Preterm Birth (PTB, birth before 37 weeks of gestation (w.g.)). E.g.: the leading risk factor for PTB is a previous preterm birth and mothers themselves born preterm also have an increased risk of a PTB. PTB is most likely to be caused by multiple genetic and environmental factors. Many environmental factors that are known to activate the cytokine mediated inflammatory pathways have been associated with PTB. The aim of this pilot study was to elucidate if any of 289 selected SNPs distributed in 47 selected cytokine loci could be associated with PTB. The SNPs found interesting here will be tested in a cohort study consisting of app. 3,900 pregnant women. Three groups of 40 patients, all Caucasian women, from the Danish National Birth Cohort were included into this study. The three groups were; controls 37 w.g., PTB >34 w.g. (moderate preterm) and PTB 34 w.g. (very preterm). DNA was extracted from dried blood spots (Guthrie cards) and used for whole genome amplification using Genomeplex (Sigma). Samples were shipped to Illumina Inc., USA for genotyping. In time of writing, preliminary statistical analysis of the two PTB subgroups against controls has revealed a total of 31 different SNPs associated with PTB. Moderate PTB was associated to 16 SNPs located in 8 different loci, IFNA1, IFNGR2, IL1A, IL1B, IL2, IL26, IL2RB, and IL7. Very PTB was found associated to 15 SNPs located in 8 loci, IFNA1, IFNGR2, IL18, IL1A, IL2RB, IL2RG, IL6 and IL7. When analyzing all PTB cases against controls, there were 15 SNPs associated in 8 loci, IFNA1, IFNGR2, IL1A, IL2, IL26, IL2RB, and IL7 remained in the list and IL4 was added. The difference in loci associated to moderate and very PTB, is consistent with the idea of different causal pathways are involved in PTB. This pilot study suggests that SNPs in and surrounding the genes IFNA1, IFNGR2, IL18, IL1A, IL1B, IL2, IL26, IL2RB, IL2RG, IL4, IL6 and IL7, should be investigated further both in a larger study as well as in populations with other ethnicities.

Allele frequency estimates from DNA pools for 317,000 SNPs for multiple European and worldwide populations and discovery of Ancestry Informative Markers for Europe. *J. Li[1], D. Absher[1], A. Southwick[1], M.D. Shriver[3], M. Bauchet[3], P.A. Underhill[2], L.L. Cavalli-Sforza[2], G. Barsh[2], R.M. Myers[2]* 1) Stanford Human Genome Center; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Department of Anthropology, Penn State University, University Park, PA.

The identification of Ancestry Informative Markers (AIMs) and inference of individual genetic history is useful in many applications, including studies of geography and evolution of human populations, forensic sciences, pharmacogenomics, admixture mapping and association studies of complex diseases. While many AIMs have been reported that define strong genetic differences between major continents, it is more difficult to identify markers that reflect subtle, within-continent diversity, such as the heterogeneous ancestry of European Americans contributed by different populations within Europe. We have analyzed DNA pools, each for a different population, on Illumina HumanHap300 BeadArrays to estimate allele frequencies for ~317,000 Single Nucleotide Polymorphisms for 9 European, 6 African, and 2 Amerindian populations in the Human Genome Diversity Project collection. We have also evaluated the performance of this method by analyzing three HapMap pools (YRI, CHB, and JPT), for which the true allele frequencies are already known from the International HapMap Project. We found that the allele frequency estimates differed between replicate chips by less than +/-5% for 95% of the SNPs, and that the estimated frequencies and the true frequencies differed by +/-5-10% for 90% of the SNPs. The data for nine European populations, from western Caucasus, Scotland, Tuscany, Sardinia, France, Iberia, Russia, Northern Italy, and a Basque region, showed a clear excess of SNPs having large allele frequency differences (e.g. >30%) between most pairs of populations, compared to what would be expected given the sample sizes. These results provide a valuable resource of European AIMs for monitoring within-continent stratification in association studies. We are currently validating the most informative SNPs by individually genotyping samples that formed the pools as well as those from additional European populations.

Patterns of sequence variation in the human pigmentation candidate gene SLC24A5. *H. Norton, M. Hammer* ARL-Biotechnology, Univ Arizona, Tucson, AZ.

Human skin pigmentation shows a strong correlation with the intensity of ultraviolet radiation (UVR), suggesting that variation in pigmentation is the result of natural selection. Recent work has demonstrated that a derived functional allele at the pigmentation gene SLC24A5 is fixed in Europeans and absent or at very low frequencies in other populations typed in the International HapMap Project. These results argue for an independent evolution of lighter skin in European and East Asian populations. To further test the hypothesis that SLC24A5 has been shaped by positive directional selection in European (but not East Asian) populations we sequenced 4.8 kb of SLC24A5 spanning a 20 kb region in a geographically diverse panel of human populations representing Europe, Asia, Africa, and the Americas. We compare levels of nucleotide diversity (and) at SLC24A5 to four X-linked loci sequenced in the same panel of individuals. While overall levels of diversity at SLC24A5 are only slightly lower than those reported for these comparison loci, Europeans show a marked reduction in diversity (, = 0.000). Further, all Europeans share a single haplotype that is defined by the SLC24A5 111*A functional allele. This haplotype is rare or absent outside of Europe. HKA tests comparing ratios of polymorphism and divergence in Europeans between SLC24A5 and the X-linked loci indicate a departure from neutrality at 2 of the 4 loci (DMD intron 44, $p < 0.01$; AMELX $p < 0.01$) and ratios at a third locus are suggestive of reduced European polymorphism (APXL, $p = 0.057$). Taken together these results suggest that patterns of variation at SLC24A5 in Europeans are due to selection rather than to demographic processess. Finally, we examine variation at increasing distances from the functional polymorphism to assess the extent of linkage disequilibrium around the selected haplotype.

Extended family relationships in idiopathic adolescent scoliosis pedigrees: a founder effect. *M.C. Meade, L.M. Nelson, V. Argyle, T. Berry, S. Murphy, J. Braun, J.W. Ogilvie, K. Ward* Axial Biotech, Inc., Salt Lake City, UT.

Introduction: Our aim was to study the extended relationships in families with adolescent idiopathic scoliosis (AIS) using the unique genealogy data available for the Utah population. Methods: Using IRB approved protocols, four-generation pedigrees were obtained from 85 probands with AIS, 83 of which were treated surgically. Descriptive statistics and standard pedigree analyses are presented in an accompanying abstract. In order to understand extended relationships between these families, a proprietary genealogy database (GenDB) was searched for the names, birth dates, and birthplaces of the four grandparents for each of the affected probands. GenDB documents the relationships between approximately 17.5 million ancestors and 3.5 million descendants of the Utah founder population (founders are approximately 10,000 individuals). Results: In 69 of the 85 families, probands reported a positive family history of AIS within the 4 generations (n=314 affected individuals). GenDB found 426 familial connections with a range of 0 to 23 connections in the 85 families. GenDB showed a mean of 5 common ancestors between any pair of probands. Familial connections ranged from the year 1460 to 1858 with a mean connection year of 1645. In 15 of 16 families in which the proband did not know of a family history of AIS within 4 generations, GenDB showed a distant connection with one of the 85 probands. There were consanguineous relationships found in 3 probands families. 15 proband families had affected or unconfirmed individuals on the unreported side (other side) of the family. 33 of the 69 families had genealogy connections found through an ancestor on the unreported side of the family. Conclusions: This study confirms the familial nature of adolescent idiopathic scoliosis and expands our understanding of the genetic parameters. This cohort of patients supports a founder effect in this population. A genome wide scan for the loci involved in these affected families is reported separately.

***CRTAP* is required for collagen 3-prolyl hydroxylation and loss of its function causes recessive osteogenesis imperfecta.** *R. Morello[1], T.K. Bertin[1], P. Castagnola[2], H.P. Bachinger[3], F.H. Glorieux[4], P.H. Byers[5], D.R. Eyre[5], B.F. Boyce[6], B. Lee[1,7]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Istituto Nazionale per la Ricerca sul Cancro, Genova, ITALY; 3) Shriners Hospital for Children, Portland, OR; 4) Shriners Hospital for Children, Montreal, CANADA; 5) University of Washington, Seattle, WA; 6) University of Rochester Medical Center, Rochester, NY; 7) Howard Hughes Medical Institute, Houston, TX.

Osteogenesis Imperfecta (OI) is caused by mutations in the *COL1A1* or *COL1A2* genes. Although its clinical spectrum of severe to mild OI (clinical types II, III, IV, and I) has been well described, new types of OI (types V, VI, and VII), defined either genetically or histologically, have emerged. We hypothesized that this group of OI phenotypes may include recessive forms due to dysregulation of components of the collagen processing machinery. We generated *Crtap* null mice and found that they exhibit osteochondrodysplasia characterized by rhizomelia, kyphosis, and severe osteopenia. In vivo histomorphometric analyses showed significantly decreased bone mass and bone formation rate, but normal numbers of osteoblasts and osteoclasts. Moreover, *Crtap-/-* mice synthetize very little osteoid and have decreased mineralization lag time. We demonstrate that CRTAP exists in a protein complex with prolyl-3-hydroxylase-1 protein and *Crtap-/-* mice lack fibrillar collagen prolyl 3-hydroxylation by tandem mass spectrometric analysis. Finally, we identified *CRTAP* mutations in two families with recessive OI. In the original family with OI type VII, we detected a CG transversion in intron 1 that created a new splice donor site and activated a cryptic exon in most transcripts. However, normal residual CRTAP mRNA and protein were still detected suggesting the hypomorphic nature of this mutation. In the second, consanguineous family with a very severe form of OI (type II), we identified a single nucleotide deletion in exon 4 that led to a premature termination codon, and virtually complete lack of mRNA and protein. Our data demonstrate that loss of function of *CRTAP* causes recessive OI and show the biological importance of collagen prolyl 3-hydroxylation for bone formation.

Fine-mapping of *INSIG2* variation associated with obesity. *H. Lyon[1,2,3], J. Butler[1,2], T. Bersaglieri[1,2], E. Speliotes[1,2,4], X. Zhu[5], R. Cooper[5], J. Hirschhorn[1,2,3]* 1) Div Genetics, Boston Children's Hosp, Boston, MA; 2) Broad Institute, Cambridge, MA; 3) Harvard Medical School; 4) Mass General Hospital, Boston, MA; 5) Loyola University Medical School, Maywood, IL.

Background: Obesity is a heritable trait causing substantial morbidity and mortality, yet the common genetic determinants are largely unknown. **Objective:** Reproduce an association between common genetic variation and obesity, and fine-map the nearby gene to find a causal variant. **Method:** We and collaborators identified a SNP (rs7566605) 10 kb upstream of the *INSIG2* gene (insulin-induced gene) reproducibly associated with obesity.(1) The recessive genotype (frequency 10%) was significantly associated with obesity and was reproduced in 4 out of 5 large populations tested (N>10,000). The pooled odds ratio of the recessive genotype for BMI >30 was 1.26(95% CI 1.09-1.47 p=0.002). It is possible that rs7566605 is not the causal SNP but rather is in linkage disequilibrium (LD) with the causal variant. We further sought a possible causal variant in the 72 kb region (30kb upstream and 20kb downstream of *INSIG2*) by testing 58 tagSNPs, 7 SNPs highly correlated with rs7566605(R2>0.8), and 3 missense SNPs in the gene. TagSNPs were chosen using HapMap data to include a set of SNPs predictive of the LD structure in Yorubans with additional SNPs to capture the variation in Europeans resulting in a superset of tagSNPs likely to capture the variation in an African-American population. All SNPs were genotyped in the African-American population from the Chicago area used in our original report, comprised of 735 people in families and 182 lean and obese people. **Result:** While the SNPs correlated with rs7566605 demonstrated the association as expected, none of the correlated, missense or tagSNPs showed a stronger association to obesity than rs7566605, suggesting that they are not in strong LD with the causal variant. Haplotype analysis and further replication in additional populations are underway. **Conclusion:** Variation upstream of *INSIG2* is associated with obesity in African-Americans. Fine-mapping has not revealed stronger association evidence than the rs7566605 association. (1)Science 2006, 312(5771):279-83.

The influence of *YY1* and retinoic acid in the Treacher Collins syndrome gene (*TCOF1*) regulation. *C. Masotti, E. Kague, M.R. Passos-Bueno* Inst de Biociencias, Univ de Sao Paulo, Sao Paulo, Brazil.

Treacher Collins syndrome (TCS) is an autossomal dominant craniofacial malformation caused by null mutations in the *TCOF1* gene, most of them small deletions or duplications causing a premature stop codon. The hypothesis for clinical manifestation is haploinsufficiency of treacle during embryonic development. High inter and intra-familial clinical variability, ranging from mild malar hypoplasia to perinatal death due to airway collapse is observed, but, to date, no genotype-phenotype correlation has been reported. Interestingly, phenocopy of the syndrome was produced by acute exposure to retinoic acid on the ninth day postfertilization in mice. We have previously hypothesized that mutations in elements of the promoter region of the gene, in trans with a pathogenic mutation, could modulate the phenotype. Therefore, we have delimited the minimal promoter and identified a functional single nucleotide polymorphism that impairs DNA-binding to the *YY1* transcription factor (Masotti et al. *Gene*, 2005,359:44-52). Considering that in silico analysis predicted binding sites for both *YY1* and retinoic acid receptors in this promoter, the aim of the present work is to characterize the role of *YY1* and retinoic acid in the regulation of *TCOF1* expression. We performed co-transfection assays with an *YY1* expression vector and the *TCOF1* promoter constructs bearing the luciferase reporter gene that were described by Masotti et al.(2005). The results demonstrated that *YY1* acts as a repressor element in a dosage-dependent manner. In addition, to study the effect of retinoic acid, we have treated HEK293 cells with 10^{-6}M of all trans retinoic acid (ATRA), for 24h, in three independent experiments. The *TCOF1* and the *SDHA* (succinate dehydrogenase complex, subunit A) and *HPRT1* (hypoxanthine phosphoribosyl transferase 1) endogenous controls expressions were measured by real time quantitative PCR in treated and non-treated cells. We did not observe any up or down regulation of *TCOF1* in treated cells. We are currently testing different concentrations of ATRA and another ligand, the 9-cis-retinoic acid, as well as initiating the characterization of *YY1* binding sites. FAPESP/CEPID/CNPq.

Variants in FOXE1 are Highly Associated with Non-syndromic Cleft Lip with or without Cleft Palate. *MA. Mansilla[1], LM. Moreno[1], M. Johnson[1], SA. Bullard[1], A. Jugessur[2], RT. Lie[2], A. Wilcox[3], K. Christensen[4], TH. McHenry[5], BS. Maher[5], ME. Cooper[5], P. Chines[6], AC. Lidral[1], ML. Marazita[5], JC. Murray[1]* 1) U of Iowa, Iowa City, IA; 2) U of Bergen, Bergen, Norway; 3) NIEHS, Durham, NC; 4) U of Southern Denmark, Odense C, Denmark; 5) U of Pittsburgh, Pittsburgh, PA; 6) NHGRI, NIH, Bethesda, MD.

Non-syndromic cleft lip with or without cleft palate (NSCL/P) is a common birth defect that results from genetic and environmental factors. We are investigating genetic contributors to NSCL/P by using linkage and association approaches. Our linkage scan meta-analysis from 7 different NSCL/P populations identified a major locus within the 9q22-q33 region(HLOD=5.3). For fine mapping, association was performed on extended families and nuclear triads from Southeast Asia to map and identify gene(s) contributing to this signal which spans 50 Mb and contains 104 genes. 330 SNPs in that region were genotyped by CIDR on 220 multiplex families and 44 additional SNPs were genotyped in specific genes on 300 nuclear trios. Modest association was seen for SNPs in the FOXE1 region (p=0.029, rs3758249). To confirm this finding the same SNPs were genotyped in 922 nuclear triads from Northern Europe (NE) and 203 from North America (NA)revealing significant results in all tested populations with the strongest evidence found at rs37582493 with a combined p-value of 2 X 10x-6. Individual populations, NA(p=0.0002) and NE (p=0.0008), were significant by themselves even when adjusted for multiple comparisons and estimates of the attributable risk for FOXE1 ranged from 5% to 22%. Haplotype analysis showed a p-value of 7 X 10x-6 (rs3758249-rs894673). Sequence analysis of 60 NSCL/P cases with evidence of linkage to 9q failed to disclose any common etiologic coding variants. But FOXE1 lies in a 150 Kb LD block that could harbor one or more regulatory regions in which a common variant could explain this association. Mutations in FOXE1 cause the Bamforth-Lazarus syndrome that includes cleft palate. This report provides evidence for a major role for FOXE1 in NSCL/P and adds to the number of specific transcription factors playing a role in facial morphogenesis in humans.

Concordance Measurements and Genotyping Error Rate in the HapMap Dataset. *J. Huang, J. Yang, K. Hao, S. Cawley, K.W. Jones* Affymetrix Inc, 3420 Central Expressway, Santa Clara, CA.

The International HapMap Consortium has generated data for over 3M SNPs in 270 individuals from 4 distinct ethnic populations. This data has been used for both identifying patterns of common genetic variation and as a framework for genetic association studies. Although an initial set of SNPs was genotyped on multiple platforms to assess reliability of the different methodologies, once the project moved into a high-throughput mode the vast majority of SNPs were genotyped on only a single platform. Because SNPs on the Affymetrix GeneChip Human Mapping 500K arrays were selected based on their ability to generate robust genotype calls, and not as a function of reducing the overlap with previously genotyped SNPs, there is a significant number of SNPs (>300,000) on this platform which overlap SNPs genotyped in the context of the HapMap project. Here we present data demonstrating the overall concordance of genotype calls seen between the different platforms. Overall, the Mapping 500K arrays display a 99.4% concordance of calls with those generated in the HapMap project. Further analysis involving assessment of the raw intensity measurements used to make the genotype calls suggests that a small, but measurable, error rate exists in the HapMap dataset. For instance, some platforms have shown a susceptibility to allelic dropout which can manifest itself as monomorphic sequences which are not filtered out based upon Mendelian inconsistencies or deviation from Hardy-Weinberg equilibrium. Lastly, we describe a method which utilizes linkage disequilibrium between markers as a means to determine the true genotypes when calls from two platforms are discordant. The true positive and false positive rate for this analysis will be presented.

Capturing Common, Multi-Ethnic Human Variation On A Single Microarray. *S.S. Murray, P.C. Ng, K. Kuhn, D. Peiffer, L. Zhou, L. Galver, C. Taylor, K. Gunderson, R. Shen* Illumina, Inc, San Diego, CA.

Many of the common SNPs in the genome are known and the results of the International HapMap Project have shown that the information from a majority of these SNPs can be captured by genotyping 250,000-500,000 well-chosen tagSNPs (International HapMap Project, 2005). We have developed a standard tagSNP panel of over 555,000 SNP loci that capture the majority of common variation in CEPH (Caucasian), Han Chinese/Japanese, and Yoruba populations.

The CEPH, Han Chinese/Japanese, and Yoruba populations have approximately 2 million common SNPs each (minor allele frequency 0.05) identified from the HapMap Phase I+II data. To capture this variation, tagSNPs were chosen by an algorithm utilizing the linkage disequilibrium statistic r^2 (Carlson, et al. 2004). An r^2=0.8 threshold was used for common SNPs in or within 10kb of genes or in evolutionarily conserved regions. For all other regions, an r^2=0.7 threshold was used. This panel captures 90%, 87%, and 57% of the HapMap Phase I+II variation in CEPH, Han Chinese/Japanese, and Yoruba populations using pairwise tests at r^2 0.8, respectively. Ninety-six percent, 90% and 92% of all SNP loci are polymorphic in the CEPH, Han Chinese/Japanese and Yoruba populations, respectively, with average minor allele frequencies of 0.23, 0.21, and 0.22, respectively, in these populations. The average spacing between common SNP loci (MAF 0.05) is 5.5, 6.5, and 6.2kb in the CEPH, Han Chinese/Japanese and Yoruba populations, respectively. We have also included over 4,000 SNPs from recently reported LOH/copy number (CN) regions of the genome for more comprehensive coverage for LOH/CN applications and have confirmed several hundred of these regions using this panel. In addition, we have also included 180 mitochondrial SNPs and over 7,000 non-synonymous SNPs. This tagSNP panel is a valuable resource for both genome-wide association and CN studies and will help identify genetic variation affecting both human health and disease.

Mutations in the monogenic diabetes gene HNF4alpha are a novel cause of macrosomia and neonatal hyperinsulinsim. *A.T. Hattersley[1], A. Steele[1], T. Barrett[2], K. Stals[1], J.P. Shield[3], S. Ellard[1], E.R. Pearson[1,4]* 1) Peninsula Medical School, Exeter, UK; 2) Birmingham Childrens' hospital, Birmingham, UK; 3) Bristol University, Bristol, UK; 4) Ninewells Medical School, Dundee, Scotland.

Heterozygous mutations in the genes encoding the beta-cell transcription factor Hepatocyte Nuclear Factor (HNF)-4alpha are known to cause maturity onset diabetes of the young (MODY). These patients have progressive reduction in insulin secretion and present with diabetes in early adulthood. Recently a mouse with a beta cell specific deletion of HNF-4 was surprisingly shown to have lower glucose and increased insulin. We examined whether HNF-4 mutations could cause hyperinsulinaemia in man.

Reported hypoglycaemia was assessed in 106 members of 14 HNF-4 families. We also collected birth weight as insulin is a growth factor in utero and so birth weight can be considered a bioassay of insulin secretion in utero. We compared these results with 134 members of 32 HNF-1 MODY families. Comparison was by Mann-Whitney U, Wilcoxon Signed rank and fishers exact tests.

8 of 58 patients with heterozygous HNF-4 mutations had documented severe (<2 mmol/l) transient hypoglycaemia in infancy, with established hyperinsulinaemia in three cases. In contrast none of the 52 non mutation carriers had hypoglycaemia($p<0.01$). Birth weight was increased by 790g ($p<0.001$) in all mutation carriers (NM) (median corrected birth weight 4450g, IQ range 3880 to 4890g) compared to non mutation (NN) family members (BW 3660g, 3340 to 3900g). 59%NM patients were macrosomic compared with 13%NN ($p<0.001$). In contrast there was no documented severe hypoglycaemia in HNF-1 mutation carriers and the birth weight is not increased (NM 3700g (3330 to 4200g); NN 3720g (3330 to 4360g); $p=0.86$).

We conclude that HNF4- mutations are a novel cause of both transient hyperinsulinaemia of infancy and macrosomia as well as causing early-onset diabetes. This is the first beta-cell gene where a single mutation results in both increased insulin secretion in the fetus and early life and reduced insulin secretion latter in life.

Support for the homeobox transcription factor, ENGRAILED 2, as an Autism Spectrum Disorder susceptibility gene. *J.H. Millonig[1,2], R. Benayed[1,2], P.G. Matteson[1,2], N. Gharani[3], S. Kamdar[1,2], G. Lazar[1,2], I. Rossman[1], E. DiCicco-Bloom[1], L.M. Brzustowicz[3]* 1) Department of Neuroscience & Cell Biol, UMDNJ-RWJMS, Piscataway, NJ; 2) Center for Advanced Biotechnology and Medicine, UMDNJ-RWJMS, Piscataway, NJ; 3) Department of Genetics, Rutgers University, Piscataway, NJ.

We have demonstrated that the homeobox transcription factor ENGRAILED 2 (EN2) is a likely Autism Spectrum Disorder (ASD) susceptibility gene (ASD [MIM 608636]; EN2 [MIM 131310]). EN2 is encoded by two exons and a single intron, spanning 8.1kb. Two intronic SNPs (rs1861972 and rs1861973) are consistently and significantly associated with ASD in 3 separate datasets (A-C rs1861972-rs1861973 haplotype; P=0.0000004; 518 families)(Gharani et al., 2004; Benayed et al., 2005). LD mapping for 16 additional EN2 polymorphisms demonstrated that only the intronic SNPs are in strong LD with rs1861972 and rs1861973. Re-sequencing and association analysis identified the A-C rs1861972-rs1861973 haplotype as a candidate disease allele. This hypothesis is supported by current HapMap data in which rs1861973 is not in strong LD with any other SNP within 2Mb of EN2. Since disease alleles for other common complex disorders can affect the transcriptional regulation of the associated gene, we investigated whether the EN2 intron is capable of acting as a cis-regulatory element. Human intronic sequences containing either the associated A-C or the non-associated G-T haplotype were cloned in front of a luciferase reporter. These constructs plus appropriate controls were transiently transfected into 3 different cell types: HEK-293T cells (a human embryonic kidney cell line), PC12 cells (a rat neuronal cell line) and primary cultures of P6 mouse cerebellar granule cells. These experiments have demonstrated that the EN2 intron acts as a neuronal-specific transcriptional repressor (P= 0.0000055, Students T-test). Preliminary data has also revealed a difference between the A-C and G-T haplotypes. These data provide further genetic evidence that EN2 acts as an ASD susceptibility locus and suggests that the A-C rs1861972-rs1861973 haplotype is the disease allele responsible for our observed association of EN2 with ASD.

High-resolution mapping of partial trisomy breakpoints in Down syndrome patients using oligonucleotide tiling arrays. *J.O. Korbel[1], A.E. Urban[1], X.N. Chen[2], E. Stein[1], M.B. Gerstein[1], S. Weissman[1], M. Snyder[1], J.R. Korenberg[2]*
1) Yale University, New Haven, CT; 2) Cedars-Sinai Medical Center, UCLA, Los Angeles, CA.

Amplifications and deletions of chromosomal regions are involved in many genetic disorders. Down syndrome is caused by one of the most common chromosomal abnormalities in liveborn children, trisomy 21, associated with a variety of medical conditions including mental retardation and congenital heart disease. A fraction of patients carry partial trisomies involving distinct regions of chromosome 21, instead of an extra chromosome. This phenomenon is expected to provide a valuable entry point for analyzing the molecular etiology of the disease and its associated developmental malformations. In particular, precise mapping of the partial trisomies may substantially advance the analysis of phenotype-genotype relationships. Recently, we have developed ultra-high-resolution comparative genomic hybridization (UHR-CGH) and shown that it is capable of detecting accurately the extent of chromosomal aberrations on human chromosome 22; in several cases, breakpoint sequences were identified by PCR following data analysis (see e.g. Urban *et al., PNAS* 2006; 103:4534-9). Here, the same technology was used to construct chromosome 21 arrays containing 385,000 isothermal oligonucleotide probes (probe lengths: 45-85 nt; uniform hybridization temperature: 76C). All except the very highly repetitive regions of chromosome 21 are covered with a 122 nt tiling path. Using a custom Hidden-Markov-model based segmentation algorithm this allowed breakpoint-mapping at unprecedented level. The breakpoints and duplicated regions of two partial trisomies were determined by Southern blots and high resolution multicolor FISH with BAC arrays, and this could be refined using chromosome-wide UHR-CGH to below exon-level resolution. This represents a 100-1000 fold enhancement in resolution over conventional methods and provides firm evidence for sensitive detection of copy number variation in the range of 3:2 for unique and repeated genomic sequences.

How to associate the somatic mutations and a specific cancer. *K. Li[1], L. Xiao[2], Y.F. Yin[1], J. Zhang[2]* 1) Molecular Genetics, City of Hope, Duarte, CA; 2) SNP Institute, Nanhua University, Hengyang, China.

We observed that the incidence of small genetic variations between human and chimpanzee genomic sequences decays rapidly according to the size of the inserted or deleted fragments during evolution. Quantitative analysis with double-regression of small mutations deposited in the Human Genomic Mutation Database and in the human p53 somatic mutation database of nearly eighty thousands mutations revealed that the decay of small insertions and small deletions is proportional with the square of the number of base pairs inserted or deleted, which is thus described as M(i/d)N = M(i/d)1 x N2. Here M is the number of mutations with N nucleotides or 1 nucleotide inserted or deleted. This characterized decay pattern of small insertions and small deletions have immediate applications in distinguishing neutral drift and positive selections in phylogenetic studies and in association analyses for somatic mutations identified in cancers. When mutations are identified in one gene in a given cancer of a specific tissue a strict and unique association between the mutated gene and the cancer can be conclusively ruled out if the small deletions or insertions are distributed following the decay pattern as described. Otherwise, an association relationship is generally accepted to the non-randomly occurring mutations. Additionally, the decay pattern can be applied to illuminate the biochemical basis of a newly associated gene in carcinogenesis: Significantly more inframe or frameshift deletion/insertions indicate gain-of-function or loss-of-function respectively. The latter is invaluable for genes with unknown functions.

High heritabilities of metabolites in families from the GENECARD Study of early onset coronary artery disease.

E.R. Hauser[1], S.H. Shah[1,3], C.B. Newgard[2], J. Bain[2], R. Stevens[2], B. Wenner[2], M. Muehlbauer[2], E. Dowdy[3], C. Haynes[1], G.S. Ginsburg[4], W.E. Kraus[3] 1) Center for Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Sarah W. Stedman Nutrition & Metabolism Center, Duke University School of Medicine, Durham NC; 3) Department of Medicine, Duke University Medical Center, Durham NC; 4) Institute for Genome Sciences and Health Policy, Durham, NC.

Introduction. Metabolomic profiling of small-molecule metabolites holds promise for integrating genetic and biochemical data to give a more complete picture of human systems biology. Profiles can predict presence of CAD, a complex disease with a known genetic basis. However, the genetic basis of these profiles has not been established.

Methods. We identified five families from the GENECARD study of early-onset CAD. Blood was collected on family members with CAD and unaffected offspring (N=80 members in 5 families; 20 with CAD). Gas chromatography/mass spectometry (MS) with isotope-labeled internal standards were used for targeted quantitative measurements of ~60 metabolites (free fatty acids, acylcarnitines, amino acids, conventional metabolites). Variance components as implemented in SOLAR was used to calculate heritabilities (h^2).

Results. Multiple metabolites showed high heritabilities. Among acylcarnitines, C18s (steroyl, oleyl, linoleyl) and C16 (palmitoyl) were highly heritable (h^2 0.42-0.63, $p<0.002$), as were C5 (h^2 0.35, $p=0.007$) and C2 (h^2 0.63, $p=0.0003$). Among amino acids, alanine, serine, proline, valine, leucine/isoleucine, methionine, glutamic acid/glutamine, ornithine and arginine were heritable (h^2 0.33 - 0.88, $p=0.02$ - 9E-13). CRP showed high h^2 (0.56, $p=0.008$), as did conventional metabolites (0.34 - 0.57, $p=0.02$ - 0.0002).

Conclusions. We found strong heritabilities of metabolites in families with a common, high propensity for early-onset CAD. The genetic architecture underlying these heritabilites remains to be elucidated.

Protein walking of hnRNP E1 with a yeast n-hybrid system. *L.R. Huo[1], W. Ju[2], N. Zhong[1,2]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) New York State Institute for Basic Research, Staten Island, NY.

hnRNP E1 is the family member of hnRNPs, which comprise of RNA-binding proteins with three KH domains. hnRNP E1 plays a pivotal role in post-transcriptional regulation for RNA metabolism and RNA function in gene expression. Alteration of cellular hnRNP E1 level may change the global transcriptional and translational profiles (Zhong et al., ASHG 2006 annual meeting). We hypothesized that the regulating function of hnRNP E1 is performed along with other proteins, with which a protein network is formed. To test our hypothesis, we have initialized a study to investigate this network. An approach of protein walking with the yeast n-hybrid system is employed for this study. The hnRNP E1 is used as the initial walker to search for its contactor(s), which could be protein molecules or RNA molecules. Candidate contactors are identified with selection mediums, reporter gene, and co-immunoprecipitation. With these candidate RNA and protein molecules, an hnRNP E1 network can be established, which may contribute to a better understanding of physiological functions of hnRNP E1.

Allelic heterogeneity in autosomal dominant hereditary motor and sensory neuropathy with proximal dominancy (HMSN-P). *K. Maeda[1], R. Kaji[1], S. Makino[2], K. Yasuno[3], H. Takashima[4], M. Nakagawa[5]* 1) Dept of Neurology,Tokushima Univ. Graduate School of Medicine,Japan; 2) Division of Human Molecular Genetics,Dept of Neurology and Neuroscience,Tokushima Univ. Graduate School of Medicine,Japan; 3) Division of Genetic Diagnosis,The Institute of Medical Science,Tokyo Univ.,Japan; 4) Dept of Neurology and Geriatrics, Kagoshima Univ.Graduate School of Medicine,Japan; 5) Dept of Neurology,Graduate School of Medical Science,Kyoto Prefectural Univ.of Medicine,Japan.

Hereditary motor and sensory neuropathy with proximal dominancy (HMSN-P; OMIM% 604484) is endemic in Okinawa Islands, Japan, which is characterized by autosomal dominant inheritance, slowly progressive proximal muscle atrophy and weakness, sensory disturbance such as paresthesia and vibration loss, leading to be bedridden. The disease locus of HMSN-P has been mapped to 3q13-14. All affected individuals share an identical haplotype within the disease locus, suggesting that the undiscovered mutation of HMSN-P originated in a single founder in Okinawa. In the middle of Japan, we newly found a large family with many members developed the similar symptoms of HMSN-P, which had no record of affinal connection with Okinawan. Physical and electrophysiological examinations in a total of 41 members, including 13 affected individuals, revealed the disease is neurogenic but not myogenic as well as HMSN-P. Our linkage study in the large family using 15 microsatellite markers around the HMSN-P locus identified a 4.6-Mb interval in 3p13 cosegregated with the disease (maximum multipoint lod score of 5.08 at theta=0.0). The candidate region was identical to the HMSN-P locus recently refined by Takashima et al, but the disease haplotype in the large family was different from that in the Okinawa families. Our results suggest that HMSN-P show allelic heterogeneity in Japan. Such allelism would facilitate the identification of the disease-causative mutation in the candidate region. Moreover, the allelic heterogeneity of HMSN-P in Japan implies the possibility that HMSN-P is common across other ethnic groups but erroneously classified into other disease categories, such as HMN, CMT, and LGMD.

Haploview: A computatioonal tool for analysis and visualization of whole genome association data. *J. Maller[1,2], D. Bender[1,2], J. Barrett[1,3], S. Purcell[1,2], M. Daly[1,2]* 1) Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford UK.

In the whole genome association era there are orders of magnitude more SNP data being collected than had previously been feasible. This huge increase necessitates computational tools which can efficiently analyze and effectively visualize these data sets. The linkage disequilibrium and haplotype analysis package Haploview has been extended to be a part of a complete set of tools for such whole genome association analysis. Here we describe some of the new functionality and integration with other tools which enable this type of analysis. This includes the ability to load genome wide association results generated by other software packages in order to view the results and pick tag SNPs for follow up genotyping. Additionally, Haploview can now automatically load phased HapMap data over the internet, which greatly simplifies LD analysis and tagging of HapMap data.

Genomic analysis of large tandem arrays in the human genome. *C. Lescale, D. Hasson, S. Gmuca, P.E. Warburton*
Mount Sinai, New York.

Copy number variation (CNV) in the human genome is important in phenotypic variation and genome dynamics. Comparative genomic microarray analysis of CNVs does not easily distinguish between low copy duplications/deletions and variation between highcopy numbers of tandem repeats. Therefore, a genome-wide bioinformatic analysis was performed that identified 18 distinct tandem repeat families with a 1.5kb or greater repeat unit in arrays of at least 4 tandem copies. All but three of these families are included in the Database of Genomic Variants (Univ. Toronto). At least five families are found in inter- and/or intrachromosomally dispersed multiple arrays, and altogether represent over 45 large tandem arrays in the genome. Arrays are often embedded within larger segmental duplications, and represent regions prone to chromosomal rearrangments such as 8p23. Repeat units usually contain multiple fragments of interspersed transposable elements. 5 arrays contain a gene in each repeat unit, while 7 arrays spanned by a single large gene contain a spliced exon in each repeat unit. The sequence assembly of many of these tandem arrays does not accurately reflect copy number, with 7 arrays spanning a gap and 4 with assembled BAC sequences ending within the repeat units. For example, ~6 copies of a 12kb repeat unit spanning an 87kb gap in band 8q21.2 in hg18 was shown by pulsed field gels to vary from ~700kb to ~1500kb (~60 to ~125 repeat units) in 13 sized arrays. The largest tandem array family seen in hg18 consists of ~3kb repeat units made up of fragments of MaLR MSTA retrotransposons, which are found in ~25 arrays on 9 different chromosomes. The largest arrays of 60kb, 80kb and 54kb are found in the pericentromeric regions of chromosomes 13q, 18p and 21q, respectively, embedded in regions of related segmental duplications. However, distinct higher-order repeat structure suggests unequal crossing over events have occurred within the arrays since these duplications. FISH analysis confirms the arrays in hg18 and shows additional large arrays on chromosomes 15, 20, and 22. Multicopy tandem arrays represent great potential for variability between individuals, and may have distinct functional roles in chromosome structure or segregation.

KAL1 mutation in two brothers with Kallmann syndrome and previously unreported concurrent deafness and renal agenesis. *D.M. Niyazov[1], D.J. Gruskin[1], P.M. Fernhoff[1], E.M. Dystrka[2], L.P. Chorich[2], L.C. Layman[2]* 1) Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Obstetrics & Gynecology, Section of Reproductive Endocrinology, Infertility & Genetics, Institute of Molecular Medicine and Genetics, Medical College of Georgia, Augusta, GA.

Kallmann syndrome (KS) is characterized by anosmia and hypogonadotropic hypogonadism (HH). KS has sporadic, X-linked (XLKS), autosomal dominant and autosomal recessive inheritance patterns. XLKS may be due to mutations in the KAL1 gene on Xp22.3. Renal agenesis (RA) has been reported in 30-50% of XLKS patients and hearing loss of varying degrees in 5-10%, with bilateral sensorineural deafness (SD) documented in only three patients. However, the occurrence of both RA and SD in one patient has not been previously described. We report a family with a KAL1 point mutation in a carrier mother and two of her sons with XLKS, one of whom had concurrent RA and SD. The proband presented at 16 years of age for an evaluation of HH, anosmia and left cryptorchidism. His chromosomes and FISH for KAL1 deletion were negative. His parents then brought his 22-year-old full brother who was never seen by a clinical geneticist. In addition to HH, anosmia and left cryptorchidism, he had SD and left RA which was discovered incidentally by ultrasound for a sports-related abdominal injury. The probands ultrasound showed bilateral kidneys. Both brothers had pes cavus and no synkinesia. Both parents denied any history of hearing loss or anosmia, however the mother also had pes cavus. To determine if a KAL1 mutation was present, the coding regions of exons 2-13 and splice junctions were amplified by PCR and sequenced. Both affected brothers were hemizygous for an R257X mutation in exon 6, which was present in the mother but not the father. This mutation within the first fibronectin III repeat region is predicted to truncate the protein, removing 27 AA from this repeat and the remaining three FNIII repeat regions. Although this nonsense mutation was previously reported, it was never associated with SD as in one of the brothers. We postulate possible molecular mechanisms to explain the different effects of the same mutation in the two brothers.

Provision of Genetic Services in the aftermath of Katrina: The LSU Experience. *Y. Lacassie[1,2], M. Marble[1,2]* 1) Dept Ped/Div Clin Genetics, LSU Health Sciences Ctr, New Orleans, LA; 2) Children's Hospital, New Orleans, Louisiana.

The occurrence of hurricanes Katrina and Rita in 2005 produced a profound impact on all medical services in New Orleans and other cities along the Louisiana, Texas and Mississippi coastline. The LSU Division of Pediatric Genetics was no exception. These catastrophic events not only jeopardize the lives of patients with inborn errors of metabolism, but also the care of patients and families with other genetic disorders. The Division of Genetics from LSU/Childrens Hospital stayed in South Louisiana in the storm aftermath providing as much care as possible to our patients. The metabolic specialist stayed at Childrens Hospital until mandatory evacuation. Thereafter, he moved to an area close to Baton Rouge and Lafayette, where the Genetics Division staffs our most important satellite clinics. Through our satellite clinics system we were able to provide uninterrupted genetics/metabolic services in South Louisiana until Childrens Hospital reopened on October 10, 2005. Numerous factors were crucial to providing direct, fast, effective, continued and appropriate medical care. Among the most important were to stay in the area. This allowed to communicate with peer physicians, university and hospital administrators and to see patients in outreach clinics. Crucial too were communications with patients and their families, satellite clinics, the Office of Public Health, the laboratory where neonatal screening was deferred, and geneticists from other cities or states. Another important factor was the availability of a system of records available to the geneticists. With all of these basic action blocks in place, our group was able to provide medical care to the genetics population of South Louisiana. We provided care to established patients, to 8 new patients with metabolic disorders detected through the newborn screening, and also to some patients from other institutions. Our experiences regarding these challenges, and how clinical, social and even legal issues can become a problem in catastrophic situations will be discussed.

Contactin-associated protein-like 2 is a positional candidate gene for idiopathic adolescent scoliosis. *L.M. Nelson, J. Braun, J.W. Ogilvie, K. Ward* Axial Biotech, Inc., Salt Lake City, UT.

Introduction: Our aim was to map the loci causing or contributing to adolescent idiopathic scoliosis (AIS). Methods: Using IRB approved protocols, parametric linkage analysis was performed in 35 families with multiple affected individuals using 750 microsatellite markers spaced at approximately 5 cM. Genome-wide association was tested using the Affymetrix HuSNP 100K array on 204 cases and 145 controls Results: Three neighboring microsatellite markers had individual LOD scores greater than 4. Location scores maximize in a 4.3 cM interval. Several single nucleotide polymorphisms (SNPs) within the region were highly associated with AIS as well ($p<0.00001$). Locus heterogeneity was evident; LOD scores increased to 7.3 when considering the subset of pedigrees most likely to be linked to this locus. These polymorphisms lie within a very large gene (over 2.5 million basepairs)the contactin- associated protein-like 2 gene. This gene codes for a neurexin-like protein expressed in the central nervous system which plays a role in the formation of functional distinct domains critical for saltatory conduction of nerve impulses in myelinated nerve fibers. Mutation scanning is underway in cases and controls. Conclusions: These data indicate the presence of an important AIS susceptibility locus that occurs at 7q35. The contactin-associated protein-like gene 2 is a candidate gene for adolescent idiopathic scoliosis. A truncating mutation in this gene was recently implicated in Old Order Amish patients with cortical dysplasia-focal epilepsy syndrome, but it has not been associated with scoliosis in animals or humans prior to this work.

The omega-6/omega-3 fatty acid ratio in transgenic animals. *J.X. Kang* Medicine, Massachusetts General Hospital , Charlestown, MA.

An important nutritional question as to whether a balanced n-6/n-3 fatty acid ratio can reduce risk of modern diseases needs to be addressed in well-qualified experimental models. The recent development of genetic approaches to balancing n-6 to n-3 fatty acid ratio by expressing the fat-1 gene (encoding an omega-3 fatty acid desaturase) in cultured mammalian cells and animals provides a new opportunity to address this issue. Our studies have demonstrated that mammalian cells or animals engineered to express the humanized fat-1 gene can effectively produce n-3 fatty acids from the n-6 type and have a balanced tissue ratio of n-6 to n-3 fatty acids, without the need of exogenous n-3 supplementation. So far, transgenic fat-1 mice and pigs rich in n-3 fatty acids have been successfully generated. As well presenting a technology to optimize fat composition in animal products by genetic means, these transgenic animals serve as novel and useful models for studying the roles played by n-3 fatty acids in the body because they have a number of advantages over the conventional feeding methods, including being free of the confounding factors of diet. We have performed a series of experiments in both fat-1 transgenic cells (in vitro) and animals (in vivo). Our data obtained so far support the notion that a reduced or balanced ratio of cellular n-6 to n-3 fatty acids can alter gene expression and cell function, and may reduce the risk of certain diseases, including cardiovascular disease, inflammatory disorders and cancer. This presentation will provide some perspectives on the impact of genetic technology on nutrition as well as the effect of lipid nutrients on gene expression.

A Statistical Method for Assessment of the Extent and Statistical Significance to which an Association Accounts for a Linkage Signal for a Quantitative Trait. *R. Hanson* Diabetes Epidemiology Clin Res, NIDDK, Phoenix, AZ.

Association studies are often used to finely map loci identified by linkage analysis of a quantitative trait. Once an association is identified, a method to determine the extent to which it accounts for linkage is desirable. To accomplish this we propose bivariate analysis of the trait and its residual after regression on associated marker genotypes. Both original and residual traits are included in a bivariate extension of the variance-components method for quantitative trait linkage analysis. The model includes nine variance-covariance components representing effects of the quantitative trait locus, along with residual genes and environment; one of the components represents the effects of the quantitative trait locus on the original trait that have been regressed out of the residual ($^2_{QO}$). $^2_{QO}$ quantifies the contribution of the associated marker to the linkage and its statistical significance is assessed by a likelihood ratio test. We conducted a simulation study to determine power with respect to extent of linkage disequilibrium and similarity in frequency between functional and marker alleles. Families consisted of 264 nuclear families, containing 1004 offspring who had participated in a linkage study. Genotypes were simulated for these individuals at: 1) a diallelic functional locus with a high-risk allele with frequency=f_A; 2) a diallelic marker locus closely linked (=0.00) to the first with an allele of frequency=f_1 associated with the high-risk allele at a specified degree of linkage disequilibrium (D'); 3) a perfectly informative marker linked (=0.05) to the other two loci. In the absence of linkage disequilibrium between functional and diallelic marker loci, type I error rates for the statistic were near nominal values; the test was also robust to simulated population stratification. Power depended on degree of concordance between alleles at functional and marker loci. For example, with $f_1=f_A$, power for $p<0.0001$ was 2% at D'=0.4, 15% at D'=0.6, 65% at D'=0.8 and 99% at D'=1.0. In fine-mapping studies, this procedure can be useful for prioritizing associations that are likely due to linkage disequilibrium with a functional locus.

Whole-Genome Association (WGA) Study for Multiple Sclerosis. *S.L. Hauser for The International Multiple Sclerosis Genetics Consortium (IMSGC)* Neurology, University of California, San Fancisco, CA.

Multiple sclerosis (MS)is a debilitating neuroimmunological and neurodegenerative disorder that affects more than 2.5 million people worldwide and has a complex and strong genetic component. The standard whole genome screening approach using genetic linkage has failed to conclusively identify any genetic susceptibility to MS apart from the well-established effect residing within the major histocompatibility complex (MHC) on chromosome 6p. The latest data from the HapMap project suggests that by genotyping a relatively small portion of the known variation across the human genome, >80% of all common variation can be interrogated. Given this, the IMSGC has designed a whole genome association (WGA) study, allowing for a much finer scale inspection of the genome for involvement in MS risk. Genotyping has been performed using the Affymetrix 500k SNP chip in 1,000 MS trio families (an affected individual and both parents) collected in the US and UK. The completed dataset will comprise approximately 1.5 billion genotypes. To date, the platform has proven very robust when using the newly released BRLMM algorithm, with genotyping efficiencies exceeding 99%. Because of the trio design, we can obtain accurate error estimations using Mendelian inheritance. The preliminary data suggest an average true error rate of approximately 0.2%. Furthermore, additional extensive quality control procedures are in place including: assessing SNP, sample, and trio genotyping efficiencies, sample contamination and relatedness tests, extensive tests of Hardy-Weinberg equilibrium, tests for population substructure, examination of linkage disequilibrium relationships, and correlation of SNP characteristics with p-values. After QC filtering, the remaining SNPs have error rates <0.1%. Preliminary analysis of a subset of these QC'd data provides the expected distribution of p-values, with an extended right-hand tail (0.09% of the markers have $p< 1x10^{-4}$). As a positive control, TDT analysis of the MHC region shows 22 markers with $p <1x10^{-6}$; the most extreme with $p <1x10^{-15}$. The results from the full 1,000 trio screen will be presented.

Use of Forensic Markers in the Assessment of Population Stratification. *C. Oddoux, S. Shajahan, D. Parrott, L. U., A. Pearlman, H. Ostrer* Div Human Genetics, New York Univ Sch Medicine, New York, NY.

Assignment of individuals to population groups is important to genetic case control association studies, admixture mapping, medical risk assessment, genealogy, and forensic studies. Polymorphic sequences can be used to infer ancestry but their utility for such an application is related to the number of alleles and relative frequency differences of these alleles between the population groups under study. Multiple study designs differing in numbers and types of polymorphic markers with differing levels of informativeness make comparison of studies difficult. The use of commercially-available highly-informative markers that are used internationally in forensic applications could provide a universal first tier analysis for assignment of individuals to population groups prior to inclusion in association and admixture studies. We evaluated the utility of the PowerPlex kit of 16 markers from Promega for this purpose. Multiple population groups including African, Bengalis, Chinese, Japanese, Koreans, Crypto Jews, Sephardic Jews, and Dutch were genotyped using the PowerPlex kit. The data were analyzed with STRUCTURE (Pritchard et al.) using an admixture model, correlated alleles and 3 clusters. Africans, Asians (Bengalis, Koreans, Chinese and Japanese), and Caucasians (Dutch, Sephardic Jews, and Crypto Jews) were clearly delineated. Individuals showing admixture were detectable and their removal resulted in more discrete clustering. An independently collected and genotyped set of Dutch individuals was indistinguishable from the original Dutch group providing reproducibility across data sets. The sensitivity conferred by the number of markers used in the analysis was assessed by removing markers. Delineation of population groups was apparent when 14 markers were used, although clusters were noisier; however it was not possible to delineate population groups when only 8 markers were used. The use of forensic markers is a promising strategy for clustering individuals into population groups and will be an inevitable outcome of their forensic use.

Adrenocortical hyperplasia or adenomas are associated with inhibition of phosphodiesterase 11A in carriers of *PDE11A* gene sequence variants and in *pde11a*$^{+/-}$ mice. *A. Horvath, C. Giatzakis, S. Boikos, K. Griffin, E. Stein, J. Surapisitchat, A. Robinson-White, I. Bossis, V. Kamvissi, P. Soni, J.A. Carney, J. Bertherat, P. Gregersen, E. Remmers, J. Beavo, C. Stratakis* SEGEN, DEB, NICHD, NIH, Bethesda, MD 20892, USA.

Increased cAMP signaling has been associated with mutations of the *PRKAR1A* and *GNAS* genes leading to adrenocortical tumors and Cushing Syndrome (CS). We recently published that the genomic area with the highest probability to harbor a susceptibility gene by LOH and other analyses was 2q31-35. Five different, previously undescribed sequence variants were identified in the coding sequence of *PDE11A* - a dual specificity PDE that is expressed in the adrenal cortex and other tissues; its activity is partially inhibited by tadalafil and other PDE inhibitors. Three of the mutations led to premature stop codon generation; the other two sequence variants are missense substitutions. At least one of them is located in a highly conserved region of the enzyme and was found to be associated with various forms of bilateral adrebnocortical hyperplasia in patients with mostly mild or cyclical CS. A panel of sporadic adrenocortical tumors showed decreased *PDE11A* expression, 2q31-35 LOH, and high cyclic nucleotide levels and CREB phosphorylation. *Pde11a* was found to be expressed widely in the developing adult mouse. A limited study of pde11a$^{+/-}$ mice confirmed the development of adrenocortical hyperplasia or adenomas in older mice. The two missense substitutions are found to be present in the general population with a frequency close to 2.5%. The three nonsense mutations were found rarely among individuals enrolled in the New York Cancer Project. These results indicate that *PDE11A* inactivation predisposes to the development of adrenocortical hyperplasia and suggest another means by which genetic dysregulation of cAMP signaling can cause endocrine tumors. We conclude that *PDE11A* - inactivating mutations are present in the population; their association with BACH and other adrenal tumors in both humans and mice points to their low penetrance but also possible involvement in predisposition to other tumors.

Agenesis of the corpus callosum with optic coloboma and colloid cyst: a possible new syndrome of cerebral development. *J. Li[1], S. Shivakumar[1], M. Wakahiro[1], S. Stefanos[1], A. Slavotinek[2], J. Barkovich[3], P. Mukherjee[3], E.H. Sherr[1]* 1) neurology, UCSF, San Francisco, CA; 2) pediatrics, UCSF, San Francisco,CA; 3) radiology, UCSF, San Francisco, CA.

Agenesis of the corpus callosum is a common brain anomaly with an incidence of approximately 1 per 4000 live births. There are only a few genes in humans that, when inactivated, result in a fully penetrant syndrome with complete ACC. In mice the corpus callosum is derived from axons arising from cortical neurons in layers 2, 3 and 5, and there is evidence that the cingulate cortex provides pioneer axons for midline crossing. Previous studies have shown that deletion of vax1 results in ACC and optic coloboma in mice. ASXL2 and KIAA1803 are linked by a balanced chromosomal translocation in a patient with ACC and optic colobomata. Here, we report a novel autosomal recessive condition with agenesis of the corpus callosum, unilateral coloboma, craniofacial and skeletal dysmorphisms, profound cognitive impairment and intractable seizures in a brother and sister of a consanguineous middle eastern family. Brain imaging showed complete ACC, colpocephaly, interhemispheric colloid cyst and probst bundles. This case presents many features similar to a syndrome, originally described by Dr. Temtamy, in which siblings from consanguineous parents presented with seizures, mild to moderate developmental impairment and bilateral optic colobomata. We performed homozygosity mapping, and this excludes the regions encompassing the genes Vax1, ASXL2 and KIAA1803 from causing this syndrome. Genome-wide mapping is ongoing and we hope the findings will help define the spectrum of Temtamy syndrome and shed light on cerebral development.

Identification of Polymorphisms with Remedial Metabolic Impact. *N. Marini[1], J. Ziegle[2], J. Gin[1], K. Hunkapiller[2], D. Ginzinger[2], D. Gilbert[2], J. Rine[1]* 1) Dept Molecular/Cellular Biol, Univ of California, Berkeley, CA; 2) Applied Biosystems, Inc, Foster City, CA.

Compelling data from human and bacterial genetics show that the phenotype of some mutations in vitamin-dependent enzymes can be suppressed by vitamin supplementation. Such vitamin-remedial mutations can affect the binding site for the vitamin cofactor, or can destabilize the protein in a way that higher vitamin concentration can remedy. The known cases from human genetics are rare and typically result in severe disease that is vitamin remedial. To test the hypothesis that there may be polymorphisms that more subtly affect enzyme activity, yet are vitamin-augmentable by the same principles, we have sequenced the coding exons in 4 prototypical genes in a large (564 individual), diverse population. All missense variations from Ornithine Aminotransferase, Thymidylate Synthase, Methylenetetrahydrofolate Reductase (MTHFR) and Glycinamide Ribonucleotide Transformylase are being evaluated in functional assays based on complementation in the yeast, Saccharomyces cerevisiae and in cell-free biochemical analyses. We have demonstrated that quantitative yeast growth assays accurately reflect vitamin-responsiveness and intrinsic activity of enzyme variants. From 32 total coding exons comprising the 4 target genes, we have identified 21 novel low frequency coding variants (allelic frequencies <1%) with at least two such variants seen in each gene. Functional analysis has centered on MTHFR variants (11 low-frequency, 3 common) and has demonstrated that nearly 50% of nonsynonymous substitutions affect enzyme function, most of which are augmented by elevated folate levels in the yeast assay. Furthermore, we have seen synergistic effects between variants in multiply-substituted versions of MTHFR indicating the need to determine all changes in a particular allele to estimate functional impact. Extrapolating these observations to the larger set of folate (or other cofactor)-dependent enzymes indicate that low frequency variants, either alone or in combination with common variants, may contribute significantly to inidividual heterogeneity in folate or other metabolic pathways.

Molecular analyses in a female with symptoms of Rett syndrome and Pelizaeus-Merzbacher disease. *G.M. Hobson[1], T. Alberico[1], K. Sperle[1], L. Banser[1], J. Taube[1], A.P. Davis-Williams[1], J.R. Jones[2], M.J. Friez[2], G. Bibat[3], S. Naidu[3]* 1) A I duPont Hosp Children, Wilmington, DE; 2) Greenwood Genetic Center, Greenwood, SC; 3) Kennedy Krieger Institute, Baltimore, MD.

We report a case of a 9-year-old female with symptoms of both Rett syndrome (RTT) and Pelizaeus-Merzbacher disease (PMD). RTT is caused by mutations in the methyl cytosine binding protein 2 gene (*MECP2*) at Xq28, and PMD is caused by mutations in the proteolipid protein 1 gene (*PLP1*) at Xq22. The patient's clinical phenotype includes rigidity, microcephaly, febrile seizures, handwringing and hand mouthing, vasomotor instability, feeding problems, and drooling, but without nystagmus. She is nonverbal and wheelchair bound. Nonprogressive hypomyelination and thin corpus callosum were observed on MRI at ages 2, 3, and 6 years. The white matter changes were inconsistent with RTT, but because of the possibility of two coexisting diseases, *MECP2* testing was performed by sequencing and multiplex ligation-dependent probe amplification (MLPA). Sequence analysis was normal and no deletions or duplications involving *MECP2* were detected in the MLPA analysis. However, one of the MLPA control probes, which hybridizes in exon 4 of *PLP1*, indicated the possibility of a deletion or mutation involving *PLP1*. Testing by semiquantitative multiplex PCR analysis confirmed that the patient has a deletion of one *PLP1* allele that extends from 980 kb proximal of *PLP1* to a region between 2.2 and 2.4 Mb distal. Sequence analysis indicated that she also has an 11 bp deletion in the promoter of her remaining *PLP1* allele in a region previously demonstrated by others to bind nuclear proteins. This 11 bp deletion is predicted to remove two Sp1 transcription factor binding sites and recreate one Sp1 site across the junction, which may affect *PLP1* expression levels. Thus, the molecular findings in this female patient are consistent with a diagnosis of PMD.

Multi-species conserved sequences within a chromosome 1q43 region linked to Multiple Sclerosis have reduced SNP density and polymorphism. *D.P. Mortlock[1], J.L. McCauley[1], S.J. Kenealy[1], E.H. Margulies[2], N. Schnetz-Boutaud[1], S.G. Gregory[3], S.L. Hauser[4], J.R. Oksenberg[4], L.F. Barcellos[5], M.A. Pericak-Vance[3], J.L. Haines[1]* 1) Center for Human Genetics Research and Dept. of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Genome Technology Branch, National Human Genome Research Institute, Bethesda, MD; 3) Center for Human Genetics and Dept. of Medicine, Duke University Medical Center, Durham, NC; 4) Dept. of Neurology, University of California San Francisco, San Francisco, CA; 5) Division of Public Health-Epidemiology, University of California, Berkeley, CA.

Although genes play a key role in complex disease, the specific genes involved in the majority of complex diseases remain largely unidentified, and effective methods are needed for screening variants in candidate regions identified through linkage analyses. Evolutionary conservation can be used as a guide to indicate noncoding or coding regions that are likely to be functional and thus may be more likely to harbor SNP variants with functional consequences. Previously, a region of chromosome 1 was linked to Multiple Sclerosis (MS) in a genome-wide screen. We devised a process for prioritizing annotated SNPs for follow-up genotyping studies based on their location within Multi-species Conserved Sequences (MCSs) in the 1q43 linkage region. We then obtained genotypes for 768 SNPs in 989 individuals from MS families. While many SNPs within MCSs were monomorphic in our data set, many were validated as polymorphic. Our analysis of HapMap SNP data across the region confirmed that annotated SNPs in MCSs were more likely to be monomorphic than SNPs in non-conserved regions. We also verified that the density of annotated SNPs is much lower in MCSs, suggesting that a random selection of noncoding SNPs would bias toward variants in nonfunctional regions. We believe that this novel approach for follow-up analysis will increase the likelihood of successfully identifying a genetic factor for MS in the 1q43 region and demonstrates a paradigm for expediting the search for additional genes in MS and other complex diseases.

An accurate and robust high density SNP genotyping microarray platform. *K. Kuhn, P.C. Ng, S.S. Murray, L. Zhou, L. Galver, C. Tsan, D. Bullis, P. Merrit, F. Steemers, K. Gunderson, R. Shen* Biochemistry Development, Illumina, Inc., San Diego, CA.

We have developed a high density SNP genotyping platform that enables genotyping hundreds of thousands of loci on a single microarray accurately and efficiently. This platform utilizes a single base extension (SBE), which requires a single bead-type per assay and 2-color fluorescent imaging (Steemers et al. Nature Genetics, 2006). The assay is a single-tube, PCR-free protocol that yields extremely high data quality. We genotyped 120 HapMap DNA samples including 25 parent-child trios and 15 replicates in a panel of >550,000 SNP loci, generating over 66 million genotypes. From this dataset, we have observed >99% call rate, >99.9% reproducibility, >99.9% genotypes consistent with Mendelian inheritance, and 99.7% genotype concordance with the International HapMap Project. Because the assay uses a single-tube sample amplification process that does not require PCR or genome complexity reduction, it has virtually unconstrained SNP selection and unlimited multiplexing potential. In addition, the laboratory process workflow has been streamlined and includes automation enabling high sample-throughput, and a laboratory information management system (LIMS) enabling positive sample tracking, integrated project and workflow management, real-time quality metrics, data storage and analysis. The single slide substrate is highly flexible and can support a range of configurations including single-sample/slide whole genome content (100,000 - >550,000 SNP loci) or multi-sample/slide custom content (12,000 - 60,000 SNP loci). The assay and workflow process will enable researchers to quickly and inexpensively generate millions of genotypes to achieve their research objectives.

A genome-wide linkage scan of adiponectin levels in the GEMS study. *H. Ling[1], H. Stirnadel[2], N. Galwey[2], V. Mooser[2], D. Waterworth[2], B.D. Mitchell[1], The GEMS Investigators* 1) University of Maryland School of Medicine, Baltimore, MD; 2) Medical Genetics, Genetic Research, GlaxoSmithKline.

Adiponectin, a protein secreted exclusively by adipocytes, is the most abundant gene product in adipose tissue. Plasma adiponectin levels are negatively correlated with BMI, especially visceral adiposity, and are lower in subjects with type 2 diabetes (T2DM) and coronary artery disease. Metabolic studies in both animals and humans suggest it has a variety of metabolic effects, including anti-diabetic, anti-atherosclerotic, and anti-inflammatory and may mediate the relationship between obesity and insulin resistance or T2DM. At least 5 genome scans for adiponectin levels have been published to date. Chromosomal regions reported likely to harbor genes influencing variation in plasma adiponectin levels include chromosomes 5p, 14p, 9p, 15, 18 and 3q. We performed a genome-wide linkage scan of adiponectin levels in two different Caucasian populations, Mediterranean origin and non-Mediterranean origin, recruited as part of the GEMS study (3,069 participants from 450 families, 789 Mediterranean and 2,280 non-Mediterranean) aged 16-70 yrs. Quantitative trait linkage analysis was carried out using a variance components approach. Analyses were adjusted for age and sex. Plasma adiponectin level was significantly higher in females than in males. The heritability of adiponectin levels was 0.68 0.06 for Mediterranean and 0.67 0.04 for non-Mediterranean. The peak LOD score was 1.8 occurring at chromosome 3q27 (231 cM) in Mediterranean subjects and 2.78 occurring at chromosome 8p (8 cM) in non-Mediterranean subjects. The suggestive linkage at 3q27 replicates a previously reported linkage to 3q27 near the adiponectin structural locus. Though the linkage for adiponectin on chromosome 8 has not been reported so far, many significant linkages of obesity-related traits are found in this region. Our results support the linkage on ch3q27 and provide evidence for a locus on chromosome 8p influencing adiponectin concentrations in non-Mediterranean populations.

msHOT: Simulating crossover and gene conversion hotspots with Hudson's (2002) ms simulator. *G. Hellenthal, M. Stephens* Statistics, University of Washington, Seattle, WA.

Hudson's "ms" simulator (2002) is a widely-used program for simulating genetic variation data for randomly-sampled chromosomes from a population. Such data can be used to test new methodology or explore expected patterns of Linkage Disequilibrium (LD) (i.e. patterns of non-random associations among alleles on a chromosome) under a vast variety of scenarios. The program allows the user to specify various aspects of population demography (e.g. variable population sizes, migration patterns) and factors governing evolution (e.g. mutation, crossover, and gene conversion rates) when generating chromosomes. However, it presently does not allow for variation in recombination rates. In particular, ``hotspots," or areas of the genome in which crossover and/or (allelic) gene conversion occur at higher rates than the genome-wide average, appear to be common in humans. These "hotspots" can significantly alter patterns of LD, which can strongly affect the inference of methods that make use of such patterns (e.g. association studies). To address this, we have incorporated both crossover and gene conversion hotspots into a freely available, updated simulator called "msHOT." The program allows users to easily place in as many crossover and/or gene conversion hotspots (which can be of variable lengths and intensities) as they wish, in addition to the other parameters of the "ms" simulator.

Haplotype association with common and high CGG repeats at the *FMR1* gene in Thai subjects. *P. Limprasert, J. Thanakitgosate, T. Sripo* Pathology, Fac. Medicine, Prince of Songkla University, Hat Yai, Songkhla, Thailand.

Fragile X syndrome (FXS) is the most common inherited cause of mental retardation. Approximately 7% of Thai subjects referred for FXS testing showed CGG repeats expansion (> 200). The three most common CGG repeats in Thais are 29 (47%), 30 (31%) and 36 (10%). We described that there was no founder effect in Thai FXS but we found associated haplotypes in 29 and 30 CGG repeats using two microsatellites and two SNPs, DXS548-FRAXAC1-ATL1-IVS10 [Am J Med Genet 2001; 98: 224-229]. To further evaluation of this finding, we studied four old markers and three new SNPs in 134 normal males and 51 FXS males. We discarded DXS548 from haplotype analysis because it was not informative. The location of the markers related to CGG repeats (Kb) were described as 5-FRAXAC1-(7.2)-WEX5-(1.2)-CGG-(5.6)-ATL1-(13.6)-rs25731-(24.5)-IVS10-(29.1)-rs25702-3. We found 14 haplotypes in controls and 4 haplotypes in FXS group. Of 14, three common haplotypes were 18-G-G-A-T-A (HapA), 19-C-A-T-C-G (HapB) and 18-C-G-T-T-A (HapC), associated with 29 (22/31; 71%), 30 (21/30; 70%) and 36 (16/21; 76%) CGG repeats, respectively. Also, we found common haplotypes in FXS group (HapA = 18, Hap B = 20, HapC = 12, other = 1) with no statistically significant difference between controls. We found 11/14 (79%) chromosomes with HapA or HapC in 37-56 CGG repeats whereas we found only 3 chromosomes with HapB. In addition, we found all 36 CGG repeats with HapA or HapC. HapA and HapC might be evolutional derived since they have only two SNPs difference while HapA and HapB were different in all markers. This suggest that HapA and HapC were associated with 36-56 CGG repeats. However, we could not prove that HapA and HapC were susceptible to high risk for CGG repeat expansion since we did not see this association in the FXS group. Other alternative predisposing factors for repeat expansion need to be further elucidated.

Distinguishing single from multiple association signals within a gene. *K.L. Lunetta, J. Dupuis* Dept of Biostatistics, Boston University School of Public Health, Boston, MA.

When investigating an observed association between variation in a specific gene and a phenotype, for example, in the follow-up of a candidate gene or whole genome association scan, it is common practice to type multiple SNPs within the gene, many of which are in linkage disequilibrium (LD). Typically, we observe several SNPs to be associated with a trait when analyzing the SNPs individually (unconditional analysis). One goal is to determine whether all observed associations are due to a single variant, with LD explaining the rest of the observed associations, or whether evidence exists for multiple effects within the gene. One way to test for additional associated SNPs, assuming one Primary SNP is associated, is to test the secondary SNP in a model which contains the Primary SNP (conditional analysis, e.g., see Cordell and Clayton, 2002). We examine the effect of LD on power to detect primary and secondary associations under two scenarios: 1) the functional SNP or SNPs are genotyped and 2) the functional SNPs are not genotyped, but SNP(s) in LD with the functional SNPs are genotyped. We show that for the first scenario, analysis of a quantitative trait conditional on the primary SNP reduces power to detect the secondary SNP linearly with LD (r^2). For unconditional analysis, when coupled alleles both increase or decrease the quantitative phenotype, the expectation of the test statistic of the secondary SNP is inflated. When coupled alleles have effects of opposite direction, the effect on the expected test statistic of the secondary SNP is nonlinear in r^2; for a range of r^2 the secondary SNP has low power in unconditional analysis, but high power in conditional analysis. Under the second scenario, we show the power to distinguish a single functional SNP from two functional SNPs depends on the underlying LD structure. Our results show that power to detect secondary associations is strongly dependent on LD. Our findings can aid in determining how many and which SNPs should be genotyped in confirmation, in planning sample size requirements for these studies, and in planning studies to have power to detect multiple associated SNPs within a gene.

PseudoFinder: a genome-wide pseudogene finding method. *Y.T. Lu, D. Haussler* Center for Biomolecular Science & Engineering, University of California Santa Cruz, Santa Cruz, CA.

Pseudogenes are genomic debris derived from retrotransposed, incompletely duplicated, or inactivated copies of functional genes. Identifying pseudogenes allows us to better understand the evolution of genes and genomes and improve gene annotation. We developed a computational method, PseudoFinder, to identify pseudogenes in mammalian genomes. PsudoFinder finds homologues of functional genes in a genome and then classifies homologues into either pseudo or functional categories using Support Vector Machines (SVMs), a machine learn approach, based on a combination of features including sequence homology, similarity of gene structure, existence of stop codons and frameshifts, insertion of repetitive elements, and other features. The ten-fold cross validation test result showed that PseudoFinder was able to achieve more than 90% accuracy. Using PseudoFinder, we identified 16527 human pseudogenes and 18324 mouse pseudogenes.This is compatible or better than current pseudogene finding methods. There are 168 predicted pseudogenes in the ENCyclopedia Of DNA Elements (ENCODE) regions, where we have significant additional experimental information for further study.

Genetic analysis of acute necrotizing encephalopathy. *D. Neilson[1,2,3], M. Adams[2], D. Tefft[2], K. Trevarthen[2], D. Kerr[3], M. Warman[1,2,3]* 1) Ctr Human Genetics, Univ Hosps Cleveland; 2) Dept. Genetics, Case Western Reserve University; 3) Dept. Pediatrics, Case Western Reserve University, Cleveland, OH.

Acute necrotizing encephalopathy (ANE) typically affects children under 6 years of age. Following the onset of a febrile illness, such as influenza, affected children become progressively lethargic and progress to develop seizures or coma. Necrotizing lesions in the brainstem and thalamus are detectable by MRI. Although ANE usually occurs sporadically, we previously reported a family in which ANE segregates in an incompletely penetrant, autosomal dominant, manner (ADANE). We also reported the mapping of ADANE to 2q12.1-2q13, which encompasses 7.6 Mb, 36 known genes, and multiple duplicated regions. We assessed all coding exons of the known, non-duplicated genes in the region. This strategy revealed no mutations, although multiple intronic single nucleotide polymorphisms were observed. The nucleoporin gene RANBP2, which is contained within the candidate interval, has had its 5 sequence duplicated eight times across chromosome 2. However the 3coding portion of RANBP2 is unique. We used this unique 3 sequence to amplify RANBP2 cDNA from patient lymphoblast-derived RNA. Sequencing RANBP2 revealed a c.1754C>T transition, resulting in a threonine to methionine substitution (p.T585M), that segregates with the linked disease-associated haplotype. Duplicated portions of RANBP2 in mammalian genomes, coupled with the incomplete sequencing of many genomes, has made it difficult to identify RANBP2 orthologs across species; however, the disease-associated amino acid change does not appear to be present among known orthologs. To determine whether this coding change is a human polymorphism, 200 human control DNAs were sequenced and denaturing HPLC was used to screen additional controls from the CEPH genomic diversity panel. The allele was not observed in 2346 chromosomes. These results indicate that c.1754C>T is not a polymorphism and suggest it may be disease-causing. However, the demonstration of a functional consequence for this mutation or the identification of mutations in other patients or families will be needed to establish RANBP2s role in ADANE, and possibly ANE.

Nonsense-medicated mRNA decay is not a major contributor to downregulate the *Alu*-containing splicing variants. *K. Inoue, K. Takano, Y. Goto* Dept MR & BD Res, Natl Inst Neurosci, NCNP, Kodaira, Tokyo, Japan.

Alu is a primate specific family of short interspersed elements that is most abundantly present in primate genomes, accounting for >10% of the human genome. Genomic integration of *Alu* elements has been suggested to play multiple roles in the primate genome evolution, including the generation of new alternative exons utilizing splice donor/acceptor-like sequences present in *Alu* elements. However, only a small number of genes have been identified to carry *Alu*-containing splicing variants (ASV) despite the facts that *Alu* elements are abundantly present in genic introns, suggesting a presence of mechanisms that prevent exonization of *Alu* elements. Nonsense mediated decay (NMD) is an mRNA surveillance system by which mRNAs carrying premature termination codons (PTCs) are selectively detected and disrupted to prevent production of truncated proteins. Because the vast majority of potent ASV in the EST database carries PTC in its coding sequence, we hypothesized that NMD may play a role in suppressing the expression of ASV. To examine this hypothesis, we measured the expression level of ASV in 9 human genes in which EST database search and RT-PCR using HeLa cells confirmed the presence of ASV. Expression level of ASV was very low compared to wild type alleles. Similarly, expression of ASV appeared to be minor in multiple human tissues. Interestingly, removal of NMD in HeLa cells showed little effect in upregulating ASV in all genes examined, suggesting a limited role of NMD in suppressing ASV expression. To delineate whether this insensitivity to NMD is modulated by low efficiency of alternative splicing of ASV, we employed the ADAR2 gene, in which ASV became a major transcript with no premature termination, thus representing a suitable model to examine the effect of NMD on alternative ASV transcript. We generated a series of minigene expression vectors with PTCs in ASV, which were transiently transfected into HeLa cells. Unexpectedly, PTCs generated in the ASV failed to trigger NMD. These results suggested that NMD is not a major contributor to downregulate the alternatively spliced ASVs, despite carrying PTCs.

Non-Allelic Heterogeneity in Langer Mesomelic Dysplasia. *P.D.R.D. Nicola, A.B.A. Perez* morphology, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil.

The Langer Mesomelic Dysplasia (LMD; OMIM 249700), is a skeletal dysplasia characterized by severe short stature with hypoplasia/aplasia of the ulna and fibula. The envolved gene is located in the pseudoautosomal region (PAR1) of the X and Y chromosomes. The SHOX (short-stature homeobox-containing) gene is present in the locus Ypter-p11.2 and Xpter-p22.32. The SHOX gene encodes isoforms of a homeodomain transcription factor important in human limb development. SHOX haploinsufficiency has been implicated in three human growth disorders: Turner syndrome, idiopathic short stature, and Leri-Weill dyschondrosteosis. A partial deficiency of the SHOX gene in heterozygous individuals is responsible for Leri-Weill Dyschondrosteosis (LWD; OMIM 127300), which is characterized by disproportionate short stature with predominantly mesomelic limb shortening. The complete deficiency of the SHOX gene in homozygous individuals is responsible for a rarer and more severe form of osseous dysplasia, the LMD. We report a male patient, the only child of an incestuous relationship (father-daughter), presenting normal intelligence, short stature with disproportionate mesomelic of upper and lower limbs, frontal bossing, hypertelorism, low-set ears, long philtrum, micrognathia, normal thorax, scoliosis and bilateral Madelungs deformity of the forearm, a clinical phenotype that suggests LMD. X-ray shows mandibular hypoplasia, normal spine, bilateral short radii, bilateral short and broad ulna, bilateral short femoral neck, bilateral short tibia and bilateral short fibula, which are typical of mesomelic dysplasia. The reported case shows that in this patient the mutated gene cannot be in the pseudoautosomal region, since the degree of kinship between the parents is high and none of them presents other anomalies or Madelungs deformity, which is typical of LWD. Therefore, we can assume that the mutated gene is in an autosomal chromosome, suggesting an non-allelic heterogeneity in LMD. Another hypothesis is that the reported case is a new type of mesomelic dysplasia.

Influence of 2-adrenergic receptor (*ADRB2*) haplotypes on obesity-related traits and interaction with physical activity in adolescent Caucasians. *C.N. Moran[1], M.E.S. Bailey[1], A. Tsiokanos[2], A.Z. Jamurtas[2], Y.P. Pitsiladis[1], R.H. Wilson[1]* 1) Div. of Molec. Genet. and IDEAL, IBLS, Univ. of Glasgow, Glasgow, UK; 2) Dept of Phys. Education and Sport Sci., University of Thessaly, Trikala, Greece.

Genetic variation in human ?adrenergic receptor genes has been reported to be associated with obesity and degree of adiposity. We have carried out an association study of obesity-related phenotypes and the *ADRB2* gene in 1084 teenage Greeks. Three polymorphisms were investigated, p.G16R (c.46G>A), p.E27Q (c.79G>C) and the rarer p.T164I (c.491C>T). Ancestral and derived alleles are known from primate sequences and from existing haplotype data. The receptor encoded by the A-allele at codon 16 (p.16R) is known to desensitise less quickly in the presence of agonist, thus extending signalling half-life and probably affecting downstream lipolytic pathways in adipocytes. Associations (tested by ANOVA) were found only in males, there being a strong association between p.G16R genotype and both BMI (P=0.002), and skinfold thicknesses. These associations were best explained by an A-allele dominant model with homozygotes and heterozygotes for the derived A-allele exhibiting lower values of BMI. Investigating the influence of lifestyle on these associations, we found that the association was strongest in very active males, accounting for up to 9.4% of the phenotypic variance in BMI by ANOVA. Cumulative probability plots showed that the association acts across the full phenotype distribution. The three common haplotypes defined by the p.G16R and p.E27Q polymorphisms showed the same degree of association with BMI as p.G16R alone. p.T164I arose on a haplotype that contained the ancestral p.16G and derived p.27Q variants. When p.16G-27Q haplotypes were split into those with and without the derived p.164I variant (MAF=2%), the proportion of phenotypic variance in BMI explained rose from 3.2% to 5.2%, suggesting that the p.T164I polymorphism influences adiposity phenotypes through interaction effects with other coding or noncoding variants. These findings are commensurate both with a history of selection at this locus and an impact on body composition and response of adipose tissue to exercise in modern populations.

Delineation of breakpoints in chromosomal rearrangements: Continued examination of the mechanism and complexity of rearrangements. *H. Ho[1], C. Astbury[2], L. Christ[3], M. Falk[3], C. Fitzpatrick[1], M. Graf[4], H. Mashek[1], S. Schwartz[1]* 1) Human Genetics, Universitry of Chicaago, Chicago, IL; 2) Southern California Permanente Med Group, Los Angeles CA; 3) Case Western Reserve University, Cleveland, OH; 4) TGEN, Pheonix.

Our initial work showed that several patients with balanced rearrangements had previously undetected deletions with more complexity than originally thought. We have continued these studies to now include 32 patients with initially reported balanced rearrangements, including both de novo and familial cases. Using FISH with both BACs and fosmids, this work has identified over 80 breakpoints in these cases. Our findings show that 58% of the de novo cases had a deletion; however none of the 8 familial balanced rearrangements had a deletion. The vast majority of all cases involved either 2 or 3 breaks; however a subgroup (of 10 cases) involved multiple (5-12) breaks; 80% of these had a deletion. Results from these studies are interesting and reveal important information including that: (1) Patient ascertainment is correlated to the presence of a deletion; the more complex the phenotype and the involvement of multiple systems - the more likely that a deletion will be present; (2) Remarkably, 3 of the 14 cases with deletions had two different deletions; (3) Of the 14 cases with a deletion, many also had another breakpoint within a gene, which could confound the expected phenotype; (4) In the familial cases, gene disruption occurred as a result of the translocation in several cases; in two of these the gene and phenotype segregated together. However, in several cases both a normal parent and affected child had the translocation suggesting that either the gene causes no effect if haploinsufficient, and the phenotype is unrelated to the finding ,or the effect of the gene is more complex and requires careful interpretation; (5) No specific difference were seen between the de novo translocations with deletions, those without a deletion or the familial cases with respect to the involvement of low copy repeats, evolutionary breakpoints, or the recombination rates of the DNA segments involved in the rearrangements.

Elucidation of the Structure of Inverted Duplications: Heterogeneity in the Mechanism of Formation. *A.E. Murmann[1], C.A. Curtis[2], L.A. Christ[2], D.F. Conrad[1], H. Mashek[1], S. Schwartz[1]* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Case Western Reserve University, Cleveland, OH.

The development of molecular technologies in cytogenetics has lead to a better understanding of the mechanism of the formation of a variety of chromosomal abnormalities. Inverted duplications (inv dup), although rare, comprise approximately 13% of all intrachromosomal rearrangements and broadly fall into four categories: inv dup; inv dup with concomitant deletion; accessory acentric inv dup (acentric inv dup); and accessory dicentric inv dup. We have acertained 12 different inv dups (most with a concomitant deletion) and an additional 14 acentric inv dups and have completed precise breakpoint analysis in 9 and 5 of these cases, respectively, using FISH analysis, qRT-PCR, and quantitative SNP-microarray analysis. These analyses were performed to determine if the same mechanism is involved in the formation of one category of inv dups or even shared between different categories. This study demonstrates a number of very intriguing findings regarding the mechanisms of formation on these inv dups: (1) There is no specific mechanism of formation leading to the different types of inv dups; (2) We found heterogeneity of the breakpoints localized to both chromosomes 13 and 15; (3) None of the five acentric inv dups were associated with the presence of low copy repeats (LCR); (4) The formation of one acentric inv dup of chromosome 9 was highly unique in that it did not start at the breakpoint on chromosome 9; but rather involved a deletion of material; (5) Four of the nine inv dups with deletion involved the fusion of two chromosomal segments that were nonsymmetrical leaving a deletion, a stretch of single copy material followed by the duplication; (6) Four of the inv dups were associated with LCR elements; however these were very chromosome specific (one on chromosome 22 and three on chromosome 8); (7) All three chromosome 8p abnormalities involved the same breakpoint; and (8) All 5 analyzed breakpoint regions of acentric inv dups coincided within regions of evolutionary breakpoints, as did half of the analyzed breakpoints of the other inv dups.

The complete set of designs for maximum power candidate gene association studies. *B. Han[1], N. Zaitlen[2], H. Kang[1], E. Eskin[1,2]* 1) Computer Science and Engineering, UC San Diego, La Jolla, CA; 2) Bioinformatics Program, UC San Diego, La Jolla, CA.

Discovering correlation between causal genetic variation and clinical traits through association studies is an important method for identifying causal variation. Ahead of performing a real genetic association study, a researcher should design a study that maximizes the power to detect causal variants while minimizing the cost of the study. The design of a study involves choosing a set of tag SNPs and the number of individuals to be genotyped. The recent release of reference data sets such a the HapMap provide an opportunity to evaluate the effectiveness of designs through simulations. These simulation studies allow us to empirically measure the power of a set of candidate designs. By evaluating candidate designs, we can choose the most efficient design that achieve the desired power. However, designing efficient association studies requires addressing many computational challenges including the exponential number of possible designs in a region as well as the computational costs of performing the simulations to evaluate their power. We introduce a new association study design methodology which allows us to efficiently design association studies. Our methodology allows the approximation of the power of an association study from the correlation structure estimated from a reference data set such as the HapMap data. This allows us to avoid evaluating the power by simulations. Our methodology also presents new efficient algorithms for choosing a set of tag SNPs which maximize power, improving on current approaches which choose tag SNPs based on a r-square criterion. Our method can either maximize average power for all SNPs in a region or maximize the minimum power for each SNP in the region. In our experiment with ENCODE region, our method significantly outperforms r-square based tagging in power, resulting in cost reduction. We have applied our method to the entire set of human genes and the resulting designs are available as a resource for the community.

BDNF haplotypes differentiate schizoaffective and affective disorders from schizophrenia. *T. Lencz[1,2,3], R.H. Lipsky[4], P. DeRosse[1], K.E. Burdick[1,2], J. Jaeger[1,2,3], J.M. Kane[1,2,3], D. Goldman[4], A.K. Malhotra[1,2,3]* 1) Dept. of Psychiatry Research, The Zucker Hillside Hospital, Glen Oaks, NY; 2) Dept. of Psychiatry, Albert Einstein College of Medicine, Bronx, NY; 3) Center for Neuroscience, Feinstein Institute for Medical Research, Manhasset, NY; 4) Laboratory of Neurogenetics, NIAAA, Bethesda, MD.

Background: Recent population genetic studies suggest a partial overlap in genetic transmission of schizoaffective disorder and mood disorders. Allelic variation in the gene encoding Brain Derived Neurotrophic Factor (BDNF) has been associated with affective disorders in several family-based studies, but studies of schizophrenia have been generally negative. It is hypothesized that BDNF allelic variation is associated with the mood component of disorder, and that haplotype frequencies will be similar in patients with schizoaffective disorder and primary mood disorders, as distinct from patients with schizophrenia and healthy volunteers.

Methods: We tested for an association between a 5-marker BDNF haplotype and SCID-based, consensus DSM-IV diagnosis in 220 Caucasian healthy subjects and 373 Caucasian patients diagnosed with schizophrenia (n=208), schizoaffective disorder (n=60), bipolar disorder (n=76), or major depressive disorder (n=29).

Results: There was a significant association between BDNF haplotypes and illness manifestation. The common haplotype (containing the valene variant of the Val66Met polymorphism) was overrepresented in patients with schizoaffective and primary affective disorders compared to healthy volunteers. Moreover, the common haplotype showed significantly greater frequency in schizoaffective patients compared to patients with schizophrenia. Patients with schizophrenia did not significantly differ from healthy volunteers.

Conclusions: This is the first candidate gene study to differentiate schizoaffective disorder from schizophrenia. BDNF genetic variation may be associated with the clinical phenotype of affective dysregulation across several DSM-IV diagnostic categories.

Surveyor nuclease scanning and DNA sequencing reveal a high frequency of von Hippel-Lindau gene mutations in sporadic renal cell carcinoma tumors from Eastern Europe. *M.L. Nickerson[1], E. Jaeger[2], J.A. Durocher[1], K.B. Walters[3], Y. Shi[1], S. Mahurkar[1], M. Smithhisler[1], L.S. Schmidt[4], J.R. Toro[5], B. Zbar[6], W.-H. Chow[5], G.F. Gerard[1], S. Lilleberg[7], F.M. Waldman[2], L.E. Moore[5]* 1) Transgenomic, Gaithersburg, MD; 2) Comprehensive Cancer Center, UCSF, San Francisco, CA; 3) Biological Sciences Program, GWU, Washington, DC; 4) SAIC, NCI-Frederick, Frederick MD; 5) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 6) Laboratory of Immunobiology, NCI-Frederick, Frederick, MD; 7) Transgenomic, Omaha, NE.

Mutation of the von Hippel-Lindau (VHL) tumor suppressor gene has been implicated in the pathogenesis of clear cell renal cell carcinoma (RCC). A large case-control epidemiology study of kidney cancer is underway in Eastern Europe, which will examine how exposure history relates to the spectrum of VHL mutations. Three methods of mutation detection were initially compared: denaturing high performance liquid chromatography (DHPLC), double-stranded (ds) sequencing, and Surveyor endonuclease scanning. Surveyor nuclease scanning was as sensitive as DHPLC and provided additional detail about the location of a variant/mutation in an amplicon. An approach using both Surveyor nuclease and ds sequencing was then applied to analysis of VHL in 205 tumors from Eastern European patients with sporadic clear cell RCC. Using these two methods, 171/205 tumors (83.4%) were VHL mutation positive. An unexpectedly high proportion of mutations (45%) were difficult to detect by ds sequencing alone. PCR products were re-amplified from 91 tumors using a proofreading polymerase and Surveyor digests showed 100% agreement with the original data set. Analysis of Surveyor digests on a 96 well capillary electrophoresis instrument was amendable to high sample throughput that matched ds sequencing. Significantly, Surveyor scanning dramatically reduced staff time required for manual review of sequencing chromatograms. These two methods are complementary and sensitive, and can be used to meet current demand for large scale genetic analysis of patient tumor samples to detect somatic and inherited mutations relevant to personalized medicine.

Significant linkage of major depression on 15q25-q26 after SNP fine-mapping. *J. Knowles[1], D.F. Levinson[2], O.V. Evgrafov[1], J.B. Potash[3], M.M. Weissman[4], W.A. Scheftner[5], J.R.Jr. DePaulo[3], R.R. Crowe[6], K. Murphy-Eberenz[7], D.H. Marta[5], M.G. McInnis[8], P. Adams[4], M. Gladis[7], E.B. Miller[3], J. Thomas[3], P.A. Holmans[9]* 1) University of Southern California, Los Angeles, CA; 2) Stanford University, Stanford, CA; 3) Johns Hopkins University, Baltimore, MD; 4) Columbia University and NY State Psychiatric Institute, New York, NY; 5) Rush University Medical Center, Chicago, IL; 6) University of Iowa, Iowa City, IW; 7) University of Pennsylvania, Philadelphia, PA; 8) University of Michigan, Ann Arbor, MI; 9) Cardiff University, Cardiff, UK.

The authors studied a dense map of single nucleotide polymorphism (SNP) DNA markers on chromosome 15q25-q26 to maximize the informativeness of genetic linkage analyses in a region where they previously reported suggestive evidence for linkage of recurrent, early-onset major depressive disorder (MDD-RE). In 631 European-ancestry families with multiple MDD-RE cases, 88 SNPs were genotyped and multipoint allele-sharing linkage analyses carried out. Marker-marker linkage disequilibrium (LD) was minimized (r2 0.05), and a simulation study using founder haplotypes from these families suggested that linkage scores were not inflated by LD. The dense SNP map increased the information content of the analysis from around 0.7 to over 0.9. The maximum evidence for linkage was Zlr = 4.69 (Kong-Cox LOD = 4.78) at 109.8 cM (92.6 Mb, NCBI Build 34). The exact p-value (0.0000014) was below the genome-wide significance threshold (0.00002). By contrast, in the genome scan using microsatellite markers at 9 cM spacing, the maximum Zlr score for European-ancestry families was 3.43 (106.53 cM, LOD=2.56). It was estimated that the linked locus or loci in this region might account for a population-wide increase of 20% or less in risk to siblings of cases. This region has produced modestly positive evidence for linkage to depression and related traits in other studies. These results suggest that DNA sequence variations in one or more genes in the 15q25-q26 region can increase susceptibility to major depression, and that efforts are warranted to identify these genes.

A member of the immunoglobulin superfamily, CD96 contributes to cell adhesion and growth. *T. Kaname[1,2], K. Yanagi[1], H. Maehara[3], F. Kanaya[3], Y. Kubota[4], Y. Oike[4], K. Naritomi[1,2]* 1) Deptartment of Medical Genetics, University of the Ryukyus, Nishihara, Japan; 2) SORST, Japan Science and Technology, Kawaguchi, Japan; 3) Deptartment of Orthopedics, University of the Ryukyus, Nishihara, Japan; 4) Deptartment of Cell Differentiation, Keio University School of Medicine, Tokyo, Japan.

CD96 was identified as a human T-cell antigen, which expression was increased during 6th and 9th day after activation by IL-2. It is known that CD96 is expressed in several T-cell lines (e.g.; MOLT-15, PEER), naïve T-cells, and weakly in NK cells. However, its function and expression in other tissues are still unknown. Our aim is to understand the function of CD96 *in vivo* and *in vitro*. Fist, we investigated its expression in adult tissues and in embryos by using RT-PCR and whole mount *in situ* hybridization. In human, *CD96* is strongly expressed in the lung, spleen, and thymus, and moderately expressed in the brain, spinal cord, trachea, digestive tissues, prostate, and testis. In mouse embryo, the *Cd96* gene is expressed in the forebrain, cardiac jerry, endothelial cells, pharynx, and blood cells at 10 dpc. Next, we investigated function of CD96 *in vitro* by characterization of HT1080 cells or K562 cells stably expressed CD96. The HT1080 cells expressing CD96 increased adhesive activity to cell-culture plates and increased cell growth activity. The K562 cells expressing CD96 increased cell aggregation. Thus, we concluded that CD96 would be involved in cell adhesion and growth control.

Obstetrics and Obstetrical Anesthesia Issues in Women with Dwarfism. *J. Hoover-Fong[1], G. Oswald[1], D. Miller[1], J. Leadroot[1], H. Barnes[1], J. Rossiter[1,2], D. Krakow[3], D. Penning[1], I. Berkowitz[1]* 1) Institute of Genetic Medicine, Greenberg Center for Skeletal Dysplasias, Johns Hopkins University, Baltimore, MD; 2) St. Joseph Medical Center, Baltimore, MD; 3) Cedars-Sinai Medical Center, Los Angeles, CA.

OBJECTIVE:There is a paucity of medical literature regarding obstetrics and obstetrical anesthesia in dwarf women (aka Little People, LPs).This population has no recognized infertility predisposition.Thus, dissemination of information about pregnancy and delivery in dwarf women would be extremely useful to LPs and their healthcare providers. METHODS: A 2 part assessment; part 1 is a comprehensive survey of the Society for Obstetric Anesthesia and Perinatology (SOAP) members regarding formal training, clinical practice and opinions about 3 hypothetical case scenarios concerning anesthesia for pregnant dwarfs.Part 2 is a retrospective cohort study of LPs with 1 prior conception, regarding pregnancy and delivery experience, physical status pre- and post-partum, and general opinions about pregnancy in LPs. RESULTS: SOAP members were recruited via membership roster mailing; 149 completed the survey (99 male, 50 female) and 134 are board certified in general anesthesia or a related field.LPs were recruited via a gender- and age-specific mailing to members of the Little People of American,Inc.To date, 37 women with 10 different skeletal dysplasias (76 pregnancies) have completed the survey.There were 13 miscarriages, 1 termination, and 60 live infants delivered via cesarean section (31 general anesthesia-GA, 29 spinal and/or epidural anesthesia).Two live infants were delivered vaginally without anesthesia to a mother with hypochondroplasia. CONCLUSIONS: We do not promote or deter childbearing in LP women.However there is little formal training and no practice guidelines regarding pregnancy and delivery in dwarfs.Many have carried successful pregnancies and delivered with adequate pain control (under regional and GA).We present practical experiences with obstetrics and obstetrical anesthesia from the dwarf and healthcare provider perspective for others who choose to have children and those who provide their medical care.

Informed consent in the era of identifiable publicly released DNA data. *A.L. McGuire*[1], *R.G. Gibbs*[2] 1) Center for Medical Ethics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Increasing numbers of investigators are adding DNA banking and analysis to their research protocols, resulting in the rapid proliferation of DNA databases. These databases contain increasingly valuable information that will be used by scientists around the world to study the complex relationship between genetic variation and human health. To maximize the scientific and clinical utility of this information, existing research policy calls for the rapid public release of all generated data on the World Wide Web. Ethical concerns about subject privacy have largely been addressed by de-identifying sequenced data, but we now know that an individual can be uniquely identified from a limited amount of genetic information. Informed consent for the public release of sequenced DNA data is therefore required. Federal agencies have begun to address this problem by requiring informed consent for public data release, but the degree to which potential subjects are invited to participate in decision making about public data sharing and the amount of control that potential subjects are given over the release of their DNA data remain controversial. Draft consent documents for large scale sequencing projects such as the Human Genome Project, the International HapMap Project, and The Cancer Genome Atlas Project all adopt a traditional take-it-or-leave-it approach, where consent to public data sharing is required for participation in the study. This approach can be contrasted with a stratified consent model that gives potential subjects more authority to decide whether, how, and with whom they want their DNA data shared without effecting their participation in the primary research study. Whereas the traditional model promotes international coordination and collaboration, stratified consent is more responsive to individual preferences and judgments about the privacy-utility trade-off. Which approach to adopt will depend partly on the degree of variation in potential subjects' judgments about the privacy-utility trade-off and the impact of each approach on enrollment rates in genetic research.

Association Mapping in Model Organisms under the Effect of Population Structure. *H.M. Kang[1], N.A. Zaitlen[2], C. Kadie[4], C.M. Wade[3], A. W. Kirby[3], M.J. Daly[3], D. Heckerman[4], E. Eskin[1,2]* 1) Computer Science and Engineeing, UC San Diego, La Jolla, CA; 2) Bioinformatics Program, UC San Diego, La Jolla, CA; 3) Broad Institute of M.I.T. and Harvard, Cambridge, MA; 4) Microsoft Research, Redmond, WA.

Genetic association mapping in model organisms has tremendous potential to identify genetic determinants of complex traits related to human disease. A tremendous amount of genotype and phenotype information is available for in-slico association mapping in various model organisms such as inbred mice, Drosophila, or Arabidopsis thaliana. The mouse model is a very important model organism for many human diseases. These association mapping studies are often complicated by the complex population structure between the strains due to historical breeding patterns which can cause a significant amount of false positives. Traditional methods for coping with population structure assume the presence of a handful of populations within the data and can not correct for mutliple levels of complex population structure. We present a statistical test correcting for population structure in association mapping for model organisms by taking a phylogenetic tree as a confounding factor to correct for population structure effects. Our method can be extended to arbitary genetic correlation structure beyond phylogenetic tree, and the model is mathematically equivalent to unified mixed model proposed by Yu et. al. However, our method is more advantageous in the sense that it is computationally more efficient than the typical iterative procedure in mixed model and has better convergence properties, enabling us to perform genome wide association mapping much more efficiently. Our genome wide analysis with inbred mouse strains and Arabidopsis shows that our approach significantly reduces the inflation of false positives while identifying many associations consistent to previously known genes or QTLs.

Constructed eukaryotic expression plasmid of small hairpin RNA of PCNA and investigated the inhibitory effect on HeLa carcinoma cells. *Hao. Huang[1], Xin. Tu[2], Nancai. Yu[1], Wenli. Wu[1], Qian. Liu[1], Wei. Ma[1], Jianjun. Hao[1], Yandong. Yi[1]* 1) Center of Medicine, Wuhan first hospital, Wuhan, Hubei, China; 2) Human Genome Research Center, Huazhong University of Science & Technology.

Objective: To evaluate a new plasmid mediated RNA interference (RNAi) system and nvestigate whether knock-down of PCNA by short hairpin RNA (shRNA) can inhibited proliferation of human on HeLa cell carcinoma (HeLa) line in vitro. Methods: The pGenesil-1 plasmid containing mU6 promoter was digested by Bam HIand HindIII enzyme ,recombinant plasmid expressing shRNA targeting PCNA gene was designed and constructed, and were co-transfected cells with green fluorescence protein expressing plasmid. Flow cytometry was used to analyse the cell cycle and Western blot were applied to analyze PCNA mRNA and protein levels, and MTT test were applied to estimate the inhibition of growth, Single cell gel electrophoresis was used to analyse apoptosis ,respectively. Results: The shRNA expressed by the recombinant plasmid efficiently suppressedPCNA gene expression and induced apoptosis of HeLa cell carcinoma cell in vitro Conclusion: The recombinant plasmid can sufficiently mediate RNAi in HeLaarcinoma cells, and knock-down of the PCNA expression by shRNA significantlyinhibited the proliferation and induced apoptosis in HeLa cells. The results suggest this new system, mediated RNAi can be used as a tool for the study of gene function and gene therapy.

Application of whole genome tiling arrays to formalin-fixed paraffin embedded tissue: Opening up the archives to cancer gene discovery. *E.A. Maher[1], R.R. Selzer[2], D. Castrillon[1], P.S. Eis[2]* 1) University of Texas Southwestern Medical Center, Dallas, TX; 2) NimbleGen Systems, Inc.

Study of the human cancer genome has largely been based on DNA extracted from tumor tissue frozen at the time of operative resection. While even in the most committed academic centers, relatively few tumors are saved in accessible tumor banks, thus limiting the potential value of these samples for cancer gene discovery. Historically, archival tissue has been inaccessible to high resolution genomic technologies, including array comparative genomic hybridization (aCGH), since the quality of DNA extracted from formalin-fixed paraffin embedded tissue (FFPE) has been poor. Fragment lengths are generally 50-150 bp, well below minimum length necessary for gene-specific array CGH. However, recent modifications to DNA extraction methods has enabled extraction of long intact fragments of DNA (>15 kb) from FFPE tumors (Maher et al., submitted) providing an opportunity to profile these specimens. Using DNA from FFPE glioblastomas and other solid tumors (archival time ranged from 1-10 years), we performed whole genome analysis using 25 kb-resolution tiling-path aCGH (NimbleGen Systems, Inc.). Full complexity genomic DNA from FFPE was labeled and analyzed in a 2-color format (Cy3/Cy5). The FFPE data were compared to data generated from frozen tumor DNA. No differences were detected among the profiles when examined for signal-to-noise ratios and a series of quality control parameters and, most importantly, detection capability of both large and small copy number alterations was similar for FFPE and frozen tumor DNA. Indeed, in a small number of glioblastomas, the classical amplifications including EGFR, MDM2, CDK4, PDGFRA and classical deletions including p16, PTEN, and RB were easily detected. In addition, many novel focal loci were identified. This study demonstrates the feasibility of using FFPE DNA for high resolution genomic analysis. Applying this technology to archived cancer specimens that have full clinical annotation and are readily available in most pathology departments provides an unprecedented opportunity for comprehensive investigation of the cancer genome.

Browsing Associations. *W.J. Kent, D. Haussler, UCSC Genome Bioinformatics Group* Biomolecular Engineering, University of California, Santa Cruz, CA.

The UCSC Genome Browser at genome.ucsc.edu is a popular and useful tool for finding genes and other functional areas within a region of a chromosome. We are adding several new features that make it even easier to use the genome browser to analyze the results of SNP association studies and other genome-wide scans. Weve designed a genome-wide view that displays graphs of LOD scores and other numerical values across all chromosomes in a single page. From the genome-wide view you can go to a candidate region view that contains a list of all regions above a scoring threshold on the left, and the classic genome browser on a selected region on the right. There is also a candidate-gene view that lists all known genes in the candidate regions in a table with hilights of what is known about each gene. Clicking on an individual gene takes you to a page with a great deal of additional gene-specific information. The system is designed so that you can upload the scores on pre-publication data in such a way that you can view it just in your own web browser. After publication we encourage you to contribute the scores to our public database, where others working on the same disease processes can find it.

How well do the HapMap SNPs tag functional variants in 217 Drug Metabolizing Enzyme genes? *F.C.L. Hyland[1], K. Lazaruk[1], K.A. Haque[2], R.A. Welch[2], F.M. De La Vega[1]* 1) Applied Biosystems, Foster City, CA; 2) Core Genotyping Facility, Division of Cancer Epidemiology and Genetics, SAIC Frederick, National Cancer Institute, Gaithersburg, MD.

We examined patterns of linkage disequilibrium (LD) among putatively functional polymorphisms in drug-metabolizing enzyme (DME) genes, many of which have previously been shown to alter drug responses in individuals. We have developed and wet-lab validated 2,394 specific and robust assays in 217 DME genes. Functional, especially rare, alleles may be less likely to be in high LD with a set of common tagging SNPs, such as those selected using HapMap data. We thus investigated the degree of pairwise LD among these putative functional DME SNPs, and between these putative functional variants and the HapMap SNPs (release 19). In collaboration with National Cancer Institutes Core Genotyping Facility we genotyped these polymorphisms on the HapMap samples (n=270). Few putative functional SNPs are in high or perfect linkage disequilibrium with each other: among 1702 SNP pairs within 50 kb both polymorphic in CEU, only 10.6% of the pairs have pairwise $r^2 > 0.85$. Low frequency variants (MAF < 0.05) showed less LD with the others. About 40% of the DME putative functional SNPs were found in HapMap. However, of these about 34% failed the internal HapMap quality control metrics, probably reflecting the difficulty in developing robust assays for variants in challenging, highly homologous genes such as these. 23% of DME genes have none of their non-HapMap SNPs tagged by any HapMap SNPs. By determining how many of the non-HapMap DME SNPs are tagged by HapMap SNPs, a predictive model can be generated to assess the power of an association mapping study to capture functional variants in genes. Of the SNPs polymorphic in CEU and not found in HapMap, about 38% were not effectively tagged by any combination of HapMap SNPs ($R^2 < 0.8$). Our results suggest that investigators interested in DME putatively functional SNPs should exercise caution in relying solely on tagging SNPs for disease association, drug efficacy, toxicity, and metabolism studies, and should consider typing directly the relevant variants when feasible.

Increased Specificity for the Detection MSUD by the Addition of a 2nd-tier LC-MS/MS Assay of Alloisoleucine.

D. Oglesbee[1], J.M. Lacey[1], C.D. Spolar[1], K.A. Strauss[2], B. Casetta[3], S. Tortorelli[1], S.H. Hahn[1], P. Rinaldo[1], D. Matern[1] 1) Mayo Clinic, Rochester, MN; 2) Clinic for Special Children, Strasburg, PA; 3) Applied Biosystems, Monza, Italy.

Alloisoleucine (Allo-Ile) is a metabolite of L-isoleucine. Increased Allo-Ile levels are pathognomonic for Maple-Syrup Urine Disease (MSUD), a defect of branched-chain amino acid (BCAA) metabolism. Classic MSUD presents with feeding intolerance, vomiting, lethargy and maple syrup odor in urine and cerumen. If untreated, it can progress to mental retardation, cerebral edema, and death. Newborn screening includes leucine (Leu), isoleucine (Ile), and valine (Val) quantification in dried blood spots (DBS). However, current screening methods are unable to distinguish between elevations of isobaric amino acids, Allo-Ile, Ile, Leu, and hydroxyproline (OHPro). This is problematic as high BCAA are suggestive of MSUD while a OHPro elevation occurs in hydroxyprolinemia, a benign disorder. Increased levels of BCAA are also frequently observed in newborns given total parenteral nutrition, results that can lead to further testing. We developed an LC-MS/MS method for the detection of Allo-Ile in a single dried blood spot (DBS) punch. Allo-Ile and other BCAA are extracted from DBS with methanol/H_2O, dried under nitrogen, and reconstituted into mobile phase. Chromatographic separation of Allo-Ile is achieved within 10 min. Inclusion of isotopically labeled Ile (^{15}N-Ile) internal standard permits Allo-Ile, Leu, and Ile quantification. The assay is calibrated for BCAA concentrations up to 1250 mol/L ($y=3586x+30048$; $R^2=0.9919$). In a blinded cross-center study, 100% of MSUD-positive cases (N=16) were correctly identified from collection of DBS (N=37). Allo-Ile concentrations ranged from 0.00-984.64 mol/L. In 2005, 0.1% of newborns screened at the Mayo Clinic required follow-up due to multiple AA abnormalities including BCAA elevations. Allo-Ile detection in DBS performed as a second-tier assay when elevated BCAA are encountered can aid in reducing false-positive cases requiring unnecessary follow-up. In addition, this method can resolve isolated OHPro elevations, leading to increased specificity of MSUD detection.

Molecular cytogenetic analysis of complex chromosome rearrangements. *E.N. McDonald, G.S. Sekhon, J.B. Ravnan, D.M. Stenberg* Cytogenetics Laboratory, Genzyme Genetics, Santa Fe, NM 87505.

Complex chromosome rearrangements (CCRs) are extremely rare but are usually ascertained in patients with phenotypic abnormalities or in phenotypically normal patients presenting with recurrent miscarriages or infertility. Conventional karyotyping is usually difficult and often does not completely characterize the rearrangement. Molecular cytogenetic methods can reveal subtle abnormalities not evident in the G-banded karyotype. We present two patients with CCRs. A four year old patient was referred due to developmental delay and dysmorphic features. G-banding showed a CCR involving three chromosomes (3, 7, 12) however, the precise nature of the rearrangement was not clear. Fluorescence in situ hybridization (FISH) testing, analyzed in conjunction with the G-band karyotype, revealed a more complex rearrangement with multiple insertions and translocation involving 11 chromosome breakpoints and resulting in a deletion of the long arm of chromosome 3 from 3q12 to 3q21. In a second patient, G-band analysis showed that a 37 year old female with diabetes mellitus, obesity, sleep apnea, coronary artery disease, and mental retardation had a CCR involving chromosomes 3, 7, 10, 11, and 17. FISH analysis showed the presence of a translocation and insertion between one chromosome 3 and one chromosome 10, a reciprocal translocation between one chromosome 7 and one chromosome 17, and an intrachromosomal rearrangement of chromosome 11, consistent with an inversion. We demonstrate the value of painting probes and subtelomere probes as a useful complementary tool to cytogenetic analysis for detecting complex chromosome rearrangements.

A Robust and Sensitive Method For Detection of exonic deletions in the critical gatekeeper genes: VHL, APC, and RB1 By Multiplex Polymerase Chain Reaction (Mpcr) And High-Sensitivity High-Performance Liquid Chromatography (HS-HPLC). *S. Lilleberg, J. Hempel, S. Edstrom, M. Nickerson* Translational & Clinical Res, Transgenomic, Omaha, NE.

Reliable and sensitive screening for large gene rearrangements is a vital part of molecular genetic testing, however it can be technically challenging. A variety of robust methods can detect whole-gene deletions, but fail to detect more subtle rearrangements such as single exon deletions. Here we describe the implementation of a versatile and robust technique to assess exon copy number, which utilizes a multiplex polymerase chain reaction (mPCR) and high sensitivity (HS) post-column fluorescence detection of the amplicons after separation by nondenaturing high performance liquid chromatography (HPLC). The relative peak intensity for each target exon is associated with the exon copy number present in the sample. This novel approach was used to screen various patient samples for exon deletions in the VHL,APC and RB1 genes. The use of multiplex PCR coupled with HS-HPLC allows for analysis of small gene rearrangements in biological samples with limited source DNA (e.g. biopsy samples) on an automated platform without the use of fluorescent probes.

The experience of a newborn screening referral/treatment site with expanded newborn screening. *P. Levy* Dept Pediatrics,Albert Einstein College of Medicine,Children's Hosp Montefiore,Bronx,NY.

NY State had two recent expansions of the newborn screening (NBS) program with the introduction of MS/MS technology. The second expansion occurred in February 2005. Our center's experience for 2005 was reviewed and compared with NY State totals, and recent published data. We had 48 presumptive referrals with an estimated 20,000 births per year in the Bronx. The true positives (4) from these presumptive results were GALT (0 of 2), PKU (1 of 1), HCY/Methionine (0 of 3), SCAD (1of 2), Carnitine uptake (C0) (0 of 8), CPT II/CACT (1 of 1) , CPT I (0 of 16), 3-MCC (1 of 11), and MMA/PA/MCD (0 of 3). NY State had 242,184 births in 2005. 26 of the 37 disorders tested were Inborn Errors of Metabolism. These 26 tests had 3133 presumptive positives (1:77) which resulted in the following confirmed cases (67): 5 of 11 GALT, 4 of 250 PKU, HCY (2 of 290), 7 of 128 SCAD, 5 of 501 Carnitine Uptake, 1 of 50 CPT II/CACT, 0 of 289 CPT I, 20 of 292 3-MCC, and 7 of 234 MMA/PA/MCD. Also included in the 3133 were the additional tests for which our center did not have a presumptive positive: MSUD (1 of 140), 0 of 125 Tyrosine, 2,4 Di (0 of 21), LCHAD/TFP (0 of 5), MADD/MCAD (10 of 280), VLCAD (0 of 13), M/SCHAD (0 of 19), BKT (0 of 13), GA-1 (1 of 40), IBCD (0 of 128), IVA/2-MBCD (1 of 148), HMG/3-MCC (20 of 292), MA (1 of 4), and MMA/PA/MCD (6 of 230) Initial high false positive rates may necessitate changes in cutoff levels. High true positives lead us to re-examine the natural history of a disease. Published data show that a positive screen may not lead to a symptomatic patient. For families, this lack of knowledge about a disease or a false positive result causes undue stress and interfere with the development of attachment to the newborn. For the referral/treatment sites, most states (NY State included) do not reimburse centers for the costs involved in follow-up and confirmatory testing. As the move to expand NBS and equalize NBS across the country continues, efforts must be made to minimize the impact of false positives on families, and provide assistance to referral sites to defray follow-up costs, while everyone benefits from the knowledge gained from expanded NBS.

COE3, a Member of the Collier/Olf1/EBF Family of Transcription Factors, Is Silenced by Promoter Hypermethylation and Induces Apoptosis in Human Malignant Brain Tumors. *W.T. Liu[1], A. Lo[2], P. Lai[1], P.B. Chen[1], M.Y. Lin[1], M. Hsiao[1]* 1) Genomic Research Center, Academia Sinica, Taipei, Taiwan; 2) Graduate Institute of Pathology, College of Medicine, National Taiwan University, Taipei, Taiwan.

Aberrant methylation of promoter CpG islands is known to inhibit transcriptional initiation and cause permanent silencing of tumor suppressor genes, being one of the major mechanisms in tumorigenesis. In this report we investigated the epigenetic and genotypic status of COE3 gene, a member of the COE (Collier/Olf1/EBF) family of transcription factors that was found to be involved in prenatal glial cell development, in human glioma cell lines and clinical samples. Our results showed that the all glioma cell lines (12/12) and a significant percentage of clinical samples especially in stage III and IV gliomas with either reduced or lack of COE3 expression. These results strongly correlated with the methylation status of COE3 promoter region analyzed by methylation-specific PCR and bisulfite sequencing. DNA PCR analysis of COE3 exon showed no deleltions were found in glioma cell lines and clinical samples. Genomic sequencing analysis revealed one mutation in exon 15 of SF126 glioma cell line. Moreover, overexpression of wild-type COE3 gene in non-expressing glioma cell lines suppressed tumor growth via induction of apoptosis by flow cytometry and TUNEL analysis. Taken together, our results indicated that down-regulation of COE3 gene may be associated with promoter hypermethylation in malignant human glioma. Functional expression of COE3 induced apoptosis in glioma cell lines.

Association of *POU2F1* genetic polymorphisms with type 2 diabetes in Hong Kong Chinese. *V.K.L. Lam, J.S.K. Ho, W.Y. So, R.C.W. Ma, J.C.N. Chan, M.C.Y. Ng* Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, China.

POU2F1 is a ubiquitously expressed transcription factor of the POU family of homeo domain proteins. It is involved in numerous cellular transcriptional regulations including the basal and induced expression of C-reactive protein, in which the latter is a marker of inflammation implicated in the pathogenesis of type 2 diabetes (T2D). This study aimed to investigate for the association of *POU2F1* gene, located at 1q22-23, with T2D in a Chinese population previously showing linkage at chromosome 1q for T2D.

We studied 164 families (645 members) ascertained through a proband with T2D, as well as 410 random T2D patients and 370 healthy controls. Three common SNPs from *POU2F1* (rs12139104, rs10918682 and rs3767436) were genotyped by mass spectrophotometry. Family-based association test by FBAT revealed significant association of rs3767436 with both T2D and obesity ($p < 0.05$). Moreover, rs10918682 was associated with T2D in an independent sample of unrelated cases and controls ($p < 0.01$). Haplotype analyses did not reveal more significance than single SNP analyses. Our results suggest a possible role of *POU2F1* variation on susceptibility to T2D.

Genome-wide Association Studies of Type 2 Diabetes in Mexican Americans. *M.G. Hayes[1], K. Miyake[1], C.L. Hanis[2], G.I. Bell[1], N.J. Cox[1]* 1) Medicine, Univ. Chicago, Chicago, IL; 2) Univ. Texas Health Sciences Center, Houston, TX.

We have undertaken a genome-wide association study using the Affymetrix 100K platform to localize susceptibility genes for type 2 diabetes (T2D) in Mexican Americans from Starr County, TX. Power for our study was increased by choosing the affected sibling with youngest age at diagnosis of T2D from sibships included in previous linkage studies as the case samples (350 for first-stage screen). A random sample of Mexican Americans from Starr County comprises the control sample (350 for first-stage screen). We present results from a data freeze including 287 cases and 316 controls. Using the Affymetrix DM allele-calling algorithm, per marker call rates averaged >93%, with more than 80% of markers having call rates >90%. With the DM algorithm calls, we observed a substantial number of SNPs with departures from Hardy Weinberg equilibrium (HWE) at any threshold of significance, largely attributable to SNPs with excess homozygosity, consistent with non-random missing data (heterozygotes more likely to have missing data). Using an improved allele calling algorithm (GEL) both increased the call rate and reduced non-random missing data. We observed many more significant allelic associations than expected genome wide as empirically assessed by permutation [specifically 3 below a p of $1x10^{-5}$ (1 expected), 38 below a p of $1x10^{-4}$ (15 expected), and 246 below a p of $1x10^{-3}$ (129 expected)]. Our three best signals, those with allelic association $p<1x10^{-5}$, call rates >93%, and HW departure p-values >0.001, occur on chromosomes 4q, 12q, and 20q. We are conducting admixture mapping in these same samples, and will contrast regions of interest across these methods in follow up studies in an additional 700 case and 700 random samples ascertained in the same way from Starr County. Our preliminary analyses of this genome-wide association study suggest it will successfully highlight regions of interest for follow-up in a larger case-control set. Moreover, it may reveal novel genes and pathways to further elucidate the etiology of T2D as well as new avenues for both the treatment and prevention of this complex disease.

LKB1 Tumor Suppressor Gene is Frequently Inactovated in Human Lung Cancers. *T.C. Lai[1], M.S. Huang[2], H.M. Huang[2], M. Hsiao[1]* 1) Genomics Research Center, Acdemia Sinica, Taipei, Taiwan; 2) Department of Internal Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan.

Background: Lung cancer is the second leading cause of cancer-related death in Taiwan in 2003. Discovering the new molecular targets may provide new methods on the treatments of this devastating disease. LKB1, a serine/threonine kinase, is a new tumor suppressor gene with spontaneous mutations and/or deletions found in human cancers. Some reports have recently demonstrated that LKB1 inactivating mutations are appeared in lung adenocarcinomas of sporadic origin, including primary tumors and lung cancer cell lines. Aims: In this study, we investigated LKB1 gene mutations and/or deletions frequencies in 110 Taiwan patients with non-small cell lung carcinomas (NSCLC) and seven lung cancer cell lines. Methods: Mutations and/or deletions were screened by polymerase chain reaction (PCR), sequencing and coamplification. In addition, LKB1 expressions were observed by immunohistochemical analysis (IHC). Results: Five out of 110 (4.5%) patients were found with LKB1 gene exon 8 deletions and 2 out of them were combined with exon 7 deletions. An identical mutation at codon 354 (Phe to Leu) were found in 4 out of 65 (6.2%) patients. Interestingly, a germ-line mutation was found in one patient. Various point mutations were also found in three cell lines. In addition, reduced expressions of LKB1 were observed in cell lines and clinical samples. Our data suggested that LKB1 gene may be involved in the tumorgenesis of NSCLC.

A new test for hardy-weinberg disequilibrium using genotypes. *A. Murphy*[1], *C. Lange*[1,2], *S. Weiss*[2] 1) Dept Biostatistics, Harvard Sch Public Health, Boston, MA; 2) Channing Laboratory, Brigham and Women's Hospital, Boston, MA.

We introduce a new test statistic for Hardy-Weinberg disequilibrium testing that uses only genotype frequencies in affected subjects, which may be applied to both two-sided and one-sided alternative hypotheses. This test statistic does not require specification of the allele frequency of the disease susceptibility allele, which may be over- or under-estimated (relative to the general population) in a completely ascertained sample. We investigate the behavior of the one-sided version of the test statistic under the alternative hypothesis. Additionally, the power of the test statistic is demonstrated via simulation studies, and we show that both the one-sided and two-sided tests generally have improved power in comparison to the standard testing methodology for detecting deviations from Hardy-Weinberg equilibrium in case-only designs. Additionally, we demonstrate the applicability of the new genotype-based test statistic in a candidate gene analysis for asthma.

Utility of acylcarnitine analysis by LC-MS for follow-up of abnormal C5OH on MS/MS screening. *S.E. McCandless[1], M. Stoll[4], P.E. Minkler[4], S. Yang[4], C.L. Hoppel[2,3,4]* 1) Genetics; 2) Pharmacology; 3) Medicine; 4) and Center for Mitochondrial Disease, Case Western Reserve University, Cleveland, OH.

Deficiency of 3-methylcrotonyl-CoA carboxylase (3-MCC) is the most common organic academia (OA) identified by expanded newborn screening programs. The primary marker identified by MS/MS for this disorder is a 5-carbon OH-acylcarnitine (C5OH). Several clinically relevant isomers of C5OH may be seen in OAs, including 3-MCC, beta-ketothiolase (BKT), and 3HMG-CoA lyase deficiencies. Our lab uses HPLC/MS to distinguish isomeric acylcarnitines that can't be resolved by MS/MS, thus allowing diagnosis using a single sample. We use standardized solutions of 3-methylcrotonyl-, tigloyl- and 3-OH-isovaleryl-carnitine to confirm chromatographic characteristics and generate standard curves for each compound to allow precise quantification from biological samples. **Results:** In 308 plasma samples there was a bimodal distribution of 3-OH-isovalerylcarnitine with 98% of samples below the median 0.02 mol/L (99th %ile 1.13). Several adults with known 3-MCC deficiency had concentrations below the median value during times of plasma carnitine deficiency. 3-methylcrotonylcarnitine was present only in small quantities (N=438, mean 0.002 mol/L, median 0, range 0 - 0.13), even in individuals known to have 3-MCC deficiency. Small, but measurable quantities of tigloylcarnitine were found in many plasma (N=938, mean 0.024 mol/L, 99th %ile 0.47) and urine samples (N=571, mean 2.26 mol/g creatinine, 99th %ile 19.98), with the highest concentrations found in a patient with BKT deficiency. Furthermore, like other short chain acylcarnitines, 3-methylcrotonyl-, tigloyl-, and OH-isovaleryl-carnitines are often found in the plasma and urine of patients with propionic and methylmalonic acidemias treated with carnitine, with overlap in the range seen in individuals with 3-MCC deficiency. **Conclusion:** The ability to distinguish 3-OH-isovaleryl- from 3-Me-butyryl-carnitine, and tigloyl- from 3- Me-crotonyl-carnitine by LC-MS allows distinction of several disorders of branched chain OA metabolism. Carnitine deficiency, or treatment with carnitine for other conditions, can make the interpretation more difficult.

Flip-flop associations: confirmation or spurious findings? *P.I. Lin[1, 2], J.M. Vance[2], M.A. Pericak-Vance[2], E.R. Martin[2]* 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) Center for Human Genetics, Duke University, Durham, NC.

Multiple studies in several different disorders have reported significant association with the same genetic locus, but with opposite risk alleles. Do such flip-flop associations indicate a confirmation of association or evidence for spurious association? We hypothesized that flip-flop associations may be attributable to multi-locus effects. Theoretical modeling shows that the direction of allelic association may flip when the target risk allele is inversely correlated with another risk allele at another locus, or positively associated with a protective allele at another locus. The likelihood of flip-flop associations depends on allele frequency and inter-locus correlation. This phenomenon is only seen when these two loci act in concert to influence risk of disease. We then considered these findings in review of previous reports. We found the population variation in linkage disequilibrium across the Catechol-O-Methyltransferase (COMT) gene may lead to flip-flop associations for a COMT gene polymorphism with disease risk under a putative disease model. Additionally, we re-examined the association between the glyceraldehyde-3-phosphate dehydrogenase (GAPD) gene and late-onset Alzheimer disease (LOAD). The variation in correlation between a GAPD gene polymorphism and the Apolipoprotein E 4 allele (a confirmed risk factor for LOAD) might result in flip-flop associations of this GAPD gene polymorphism with LOAD in different populations. In summary, opposite effects of the same allele may be found in populations characterized by different patterns of inter-locus correlations. A genuine risk allele may appear to be a relatively protective allele (and vice versa) when a multi-locus effect is not taken into consideration. Caution needs to be exercised when interpreting "flip-flop" associations.

Exploring cryptic genomic aberrations responsible for multiple congenital anomaly with mental retardation using in-house CGH-arrays. *S. Hayashi*[1,2,3], *S. Shozo*[1,2,3], *I. Imoto*[1,2], *J. Inazawa*[1,2] 1) Dept. of Molecular Cytogenetics, Medical Resarch Institute, Tokyo Med. and Dent. Univ, Tokyo, Japan; 2) Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Agency, Kawaguchi, Japan; 3) Dept. of Pediatrics and Developmental Biology, Graduate Medical School, Tokyo Med. and Dent. Univ, Tokyo, Japan.

We have constructed five different types of CGH-arrays as follows, (1) Whole genome array containing 4523 BAC/PACs throughout human genome (WG-array), (2) Cancer array-800, which harbors 800 different BAC/PACs containing cancer-related genes, (3) 1p36-contig array spanning about 20 Mb at 1p36 with 220 BAC/PACs, (4) Genome disorder array which contains BAC/PACs covering loci responsible for known genomic disorders for their diagnoses, and (5) X-tiling array containing 1003 BAC/PACs throughout X-chromosome other than peudoautosomal regions. Using those arrays we investigated genomic aberrations which would cause unknown multiple congenital anomalies (MCA) and/or mental retardations (MR). A total of 127 cases were analyzed and copy number aberrations (CNA) could be detected in 56 cases. In one case of them, using WG-array we detected 1Mb duplication at Xq22.3 in a girl with MCA and MR. More details were investigated by X-tiling array, FISH and real-time PCR, revealing that the duplication disrupted the IL1RAPL2 gene, which was a candidate gene for MR. This report is probably the first case in which IL1RAPL2 is likely to be involved in MCA with MR. In the other case, 5Mb hemizygous deletion was detected at Xp11.4-11.3 in a girl with severe MR and microcephaly. X-tiling array and FISH confirmed that the deletion disrupted the CASK gene which was associated with neural development in fetal brain. Real-time RT-PCR revealed that the gene expression was reduced in lymphoblastoid cell line from the patient. It may explain her anomaly of central nerves and the severe MR. We also examined parents of each proband in order to assess whether the aberrations were CNP or not. In conclusion, CGH-array was a powerful technique to detect genomic aberrations, which become a good clue to explore cryptic genomic aberrations responsible for unknown MCA with MR.

A conceptual model for developing standardized phenomic measurement scales. *N.J. Markward* Pennington Biomedical Research Center, Baton Rouge, LA.

The Human Phenome Project (HPP) has been conceptualized as an international collaboration of individuals and organizations devoted to the characterization of the phenome--the complete phenotypic representation of the human species. HPP would hypothetically entail the creation of integrated phenomic databases, the standardization of phenotypic definitions and measurement, and the development of novel analytical methods for scaling and interpreting genomic and phenomic data. An additional goal of HPP, specifically, and post-genomic research, generally, might be the construction of a tried and true phenometric system, thereby granting phenomicists the same inferential stability, social connectivity, and cross-contextual predictability afforded to physicists and engineers by the International System of Units (Le Système International d'Unités). Such a framework would be useful for 1) establishing consensus-based guidelines that align the biomedical research community around agreed-upon reference standard metrics for each facet of the phenome; 2) developing genomic surveys of SNP subsets that best map each individuals genomic profile to the error-bounded region of the appropriate phenomic scale; and 3) supporting researchers, hospital networks, and managed care organizations in applying and adapting disease-specific metrics and derived genomic surveys to improve the quality of patient care at the point-of-contact. With these ideas in mind, this research project 1) outlines the theory, mathematics, and applied process that would guide the development of standardized phenomic measurement systems; 2) demonstrates how this analytical framework can be implemented to construct and validate intra-laboratory (specifically objective) phenomic measurement scales from heterogeneous (demographic, anthropometric, clinical, laboratory, psychometric, and genomic) data; and 3) documents the process by which inter-laboratory (generally objective) phenomic reference standards can be developed and maintained by cross-calibrating, linking, and monitoring researcher-, company-, and institute-specific phenomic scales that purport to measure the same or similar health and disease constructs.

In vivo promotor analysis of bioluminescent MC4R transgenic mice. *R. Kesterson[1], C. Lamar[1], W. Wang[2], K. Zinn[3]*
1) Genetics, University of Alabama at Birmingham, Birmingham, AL; 2) Psychology, University of Alabama at Birmingham, Birmingham, AL; 3) Medicine, University of Alabama at Birmingham, Birmingham, AL.

Obesity is a multifactoral disease currently considered to be of epidemic proportions. Advances in our understanding of energy homeostasis have identified a number of genes linking peripheral signals to CNS neuroendocrine pathways, including melanocortin peptides and their cognate G protein-coupled receptors (e.g. Melanocortin-4 Receptor; MC4R). MC4R is weakly expressed throughout the CNS, including in putative satiety centers of the hypothalamus and brain stem. Genetic ablation in mice has shown that loss of one functional MC4R allele results in obesity. In linkage studies of obese cohorts, loss of function as well as hypomorphic alleles account for approximately 5% of morbidly obese patients. Unfortunately, little is known about how MC4R gene expression is regulated in vivo. We created a series of MC4R promoter-luciferase reporter gene transgenic mice to identify key regions of the promoter involved in proper temporal, spatial, and regulated expression. Bioluminescence imaging (IVIS-100 system, Xenogen) showed that transgenic mice with constructs containing 3300 bp of 5'-flanking sequence (3300MC4Luc) reproducibly displayed CNS preferential expression of the transgene (e.g. hypothalamus and brain stem); 430 bp of 5'-flanking sequence was sufficient to drive hypothalamic expression. In vivo bioluminescence imaging of mice with a heterologous promoter construct containing a highly conserved 32 bp element recapitulated a similar CNS expression profile. We report the first model system to study the regulated expression for the MC4R gene promoter in vivo.

Exclusion of the GOUT1 candidate region on chromosome 4q25 in a large Indian family with an autosomal dominant inherited hyperuricemia and gout. *R. Meda[1], S.K. Nath[2], J.V. Solanki[3], U.C. Patel[3], R. Memon[1], U. Ratnamala[1], U. Radhakrishna[1]* 1) Molecular Genetics Laboratory, Green Cross Blood Bank & Gen, Ahmedabad, India; 2) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, USA; 3) Department of Animal Genetics & Breeding, Veterinary College, Gujarat Agriculture University, Anand, India.

Gout is an arthritic condition (inflammation of the joints) characterized by the deposition of monosodium urate crystals in the joints or soft tissue. It affects more men than women mostly between 30-50 years of age. It is usually associated with chronic hyperuricemia, a long-lasting abnormally high concentration of uric acid in the blood. The incidence of gout in men and women is 13.6/1000 and 6.4/1000 respectively. Several factors cause hyperuricemia and gout including nutritional, drugs and metabolic/endocrine causes. In addition, genetic factors also contribute to the pathogenesis. The gene responsible for autosomal dominant (GOUT1; MIM 138900) has been mapped to chromosome 4q25 (Am. J. Hum. Genet. 75: 498-503, 2004), but a mutation-causing gene is yet to be identified. We have studied a large five-generation Indian hyperuricemia and gout family with an autosomal dominant mode of inheritance and full penetrance. The pedigree consists of 49 individuals with 16 affected (eight males and eight females) and the age distribution of these affected is from 32-58 years. There are no other associated anomalies present in this family. We have genotyped this family for all polymorphic microsatellite markers that flank the disease loci at chromosome 4q25. These markers were selected since they were used for the original linkage analysis for Gout1 in native Taiwanese families. Analyzing 27 individuals, all markers yielded significant negative (<-2.0) at = 0. Thus GOUT1 can be excluded as the candidate region responsible for hyperuricemia and gout in this family. We are planning to perform genome-wide linkage analysis in this family to identify the responsible locus. Email: u_c_rao@hotmail.com.

Examining the Multiple Dye-Swap Design for Efficient and Effective Microarray Studies. *T.K. Kim* Biostatistics, University of Washington-Seattle, Seattle, WA.

For 2-group comparison microarray experiments with biological replicates, Kerr (Biometrics, 2003) showed that a multiple dye-swap strategy is a very efficient, practical design. For more than two groups, the design extends naturally, but there is more than one generalization when there are four or more groups. We explore different options for the extension of the multiple dye-swap design for 3, 4, 5, and more groups and evaluate these options in terms of their efficiency for making pairwise group comparisons.

Detection and characterization of supernumerary marker chromosomes by array CGH. *S.A. Horner[1], S.G. Sulpizio[2], R.M. Lloyd[2], B.A. Bejjani[1,2], L.G. Shaffer[1,2], B.C. Ballif[2]* 1) Health Research and Education Center, Washington State University, Spokane, WA; 2) Signature Genomic Laboratories, LLC, Spokane, WA.

Small supernumerary marker chromosomes are found in ~0.04% of live births. However, the frequency of marker chromosomes is nearly ten times as high (0.41%) in individuals with mental retardation (Liehr et al., 2004). By definition, the characterization of small marker chromosomes can not be done unambiguously by conventional chromosome banding techniques. Furthermore, marker chromosomes are often found in only a small percentage of the cells which can make them difficult to detect without screening large numbers of cells. Array-based comparative genomic hybridization (array-CGH) is a powerful platform which offers high resolution analysis using genomic DNA extracted from uncultured peripheral blood. We have constructed a high-density microarray using 974 FISH-mapped BAC clones covering ~5 Mb of the most proximal unique sequence adjacent to the centromere on all 43 unique pericentromeric regions of the human genome (excluding the acrocentric short arms). This array was used to characterize the chromosomal content of 11 marker chromosomes found in routine diagnostic specimens. The enhanced coverage of this array over the pericentromeric regions not only uncovered the chromosomal origin of each marker but also distinguished between the involvement of the short arm and/or the long arm of each chromosome, and uncovered complex rearrangements or multiple markers in a single individual. Furthermore, the expanded coverage of the pericentromeric regions was adequate to refine the breakpoints in over half (56%) of the markers. However, 44% of the markers contained 5 Mb of unique sequence suggesting that additional coverage in the pericentromeric regions may be even more valuable in characterizing these rearrangements. Finally, most of these marker chromosomes were mosaic suggesting that array CGH is a powerful tool for the detection and characterization of low-level mosaicism in a clinical diagnostic setting.

Osteopoikilosis, short stature and mental retardation as key features of a new microdeletion syndrome on 12q14.

B. Menten[1], K. Buysse[1], J. Hellemans[1], T. Costa[2], C. Fagerstrom[3], G. Anadiotis[3], D. Kingsbury[3], F. Speleman[1], G. Mortier[1] 1) Center for Medical Genetics, University Hospital Gent, Belgium; 2) IWK Health Centre, Halifax, Nova Scotia, Canada; 3) Legacy Emanuel Childrens Hospital, Portland, Oregon, U.S.A.

We have identified a microdeletion of chromosomal band 12q14 in two unrelated patients with mild mental retardation, osteopoikilosis and short stature. Using array-CGH the size and boundaries of both deletions were determined. Both microdeletions are ~6 Mb in size with a 5.3 Mb common deleted region. This region encompasses 28 known genes, including LEMD3 which was previously shown to be the causal gene for osteopoikilosis. The observation of two unrelated patients with a similar microdeletion and sharing a common phenotype, suggests that this might represent a new chromosomal microdeletion syndrome. Reporting additional patients with deletions in this chromosomal region will allow more accurate genotype-phenotype studies. In particular, the identification of a new autosomal gene for short stature within this region could provide us with more insights in the pathways controlling linear growth.

Study of CFTR gene mutations in Iranian CF patients. *F. Mirzajani[1], R. Mirfakhraie[1], M. Amiri[2], M. Jalalirad[1], H. Kianifar[3], M. Rafiei[4], E. Talachian[5], M. Houshmand[1]* 1) Medical Genetics, NIGEB, Tehran,Iran; 2) Khatam university, Tehran, Iran; 3) Mashhad Medical University, Mashhad, Iran; 4) Tabriz Medical University, Tabriz, Iran; 5) Iran Medical University, Tehran, Iran.

Numerous mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene have been found to impair CFTR activity to different extent, causing CF. This disorder exhibits considerable allelic heterogeneity in different populations and ethnic groups. Due to very high heterogenousity of Iranian population identification of mutations specific to the Iranian population would be helpful in designing an appropriate CF molecular diagnosis. 85 blood samples from unrelated CF families were collected from different provinces of Iran. DNA samples were screened for the most common mutations including delF508, G542X, W1282X, and N1303K using ARMS-PCR. Exons 4, 7, 9, 10, 11, 13, 20, and 21 were screened using SSCP-Sequencing. DelF508 mutation covered only 18%; of the mutated alleles, followed by W1282X(11%), G542X(7%) and N1303K(2.5%) respectively. SSCP-Sequencing also revealed the occurrence of some rare mutations including R117H, R347H, A120T, S549R, 1677delTA and 2183AAG. Moreover M470V mutation was found in high number of Iranian CF patients.

Midkine as a prognostic marker and therapeutic target in osteosarcoma. *H. Maehara[1], T. Kaname[2,3], K. Yanagi[2], I. Ohwan[1], K. Naritomi[2,3], F. Kanaya[1]* 1) Department of Orthopedics, University of the Ryukyus, Nishihara, Okinawa, Japan; 2) Department of Medical Genetics, University of the Ryukyus, Nishihara, Okinawa, Japan; 3) Solution Oriented Research for Science and Technology (SORST), Japan Science and Technology, Kawaguchi, Japan.

A heparin-binding growth factor, midkine and its truncated form are involved in generation and progression of various tumors. It is, however, the relationship between midkine and osteosarcoma is unclear yet. We show midkine is overexpressed in osteosarcoma patients and its intensity correlated with their prognosis ($p<0.05$). No truncated form of midkine was observed in any osteosarcoma cells, which may suggest that there is no association between intronic mutation of midkine gene and tumorigenesis of osteosarcoma. Treatment with functional antibodies against midkine has inhibited cell growth between approximately 20% and 60% in osteosarcoma cell lines, 9N2, 3N1, Saos2 and Nos1 in vitro. Reducing of midkine expression in those cells by RNAi gave the same results. Our findings suggest that midkine will be used as a prognostic marker and will be one of the strong candidate for therapeutic target for osetosarcomas.

Molecular diagnostics for Autosomal Recessive Polycystic Kidney Disease (ARPKD). *M. Losekoot, C.R. Haarloo, S.J. White, M.H. Breuning, D.J.M. Peters* Center for Human & Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands.

ARPKD is a severe form of polycystic kidney disease characterized by enlarged kidneys and congenital hepatic fibrosis. It is caused by mutations in the Polycystic Kidney and Hepatic Disease 1 (PKHD1)-gene, which consists of 86 exons that are variably assembled into a number of alternatively spliced transcripts. Mutation analysis was performed by direct sequencing of the 67 exons encompassing the largest open reading frame. So far, in 55 families the following mutations were found: 12 nonsense, 20 deletions/insertions, 8 splice site mutations, and 47 missense mutations. To classify missense variants we combined evolutionary conservation, using the human, chimpanzee, dog, mouse, chicken and frog Pkhd1 sequences, with the Grantham score for chemical differences. Thirty-nine missense mutations were considered pathogenic and 8 were classified as rare, probably or possibly pathogenic variants. In 39 patients two mutations were found while in 6 patients only one mutation was found, leading to a mutation detection ratio of 76%. The analysis of amino acid conservation as well as applying the Grantham score for chemical differences allowed us to determine the pathogeneity for almost all new missense variants and thus proved to be useful tools to classify missense variants. In addition to sequence analysis, MLPA was used to identify multiple exon deletions. We selected 9 probes equally spread over the gene but did not find deletions, indicating that large deletions in the PKHD1 gene are not a frequent cause of ARPKD.

Identification of the gene responsible for defect in hair development of the hairpoor mouse derived from ENU mutagenesis. *J. Kim[1], E. Kim[2], D. Cha[2], C. Song[2], J. Yoon[3], S. Kim[1]* 1) Biomedical Sciences, Catholic University of Korea, Seoul, Korea; 2) Korea Institute of Toxicology, Yusong-gu, Daejon 305-343, Korea; 3) Department of Biochemistry and Protein Network Research Center, Yonsei University, Seoul 120-749, Korea.

The hairpoor mouse strain (hrutr) was established from a pheno-deviant which was generated by ENU mutagenesis. The single locus determined the phenotype of total hair loss in the homozygotes, while the heterozygotes showed intermediate phenotype such as less than about 30% hair compared to that of the normal littermates. Thus, the hrutr phenotype was inherited as single locus in a semidominant mode. To identify the gene responsible for the hairpoor phenotype, the positional candidate gene approach was applied. The genetic linkage analysis was performed using F2 mice produced from the mating between the offspring of the BALB/c mutant and the C57BL/6 normal mice. We examined the genotype of 50 mice, 25 homozygote and 25 littermate wild type mice by PCR-SSLP using the STRs. The hrutr locus was found to be linked to mouse chromosome 14 and the order of the markers was D14Mit142-D14Mit203-D14Mit34-hrutr-D14Mit228-D14Mit107. D14Mit34 (40.0 cM) showed the complete linkage to the hrutr locus. The mutation analysis by PCR followed by sequencing of the strongest candidate gene in the region, the hr gene, revealed the single nucleotide change, T403A, at exon 1. Currently, the analysis is under way to delineate its effects on hr gene at the molecular level.

Analysis of Inquiries to a Federal Public Education and Health Care Professional Resource on Genetic and Rare Diseases. *J. Lewis[1], D. Lea[2], H. Hyatt-Knorr[3]* 1) Dept Health, LockheedMartinAspenSystemsCorp, Rockville, MD; 2) National Human Genome Research Institute (NHGRI), Bethesda, MD; 3) Office of Rare Diseases (ORD), Bethesda, MD.

For more than 4 years, the Genetic and Rare Diseases Information Center (GARD) has provided information and reliable resources on genetic and rare diseases. A rare disease is considered to have a prevalence of fewer than 200,000 affected individuals in the United States. Together, the more than 6,000 rare diseases affect approximately 25 million Americans. Information about many of these conditions can take hours to locate and may be hard to understand; this difficulty can, in turn, add to the stress of a genetic or rare disease diagnosis for a patient, a patients family, and the health care provider.

To help ease the frustration of this process, the National Human Genome Research Institute (NHGRI) and the Office of Rare Diseases (ORD), National Institutes of Health, launched GARD to provide free and timely access to accurate, reliable information about genetic and rare diseases in English and Spanish.

Data have been collected for the 14,500+ inquiries on more than 3,500 diseases handled by GARD to date. Of the people who provided information about themselves (86%), inquiries came from patients (28%), their families (42%), health professionals (10%), and the general public (20%). Approximately 92%; of GARD users request information about a specific disease. The diseases for which GARD has received the most information requests are porphyria and trimethylaminuria.

Being aware of the types of information people are seeking when they contact GARD will help genetics professionals stay abreast of their clients information needs. Other stakeholders in genetics (researchers, allied health professionals, and others) might also find it helpful to know how they can use GARD to assist them in connecting people to information and resources about genetic and rare diseases.

Oral-facial-digital syndrome type I. Case report. *D.M. Mendoza-Ugalde[1], G. García-Sánchez[1], C.F. Martínez-Cruz[2,3], A. García-Huerta[1], M.R. Baez-Reyes[4], M. Díaz-García[1]* 1) Instituto Nacional de Rehabilitación.Genética; 2) Instituto Nacional de Perinatología.Departamento de Seguimiento Pediatrico. Comunicación Humana; 3) Instituto Mexicano del Seguro Social.Hospital General de Zona 53.Pediatría; 4) Instituto Nacional de Perinatología. Genética. E mail:guillegs@yahoo.com.mx.

Oral-facial-digital syndrome type 1 (OFD1) is characterised by an X linked dominant mode of inheritance with lethality in males. The clinical features include facial dysmorphism with oral, tooth, digits and distal abnormalities, sometimes associated with polycystic kidney disease and central nervous system malformations. The gene responsible for this syndrome is OFD1 in the Xp22 region and sometimes its diagnosis can be difficult because there is an overlap with other types of oral-facial-digital syndromes. We report a 5 years old female patient with clinical characteristics compatible with an OFD1 syndrome which presented cleft lip (between the medial third and the internal third), cleft palate, dental caries, hypoplastic nostril, ears with bilateral low implantation, hypoplastic helix and antihelix, redundant skin on elbows and appendix in right elbow, hypotrophy of shoulders and arms, in right hand with syndactylya between the third and fourth fingers and absence of nail in the second finger, right hand with agenesis of distal phalange of the third finger, right foot with syndactylya between the third and fourth toes and absence of nail in the fourth toes, systolic blowing in aortic focus. Audiogram showed a mild conductive hearing loss due to otitis media. Analysis of the familial pedigree shows this case like a sporadic type.

Jervell and Lange-Nielsen syndrome. *C.F. Martínez-Cruz[1,2], M. Marquez-Murillo[3], G. Garcia-Sanchez[4], D.M. Mendoza-Ugalde[1]* 1) Instituto Nacional de Perinatología. Departamento de Seguimiento Pediatrico. Comunicacion Humana. Mexico, D.F; 2) Instituto Mexicano del Seguro Social.HGZ 53. Pediatria. Mexico, D.F; 3) Instituto Nacional de Cardiologia. Electrocardiografia. Mexico, D.F; 4) Instituto Nacional de Rehabilitacion. Genetica. Mexico, D.F.E. mail: guillegs@yahoo.com.mx.

The Jervell and Lange-Nielsen syndrome (J-LN), the long-QT syndrome (LQTS) variant associated with deafness and caused by homozygous or compound heterozygous mutations on the KCNQ1 or on the KCNE1 genes encoding the I(Ks) The patients can present episodes of syncope and undergo sudden death. Prevalence 1:200 000 individuals. The intention of this work is to present a Mexican family with JLNS of which two affected brothers (male and female) of 3 and 4 years of age respectively, consanguineous matting children of prime brothers; they present congenital deafness. The physical exam was negative. The pedigree showed two relatives with deafmutism who presented sudden death after emotional problem; by the previous things we suspected JLNS. EKG type Holtter was made demonstrating long QTc (>499 mseg) in both brothers. Conclusion: In patients wit clinical diagnosis the study of molecular genetics must be made and in positive cases early therapy with beta-blockers and/or implanted cardioverter/defibrillators must be considered.

Cell Cycle in Adult Mesenchymal Stem Cells. *R. Izadpanah[1], F. Tsien[3], C. Kriedt[1], B. Bunnell[1,2]* 1) Division of Gene Therapy, Tulane National Primate Center, Tulane University Health Sciences Center, Covington, LA; 2) Center of Gene Therapy, Tulane University Health Sciences Center, Tulane University, New Orleans, LA; 3) Department of Genetics, LSU Health Sciences Center, New Orleans, LA.

Gene Therapy holds great promise for treating many human degenerative diseases such as lysosomal disorders and neural degeneration. Stem cells are undifferentiated cells with the ability to proliferate, duplicate, produce a large number of differentiated progeny, and regenerate tissue after injury. The therapeutic efficacy of stem cells largely relies on their ability to replicate. Therefore, strategies to manipulate stem cells require an understanding of their cell cycle control. The result of this study demonstrated that the cell cycle kinetics of adult stem cells is similar to the general cell cycle regulation in mammalian cells. Cell cycle in mesenchymal stem cells (MSCs) isolated from two distinct tissues, bone marrow and adipose tissue were evaluated in these studies. MSCs derived from human and nonhuman primate tissue sources were compared. MSC cultures were established up to 30 passages for human adipose tissue and monkey bone marrow MSCs. Human bone marrow and monkey adipose tissue cultured up to 20 passages. Comparison the human and Rhesus karyotypes showed many similarities in G-banding pattern were observed, with most of the chromosomal differences between monkeys and humans apparently resulting from inversions, duplications, and translocations. Human bone marrow and adipose tissue derived MSCs maintained the diploid karyotype (46 chromosomes) up to passage 20 and 30 respectively. Rhesus chromosomes transformed from the normal diploid chromosome number of 42 at passage 1 to tetraploid (84 chromosomes) with increased cell passage, beginning at passage 20. Cell cycle analysis of MSCs by flowcytometry revealed a large population of MSCs in S phase in human MSCs at passage 20 and higher, while there was a significant aneuploidy in rhesus MSCs at passages 20 and higher. These results indicate that the long-term culture of MSCs results significant changes in cell cycle kinetics. This suggests that it is imperative to track the cell cycle kinetics in MSCs prior to their clinical application.

IL-6 promoter polymorphisms and quantitative traits related to the metabolic syndrome in KORA S4. *T. Illig[1], H. Grallert[1], C. Huth[1], M. Kolz[1], C. Meisinger[1], C. Herder[2], K. Strassburger[3], G. Giani[3], H.-E. Wichmann[1], J. Adamski[1], W. Rathmann[3]* 1) Institute of Epidemiology, GSF- Research Center for Environment and Health, Munich, Germany; 2) German Diabetes Clinic, German Diabetes Center, Leibniz Institute at the Heinrich-Heine-University, Düsseldorf, Germany;; 3) Institute of Biometrics and Epidemiology, German Diabetes Center, Leibniz Institute at the Heinrich-Heine-University, Düsseldorf, Germany,.

Interleukin-6 (IL-6) is a pleiotropic cytokine which is linked to age related metabolic disturbances such as the metabolic syndrome or type 2 diabetes. Polymorphisms located in the promoter region of IL-6 have been reported to be involved in the regulation of IL-6 transcription. This study investigates whether IL-6 promoter variants -174 G/C and -573 G/C are associated with quantitative traits related to the metabolic syndrome (International Diabetes Federation criteria) in a population of normoglycemic subjects (n=878) from the latest KORA survey (KORA S4). Genotyping was performed using MALDI-TOF MS. Besides lower height (p=0.01) the -174 CC genotype was independently associated with lower waist (p=0.002) and hip (p=0.01) circumferences in men. Furthermore, the -174 CC genotype was associated with BMI (p=0.004) when adjusted for waist and hip circumference. The present study does not suggest associations with further components of the metabolic syndrome. The association with height seems to be the central factor indicating an influence of IL-6 on growth through impaired bone metabolism. However, the complex relationships need further investigation.

Different evolutionary fates of recently integrated human and chimpanzee LINE-1 retrotransposons. *K. Han[1], J. Lee[1], R. Cordaux[1], J. Wang[2], D.J. Hedges[1], P. Liang[2], M.A. Batzer[1]* 1) Department of Biological Sciences, Biological Computation and Visualization Center, Center for BioModular Multi-Scale Systems, Louisiana State University, 202 Life Sciences Building, Baton Rouge, LA 70803, USA; 2) Department of Cancer Genetics, Roswell Park Cancer Institute, Elm and Carlton Streets, Buffalo, NY 14263, USA.

The long interspersed element-1 (LINE-1 or L1) is a highly successful retrotransposon in mammals. L1 elements have continued to actively propagate subsequent to the human-chimpanzee divergence, ~6 million years ago, resulting in species-specific inserts. Here, we report a detailed characterization of chimpanzee-specific L1 subfamily diversity and a comparison with their human-specific counterparts. Our results indicate that L1 elements have experienced different evolutionary fates in humans and chimpanzees within the past ~6 million years. Although the species-specific L1 copy numbers are on the same order in both species (1,200-2,000 copies), the number of retrotransposition-competent elements appears to be much higher in the human genome than in the chimpanzee genome. Also, while human L1 subfamilies belong to the same lineage, we identified two lineages of recently integrated L1 subfamilies in the chimpanzee genome. The two lineages seem to have coexisted for several million years, but only one shows evidence of expansion within the past three million years. These differential evolutionary paths may be the result of random variation, or the product of competition between L1 subfamily lineages. Our results suggest that the coexistence of several L1 subfamily lineages within a species may be resolved in a very short evolutionary period of time, perhaps in just a few million years. Therefore, the chimpanzee genome constitutes an excellent model in which to analyze the evolutionary dynamics of L1 retrotransposons.

Genetic contribution and characteristics of founders of Irish origin in the population of Quebec (Canada). *M. Letendre, L. Houde, H. Vézina, M. Tremblay* University of Quebec at Chicoutimi, Chicoutimi, Quebec, Canada.

This study is part of a research project on the formation and the structuration of the Quebec (Canada) population. European settlement in Quebec began in the early 17th century, with the arrival of the first French pioneers. After the British Conquest in 1760, immigrants from the British Isles began to settle in some parts of the Quebec territory. Several of these migrants, or their descendants, have intermixed with the French catholic population of Quebec. Three mutations identified in the Quebec population, R408W[H1] and I65T for phenylketonuria & W138X for cystinosis, are believed to have been introduced by Irish immigrants. The purpose of this study is to identify and characterize the immigrant founders of Irish origin in the Quebec population and to estimate and compare their genetic contribution to Quebecs total and regional gene pools. Genealogical data was retrieved from the BALSAC-RETRO database, to form a set of 2223 ascending genealogies covering the entire Quebec territory. These genealogies go back to the early 17th century and contain information on places and dates of marriage of the 155000 ancestors that were identified. On average, the genealogical depth is over 9 generations, with many branches reaching 16 or 17 generations. Characterization of immigrant founders and measurement of their genetic contribution has been performed using various procedures developed by the GRIG and the BALSAC research teams. Results indicate that nearly 21% of the 2223 subjects have at least one ancestor of Irish origin and the genetic contribution of the 203 Irish founders identified in the genealogies constitute 1% of the samples total gene pool. A majority of these Irish founders settled in Quebec in the 19th century. Children of founders from the 1815-1860 period tended to marry more frequently within the Irish group. Accordingly, subjects with Irish ancestors have a higher kinship coefficient than the rest of the subjects. Results also show that Irish founders who settled in Quebec during the French Regime (1608-1760) have a proportionally higher genetic contribution than founders who immigrated after this period.

Identification of a SNP haplotype of the PON1 gene associated with acute rejection in kidney allografts using a custom SNP chip. *W.S. Oetting[1], S. Basu[2], M.J. Brott[1], A.J. Matas[3]* 1) Dept. Medicine, Univ. Minnesota, Minneapolis, MN; 2) Dept. Biostatistics; 3) Dept. Surgery.

Studies attempting to associate specific DNA variants to transplant outcome have been restricted to a select set of candidate DNA polymorphisms. We have designed a custom chip that allows for the analysis of 3,590 single nucleotide polymorphisms (SNPs), many of which are thought to be functional variants within biologically relevant genes. We have also included haptag SNPs in candidate genes with no obvious functional variant. We have used this chip to analyze individuals with and without acute rejection (AR) to identify predisposing patterns of SNPs. **Methods:** Blood was obtained with informed consent and DNA isolated from 91 kidney allograft recipients, 46 of whom had AR within 6 months of transplant, and 45 of whom did not have any detectable AR after at least 8 years post-transplant (NoAR). All received Ab induction and CNI with either MMF or sirolimus. SNPs were genotyped using a chip based system (Affymetrix) for SNP detection and genotyping. SNPs were selected within genes associated with multiple metabolic pathways including immunity, cell signaling, cell cycle, ADME related genes and cell growth and proliferation. **Results:** Of the 10 most significant variants, 4 were within the paroxonase gene (PON1) including a nonsynonymous SNP (rs 662; p.192R/Q; c.575A/G). A total of 15 SNPs within the PON1 gene were analyzed and 4 yielded a P value less than 0.008. Logistic regression analysis associated one haplotype with AR ($p = 0.0277$) and a second haplotype with NoAR ($p = 0.0369$), after multiple comparison adjustment. This haplotype was constructed using the four SNPs that showed significant association with AR. **Conclusion:** We have created a chip that allows us to analyze multiple SNPs to help us identify patterns of DNA variants, at a substantially less cost than analyzing each SNP individually. Our analysis has identified a haplotype within the PON1 gene as being associated with AR. This haplotype contains a potentially functional SNP and may be the causative variant. If this association is verified in a larger sample it could be used to individualize immunosuppression.

***NALP1*, a key regulator of the innate immune system, is a novel major gene for multiple autoimmune/autoinflammatory disease.** *Y. Jin[1], C. Mailloux[1], D. Bennett[2], C. Dinarello[3], P. Fain[1,3], R. Spritz[1]* 1) Hum Med Genet Prog, Univ Colorado Hlth Sci Ctr, Aurora, CO; 2) Div Basic Med Sci, St. George's, Univ London, UK; 3) Dept Med, Univ Colorado Hlth Sci Ctr, Aurora, CO.

Autoimmune/autoinflammatory diseases involve multiple genetic risk factors and environmental triggers. We previously defined epidemiological association among a specific group of autoimmune/autoinflammatory diseases (generalized vitiligo, autoimmune thyroid disease, adult-onset autoimmune diabetes mellitus, rheumatoid arthritis, psoriasis, pernicious anemia, systemic lupus erythematosus, Addisons disease), and by genetic linkage mapped a susceptibility locus for vitiligo and associated autoimmune/autoinflammatory disease to chromosome 17p, co-localizing with a lupus/vitiligo susceptibility locus, *SLEV1*. By high-density SNP genotyping across the linkage region and pedigree-based association analysis in 114 multiplex families, we defined a preliminary high-risk SNP haplotype that spans the proximal coding region and extended promoter of *NALP1*. By DNA resequencing across 76 kb in 15 individuals heterozygous or homozygous for the high-risk haplotype, we identified a large number of additional SNPs, and by pedigree-based association analysis defined a more specific high-risk haplotype that includes a *NALP1* missense substitution. Highest risk, both for vitiligo alone and for a broad spectrum of autoimmune/autoinflammatory diseases, is associated with homozygosity for the high-risk haplotype, consistent with segregation analyses indicating that vitiligo results from homozygosity at multiple recessive loci. *NALP1* encodes a key regulator of the innate immune system, playing a central role in initiation of both inflammation and cellular apoptosis. Functional analyses of peripheral blood monocytes from patients with the high-risk *NALP1* haplotype show a defect of apoptosis compared to controls lacking this haplotype. Our findings indicate that *NALP1* is a broad-spectrum autoimmune/autoinflammatory disease susceptibility gene. NALP1 and the innate immune system may provide targets for both genetic susceptibility testing and treatments to reduce risk for this group of autoimmune/autoinflammatory diseases.

Identification and characterization of novel polymorphic LINE-1 insertions through comparison of two human genome sequence assemblies. *M.K. Konkel[1], J. Wang[2], P. Liang[2], M.A. Batzer[1]* 1) Dept. of Biological Sciences, Biological Compution and Vizualization Center, Center for BioModular Multi-Scale Systems, Louisiana State University, Baton Rouge, LA; 2) Department of Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY.

Mobile elements represent a relatively new class of markers for the study of human evolution. Long interspersed elements (LINEs) belong to a group of retrotransposons comprising approximately 21% of the human genome. Young LINE-1 (L1) elements that have integrated recently into the human genome can be polymorphic for insertion presence/absence in different human populations at particular chromosomal locations. To identify putative novel L1 insertion polymorphisms, we computationally compared two draft assemblies of the whole human genome (Public and Celera Human Genome assemblies). We identified a total of 148 potential polymorphic L1 insertion loci, among which 73 were candidates for novel polymorphic loci. Based on additional analyses we selected 34 loci for further experimental studies. PCR-based assays and DNA sequence analysis were performed for 34 loci in 80 unrelated individuals from four diverse human populations: African-American, Asian, Caucasian, and South American. All but two of the selected loci were confirmed as polymorphic in our human population panel. Approximately 47% of the analyzed loci integrated into other repetitive elements, most commonly older L1s. One of the insertions was accompanied by a BC200 sequence. Collectively, these mobile elements represent a valuable source of genomic polymorphism for the study of human populations. Our results also suggest that the exhaustive identification of L1 insertion polymorphisms is far from complete, and new whole genome sequences are valuable sources for finding novel retrotransposon insertion polymorphisms.

Mucopolysaccharidosis IVA: Characterization of novel mutations causing attenuated phenotype. *A.M. Montaño[1,2], K. Sukegawa[2], Z. Kato[2], R. Carrozzo[3], P. Di Natale[4], E. Christensen[5], T. Orii[2], N. Kondo[2], S. Tomatsu[1]* 1) Department of Pediatrics, Saint Louis University, Saint Louis, MO,USA; 2) Department of Pediatrics, Gifu University, Gifu, Japan; 3) Servizio di Genetica Medica, Istituto Scientifico Ospedale San Raffaele, Milan, Italy; 4) Department of Biochemistry and Medical Biotechnologies, University of Naples Federico II, Naples, Italy; 5) Department of Clinical Genetics, The Juliane Marie Center, Copenhagen University Hospital, Denmark.

Mucopolysaccharidosis IVA (MPS IVA, Morquio A disease), is an autosomal recessive lysosomal storage disorder caused by the deficiency of N-acetylgalactosamine-6-sulfate sulfatase (GALNS) leading to generalized skeletal dysplasia in patients while not affecting their intelligence. Molecular characterization of MPS IVA has resulted in the identification of 148 unique mutations in the GALNS gene. The clinical manifestations of this disease include severe and attenuated forms. We report three families with different ethnical backgrounds, from which seven patients exhibit attenuated phenotypes. We identified the presence of the mutations of p.F167V, p.R253W, and p.P484S as the cause for the attenuated phenotypes with a residual activity of 7.5%, 9.1%, and 10.1%, respectively, by stably transfecting the mutants into pCXN. Although the reported p.N204K mutation showed a lower residual enzyme activity (1.2%) after in vitro mutagenesis, it is still responsible for an attenuated phenotype. Tertiary structure analysis and kinetic studies revealed that the stability and affinity towards the substrate were very different among the mutants studied. This study reveals that mutant proteins leading to attenuated phenotypes are heterogeneous in the property and the location of the mutation.

Association of APOE with Obstructive Sleep Apnea (OSA) in Children. *M. KALRA[1], R. KAUSHAL[2], P. PAL[2], R. DEKA[2], K. FITZ[1], R. CHAKRABORTY[2]* 1) Division of Pulmonary Medicine, Cincinnati Children's, Cincinnati, Ohio; 2) Department of Environmental Health, University of Cincinnati , Cincinnati, Ohio.

Obstructive sleep apnea (OSA) is a major cause of morbidity in children and both morbidity and mortality in adults. APOE variants have been reported to be associated with increased risk of adult OSA. The goal of this study was to test this association in a pediatric population. All Caucasian children diagnosed with OSA at Cincinnati Childrens Sleep Center between January and April 2006 were recruited as cases and ethnicity matched controls were selected from the population-based Princeton School District Study. The 5 SNPs for the APOE gene that were selected using SNP browser version 3.5 included rs157580, rs2075650, rs8106922, rs405509, rs7412. Genotyping was performed using the SNPlex (Applied Biosystems) high-throughput genotyping platform. OSA was determined based on apnea hypopnea index >1 as measured by overnight polysomnogram; cases were then compared to population-based controls. Hardy-Weinberg (HWE) test of genotype frequencies and haplotype inference was performed by Helix Tree version 3.0. Significant associations at allelic and haplotypic level were ascertained using the permutation test of r x c contingency tables with 10,000 replications. The mean age of the 60 OSA cases was 14.0 years (S.D. 3.8), 62% were males, and mean BMI was 27.0 (S.D. 11.6). The mean age of the 106 controls was 14.6 years (S.D. 2.6), 62 % were males, and mean BMI was 23.6 (S.D. 7.9). The genotype frequencies of all SNPs were in HWE. Allele frequencies of the SNP rs157580 were significantly different in cases versus controls (44% vs. 32% respectively; p=0.03). Haplotype analysis using 5 SNPs revealed a significant difference in the groups (overall p=<0.0001). The haplotype GAACC was found in 16% of cases but was completely absent in controls (p=<0.0001). There was no difference for allele frequencies or haplotypes between the groups divided by BMI. This is the first report of association of APOE with OSA in children, supporting the role of APOE in the pathogenesis of pediatric OSA independent of obesity.

Clinical phenotype and autozygosity mapping of phenotypic diarrhoea of infancy. *J.L. Hartley[1,2], P. Gissen[1,2], B. Dawood[3], S. Watson[3], R. Pollitt[4], W.H. Kahr[5], D. Chitayat[6], D.A. Kelly[2], C.A. Johnson[1]* 1) Section of Medical and Molecular Genetics, Division of Reproductive & Child Health, University of Birmingham Medical School, Birmingham B15 2TT, U.K; 2) The Liver Unit, Princess of Wales Childrens Hospital, Steelhouse Lane, Birmingham B4 6NH, U.K; 3) Centre for Cardiovascular sciences, Institute of Biomedical Research, University of Birmingham Medical School, Birmingham B15 2TT, U.K; 4) Clinical Chemistry Department, The Childrens Hospital, Sheffield, S10 2TH, U.K; 5) Department of Paediatrics, Division of Haematology/Oncology, The Hospital for Sick Children, 555 University Avenue, Toronto, Ontario, M5G 1X8, Canada; 6) Department of Paediatrics, Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, University of Toronto, 555 University Avenue, Toronto, Ontario, M5G 1X8, Canada.

Phenotypic diarrhoea of infancy (PDI; also known as tricho-hepato-enteric syndrome, MIM 222470), an autosomal recessive disorder with multisystemic involvement is characterized by intractable diarrhoea, dysmorphism, hepatic dysfunction and brittle hair. Our cohort of consanguineous (n=6) and non-consanguineous (n=4) families provide the first comparative description of the PDI phenotype in a large cohort. Dysmorphic features included broad forehead, hypertelorism and broad flat nasal root. Hair was brittle, with trichorrhexis nodosa and a characteristic amino acid composition. Severe secretory and osmotic diarrhoea presented in the first few months of life. Some cases developed liver cirrhosis in the neonatal period. Decreased immunoglobulins, with IgG the being most severely affected. Platelet electron microscopy revealed intermittently enlarged platelets, decreased or abnormal platelet alpha granules and abnormal surface-connected canalicular system. Studies showed a defective release of granule contents. To our knowledge, the platelet defects are unique features of this disorder. A genome-wide linkage search using the strategy of autozygosity mapping in consanguineous families is being used to identifying the causative disease gene. The identification of the PDI gene will enable genetic testing, prognostication and identification of therapeutic targets.

Linkage and association study of *MYO9B* variants in Finnish and Hungarian populations supports the role of *CELIAC4* locus (19p13) in celiac disease. *L. Koskinen[1], K. Viiri[2], I. Korponay-Szabo[3], K. Mustalahti[2], K. Kurppa[2], K. Kaukinen[2], C. Wijmenga[4], J. Kere[1,5], M. Mäki[2], J. Partanen[6], P. Holopainen[1]* 1) University of Helsinki, Finland; 2) University of Tampere and Tampere University Hospital, Finland; 3) Heim Pal Childrens Hospital, Budapest and University of Debrecen, Hungary; 4) University Medical Center Utrecht, the Netherlands; 5) Karolinska Institute, Huddinge, Sweden; 6) Finnish Red Cross Blood Service, Helsinki, Finland.

Celiac disease (CD) is an autoimmune intestinal inflammation triggered by dietary gluten in genetically susceptible individuals. Recently, myosin IXB (*MYO9B*) gene in 19p13 (*CELIAC4*) was associated with CD in Dutch population with highest relative risk in homozygous carriers of the found risk haplotype. Three *MYO9B* SNPs tagging the Dutch risk haplotype were genotyped from altogether 472 Finnish and Hungarian CD pedigrees including 933 patients and 563 healthy family members. The *MYO9B* markers showed linkage to CD in the combined material (NPL 2.57, p=0.005) which was mainly due to Hungarian pedigrees alone (NPL 2.65, p=0.003). Neither the Dutch risk haplotype nor any other haplotype or allele showed transmission tendency to affected offspring in our pedigrees. Electrophoretic mobility shift assay (EMSA) showed binding of nuclear proteins to the probe spanning the highest risk SNP, which is a putative transcription factor binding site, but the binding did not differ between the two alleles. The observed linkage at 19p13 supports the role of *CELIAC4* locus in CD susceptibility. However, the lack of significant association in our materials indicates that presence of the primary risk haplotype or gene elsewhere in the region can not be excluded. The EMSA results imply that the risk allele in SNP rs2305764 does not affect protein binding of the gene and may not be crucially involved in gene regulation. In concordance with recent findings in UK and Swedish-Norwegian populations, this may be due to population differences, lower relative risk than previously estimated, or possibly a type I error in the Dutch study. Further studies in *MYO9B* gene and neighboring genes will be required.

Genome-wide detection of human copy number variations using high density DNA oligonucleotide arrays. *S. Ishikawa[1], K. Fitch[2], D. Komura[1], J. Hung[2], F. Shen[2], W. Chen[2], R. Mei[2], J. Zhang[2], G. Liu[2], K. Nishimura[1], H. Nakamura[1], S. Ihara[1], M.H. Shapero[2], K.W. Jones[2], H. Aburatani[1], Genome Structural Variation Consortium* 1) Genome Science & Dependable and High-performance Computing, Research Center for Advanced Science and Technology, University of Tokyo; 2) Affymetrix, Inc., Santa Clara, CA.

In the recent years following completion of the human genome sequence, new progress in unraveling the complexities of the genomes architecture has revealed a remarkable degree of structural variation present among normal individuals. In particular, copy number variations (CNVs) appears to contribute more to the nucleotide diversity than single nucleotide polymorphisms (SNPs) within the human genome. Additionly, the contribution of CNVs to human disease susceptibility may be greater than previously expected, although a complete understanding of the phenotypic consequences of CNVs is incomplete. As the part of the Genome Structural Variation Consortium project, we report here a comprehensive view of CNVs among 270 HapMap samples using the Affymetrix GeneChip Human Mapping 500K Early Access (500K EA) arrays. Using a novel approach which combines an improved version of the Genomic Imbalance Map (GIM) algorithm and an adapted SW-ARRAY procedure, we introduced large scale data processing for all the pair-wise signal comparisons among 270 samples to precisely define CNV boundaries and accurately estimate CNV copy number. With median probe spacing of 2.3Kbp on the 500K EA array, 1,203 unique CNVs were identified, ranging in size from 103 bps to 106 bps. Independent testing of a subset of CNVs by quantitative PCR and mass spectrometry demonstrated a greater than 95% verification rate. To increase the coverage in more complex genomic regions, arrays containing quantitative probes which reside on the more than 1.3M fragments which can be interrogated with the 500K NspI biochemistry were made. The use of high resolution oligonucleotide arrays allow precise boundary information to be extracted, thereby enabling a accurate analysis of the relationship between CNVs and other genomic features.

Simultaneous detection of common alpha-thalassemia point mutations and deletions by reverse-hybridization. *C. Oberkanins[1], H. Najmabadi[2], H.-Y. Law[3], W. Krugluger[4], E. Baysal[5], V. Viprakasit[6], S. Pissard[7], A. Taher[8], A. Al-Ali[9], H. Puehringer[1]* 1) ViennaLab Labordiagnostika GmbH., Vienna, Austria; 2) Genetics Research Center, The Social Welfare and Rehabilitation Sciences University, Tehran, Iran; 3) Genetics Service, KK Women's and Children's Hospital, Singapore; 4) Department of Clinical Chemistry, Rudolfstiftung Hospital, Vienna, Austria; 5) Genetics Department, Al Wasl Hospital, Dubai, UAE; 6) Dept. Paediatrics, Siriraj Hospital, Mahidol University, Bangkok, Thailand; 7) Lab de Genetique et de Biochimie, Hopital Henri Mondor, Creteil, France; 8) Department of Internal Medicine, American University of Beirut Medical Center, Beirut, Lebanon; 9) Department of Clinical Biochemistry, College of Medicine, King Faisal University, Dammam, Saudi Arabia.

Alpha-thalassemia is observed in high frequencies throughout Southeast Asia, India, the Middle East, parts of Africa and the Mediterranean area. It is characterized by the reduced synthesis or absence of alpha-globin chains due to mutations affecting one or both genes. The clinical phenotype varies from asymptomatic to lethal (Hb Barts hydrops fetalis) according to the number of impaired alpha-globin genes. We have developed a reverse-hybridization assay (Alpha-Globin StripAssay) for the rapid and simultaneous detection of 21 alpha-globin mutations: 2 single gene deletions (-3.7; -4.2), 5 double gene deletions (MED; SEA; THAI; FIL; -20.5 kb), anti-3.7 triplication, 2 point mutations in the alpha 1 gene (cd 14 TGG-TAG; cd 59 Hb Adana) and 11 point mutations in alpha 2 (init cd T>C; cd 19 -G; IVS1 5nt del; cd 59 G>A; cd 125 Hb Quong Sze; cd 142: Hb Constant Spring, Hb Icaria, Hb Pakse, Hb Koya Dora; poly A1 AAA-AAG; poly A2 AAA-GAA). The test is based on multiplex DNA amplification and hybridization to teststrips presenting a parallel array of oligonucleotide probes specific for each mutant and wild-type allele. The procedure is simple and convenient, and requires very small amounts of samples, which is of particular importance for prenatal diagnosis. The new assay has been carefully validated on pre-typed reference and routine diagnostic samples in a multi-center study.

Novel 22q11 deletions not mediated by Low Copy Repeats involving the Cat Eye Syndrome region. *G.R. Jalali[1], J.A. Vorstman[1], T.H. Shaikh[1], A.M. Hacker[1], D.M. McGinn[1], E.H. Zackai[1], A.E. Urban[2], B.S. Emanuel[1]* 1) Div.of Human Genet., Children's Hosp. Phila., Phila, PA; 2) Yale Univ. New Haven, CT.

The majority of deletions responsible for DiGeorge/Velocardiofacial syndromes (DGS/VCFS) are mediated by four copies of low copy repeats (LCRs) in 22q11. The LCRs are large stretches (100-450 kb) of sequence that share 96% sequence identity. They predispose 22q11 to errors in recombination leading to microdeletions and microduplications. Copy number changes within 22q11 where at least one end-point is not within an LCR are rare. We report two patients with essential features of the DGS/VCFS phenotype with novel deletions in the 22q11 region, initially detected by fluorescence in situ hybridization (FISH). Proband 1 (p1) is a 19 year old male and proband 2 (p2) is a 7 year old male. Both patients have congenital cardiac defects; a valvular pulmonary stenosis (p1) and a double aortic arch (p2). P1 has a submucosal cleft palate. P2 has no anatomic abnormalities of the pharyngeal cavity, but he did have nasal regurgitation of food as an infant. Both patients show typical facial features of DGS/VCFS, had recurrent middle ear infections and speech delay. In addition, p1 has a disorder in the anxiety spectrum and in p2 the diagnosis of autism was made. We have used a combination of FISH, Multiplex Ligation-dependent Probe Amplification (MLPA) and high density, oligonucleotide microarrays to map the deletion breakpoints in both cases. Remarkably, in both cases breakpoints are outside the LCRs. The proximal breakpoints of both deletions are centromeric to the common proximal endpoint of the 3 Mb typically deleted region (TDR) in DGS/VCFS, extending into the Cat Eye Syndrome (CES) region. The distal breakpoints also do not localize to LCRs and are proximal to the distal endpoint of the TDR. Further, in p1 the TBX1 gene is not deleted. Additional analysis is currently on-going to characterize the deletion end-points at the nucleotide level. The variant deletions associated with DGS/VCFS reported here underscore the need for improved detection methods such as high density microarrays and MLPA in the detection and diagnosis of genomic disorders resulting from deletions of 22q11.

PCSK9 variants are associated with reduced serum low-density lipoprotein cholesterol levels in childhood and adulthood. The Bogalusa Heart Study. *M. Hallman[1], S.R. Srinivasan[2], W. Chen[2], E. Boerwinkle[1], G.S. Berenson[2]* 1) Human Genetics Ctr, Univ. of Texas Health Science Center, Houston, TX; 2) Tulane Center for Cardiovascular Health, Tulane Univ. School of Public Health and Tropical Medicine, New Orleans LA.

Specific mutations in proprotein convertase, subtilisin-kexin type 9 (PCSK9) have been associated with reduced plasma low-density lipoprotein cholesterol (LDL-C) and lower coronary heart disease risk. These mutations may produce lifelong reduction in LDL-C, but data in younger individuals are lacking. We related two PCSK9 nonsense variants (Y142X and C679X) and one missense mutation (R46L) with serum LDL-C in 478 African Americans and 1086 whites examined 3-8 times (meanSD: 5.21.3) in the Bogalusa Heart Study at 4-38 years of age. Frequency of the L46 allele was 0.01670.0032 in whites (27 carriers) and 0.00150.0015 in African Americans (1 carrier). The frequency of the X142 allele was 0.00620.0031 in African Americans (5 carriers) and 0.00070.0007 in whites (1 carrier), while that of the X679 allele was 0.00950.0038 in African Americans (7 carriers) and 0.00070.0007 in whites (1 carrier). In whites, LDL-C was significantly lower in L46 carriers (78.921.8 mg/dl) than non-carriers (89.724.9 mg/dl; p=0.035) at examination 1 (mean age: 9.43.2 yrs). In African Americans, LDL-C was significantly lower in X142 carriers (66.69.6 mg/dl) than non-carriers (91.623.7 mg/dl; p=0.015) at examination 1 (mean age: 9.03.0 yrs), but did not differ significantly between X679 carriers (84.913.9 mg/dl) and non-carriers (91.023.8 mg/dl; p=0.467), although African Americans carrying *either* X142 or X679 had significantly lower LDL-C than non-carriers (77.315.1 vs 91.423.9 mg/dl; p=0.037). Multilevel models for repeated measures showed statistically significant associations between lower LDL-C at all ages and the L46 allele in whites, the X142 allele in African Americans, and the combined X142 and X679 alleles in African Americans. In combination with evidence from older cohorts, these findings show that these PCSK9 variants are associated with significantly lower LDL-C levels across most of the human lifespan.

Discovery and Profiling of microRNAs that Regulate Cancer. *G.A. Owens, C.H. Kim, J. Baer, X. Wu, E. R., D.J. Munroe* SAIC-NCI Frederick, Frederick, MD.

MicroRNAs are a class of small (~22 nt long) non-coding RNAs that regulate gene expression by translational repression or transcriptional gene silencing. The total number of known human miRNAs is rising above 800 which is >3% of all human genes. Since miRNAs regulate developmental processes and gene expression, any misregulation of miRNAs may lead to cancer. Furthermore, novel miRNAs may be activated in cancer cells. In order to discover novel microRNAs involved in cancer, we are cloning and sequencing microRNAs in cancer cell lines and tissues. In parallel, we are hybridizing purified-miRNAs to Affymetrix tiling arrays in order to identify novel microRNAs . In addition, we have developed a highly sensitive microarray of miRNAs for analyzing the miRNA expression in cancer cells. The microarray of miRNAs will allow us to identify, in a high-throughput manner, the regulatory miRNAs which are activated or inactivated in cancer. These miRNAs can serve as targets for drug therapy or as molecular diagnostic for cancer prognosis and progression. This project has been funded in whole or in part with Federal Funds from the National Cancer Institute, National Institutes of Health, under Contract No. N01-C0-12400.

The Benefit of MLPA in TSC 1 and 2 Analysis. *T.A. Maher[1], A. Milunsky[1,2], M. Ito[1,2], J. Yang[1], J.M. Milunsky[1,2,3]* 1) Center for Human Genetics, Boston University School Medicine, Boston, MA; 2) Department of Pediatrics, Boston University School of Medicine, Boston, MA; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Tuberous Sclerosis Complex (TSC) is an autosomal dominant disorder that manifests with highly variable symptoms and signs that include mental retardation, epilepsy, skin lesions, and hamartomas in multiple organ systems including heart, brain and kidneys. Fetal cardiac rhabdomyomas have almost invariably been correlated with a subsequent diagnosis of TSC. Sequencing analysis of TSC 1 and 2 enables detection of ~80% of all mutations, which are located within exons or their intron boundaries. Southern blot is able to detect large deletions of part or the entire gene, but is laborious, costly and may miss smaller exonic copy number changes. Multiplex Ligation-dependant Probe Amplification (MLPA) is now a standard technology in the molecular laboratory to detect copy number changes in targeted genes. We examined a cohort of 104 patients submitted for TSC analysis by full gene sequencing and MLPA analysis. This cohort included 8 prenatal samples submitted due to the detection of fetal rhabdomyomas on prenatal ultrasounds. 45/104 had TSC2 mutations detected by sequencing. 21/104 had TSC1 mutations detected by sequencing. MLPA revealed 5 partial TSC2 gene deletions and 1 partial TSC1 gene deletion. MLPA increased the detection of TSC mutations by ~6% in our cohort. MLPA is less expensive, quicker and more precise than Southern blot in the characterization of TSC deletions and is a recommended standard part of TSC clinical molecular diagnosis.

High through-put targeting induced mutations using Applied Biosystems 3730 series capillary electrophoresis system. *L. Joe[1], B. Finkelnburg[2], D. Baker[3], L. MacPherson[3], J. Clarke[3]* 1) Genetic Analysis R&D, Applied Biosystems, Foster City, CA; 2) Applera Deutschland GmbH, Darmstadt, Germany; 3) John Innes Centre Genome Laboratory, Norwich, United Kingdom.

Targeting induced mutations in genomes is a strategy used in reverse genetic studies to identify series of chemically induced point mutations in specific genes. The detection of point mutations exploits the ability of the CEL1 endonuclease to cleave genomic DNA at mis-matched heteroduplexes. Polyacrylamide slab-gel electrophoresis systems are traditionally used to detect the cleavage products. These methods are labour intensive and not easily automated. We have developed the use of Applied Biosystems 3730 series capillary electrophoresis system for cleavage product detection and sizing up to 1200 bp range in a 5-color dye-set. Following optimization of the CEL1 cleavage reaction, clean-up and capillary run conditions point mutations could be identified in populations with up to 12 fold pooling. For high through-put fragment analysis the AFLP Analysis Method in Applied Biosystems GeneMapper Software v4.0 was optimized for effective peak detection and enables accurate cleavage product sizing from 1Kb target regions. We present our progress in this method in a range of organisms and discuss strategies for the development of an automated processing system as well as alternative methods for high through-put detection of induced mutations.

Strong evidence for complex gene-gene interactions in multiple sclerosis using Random Forest analyses. *E. Madden, P.P. Ramsay, G. Artim, L.F. Barcellos* Division of Epidemiology, School of Public Health, University of California, Berkeley, CA.

Despite strong evidence for polygenic inheritance in multiple sclerosis (MS), only the major histocompatibility complex (MHC) on ch. 6p21 has consistently demonstrated linkage and association with risk for disease. It appears that the HLA-DRB1*15 association largely explains this linkage signal; however, the exact mechanism(s) by which MHC gene(s) operate in MS are not known. Genome screens have been performed in MS and indicate that non-MHC genes with strong individual effects in MS are not involved. Novel non-parametric approaches such as tree-based classification methods that accommodate large marker datasets and allow for genetic heterogeneity and interactions among variables are useful for MS studies. Recent theoretical work has also shown that the prediction accuracy of classification trees is significantly improved by building a collection of trees, or Random Forests. We analyzed whole genome screen SNP data (total 4,506 SNPs) for 830 ASPs from 730 multicase MS families using a Random Forest approach to identify evidence for loci potentially interacting with the MHC region. Genetic sharing (mean IBD) at other regions of the genome (1 cM map intervals), and both country and gender distribution for each MS ASP (total of 3,631 predictors) were used to predict sharing at HLA-DRB1. At least five non-MHC chromosomal regions were identified by Random Forests as predictive of HLA-DRB1 sharing status in MS ASPs: these included chromosomes 2, 12, 14, 18 and 19. Our results suggest that multiple non-MHC loci are influencing HLA-associated susceptibility for MS, and that in the context of large genetic studies where unknown interactions may exist, an initial screen using Random Forests is a powerful approach that can significantly reduce the number of variables for further study. The authors would like to acknowledge the International MS Genetics Consortium, the Nordic MS Genetics Group and Australian MS Genetics Group for providing pedigree and SNP data for these analyses.

Whole Genome Association Studies at the NCBI. *M.D. Mailman, Y. Jin, Z. Wang, R. Bagoutdinov, L. Phan, J.D. Beck, A. Graeff, K. Sirotkin, D.R. Maglott, S.T. Sherry, J. Ostell* NCBI, NLM, NIH, Bethesda, MD.

The National Center for Biotechnology Information (NCBI) has created a web resource to store and browse phenotypic information from clinical, longitudinal, and case/control studies from many sources and link them with high-throughput genotype information. All users have unrestricted access to browse variable descriptions, questionnaires and supporting documents, statistical summaries of phenotypes and allele frequencies, as well as all metadata from all studies. In addition, users may apply for controlled access accounts to obtain genotype and phenotype data from de-identified individuals in the studies, consonant with consents and permissions appropriate to each study. Clinical and epidemiological data in various formats are all converted to a common data model and stored in the new database. The best information about the meaning of data are found in associated questionnaires, protocols, and supporting documents. These are converted into a standard XML format, and specific questions and sections are linked to the appropriate phenotype measurement columns. Users can search and browse document text to locate the most thorough explanations of data columns that may be of interest, then navigate easily to summary information about that measure, identify studies relevant to a research goal, and be directed to the group with authority to grant access to more detailed data. Controlled access requests to individual data are evaluated in a distributed manner by the institution responsible for each study. Access permissions are then set in the central database with a single account per user. As much as possible, these data will be integrated with other NCBI resources such as RefSeq, Probe, dbSNP, OMIM, PubMed, and a variety of other genome resources. For some studies, such as GAIN, we will also calculate and make available some simple associations. Phenotype and genotype data managed by these methods will include the Genetic Association Information Network (GAIN); The Genes and Environment Initiative (GEI); The Framingham Heart Study; the NINDS Parkinsonism, stroke, and ALS studies; and the National Eye Institute macular degeneration study, among others.

System development of biological markers for the diagnosis and cure of cerebrovascular disease. *Y.J. Kim[1], H. Choi[1], H. Kang[1], T. Son[2], S. Hwang[2], A. Han[2], K.O. Choi[1]* 1) Functional Genome Res. Center, KRIBB, Daejeon, Daejeon, Korea; 2) Korea Bioresource Information Center, KRIBB, Daejeon, Daejeon, Korea.

Complex disorders like stroke or cancers have two or more genetic loci and environmental factors contribute to the diseases. To find the candidate genes related to a complex disease or trait and to show their relationship is necessary to reveal its mechanism. The objective of this study is to provide a systematic approach to analyze the complex effect of genes and to represent the frame of their relations associated with specific diseases. We developed gene annotation database on the association of HGNC to biological databases such as UCSC, GO, KEGG, HPRD, etc. Etiology of stroke was classified and accordingly tens of genes directly related to and hundreds of genes to the etiology of stroke were identified. Those genes were annotated to have information of transcription, translation, structural function, and relatedness to diseases. The networked stroke gene maps describing gene-gene interaction and biological pathway were also developed. We found that a PPI (protein-protein interaction) network associated with stroke follows the power-law degree distribution as other biological networks do. This stroke network can be used as a frame of the systematic genomic research for other complex diseases.

Paternal History of Linguistically diverse East African Populations. *J. Hirbo[1], S. Omar[2], M. Ibrahim[3], S. Tishkoff[1]*
1) Department of Biology, University Maryland, College Park, MD; 2) Kenya Medical Research Institute, Centre for Biotechnology Research and Development (CBRD) Nairobi, Kenya; 3) Department of Molecular Biology, Institute of Endemic Diseases, University of Khartoum, Khartoum, Sudan.

Evidence from genetic, paleobiological, and archaeological studies suggest that Africa, especially East Africa, is most likely to be the cradle of the modern human species. Despite this fact, very little is currently known about genetic diversity in African populations in general, and East African populations in particular. Genetic data demonstrate that the patterns of genetic variation in East African populations are complex. All four major language families spoken in Africa (Afro-Asiatic, Nilosaharan, Niger Congo, and Khoisan) are found in the region. As part of a large study of population genetic diversity of East and North Eastern Africa, we genotyped the following Y chromosome markers (analyzed in a hierarchical manner to construct haplotypes) in a total of ~1200 male individuals from ~ 40 Tanzanian, Sudanese, and Kenyan populations: 46 SNPs, one Alu and one LINE insertion polymorphism. To make inference about age estimates and migration pattern, we further genotyped all the individuals for 12 Y microsatellites commonly used in population genetic studies. We compared our results with published results of Y chromosome studies from other parts of Africa and the Middle East. Our results indicate that East African populations have some of the most ancestral Y chromosome lineages in Africa, suggesting that they may have been an ancient source of dispersion throughout Africa. Additionally, we find evidence for historical geneflow between East Africa and the Middle East. We also ascertained the effect of the Bantu-expansion on the peopling of East Africa, as well as the genetic signature of recent migration of Cushitic-speaking groups originating from Ethiopia throughout East Africa. We compare results of this study to patterns observed in the same populations for mtDNA and autosomal genetic diversity to check for congruity.

Novel mutation in *GJA8* linked with autosomal dominant congenital cataract in an Indian family. *Vanita. Kumar[1], H.C. Hennies[2], D. Singh[3], P. Nürnberg[2], K. Sperling[4], J.R. Singh[1]* 1) Centre for Genetic Disorders, Guru Nanak Dev University, Punjab, Punjab, India; 2) Cologne Center for Genomics and Institute for Genetics, University of Cologne, Germany; 3) Dr Daljit Singh Eye Hospital, Amritsar, India; 4) Institute of Human Genetics, Charite Humboldt-University, Berlin, Germany.

Purpose: To identify the genetic defect in an autosomal dominant congenital cataract family having 15 members in 3-generations affected with bilateral congenital cataract that gave the appearance of full moon with Y-sutural opacities. **Methods:** Detailed family history and clinical data were collected. A genome-wide scan by 2-point linkage analysis using nearly 400 microsatellite markers in combination with multipoint lod score and haplotype analysis was carried out. Mutation screening was performed in the candidate gene by bidirectional sequencing of amplified products. **Results:** Significantly positive lod scores greater than 3.0 at =0.0 indicative of linkage were obtained with markers at 1q21. Haplotype analysis placed the cataract locus to a 14.1 cM region between D1S221 and D1S498, in close proximity to gene for the gap junction channel protein connexin50 (GJA8). Mutation screening in GJA8 identified a novel G>C transversion at nucleotide position c.235. This nucleotide change resulted in the substitution of highly conserved Valine by Leucine at codon 79 (V79L). The observed change segregated only in affected individuals and was neither seen in any unaffected member of this family nor in 90 unrelated control subjects tested by sequence analysis of GJA8. **Conclusions:** The present study describes the mapping of a locus for autosomal dominant congenital cataract at 1q21 and identifies a previously unreported mutation in GJA8. These findings thus expand the mutation spectrum of GJA8.

Partial evidence of association between epidermal growth factor A61G polymorphism and the age at onset in male schizophrenia. *K.Y. Lee[1], E.J. Joo[3], Y.M. Ahn[1,2], S.H. Kim[2], Y.S. Kim[1,2]* 1) Department of Neuropsychiatry, Seoul National University Hospital, Seoul, Korea, MD; 2) Department of Psychiatry and Behavioral Science, Seoul National University College of Medicine, Seoul, Korea, MD; 3) Eulji University School of Medicine, Department of Neuropsychiatry, Daegeon, Korea, MD.

Epidermal growth factor (EGF) is well known to enhance development of dopaminergic neuron as well as regulate the various neuronal cells. From animal studies and postmortem studies, dysfunction of EGF signals has been demonstrated to risk factor for schizophrenia, suggesting important candidate gene. Recently, several association studies including ages at disease onset with EGF A61G, functional polymorphism, have been performed but yielded controversial results. Thus, we investigated whether this polymorphism on EGF gene has a role for predisposition of schizophrenia and effects on the ages at onset. Total 190 of patients with schizophrenia and 347 healthy controls were included in this study. The 3 different points of age at onsets, 1) age at first occurrence of positive psychotic symptoms, 2) age at first medication, 3) age at first hospitalization as schizophrenia, were assessed. In this study, we did not find the differences in allele and genotype frequencies between patients with schizophrenia and controls. In turn, we also did not find any associations between this polymorphism and the ages at onset across stratified points in general but patients with AA genotype showed significant gender difference in the ages at onset of all stratified points although significant impact of interactions with gender by genotype to age at onset was not obtained. When we re-analyses the G allele distribution between clinical subsets with 20 years as the cutoff of ages at onset, patients with early onset schizophrenia showed more common AA homozygote than patients with adult-onset schizophrenia in male. In conclusion, though we could not support an association of this polymorphism and schizophrenia, AA genotype in EGF gene might have a disease modifying role differentially according to gender.

Prospective study of warfarin dosage requirements based on CYP2C9 and VKORC1 genotypes. *M. Lee[1], M.H. Weng[2], L.S. Lu[1], H.P. Juang[1], T.H. Lee[2], F.M. Sun[1], J.Y. Wu[1], Y.T. Chen[1]* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Chang-Gung Memorial Hospital, Linko, Taiwan.

Warfarin is a widely prescribed anticoagulant for the prevention of thromboembolic diseases. However, warfarin treatment is problematic because the dose requirement for warfarin is highly variable, both inter-individually and inter-ethnically. Therefore, a patients INR needed to be monitored regularly to prevent serious complication. We recently reported a novel functional VKORC1(vitamin K epoxide reductase complex, subunit 1) promoter polymorphism which was highly associated with warfarin dosage requirement. This promoter polymorphism, in conjunction with CYP2C9 variants, could underscores the inter-individual and inter-ethnic differences in warfarin sensitivity. In this prospective study, we aimed to predict an individuals warfarin dosage requirement by determining the genotypes of the VKORC1 promoter -1639 A>G polymorphism and CYP2C9 variants. Patients were prescribed appropriate warfarin dosage based on the genotypes and were then asked to returned once a week for monitoring for minimum of 5 weeks. Patients plasma was banked to determine vitamin K status during the course of treatment and INR was also measured to ensure the INR falls in the desired range of 2-3. Warfarin Doses were adjusted if the INR do not fall in this range. Age, BMI, medication and dietary intake were also recorded. 80 Han Chinese patients have been recruited from the cardiology clinics. By using this pharmacogenetic dosing, patients with VKORC1 and CYP2C9 variants reached stable, therapeutic doses quicker than those without pharmacogenetic dosing. Without taking account of patients age, sex, BMI, other medications and dietary history, 70% of the patients maintenance dose did not deviate from the predicted dose. 23% of the patients maintenance dose was approximately 1 mg higher than predicted and the rest was over-estimated by 1 mg. The high sensitivity of this pharmacogenetic dosing demonstrated feasibility of this strategy for a safer, less cumbersome and more effective warfarin treatment.

Genetic variation in upstream stimulatory factor 1 (*USF1*) - a key transcriptional regulator of cardiovascular genes - associates with the severity of coronary atherosclerosis and risk of sudden cardiac death. *K. Kristiansson[1], E. Ilveskoski[2], T. Lehtimäki[2], L. Peltonen[1,3], M. Perola[1,3], P.J. Karhunen[2]* 1) Dept. Molecular Medicine, NPH Inst, Helsinki, Finland; 2) School of Medicine, Univ. Tampere, Finland; 3) Dept. of Medical Genetics, Univ. Helsinki, Finland.

Atherosclerosis is a complex disease with multigenic background and various phenotypes. Upstream Stimulatory Factor 1 (USF1) is known to regulate the transcription of more than 40 cardiovascular genes involved in lipid metabolism, hemostasis, inflammation and endothelial function. Genetic variation in the *USF1* locus has been recently associated with abnormalities in lipid metabolism characterizing familial combined hyperlipidemia (FCHL). Although FCHL dramatically increases the risk for early myocardial infarct, the effects of variants of *USF1* gene on coronary and aortic atherosclerosis have not been studied. We analyzed the association of genetic variation across the *USF1* gene locus to the severity of morphometrically measured coronary and aortic atherosclerosis and risk of sudden prehospital cardiac death (SCD) among two independent autopsy series of middle-aged (33 - 70 years) males (The Helsinki Sudden Death Study, n=700). Due to the high linkage disequilibrium on the *USF1* locus on chromosome 1q23, six haplotype tagging SNPs (htSNPs) captured the common genetic variation of the gene. We found that the htSNP *rs2516839* showed the strongest association to the phenotypes studied with the common allele (T) of the SNP harboring a 2 -fold risk of SCD when compared to non-carriers of the allele (OR 2.00, 95 % CI 1.16-3.44, p=0.01). Among study subjects with coronary atherosclerosis, the T-allele of *rs2516839* was also associated with larger total plaque area in abdominal aorta (p=0.003), as well as with larger fibrous (p=0.002), complicated (p=0.02) and calcified (p=0.01) plaque areas in the coronary artery. The data emerging from the vessel-wall analyses of the study sample collected from the genetically homogenous Finnish population would imply that the allelic variant(s) of the *USF1* gene significantly contribute to the risk of atherosclerosis and SCD.

High prevalence of autosomal dominant spinocerebellar ataxia linked to 16q22.1 (16q-ADCA) in the Japanese families with autosomal dominant cerebellar ataxia. *Y. Ichikawa, S. Tsuji, J. Goto* Neurology, The University of Tokyo, Tokyo, Japan.

Autosomal dominant cerebellar ataxias (ADCA) are heterogeneous neurodegenerative diseases characterized by progressive cerebellar ataxia occasionally accompanied with other features, such as extrapyramidal signs, pyramidal signs and ophathalmoplegia. A single nucleotide substitution (-16C>T) in the 5 UTR of the puratrophin-1 gene has recently been identified as the putative mutation in patients of families linked to chromosome 16q22.1 (16q-ADCA). The clinical features of the patients with 16q-ADCA have been shown to be characterized by slowly progressive cerebellar ataxia occasionally accompanied by hearing impairment. (Ishikawa et al., Am J Hum Genet; 2005). To investigate molecular epidemiology of 16q-ADCA in Japanese AD-SCA, we examined the -16C>T substitution in the 5 UTR of the puratrophin-1 gene by denatured high performance liquid chromatography (DHPLC) on the 87 Japanese ADCA families, 61 sporadic cases and 51 with undetermined mode of inheritance cases. The possibilities for spinocerebellar ataxia types (SCA) 1, 2, 6, 7, 8, 12, 17, Machado Joseph disease/SCA3, and dentatorubral-pallidoluysian atrophy (DRPLA) have been excluded. Of the 87 ADCA families, 24 families (27.6%), and 2 of the 51 with undetermined mode of inheritance (3.9%) carried the -16C>T substitution. Their clinical features are available for the 25 families from the medical information. The average age at onset was 56.1 years (40 to 68 years), all patients showed ataxic gait or dysarthria as their initial symptoms, 13 patients (46.4%) had hyper tendon reflexes, and only one patient (3.7%) suffered from hearing impairment. The present study demonstrates that 16q-ADCA comprises a substantial proportion among the ADCA families without mutations in the previously identified genes. The present study further demonstrates a strong founder effect in the Japanese 16q-ADCA families.

Thyroid phenotype associated with sensorineural hearing loss and enlarged vestibular aqueducts. *A.C. Madeo[1], S.P. Pryor[1], Y. Yang[1], C.C. Brewer[1], C.K. Zalewski[1], J.A. Butman[1], K.S. Arnos[2], W.E. Nance[3], J. Thomsen[4], J.C. Reynolds[1], A.J. Griffith[1]* 1) National Institutes of Health, Bethesda, MD; 2) Gallaudet University, Washington, DC; 3) Medical College of Virginia, Richmond, VA; 4) Pediatric ENT of Atlanta, GA.

SLC26A4 mutations can be associated with sensorineural hearing loss and an enlarged vestibular aqueduct (EVA) in combination with goiter (Pendred syndrome: PS), or with nonsyndromic EVA (NSEVA). The PS goiter has a delayed onset and is incompletely penetrant, so the perchlorate discharge test (PDT) has emerged as a sensitive test to detect the underlying iodine organification defect. We previously reported a genotype-phenotype correlation in 39 EVA subjects (J Med Genet 42:159-165, 2005): sequence analysis of PCR-amplified *SLC26A4* exons and flanking intronic sequences revealed biallelic *SLC26A4* mutations in subjects with PS, whereas NSEVA was associated with one or zero detectable *SLC26A4* mutations.

Here we present *SLC26A4* genotypic and phenotypic results for an expanded cohort of 80 EVA subjects (43 F, 37 M; $1^{7/12}$-59 y, avg $11^{11/12}$ y). Evaluations included a history and physical examination, thyroid ultrasonography, serologic tests of thyroid function and anti-thyroid antibodies, *SLC26A4* mutation analysis and, in some cases, a PDT (n=40). Eleven subjects (9 F, 2 M; $13^{8/12}$-59 y, avg 35 y) had a goiter: seven of these had two mutant alleles. Clinical findings in the four goitrous subjects with no *SLC26A4* mutations were inconsistent with PS as the etiology of goiter. Our results confirm the correlation of PS with two mutant alleles of *SLC26A4*, and NSEVA with one or zero mutant alleles ($p<=.001$). This correlation is predicated upon detection of goiter phenocopies and other thyroid conditions that confound interpretation of the PDT. We present the ultrasonographic findings, thyroid serologic test results, and PDT conditions and interpretation that detect the thyroid gland abnormality associated with biallelic *SLC26A4* mutations with high sensitivity and specificity. These results should facilitate evaluation and management of the thyroid gland in patients with EVA.

Colorectal Cancer Risks in Relatives of Young Onset Cases: Greater in Sibs Than in Parents. *S.K. Nigon[1], L.A. Boardman[1], B.W. Morlan[1], K.G. Rabe[1], G.M. Petersen[1], J. Goldberg[3], S. Gallinger[2], N.M. Lindor[1]* 1) Mayo Clinic College of Medicine, Rochester, MN USA; 2) Mount Sinai Hospital, University of Toronto, Toronto CANADA; 3) Tufts University, Boston MA.

Background: Several single-gene Mendelian disorders have been discovered that account for some of the familial aggregation detected in large population studies of CRC. Mutations in the DNA Mismatch Repair (MMR)genes cause HNPCC-Lynch Syndrome, the most common of the recognized CRC-predisposition syndromes. It is unclear how fully this recognized syndrome accounts for observed familial aggregation particularly among first degree relatives of younger onset CRC patients. **Aim**: To assess familial risk, we studied cases with CRC diagnosed under age 50 years identified through Minnesota Cancer Surveillance System (MCSS) and Mayo Clinic, Rochester, MN. CRC patients were excluded if there was evidence of DNA MMR deficiency by tumor microsatellite instability. A total of 278 probands (131 from MCSS; 147 from Mayo Clinic) were included in this study. Data on a total of 1862 relatives was collected, of whom 68 had had CRC, and an additional 165 had had primary cancers of other types. Standardized incidence ratios (SIR) were estimated by comparing to the Surveillance Epidemiology and End Results (SEER) database. *MYH* gene mutations were tested in probands with affected siblings. **Results**: Compared to SEER data, relatives of young onset CRC probands had increased risks for developing CRC. The SIR for CRC was increased among first degree relatives (SIR=1.65; 95% C.I. =1.29-2.07), and this risk was greater for siblings (SIR = 2.67; 95% C.I=1.50-4.41) than for parents (SIR= 1.5; 95% C.I. =1.14-1.94). No mutations were found in the *MYH* gene in the probands who had siblings diagnosed with CRC. **Conclusions**: While the risk of CRC among relatives of young onset probands is significantly higher than the general population, and was elevated in parents, the risk was much greater among siblings. This increased sibling risk was not accounted for by *MYH* gene mutations. *This work was supported in part by the National Cancer Institute of the National Institute of Health under RFA #CA-95-011*..

A tree based approach to modelling disease associations in the MHC, reveals evidence of class II-independent type 1 diabetes susceptibility loci. *J.M.M. Howson, S. Nejentsev, N.M. Walker, S. Field, J.S. Szeszko, H.E. Stevens, D.G. Clayton, J.A. Todd* JDRF/WT Diabetes and Inflammation laboratory, Cambridge Institute for Medical Research, Cambridge University, Cambridge, United Kingdom.

The MHC class II loci, *HLA-DRB1* and *HLA-DQB1*, are well known to be involved in the etiology of type 1 diabetes (T1D). Not all the linkage in the region however, is thought to be accounted for by these loci alone. Over the past 10 years, the hunt has intensified to find other MHC loci that also contribute to T1D susceptibility. A number of positive and negative associations have been found with *HLA-A, -B, -C* from the class I region, *MICA, BTNL2* and *HLA-DPB1*. However many of these studies suffered from small sample sizes and resort to subgroup analysis due to statistical difficulties in the modelling of the class II effects (100s of genotypes). This is why no non-class II loci from the region are generally accepted to be associated with T1D in a specific and convincing way. Here we describe the use of recursive partitioning to the modelling of the confounding effects of *HLA-DRB1* and *HLA-DQB1* caused by linkage disequilibrium between their alleles and non-class II test loci. The grouping method does not rely on risk estimates. However the splitting criteria are based on categorizing individuals as cases and controls according to genotype, so can be considered a risk-based method. Both phased and unphased genotypes were considered. We applied recursive partitioning to 458 UK and 365 USA families typed at 82 microsatellites and SNPs from across the MHC. We obtained evidence for two non-class II loci associated with T1D. The results were replicated in an independent sample set of 1500 British cases and 1500 controls, which further strengthens the candidacy of these immune response genes in T1D susceptibility.

Genome-wide association study of acute post-surgical pain in humans. *H. Kim[1], H. Lee[1], J. Brahim[2], J. Rowan[3], S. Wahl[2], R.A. Dionne[1]* 1) NINR/NIH, Bethesda, MD; 2) NIDCR/NIH, Bethesda, MD; 3) Dept. of Nursing, NIH, Bethesda, MD.

Candidate gene studies on the basis of biological hypotheses have been performed to identify relevant genetic variation in complex traits such as pain. However, the complicated mesh of contributing factors and the thousands of molecules involved in different pain phenotypes makes it difficult to detect responsible genetic variations for an individuals unique susceptibility to pain or response to analgesics. It is unlikely that one common variation in a single gene acts dominantly on pain. The contribution of each gene seems to be subtle on multiple pain pathways, making its signal difficult to detect. Therefore, most of genetic associations reported with pain phenotypes so far are weak and debatable. To overcome the limitations of candidate gene association studies, we have genotyped 500,768 single nucleotide polymorphisms from the whole genome in humans who underwent standardized surgical removal of impacted third molars. Based on maximum post-operative pain ratings with a 100 mm visual analogue scale (VAS) anchored to no pain as 0 and most pain imaginable as 100, pain sensitive patients (N=28, VAS = 83.3 8.3, range 72-99, 'severe' pain) and pain insensitive patients (N=31, VAS = 41.4 5.3, range 30-49, 'slight' to 'moderate' pain) from a total of 112 European American patients were analyzed with Helix Tree. There were no significant differences between groups in gender, age, surgical difficulty and adjunctive drugs. The analysis revealed that 7 SNPs show associations with maximum post-operative pain after local anesthetics offset at the level of $p < 10^{-6}$. Four of them are uncharacterized, two of them are located in untranslated region (LOC283867 and SIPA1L1) and one is located in an intron (CDKAL1). Further characterization of these 7 regions with dense genotyping may identify genetic loci that contribute to interindividual variability in pain due to tissue injury and the acute inflammation responses following minor surgery.

Gene-Gene Interaction Associated with Drug Response in Unipolar Major Depression Disorder. *A.A. Motsinger[1], K. Haman[1], M.K. Hahn[2], A. Steele[3], B. English[3], H. Fentress[3], R. Meyers[3], L. Hazelwood[3], M. Mazei[3], E. Sanders-Bush[3], R.D. Blakely[2], M.D. Ritchie[1], R. Shelton[3]* 1) Center for Human Genetics Research, Vanderbilt Univerity, Nashville, TN; 2) Department of Psychiatry, Vanderbilt Univerity, Nashville, TN; 3) Department of Pharmacology, Vanderbilt Univerity, Nashville, TN.

Unipolar major depression disorder (MDD) is a complex disorder that affects nearly 10 million people each year in America. Fortunately, the disorder is often treatable. Several antidepressants are currently available. However, not all patients respond and many factors are assumed to contribute to this. We hypothesize that genetic variants may be associated with treatment response. In the current study, we ascertained genetic data on a group of 50 subjects (mean age 42.8, 39% male) with MDD. Response was assessed using the Hamilton Rating Scale for Depression (HAM-D). Individuals were treated with serotonergic antidepressants and response was measured at 16 weeks. Of the subjects ascertained, 18 had no response to medication and 32 had a significant response or remitted. We genotyped 14 single nucleotide polymorphisms (SNPs) in 8 genes hypothesized to be important in the pharmacogenomics of depression. To detect genetic variations associated with drug response we used Multifactor Dimensionality Reduction (MDR), a powerful statistical approach used to detect gene-gene interactions with or without main effects. We detected an interesting interaction between SNPs 5HT2A A_1438G and MAOA VNTR longshort variant that predicted response with 73.33% ($p<0.055$) accuracy. This model is marginally significant and is likely to reach highly significant levels with an increased sample size. These findings highlight the importance of looking for gene-gene interactions in the study of complex phenotypes, like drug response. Such associations hold the promise of individualized medicine, where appropriate treatment regimens are tailored to individuals genetic profile.

JAG1 mutations in patients affected by atypical Alagille syndrome. *G. Massazza[1], D. Marchetti[1], P. Stroppa[2], L. Melzi[2], A.R. Lincesso[1], A. Sonzogni[3], G. Torre[2], M. Iascone[1]* 1) Lab. Genetica Molecolare; 2) USC Pediatria; 3) USC Anatomia Patologica, Ospedali Riuniti, Bergamo, Italy.

Alagille syndrome (AGS) is a dominantly inherited multisistem disorder involving the liver, heart, eyes, face and skeleton, caused by mutations in JAG1, located on chromosome 20p12. In approximately 15% of the AGS patients, the liver disease progresses to cirrhosis and liver failure, necessitating liver transplantation. AGS shows highly variable penetrance, and diagnosis in mildly affected patients can be difficult. Here we report the genetic characterisation of 34 patients (mean age 8 months, range 50 days-30years): 13 patients with a strong clinical evidence of AGS while 21 with unexplained cholestasis and not complete features of AGS. All 26 exons and flanking intronic regions of JAG1 gene were analysed by SSCP or dHPLC. The abnormal samples were re-amplified and sequenced. JAG1 mutations were identified in 11 of 13 AGS patients and no clear pathogenic variation was found in patients affected by unexplained cholestasis. Eight mutations were nonsense/frameshift while the remaining 3 were missense. Five mutations were parental inherited. JAG1 is the only gene currently known to be associated with AGS. The diagnosis of AGS is primarily based on clinical findings and the majority of individuals who meet clinical criteria presents JAG1 mutations. Molecular test is not routinely recommended in mildly affected or atypical cases, except for relatives of a clinical diagnosed AGS patient. No genotype-phenotype correlation exists between clinical manifestations of AGS and JAG1 mutations. However, our data seems to suggest a correlation between the severity of hepatic manifestation and type of mutation because the 3 patients with missense mutation have a mild liver disease while the remaining eight patients underwent liver transplantation.

R1514Q substitution in Lrrk2 is not a pathogenic Parkinson disease (PD) mutation. *W.C. Nichols[1,5], D.K. Marek[1], M.W. Pauciulo[1], N. Pankratz[2], C.A. Halter[2], A. Rudolph[3], C.W. Shults[4,6], J. Wojcieszek[2], T. Foroud[2], The Parkinson Study Group - PROGENI Investigators* 1) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Indiana Univ. Medical Center, Indianapolis, IN; 3) Univ. of Rochester, Rochester, NY; 4) Univ. of California, San Diego, San Diego, CA; 5) Univ. of Cincinnati College of Medicine, Cincinnati, OH; 6) VA San Diego Healthcare System, San Diego, CA.

PD is the second most common neurodegenerative disorder. Clinical features include resting tremor, rigidity, bradykinesia, and postural instability. The fifth, most recently identified PD gene is leucine-rich repeat kinase 2 (*LRRK2*). Reports of pathogenicity the substitution of arginine 1514 with glutamine (R1514Q) have been conflicting. In our ongoing effort to identify additional PD susceptibility genes, we have recruited 954 PD patients from 429 families through 59 Parkinson Study Group sites located throughout North America. Sixteen of 954 (1.8%) PD patients from 12 different families were shown to be heterozygous carriers of the R1514Q variant. Of the 28 PD patients in these 12 families, 12 of them do not carry the R1514Q variant. No significant difference between the R1514Q carrier group (16) and the non-carrier group (938) was detected for age of disease onset, disease duration, MMSE score, Blessed Functional Activity Scale, Hoehn and Yahr, and ethnicity. In addition, two of 92 (2.2%) control subjects were found to be heterozygous for R1514Q. Taken together, our data suggest that R1514Q is a non-pathogenic Lrrk2 variant that does not contribute to the development of PD. Due to their low frequency, penetrance estimates for most *LRRK2* mutations are not available. However, we believe data regarding pathogenicity, penetrance, and variability in age of onset for putative mutations are necessary for proper genetic counseling of patients undergoing genetic testing. This is especially critical for at risk individuals undergoing presymptomatic testing. We urge caution and due diligence in implementation of *LRRK2* genetic testing to ensure that the patients best interests are realized, and the risks of misinterpretation and potential harm are minimized.

The IKBL protein inhibits activation of gene expression by NF kappa B. *A. K. Mankan[1,2], J. Daly[1,2], E. Caraher[1,2], D. Kelleher[1,2], R. McManus[1,2]* 1) Department of Clinical Medicine, Trinity College Dublin, Dublin,Ireland; 2) Institute of Molecular Medicine, Dublin Molecular Medicine Centre, Trinity Centre for Health Sciences, Trinity College Dublin, Dublin, Ireland, 8.

The Inhibitor of NF Kappa B like (IKBL) gene encodes a protein homologous to the IKB family. A number of different polymorphisms in the gene have been reported to be associated with diseases such as Rheumatoid Arthritis, Diabetes Mellitus, Celiac Disease, Crohns Disease and Myocardial Infarction. One of these polymorphisms, in the E-box element of the IKBL promoter region, differentially binds to the E-box protein, E47, and the ubiquitously expressed transcription factor, USF1.

So far the exact function of IKBL protein has not been reported. Using a GFP tagged IKBL vector we have demonstrated, by both EMSA and Luciferase Assays, that over-expression of IKBL in HCT-116 cell lines inhibits the activity of NF kappa B.

We have further demonstrated, using an IL-8 promoter Luciferase construct that IKBL regulates the expression of the pro-inflammatory cytokine IL-8. We have shown that localisation of IKBL is limited to the nucleus in HCT-116 cells, but that there is no apparent interaction between IKBL and the p65 and p50 subunits of NF kappa B following stimulation of these cells with IL-1beta. Finally dissection of the protein shows NF kappa B inhibition to be dependent on the presence of the IKBL ankyrin repeats.

Expression of IKBL increases in cells stimulated with Dexamethasone and decreases with IL-1 Beta stimulation. This pattern also reflects the anti-inflammatory nature of the protein.

Our study suggests that IKBL is a member of the novel inhibitors of NF kappa B such as MAIL that are located in the nucleus and may inhibit the activity of NF kappa B by regulating the activity of other proteins that bind to NF kappa B within the nucleus.

Association of the IL18 gene with celiac disease in the Irish population. *R. McManus[1], K. Brophy[1], A. Ryan[1], C. Feighery[1], C. O'Morain[1], N. Kennedy[2], R. McLoughlin[1], F. Stevens[3], D. Kelleher[1]* 1) DMMC and University of Dublin, Trinity College, Ireland; 2) Dept. Medicine, University of Dublin, Trinity College, Ireland; 3) NUI, Galway, Ireland.

IL18 is a proinflammatory cytokine which promotes development of the Th1 lymphocyte response. IL18 is known to play an important role in inflammatory, autoimmune and infectious diseases. The aim of this study was to investigate any genetic association between IL18 and celiac disease in the Irish population. We genotyped 395 celiac disease patients and 354 controls for 4 SNPs within IL18. SNPs were chosen to allow a haplotype tagging approach based on previously defined haplotypes consisting of 27 SNPs as characterised in a European population. SNPs were also chosen based on potential effects on protein structure or expression. Haplotypes were constructed computationally and compared between groups. Three SNPs in IL18 (IL18_S2-137_rs187238, IL18_S3_rs5744241 and IL18_S4-607rs1946518) showed a significant association with disease either at allele frequency, genotype frequency or carrier status level prior to correction for multiple testing. IL18-137 was significantly associated with disease at the genotype level (p=0.0380). IL18_S3 was significantly associated with disease when allele frequencies (p=0.0385) and carrier status (G allele; p=0.0490) were examined. IL18_S4-607 also showed a significant association at the allele frequency level (p=0.0100), the genotype level (p=0.0265), and at the allele carrier status level. (G allele; p=0.0159). Total gene haplotype analysis was carried out using all four SNPs. A significant association was observed for haplotype rs1946518T, rs187238G, rs2043055A, rs5744241A (p=0.0379). Analysis of the IL18 promoter SNPs (S4-607 and S2-137), which have been associated with altered IL18 expression, revealed a significant association for two promoter haplotypes (haplotype -607 G, -137 G) (p=0.0153), (haplotype -607 T, -137 G) (p = 0.0053). We have shown that IL18 is significantly associated with disease status at the level of haplotype and functional SNP allele and genotype distribution suggesting that IL18 is involved in the pathogenesis of celiac disease.

Computing power for association studies using DNA pooling with incorporation of genetic model parameters. *F. Ji[1], C. Haynes[1], N.R. Mendell[2], S.J. Finch[2], D. Gordon[3]* 1) Lab of Statistical Genetics, Rockefeller Univ, New York, NY; 2) Department of Applied Math and Statistics, Stony Brook University, Stony Brook, NY; 3) Rutgers University, Piscataway, Piscataway, NJ.

Power calculations for association methods using DNA pooling to date have focused primarily on the effects of machine-error, replicate size and the size of the pool. We extend previous work on these calculations by incorporating genetic model parameters as part of the design. We use the non-centrality parameter (NCP) for one way Analysis of Variance test to compute analytic power for genetic association tests with DNA pooling data on cases and controls. Parameters involved in the power calculation are disease allele frequency, SNP marker allele frequency of the marker SNP in coupling with the disease locus, disease prevalence, genotype relative risk, sample size, genetic model, number of replicates, number of individuals per pool, and proportion of total error variance due to machine error. Several significance levels are considered, including stringent significance levels (due to the increasing popularity of 100K and 500K SNP chip data). We examine the effects of these parameters on analytic power using a 2^k factorial design given two settings of each parameter. We perform regression analysis to examine what parameters most significantly affect power. The top four most significant parameters affecting power for association are: (1) genotype relative risk (F statistic1,466=840), (2) genetic model (F statistic1,466=549), (3) sample size (F statistic1,466=282), and (4) the interaction term between disease and SNP allele frequencies (F statistic1,466=97). Of relatively minor importance are the design parameters: number of the replicates of the pool (F statistic1,466=30), proportion of total variance due to machine error (F statistic1,466=6), and the number of individuals per pool (F statistic1,466=4). The optimal number of individuals per pool and the number of replicates of the pool is given as a function of machine error and the genetic error model parameters.

Association study of cerebrospinal fluid amyloid levels with late-onset Alzheimers disease associated polymorphisms. *J.S.K. Kauwe[1], A.M. Fagan[2], M.L. Spinner[2], A.R. Shah[2], K. Mayo[1], D.M. Holtzman[2,3], A. Grupe[4], A. Goate[1,2,3]* 1) Dept Psychiatry, Washington Univ, St Louis, MO; 2) Dept Neurology, Washington Univ, St Louis, MO; 3) Alzheimers Disease Research Center, St. Louis, MO; 4) Celera Diagnostics, Alameda, CA.

Amyloid (A) peptides are normal products of -amyloid precursor protein processing and can be detected in cerebrospinal fluid (CSF). It has been suggested that the aggregation of amyloid peptide into insoluble plaques in the brain is a central feature of Alzheimers disease (AD) pathology. Reduced levels of CSF A42 in AD CSF are one of the most consistent findings in the AD biomarkers field. In addition, low levels of CSF A42 have recently been shown to correlate with the presence of brain amyloid. We hypothesize that the use of CSF A levels as an endophenotype will lead to the identification of novel genetic risk factors for AD. To test this hypothesis we have genotyped 12 SNPs from strong candidate genes in 120 individuals for whom we have CSF A40 and A42 measurements. We genotyped 12 SNPs in these samples. Included in this group of SNPs are 10 SNPs, which are significantly associated with AD in the meta-analysis of published data provided at Alzgene.org and 2 SNPs that have shown association with late onset AD in multiple datasets from our own studies. CSF A levels were adjusted for age, disease severity (based on CDR), and presence or absence of the APOE4 allele by regression. Due to the large effect of gender on the levels of both A40 and A42, the genetic analyses were stratified by gender (Males, N=50; Females, N=70). Genotypes at these SNPs were tested for association with levels of CSF A40, A42, as well as the ratio of A42/A40 using ANOVA. In males an uncorrected p-value of 0.004 was observed between rs4877365 (DAPK1) and the ratio of A42/A40. In females rs440446 (APOE) showed significant association with A40 levels (uncorrected p-value = 0.008). These findings suggest that these polymorphisms may affect risk for AD through an A related mechanism. We are currently genotyping these SNPs in additional samples to increase our power to detect association with CSF A levels.

Molecular dissection of NF1-related disease features in segmental NF1 patients. *O. Maertens[1], S. De Schepper[2], J. Vandesompele[1], S. Janssens[1], F. Speleman[1], E. Legius[3], L. Messiaen[1, 4]* 1) Center for Medical Genetics, Ghent University, Ghent, Belgium; 2) Department of Dermatology, Ghent University, Ghent, Belgium; 3) Department of Human Genetics, Catholic University Leuven, Leuven, Belgium; 4) Department of Genetics, University of Alabama at Birmingham, Birmingham, United States.

Within segmental neurofibromatosis type 1 (NF1) different clinical subtypes emerge. Analysis of these phenotypes may provide insight into the cell types and mutational mechanisms involved in the development of particular NF1-related disease features. For this purpose three segmental NF1 patients with different clinical manifestations were investigated at the molecular level.

The first patient presented with several café-au-lait macules (CALMs) within a pigmented background. MLPA analysis revealed an *NF1* microdeletion exclusively present in the melanocytes. A second alteration in the wild-type *NF1* allele was only detected in the melanocytes of the CALM. The second patient had several neurofibromas. Mutation screening on cultured Schwann cells derived from two neurofibromas revealed an identical mutation in addition to two tumor specific alterations. Real-time qPCR demonstrated low percentages of the first hit in fibroblasts derived from both neurofibromas. The third patient had CALMs and several neurofibromas located on the hand within a hyperpigmented background. Analysis of neurofibroma derived Schwann cells and melanocytes derived from the hyperpigmentation lesions revealed an identical *NF1* mutation in all samples. Moreover, LOH was detected in the melanocytes. Real-time qPCR revealed low percentages of the intragenic *NF1* mutation in fibroblasts derived from both the neurofibroma and hyperpigmented area. Fibroblasts derived from the peripheral CALM were negative.

These data confirm the tumorigenic properties of Schwann cells in neurofibroma development and demonstrate for the first time that bi-allelic *NF1* inactivation in melanocytes might be an important trigger for NF1-related CALM development. Interestingly, both disease features arise even within a background containing predominantly $NF1^{+/+}$ cells.

Understanding genetic heterogeneity in kidney disease among African American patients. *M. Orloff[1], J. Sedor[2,3], C. Winkler[4], J. Schelling[2,3], J. Kopp[5], S. Iyengar[1]* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Department of Medicine, Case Western Reserve Univ, Cleveland, OH; 3) Kidney Disease Research Center, MetroHealth System, Cleveland, OH; 4) Laboratory of Genomic Diversity, NCI, Frederick, MD; 5) Kidney Disease Section, NIDDK, NIH, Bethesda, MD.

Focal Segmental Glomerulosclerosis (FSGS), a common kidney disorder, often progresses to renal failure; is caused by diverse etiologies, and has significant genetic heterogeneity with each disease allele having modest effect. To test if the joint effect of variations in Wilms tumor telomeric neighbor 1 (WIT1), Wilms tumor (WT1), Wilms tumor interacting protein (WTIP), a WT1 transcriptional repressor, and Wilms tumor associating protein (WTAP) genes mediate susceptibility to idiopathic FSGS, 19 SNPs in 499 (Cases=218, Controls=281) African American (AA) subjects, in a multicenter study, were genotyped. WT1 controls differentiation of podocytes, a critical determinant of the filtration barrier; WTIP and WTAP directly interact with WT1 and regulates its function. After adjusting for population stratification, single locus and haplotype analyses showed rs6508, a nonsynonymous SNP in WIT1, and 5region SNPs in the WT1 promoter, associated with FSGS (p-value= 0.001). SNPs in the WTIP LIM domain (p-values= 0.025 and 0.048) and at the 5 end of the WTAP (p-values= 0.012 and 0.047) genes also were associated with FSGS. Cladistic and hierarchical cluster analyses of each of the four genes revealed significant associations of haplotype groups and interaction effects of diplotypes, which either share a recent common ancestor or have similar haplotype profiles. Significant interactions between WIT1, WT1, WTAP and HIV-1 status were also observed (p-value= 0.001). Interestingly, HIV-1 status and gender were additional factors contributing to the heterogeneity influencing the FSGS phenotype. Using models, we show that the genetic variants of four genes from a single pathway interact with gender and HIV-1 status to influence FSGS. Multiple risk alleles in WT1 and genes encoding proteins that regulate its function may combine to cause FSGS in AAs..

A novel method for rapid carrier screening of Fragile X syndrome. *D. Huang[1], Y. Li[1], J. Rooke[2], S. Potts[1], W. Sun[1], M. McGinniss[1], C. Strom[1]* 1) Quest Diagnostics Inc., San Juan Capist, CA; 2) U.S. Genomics, Woburn, MA.

Fragile X syndrome (FX) is the most common cause of inherited mental retardation, seen approximately 1 in 4,000 males and 1 in 8,000 females. The mutation responsible for FX involves the expansion of CGG repeats in the FMR-1 gene on the X chromosome. Pilot studies have revealed carrier frequencies 1:70, 1:113 and 1:259 in British, Israeli and French Canadian populations respectively. Since FX is an X-linked disorder, population- based carrier screening would have a higher yield than already implemented programs for Cystic Fibrosis, Tay Sachs Disease and Canavan Disease. Current FX carrier testing involves a combination of PCR and Southern blot analysis in order to detect all possible carrier range repeat sizes. This procedure is not suitable for high throughput automated testing that would be required for population-based carrier screening. We developed a novel method of automated, rapid detection of all FX carriers. Genomic DNA is prepared in 96 well microtiter plates format on an automated DNA purification robot and then digested with restriction enzymes yielding fragments containing the CGG repeats. DNA is fractionated by capillary electrophoresis, and fractions are collected corresponding to expected sizes for normal, premutation and expanded alleles. Each fraction is further restriction-digested to release the 3 flanking sequence from the repeats, and a multiplex fluorescent PCR is then performed to detect the presence of the flanking sequence in each fraction. In addition, restriction fragments with sizes reflective of each collected fraction are co-amplified in the PCR reaction to serve as internal controls for both the capillary fractionation as well as the PCR process. This assay detected 24 known female carriers and 41 normals with no false positives or false negatives. This series contained 5 carriers with premutations and 19 affected patients with expanded allele ranging from 250 to 1450 repeat. The results are completely concordant to the results of Southern blotting. This method is robust, automated, high throughput and accurate enough to enable population based carrier screening for FX.

USF1 and coronary heart disease; Allelic imbalance of a transcription factor results in differential regulation of lipid metabolism- and immune genes. *J. Naukkarinen[1,2], V. Lyssenko[3], L. Groop[3,4], M-R. Taskinen[4], L. Peltonen[1,2,5]*
1) Dept Molecular Medicine, National Public Health Inst, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Biomedicum, 00290 Helsinki, Finland; 3) Department of Clinical Sciences/Diabetes and Endocrinology, Malmö University Hospital, Lund University, Malmö, Sweden; 4) Department of Medicine, Helsinki University Central Hospital, Helsinki, Finland; 5) The Broad Institute of MIT and Harvard, Boston, MA.

We recently reported the association in Finnish families of allelic variants of USF1 with FCHL, a common dyslipidemia predisposing to cardiovascular disease (CVD) (Pajukanta et al, 2004). This association with CVD was also replicated in a large prospective follow-up study of a Finnish population sample (Komulainen et al, 2006). We here defined for the first time, allele-specific expression differences of this low-abundance transcript USF1 in subject fat-biopsies by monitoring for allelic imbalance in subjects heterozygous for the best associating SNP, located in the 3-UTR of the gene. Quantitative sequencing of genomic- and cDNA revealed an average of ~20% lower expression of the risk-allele of USF1 in 10 out of 13 samples tested. In a set of 47 expression arrays of subject fat-biopsies, differential expression of numerous USF1 target genes was evident -among them many genes of lipid metabolism and immune-response. Interestingly, several genes in the 1q locus, flanking USF1 also showed allele-dependent expression, most notably the neighboring F11R gene. This suggests the possibility of a strong cis-regulatory element controlling the expression of regional genes. These findings are currently being confirmed in muscle tissue biopsies -another relevant target tissue for dyslipidemia and the development of CVD. In summary, common non-coding polymorphisms of the the USF1 transcription factor, with risk-alleles decreasing its expression, result in differential expression of numerous target genes and predispose carriers of risk alleles to dyslipidemia and coronary heart disease.

A Hybrid Bayesian Method for Detecting Multiple Causal Variants from Genome-Wide Association Studies. *C.J. Hoggart[1], T.G. Clarke[1], M. De Iorio[1], J.C. Whitaker[2], D.J. Balding[1]* 1) Department of Epidemiolgy and Public Health, Imperial College, London; 2) Epidemiolgy and Public Health, London School of Hygiene and Tropial Medicine.

Testing one SNP at a time does not fully realise the potential of genome-wide association studies to identify multiple causal variants of small effect, which is a plausible scenario for many complex diseases. Moreover, many simulation studies assume a single causal variant and so more complex realities are ignored. Analysing large numbers of variants simultaneously is now becoming feasible, thanks to developments in Bayesian stochastic search methods. We combine Bayesian shrinkage methods together with a local stochastic model search to identify complex interactions, both local and distal. Our approach can analyse up to 10,000 SNPs simultaneously, and leads to multiple potential disease models each with an associated probability. We illustrate its power in comparison with a range of alternatve methods, in simulations that incorporate multiple causal loci, acting singly or in interacting pairs, among 4,000 SNPs in a 20Mb region. We argue that, implemented in a two-stage procedure, our hybrid Bayesian analysis can provide a powerful solution to the problem of extracting maximal information from genome-wide association studies.

Identification of der(1;19)(q10;p10) in 5 oligodendrogliomas suggests mechanism of concurrent 1p and 19q loss characteristic of this tumor. *L. Morsberger, K. Murphy, P. Burger, C. Griffin* Dept of Pathology, Johns Hopkins University, Baltimore, MD.

Deletions of portions of chromosomes 1p and 19q are closely associated with the oligodendroglioma (OG) histological phenotype. In most cases, 1p and 19q are co-deleted, often involving the entire chromosomal arm, yet the mechanism of dual loss is unexplained and the few reported metaphase cytogenetic analyses of OG have not elucidated this. We have analyzed 5 cases of OG (WHO grade III) in which metaphase cytogenetics suggests a possible mechanism for concurrent 1p and 19q loss. The G-banded metaphases of 4 OGs were near diploid and included a derivative chromosome consisting of what appears to be the whole arms of 1q and 19p joined at the centromere forming a der(1;19)(q10;p10). A fifth case was near tetraploid and contained 2 or more copies of the derivative chromosome. Metaphase FISH with 1p, 1q, 19p, and 19q probes (Vysis/Abbott Molecular) confirmed loss of 19q and 1p and that the derivative chromosome was composed of 1q and 19p material in 3 cases; in 2 cases with few metaphases, FISH was limited to the 19p/19q probe set where we found loss of 19q, and presence of 19p material on the derivative chromosome. In all cases, interphase FISH showed net loss of 1p and 19q in 77-92% of cells. Microsatellite studies were consistent with 1p and 19q loss in 4 cases and are pending in 1. To our knowledge this is the first report of metaphase cytogenetic analysis of OG identifying a derivative chromosome comprised of 1q and 19p. We hypothesize that the following occurs in OG: formation of a balanced whole-arm translocation between chromosomes 1 and 19, forming two derivative chromosomes, one composed of 1q and 19p, the other composed of 1p and 19q. Subsequent loss of the der(1;19)(p10;q10) would then result in the simultaneous 1p and 19q loss observed in OG, with retention of the der(1;19)(q10;p10) as observed in these 5 OGs.

Multivariate distance based methods for testing and accommodating population substructure. *C.M. Nievergelt, J.R. Kelsoe, C. Shimizu, J.C. Burns, N.J. Schork* UCSD, La Jolla, CA.

It is well known that ignoring cryptic population structure, which arises from mechanisms such as genetic drift, admixture, and assortative mating, can have negative impacts on association studies by generating spurious results and/or mask the effect of truly disease-associated loci. Anecdotal information about population history often exists, but the precise effects of events such as migration or mating patterns on an individuals gene pool requires a more detailed empirical assessment. Self-identified ethnicity contains some information, but is often not detailed enough, especially in admixed populations such as African and Mexican Americans. Sophisticated model-based methods to assess individual ancestry have been developed and successfully applied (e.g., maximum likelihood and bayesian methods). They usually require 1) prior knowledge of the populations ancestry, 2) DNA from ancestral populations, and 3) availability of specific, ancestry informative markers (AIMs). Study subjects are typically genotyped on 50 - 100 AIMs. High costs associated with the collection and phenotyping of study subjects in combination with decreasing genotyping costs have resulted in the availability of hundreds or thousands of genetic markers (e.g., microsatellites, SNPs) genotyped for specific candidate genes or in whole genome linkage and association studies, of which only very few will be associated with disease. Here we describe intuitive distance based methods to test and accommodate population substructure that make use of these available genotypes. We applied these methods to large cohorts genotyped on several hundred markers, such as a collection of mostly European American multi-generational bipolar families, and multi-ethnic studies such as the Family Blood Pressure Program including unrelated hypertensives, and a Kawasaki disease candidate gene association study. Our results show evidence for significant substructure and we consider methods to incorporate this information into association studies. Our procedures are powerful and comparable to model-based methods, make use of any available genotype data, and can be applied retrospectively to existing datasets.

Attitudes Regarding Genetics and Genetic Testing: A Pilot Community Survey. *V. Henrich[1], C. Christianson[1], K.P. Powell[1], S.E. Hahn[2], D. Spoon[1], D. Bartz[1], S. Blanton[2], P. Lietz[3], J. Vance[2], M. Pericak-Vance[2]* 1) Univ North Carolina Greensboro; 2) Duke University, Durham, NC; 3) Moses Cone Health System, Greensboro, NC.

The Guilford Genomic Medicine Initiative is developing a survey to ascertain the general populations knowledge and attitudes regarding genetic testing. Survey questions were developed from community focus group transcripts. As part of the development process a pilot survey was administered to 301 college students. Respondents correctly answered questions about the importance of family history (93%), age at diagnosis (83%), and race (82%) as disease risk determinants. Most knew that gene-environment interactions underlie disease risk (88%), and that breast cancer can be inherited from both sides of the family (89%). The vast majority (91%) thought everyone with a family history of a disease would benefit from genetic testing. Over half (60%) thought genetic testing was appropriate for everyone with breast cancer. Almost half (46%) knew that pharmacogenetic tests exist. Three factors were extracted using a principal component analysis of the surveys attitude assessment portion. Responses in this section suggested that most students are comfortable with genetic testing (87%) and think it should be done (86%). The majority (90%) would have a genetic test if they had a family history of cancer. Most students are not worried about discrimination (79%) or privacy issues (75%). A majority (89%) knew that North Carolina laws prevent discrimination by employers, and 64% believe the government will protect them from discrimination. Over half (60%) of respondents think insurance companies will use genetic tests to determine health insurance rates. Conclusions: Respondents are generally knowledgeable about the benefits of family history, but education in the area of genetic testing is warranted. Attitudes towards testing are generally favorable. Students apparently are confident that government agencies will protect them from discrimination based on genetic testing, but are concerned about insurance discrimination. Based on the pilot, a community wide survey will be conducted in summer 2006.

Effects of carbonic anhydrase 8 deficiency on cerebellar gene expression profiles in the wdl mouse. *Y. Jiao[1], J. Yan[2], F. Jiao[1], H. Tu[1], J. Stuart[2], L.R. Donahue[3], W.G. Beamer[3], X. Li[4], B. Roe[5], M.S. LeDoux[6], W. Gu[1]* 1) Orthopaedic Surgery, Univ Tennessee HSC, Memphis, TN; 2) Department of Medicine, University of Tennessee Health Science Center, Memphis, TN; 3) The Jackson Laboratory, Bar Harbor, ME; 4) Functional Genomics Facility, University of Chicago, Chicago, IL; 5) Department of Chemistry and Biochemistry, University of Oklahoma, Norman, Ok; 6) Departments of Neurology and Anatomy & Neurobiology, University of Tennessee Health Science Center, Memphis, TN.

The waddles (*wdl*) mouse is a unique animal model that exhibits ataxia and appendicular dystonia without pathological abnormalities of either the central or peripheral nervous systems. Recently, we detected a 19 bp deletion in exon 8 of the carbonic anhydrase-related protein VIII gene (Car8) within the wdl locus on mouse Chr 4 from wdl mice by high-throughput temperature gradient heteroduplex analysis (Jiao et al., Genetics. 2005 Nov;171(3):1239-46). Although regarded as a member of the carbonic anhydrase gene family, the encoded protein (CAR8) has no reported anhydrous enzymatic activity. However, CAR8 has recently been reported as an inositol triphosphate receptor 1-binding protein expressed at high levels in cerebellar Purkinje cells. Our study shows that, in +/+ mice, CAR8 is abundantly expressed in cerebellar Purkinje cells as well as several other cell groups. Compatible with nonsense-mediated decay of mutant transcripts, CAR8 is virtually absent in wdl mice. To examine the molecular aberrations contributing to motor dysfunction in wdl mice, cerebellar gene expression profiles were examined and key genes were confirmed by qPCR. Our data indicate that genes involved in signaling, cell division, zinc-ion binding, synapse integrity and plasticity are down-regulated in wdl mice. Gene expression profiling also detects several up-regulated genes which encode proteins that function in the Golgi apparatus, suggesting that CAR8 deficiency has an important impact on synapse vesicle formation and transport.

Chondrodysplasia Punctata in Infants of Mothers With Autoimmune Diseases. *V. Kirkland[1], U.T. Sundaram[1], G. Brookshire[2], M. Nino[3], M. Bober[4], N. Braverman[5]* 1) Dept Human Genetics, Virginia Commonwealth University, Richmond, VA; 2) Children's Medical Ctr, Dallas, TX; 3) NIH/NIDA, Baltimore, MD; 4) DuPont Hosp for Children, Wilmington, DE; 5) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Med Ctr, Baltimore, MD.

Chondrodysplasia punctata (CDP) is a skeletal dysplasia characterized by punctate calcific stippling in multiple epiphyses. It can be inherited in an autosomal or X-linked, dominant or recessive manner. In addition, there are phenocopies consequent to maternal Warfarin exposure and other vitamin K deficiency states in pregnancy. There are ~10 case reports that link maternal SLE and a fetus with CDP; the clinical picture resembles that seen in CDP caused by gene changes or maternal Warfarin use. We present two additional cases associated with non-SLE maternal autoimmune diseases. The first is a female infant of a mother with Sjogrens disease. Prenatal ultrasound at 23 weeks showed a 3 week delay in growth with shortened femurs and humeri, depressed nasal bridge and punctate calcifications involving numerous epiphyses. The infant was delivered prematurely. Examination showed a depressed nasal bridge with small upturned nares, absent skin ichthyosis, small hands with brachytelephalangy, stippled epiphyses and rhizomelia. She developed pneumonia and expired shortly. The second is a 2 yo male born to a mother with an unclassified autoimmune renal disease, Graves disease and rheumatoid arthritis. Postnatally, the infant was noted to have generalized CDP, rhizomelia and brachytelephalangy. He also had hearing loss, hypospadius and hypothyroidism. Testing on both infants excluded most known etiologies for CDP and included normal RBC plasmalogens, plasma 8(9)-cholestenol levels, karyotype analysis and for case 2, mutation analysis of Arylsulfatase E, a vitamin K dependent enzyme. Eye exams were normal. These cases highlight the possibility that a factor common to several autoimmune diseases relates to CDP. Comparison of maternal autoantibodies amongst these cases may provide clues to the underlying mechanism of CDP. Knowledge about this association will help management of pregnancies with maternal autoimmune diseases.

A reliable, quantitative method for GSH and GSSG determination using tandem mass spectrometry. *A.K. Niemi*[1], *G.M. Enns*[1], *T. Kwan*[3], *K.R. Atkuri*[2,1], *T.M. Cowan*[3,1] 1) Dept Pediatrics, Stanford University, Stanford, CA; 2) Dept Genetics, Stanford University, Stanford, CA; 3) Dept Pathology, Stanford University, Stanford, CA.

Glutathione (-glutamylcysteinylglycine, GSH) is important in the defense against oxidative stress, as occurs with mitochondrial disorders and organic acidemias. Decreased GSH may play a role in the pathophysiology of these and other disorders, although this has been difficult to demonstrate in practice because of its inherent instability and propensity to autooxidize to GSSG. We have developed a rapid, reliable method for measuring GSH and GSSG in whole blood using tandem mass spectrometry (MS/MS) that has widespread clinical applicability. Blood is mixed in a 1:5 ratio with sulfosalicylic acid, N-ethylmaleimide and EDTA in a single preparative step. After centrifugation, supernates are mixed with stable-isotope standards of GSH and GSSH, and are analyzed without column separation by MS/MS. Results are linear(r^2>0.9999) over the ranges of physiologic normal for both analytes, with intra- and inter-assay CVs < 3% for GSH, and 14% and 27% respectively for GSSG. GSH and GSSG are stable in refrigerated whole blood for 3 days, and in deprotienized supernatants stored at -80C C for at least 3 months. This method was used to evaluate 19 metabolic patients (mitochondrial myopathies, organic acidemias, cystinosis and G6PD deficiency) and 22 normal controls. GSH and GSSG levels in the metabolic patients, the majority of whom were clinically well, did not differ from normal controls (GSH normal mean, SD = 1115, 187; GSSH normal mean, SD = 1.6, 1.3). The patient with G6PD deficiency, evaluated during an acute crisis, had significantly decreased GSH (95.2M)) and mildly increased GSSG (4.1M). Results compare favorably to those using Hi-D fluorescence activated cell sorting (FACS), previously reported for evaluating markers of oxidative stress in metabolic patients. These studies will be extended to the broader evaluation of metabolic patients, as well as to more common conditions (e.g., diabetes, neurodegenerative disorders) for which oxidative stress may play an important role in pathogenesis.

Y Chromosome and Mitochondrial DNA Analysis of First Settlers of the Chesapeake Bay's Hoopers Islands to Investigate the Presence of Native American Lineages. *H. McCammon, U.A. Perego, J. Ekins, K. Ritchie, N. Myres, R. Hughes, N. Angerhofer, I. Masannat, S.R. Woodward* Sorenson Molecular Genealogy Foundation, SLC, UT.

The first European(-made) map of the Chesapeake Bay dates to 1608 and included three islands known as Hoopers Islands (Upper Hoopers Island, Middle Hoopers Island and Lower Hoopers Island). The first colonial families (Creighton, Gibson, Hooper, Meekins, Parker, Phillips, Price, Ruark, Tolley, Travers, Wallace, and Woodland) began settling on the island in 1659, when the Chesapeake Bay became an important fur-trading center. Oral histories surviving to this day purport early admixture with the islands' natives. Genetic analysis can support the legitimacy of such historical accounts as they are reflected in the extant genetic composition of the descendants of Hoopers Islands' first settlers. The present analysis correlates genetic data to oral and written genealogical records to estimate the degree of Native American admixture present in today's descendants. 43 Y chromosome STR loci and mitochondrial DNA sequences from HVR1 and HVR2 were analyzed from a dataset of over 100 descendants of the first settlers and compared to known Native American haplogroups. The combined Y chromosome and mitochondrial DNA analysis revealed a complex genetic history of Hoopers Islands.

Formalization of matching strategies for duplicated Y chromosome STR loci. *L.A.D. Hutchison[1,2], N.M. Myres[2], K. Ritchie[2], R. Hughes[2], N. Angferhofer[2], J. Ekins[2], B.A. Berger[1], S.R. Woodward[1]* 1) Computational Biology Lab, CSA, MIT, Cambridge, MA; 2) Sorenson Molecular Genealogy Foundataion, Salt Lake City, UT.

Two different alleles are typically observed at duplicated Y chromosome STR loci such as DYS385 and DYS459. Current cost-effective genotyping techniques do not yield information about the originating locus homolog for each allele of a duplicated-locus genotype. Though several of these loci are in common use, the literature employs a variety of different approaches for counting matches and mismatches at these loci. It has also been debated as to whether a duplicated locus should be treated as one locus or two, and a formal analysis of the relative merits of different approaches has not previously been performed. In this research we analyze the error rate of various matching strategies for duplicated-locus genotypes, and compare the observed number of matches between two genotypes to the actual number of matches that would be expected if locus copies were distinguishable. We are able to measure the error rate of various matching strategies by pairing non-duplicated Y chromosome STR loci to produce a pseudo-duplicated genotype consisting of alleles of known origin. We show that there is a dramatic difference (an order of magnitude) in the error rate of various matching strategies that on the surface all seem somewhat plausible. We formalize a new matching strategy that delineates exactly when a duplicated-locus match or mismatch may be unambiguously treated as two loci, and when it cannot be treated as two different loci without possible spurious matching. The error rate of the new matching strategy in predicting actual number of matches from observed number of matches is measured and shown to be significantly lower than the alternatives. We suggest how to further lower the error rate, and discuss the extension of this technique to the related problem of the matching of autosomal loci. This work should enable improved accuracy of genotype matching in several fields such as forensics, genetic genealogy and population genetics.

IGF1 and IGFBP3 gene polymorphisms are associated with plasma levels and prostate cancer risk in African Americans. *R.A. Kittles[1], C. Grenade[1], C. Bonilla[1], E.R. Santos[1], W. Hernandez[1], C. Ahaghotu[2]* 1) Ohio State Univ, Columbus, OH; 2) Howard Univ, Washington, DC.

IGF1 is a strong inhibitor of apoptosis and mediates the effects of growth hormone. The interaction between IGF1 and its receptor is predominantly regulated and directed to its target tissues by IGFBP3. In addition to regulating and protecting IGF1 from proteolytic degradation, IGFBP3 can mediate apoptosis independent of IGF1. Previous studies have linked IGF1 and IGFBP3 plasma levels to cancer risk. Here, we investigate the relationship between a C/T SNP (rs7965399) and dinucleotide repeat $(CA)_n$ within the 5 region of the IGF1 gene, the -202 A/C SNP in the IGFB3 gene, and corresponding plasma levels and prostate cancer risk (Pca) in 767 African Americans (AAs) enrolled in a clinic-based case-control study at Howard University Hospital. Total IGF1 and IGFBP3 levels were measured using ELISA and the polymorphisms were typed in all Pca cases (n=401) and healthy age and ethnicity matched controls (n=366). Multiple linear regression and multivariable unconditional logistic regression were used to test for associations between genotypes and circulating IGFs (including molar ratio of IGF1/IGFBP3) and Pca risk, respectively. No relationship was observed for plasma IGF levels and Pca risk. We did observe that the IGBP3 -202 C allele was strongly correlated with decreased IGFBP3 plasma levels (3,532ng/ml versus 3,106ng/ml; P=0.008). This result is in strong agreement with a previous study examining -202A/C and IGFBP3 levels. More importantly, we observed a two-fold increase in Pca risk for individuals homozygous for the IGBP3 -202 C allele (OR=2.1; 95%CI=1.2-4.3). Contrary to previous findings in European Americans, no association with Pca risk was observed for IGF1 $(CA)_n$ repeats or the IGF1 rs7965399 SNP in AAs. This suggests that different genetic and environmental factors may influence IGF1 plasma levels and Pca risk across populations and reveals the need to fully explore IGF1 and IGFBP3 genetic variation across diverse populations. Our study adds further clarity and support to previous findings implicating plasma IGFBP3 levels and IGFBP3 -202A/C in prostate carcinogenesis.

Genetic and neural basis of Williams syndrome in a six-member family. *J.R. Korenberg[1], X.-N. Chen[1], U. Bellugi[2], P.S. Eis[6], A.M. Galaburda[3], D.L. Mills[4], A.L. Reiss[5], T.A. Richmond[6], R.R. Selzer[6]* 1) Depts Medical Genetics/Pediatrics, Cedars-Sinai Med Cntr/UCLA, Los Angeles, CA; 2) Salk Institute Laboratory for Cognitive Neuroscience, La Jolla, CA; 3) Dept Neurology, Harvard Medical School, Boston, MA; 4) Dept Psychology, Emory University, Atlanta, GA; 5) Stanford Psychiatry Neuroimaging Laboratory, Dept Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, CA; 6) NimbleGen Systems, Inc, Madison, WI.

Williams syndrome (WS) is a compelling model for understanding the genetic origins of human cognition and behavior. To focus hypotheses on the genetic contributions to brain development and adult function of single genes or clusters in the WS region, we used a multidisciplinary approach to characterize the genes deleted in a large cohort of persons with WS. We identified a small subset of persons, each with a smaller, unique deletion, and previously showed that part of the variability of WS visual-spatial processing correlated with deletion of the genes encoding GTF2I and GTF2IRD1. Further, parental origin of the deletion contributed to the variation in gene expression. We now report the analysis of a six-member family with a subset of WS features associated with a smaller deletion. We used multicolor fluorescence in situ hybridization (FISH) with a BAC array, combined with somatic cell hybrids and quantitative RTPCR, to show a 500 kb deletion including the genes ABHD11, CLDN3, CLDN4, WBSCR27, WBSCR28, ELN, LIMK1, WBSCR1, LAT2, and RFC2 in all six family members. Further, we mapped the breakpoints of this deletion at exon-level resolution using oligonucleotide array CGH [Selzer et al. (2005) Genes Chromosomes Cancer 44:305] with a probe tiling-path design of Chr 7 (isothermal probes with Tm = 76C; median probe spacing of 135 bp). We combined these data with sequence-specific haplotype analyses to show the contribution of each of the maternal chromosomes 7 to different siblings. Combining genetic and cognitive data strongly support the hypothesis that the genes deleted in this family contribute more subtlety than GTF2IRD1 or GTF2I to the typical cognitive and physical features of WS.

Deletion or duplication of multiple exons account for a significant percentage of mutant *GLDC* alleles in glycine encephalopathy. *B. Kuchinka[1], J. Toone[2], J. Mitchell[3], R. Martin[4], K. Martin[4], D. Applegarth[2], B. Casey[1,2]* 1) Children's Hospital, Vancouver, British Columbia; 2) University of British Columbia, Vancouver, British Columbia; 3) McGill University, Montreal, Quebec; 4) Washington University, St. Louis, Missouri.

Glycine encephalopathy, also known as non-ketotic hyperglycinemia (NKH), results from impaired glycine metabolism and is characterized biochemically by an increased ratio of CSF:plasma glycine. Hepatic enzyme analysis, though the diagnostic gold standard, requires a large biopsy, and prenatal diagnosis utilizing CVS has both false positives and false negatives. We have developed a DNA-based assay for this disorder that encompasses direct resequencing, deletion/duplication detection utilizing multiplex ligation-probe amplification (MLPA), and allele tracking with polymorphic repeats. Of 24 cases analyzed to date, we identified 3 with *AMT* mutations and 18 with *GLDC* mutations. The *GLDC* nonsense mutation R424X appeared in three probands of different ethnic and geographic backgrounds, suggesting the possibility of a mutation hotspot. Five multi-exon deletion alleles were identified as well as the first reported multi-exon duplication within *GLDC*. These six alleles account for approximately 25% of the unique *GLDC* mutations. One of the deletions was shown to have occurred *de novo*, an event initially suggested by non-mendelian inheritance of polymorphic alleles and one that may be unexpectedly common. The combination of direct resequencing, deletion/duplication detection by MLPA, and allele tracking will provide a valuable alternative or complement to standard confirmatory or prenatal enzyme diagnosis.

Direct isolation of short sequence length polymorphisms in 3' flanking sequences of Alu repeats for microarray analysis. *J.J. Jonsson[1,2], H.G. Thormar[1,2], B. Gudmundsson[3], G.H. Gunnarsson[2,3], M.H. Halldorsson[4], Y. Vigfusson[4], H. Thorgeirsson[4]* 1) Dept Genetics/Molecular Med, Landspitali-Univ Hosp, Reykjavik, Iceland; 2) Dept Biochem/Mol Biol, Faculty of Medicine, Univ of Iceland, Reykjavik, Iceland; 3) BioCule Inc., Reykjavik, Iceland; 4) Dept Computer Science, Univ of Iceland, Reykjavik, Iceland.

Approximately 1.2 million Alu repeats are distributed over the human genome. A fraction of them contains short sequence length polymorphisms (SSLPs) in their adenine-rich 3' flanking (Alu3F) sequences. We developed a method for direct isolation of Alu3F-SSLPs based on two-dimensional conformation-dependent gel electrophoresis (2D-CDE) (Gunnarsson et al, Nucleic Acid Res 2004:e23). The Alu3F sequences were selectively amplified with complex PCR (Alu3F-PCR) on DNA samples from ten individuals. The amplicons were pooled, denatured and renatured. Mismatched heteroduplexes were isolated from perfectly matched homo- and heteroduplexes using 2D-CDE and cloned. Up to 80% of sample Alu3F sequences isolated with this approach contained SSLP. We designed a microarray platform for large scale genetic studies of SSLPs in Alu3F sequences. We wrote a computer program CATTAGAT for virtual PCR reactions on the entire human genome.The program is accessible for use on www.genome.cs.hi.is and available under the terms of the GNU General Public License. This program simulates complex PCR reactions and extracts sequences between primer binding sites with or without mismatch and adaptors at restriction sites. Length restrictions can be specified. The program predicted that Alu3F-PCR amplifies 200 thousand sequences. Further software was created allowing automatic microarray probe design based on sequences extracted using GATTAGAT. These probe sequences have been used to construct oligomer microarrays (NimbleGene) to select optimized probes corresponding to Alu3F-SSLP in the human genome.

An Ethnic-Specific Polymorphism in Glutamate Cysteine Ligase Affects Cellular Survival Following Oxidant Injury. *T.M. Le[1], F.E. Barr[1], A.S. Willis[2], M.L. Summar[3]* 1) Division of Pediatric Critical Care Medicine, Vanderbilt Children's Hospital, Nashville, TN; 2) Department of Genetics, Johns Hopkins University, Baltimore, MD; 3) Division of Medical Genetics, Vanderbilt University, Nashville, TN.

Background: Polymorphisms within the gene encoding the catalytic subunit (GCLC) may affect an individual's ability to produce glutathione and respond to oxidant injury. Previously, we have identified 11 polymorphisms in the GCLC gene and demonstrated that some of these polymorphisms are associated with an increased incidence of post-operative pulmonary hypertension as well as increased markers of oxidant injury. Of note, only one of these polymorphisms was a nonsynonymous polymorphism (1384T), and this polymorphism was only found in individuals of African descent.

Objective: To determine the effects of the 1384T polymorphism on the viability of mammalian cells subjected to oxidant injury.

Design/Methods: Wild-type GCLC enzyme and the enzyme encoded by the 1384T polymorphism were expressed and used in an *in vitro* assay to produce -glutamylcysteine (-GC), a glutathione intermediate. Wild-type and 1384T GCLC enzymes were also overexpressed in MRC5 cells. These cells were exposed to H_2O_2 and cell viability was subsequently determined using Trypan blue staining.

Results: In an *in vitro* assay, the 1384T GCLC enzyme produced less -GC as compared to the wild-type enzyme. In addition, MRC5 cells overexpressing the 1384T variant enzyme had increased susceptibility to oxidant injury as compared to wild-type.

Conclusions: Mammalian cells that overexpress a nonsynonymous, ethnic-specific polymorphism in the GCLC gene have increased susceptibility to oxidant injury as compared to cells overexpressing the wild-type gene. This ethnic-specific polymorphism may predispose certain segments of the population of African descent to rapid glutathione depletion and increased cellular injury following oxidative stress.

Gene-Gene Interaction Models Identified for Alzheimer Disease using MDR-PDT. *L.W. Hahn[1], T.L. Edwards[1], J.R. Gilbert[2], M.A. Pericak-Vance[2], E.R. Martin[2], M.D. Ritchie[1]* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics, Duke University, Durham, NC.

Alzheimer disease (AD) is the most common form of progressive dementia in the elderly. It is a neurodegenerative disorder characterized by the neuropathologic findings of intracellular neurofibrillary tangles and extracellular amyloid plaques that accumulate in vulnerable brain regions. In this study, we examined Alzheimers susceptibility in 738 Caucasian families in 10 candidate genes using 48 SNPs. All cases met the National Institute of Neurological Disorders and Stroke/Alzheimer Disease and Related Disorders Association (NINDS/ADRA) criteria for probable or definite AD, and 82% of the families had a positive family history. The Multifactor Dimensionality Reduction Pedigree Disequilibrium Test (MDR-PDT) was used to search for single locus through four-locus gene-gene interaction models associated with AD. MDR-PDT is a novel computational approach for the detection of gene-gene interactions in pedigree data. MDR-PDT was performed in the full dataset, and in the dataset with the known risk locus Apolipoprotein E (APOE) removed so that it did not obscure less potent associations. Significant two-locus and three-locus interaction models were identified in the dataset without APOE. MDR-PDT detected a two-locus model between individual markers in the genes leucine rich repeat transmembrane 3 (LRRTM3) and angiotensinogen converting enzyme (ACE), $p = 0.009$. In addition, a three-locus model was detected which included the same markers in these genes and also a marker in the alpha 2 macroglobulin (A2M) gene, $p = 0.005$. These findings suggest a multilocus model among candidate genes influencing Alzheimer disease risk, as well as demonstrate the utility of exploring interactions in family data using MDR-PDT.

Improving Regulation with Genetic Information: The Case of Particulate Matter and Asthmatics. *C. Kramer*[1, 2], *A. Cullen*[1, 2], *E. Faustman*[1, 2] 1) University of Washington, Seattle, WA; 2) Center for the Study & Improvement of Regulation.

Government efforts to improve public health increasingly acknowledge the potential of genetic information as they set research strategies and policy to elicit the best possible science. Government agencies fund, develop, and use human health risk assessment, epidemiological, and toxicological studies to set regulatory standards on pollutants. These standards aim to protect the most susceptible citizens from harmful exposures. For example, we consider the case of asthmatics and exposure to particulate matter (PM). The federal Clean Air Act requires the Environmental Protection Agency to set National Ambient Air Quality Standards for criteria pollutants at levels to protect sensitive subpopulations from adverse health effects with an adequate margin of safety. Asthmatics, an identified subpopulation, may carry multiple genetic susceptibilities to disease onset and progression that are exacerbated by exposure to pollutants regulated under the CAA, such as PM. In an effort to evaluate and facilitate maximizing the potential of incorporating genetic information into health science used in regulatory standard setting, we reviewed government documents used in PM standard setting along side current developments in research on genetics and asthma. Given that asthma is a complex genetic disease with varied environmental and social influences, we developed a guiding paradigm to encourage health science on asthma genetics most relevant to supporting PM standard setting (or other air pollutants). We establish and use criteria specific to regulation to identify IL-13 as an exemplary candidate gene, or biomarker for susceptibility to asthma. We then illustrate within a decision analytic framework how association studies on the -1111 C/T promoter polymorphism and future scientific studies may improve decision making in PM standard setting. Our analysis identifies substantial research gaps in associating genetic information with asthma, PM exposure and related health effects. Consequently, we recommend a coordinated research strategy to assess effective regulatory protection of susceptible subpopulations, including those genetically predisposed to asthma.

Frequency of variants in 184 genes involved with metabolism and transport using a novel analytical platform. *R. Hockett[1], T. Daly[1], P. Hardenbol[2], X. Miao[2], C. Bruckner[2], R. Njau[1], N. Bauer[1], C. Dumaual[1], R. Haman[1], N. Lewin-Koh[1], S. Kirkwood[1]* 1) Dept Diag & Exper Medicine, Eli Lilly, Indianapolis, IN; 2) Affymetrix, South San Francisco, CA.

It is estimated that a significant fraction of therapeutic unresponsiveness and drug related adverse events is accounted for by differences in drug disposition. In addition, understanding drug metabolism and transport are increasingly important to the concept of personalized medicine. Currently available assay systems for genotyping patients measure only a fraction of the known drug metabolic enzymes and transporters (DMETs). To solve this problem, we developed a genotyping platform to comprehensively measure ~2,000 polymorphisms in the 184 known DMETs. The system uses Affymetrix Molecular Inversion Probes and Affymetrix Tag arrays. A subset of 29 genes (168 variants), with documented effects on drug disposition, have been validated for clinical use according to regulatory guidelines. Data on >1,000 patients, on all 2,000 variants, will be presented, with emphasis on the frequency of alleles in ethnic subsets. A summary of the comparison of data generated on this system to the literature will be discussed, highlighting the discrepancies uncovered. Finally, the potential applications of this tool will be outlined, including how the frequency of gene variants impacts building a patient database of known genotypes that could be recruited into new clinical trials.

Chromosome 2q37 Deletion Syndrome: Defining Clinical Features. *F. Lacbawan, M. Jones, A. Dutra, V. Rodriguez, S. Chandrasekharappa, E.S. Doherty* National Human Genome Research Institute, Bethesda, MD.

The chromosome 2q37 deletion syndrome is gaining increasing clinical recognition. Here, we describe molecular breakpoint-phenotype correlation for 10 patients (ages 3 to 16 years) with apparently pure chromosome 2q37 deletions. The karyotypes ranged from a cryptic deletion to del(2)(q37.1). The breakpoints ranged in size from 1 Mb to 10 Mb. We compared our clinical findings with more than 25 previously published genotyped cases of comparative size. The clinical gestalt that emerged may be helpful for evaluation and counseling of individuals with a pure terminal 2q37 deletion. The functional outcome was most affected by the presence of major congenital anomalies and clinically diagnosed autism. In our experience, patients with larger deletions tended to have more severe developmental delay and behavioral problems. Incomplete documentation in the literature gives partial support to this finding. Midline defects were not common, and no patient had holoprosencephaly. The AHO-like phenotype comprising short stature, round facies, obesity, and brachymetaphalangy is a useful mnemonic for clinical consideration of the 2q37 deletion syndrome. However, the mnemonic did not hold up well to closer scrutiny. Four patients with brachymetaphalangy had normal stature, and their facies were not always round. The facial dysmorphisms typical of the 2q37 deletion syndrome have been variably described in the past. In our experience, patients had thin, arched brows with deeply set eyes, a flat midface, hypoplastic nares, prominent columella, and a thin vermilion border. Individuals presenting with this facial gestalt and developmental delay should be evaluated for a 2q37 deletion. Molecular breakpoint analysis was performed with informative microsatellite markers. Results of further refinement of the breakpoints using molecular cytogenetic methods: oligonucleotide arrayCGH (Agilent Technologies) and FISH will also be presented.

High-density oligonucleotide array-based genotyping using whole genome amplified DNA. *M. Kibriya, F. Jasmine, I. Andrulis, E. John, J. Chang-Claude, H. Ahsan* Department of Epidemiology, Mailman School of Public Health, Columbia University, New York, NY.

In large scale genome-wide single nucleotide polymorphism (SNP) association study, the quantity of available high quality genomic DNA (gDNA) is a practical problem. We therefore studied the feasibility of utilizing whole genome amplification (WGA) to overcome this issue. We also compared the conventional dynamic model (DM) and recently available BRLMM statistical algorithms for calling genotypes using high-density oligonucleotide array. We studied a set of 60 gDNA samples run on 60 early access Affymetrix Mendel Nsp Array chip containing 224,940 SNPs/ chip. The overall genotype call rate (meanSD) was significantly higher using BRLMM algorithm compared to DM algorithm (97.3% 1.37 vs. 89.5%3.36%, $p<0.001$). Concordance rate was 99.44%. We compared the genome-wide genotype call concordance using a total of 14 gDNA samples from 3 different centers (4 samples / center and 2 reference samples) and their corresponding 14 WGA samples on the same 224,940 SNPs. We used Repli-g DNA Polymerase for WGA from 25 ng gDNA. Overall, genotype call rate was 97.07% 1.55 for gDNA and 97.77% 0.87 for WGA DNA ($p=0.435$). There was no significant difference in call rates within the gDNA from different centers [96.66%1.04%, 96.161.86 & 97.671.59%, $p=0.405$] as well as within their corresponding WGA samples [98.17%0.41, 97.41%0.71 98.36%0.60, $p=0.109$]. We also did not observe any change in call rates using 60 g or 90 g of amplified PCR product of WGA samples for hybridization. Concordance between genotype calls from gDNA and WGA was 97.64% 1.29 without significant difference between centers [97.50%1.09, 97.001.41, 98.40%1.26, $p=0.32$]. Reproducibility, calculated as concordance in duplicate sample, was 99.45% for gDNA. Detailed characteristics of the small fraction of SNPs producing discordant calls for each of the comparisons will be presented in the meeting. Our study confirms that high density oligonucleotide array-based genotyping can yield reproducible data and WGA DNA products can be effectively used for genome-wide SNP analysis.

Genomic Copy Number Analysis Using High Density SNP Chips and Tiling Arrays. *B. Merriman, Z. Chen, M. Ogdie, S.F. Nelson* Deptartment of Human Genetics, University of California, Los Angeles, Los Angeles, CA.

Identifying genomic deletions or duplications can help localize genes that contribute to genetic disease or tumor progression. Traditional detection methods based on karyotping and FISH analysis have resolution limited to several megabases or larger, while the ongoing advances in DNA microarray technology are enabling rapid improvements in array-based copy number detection. Here we summarize the resolution limits, genomic coverage, and discovery rates from applying the highest density arrays presently available to a large number of human samples. Specifically, we apply Affymetrix 500k SNP chips and Human Genome Tiling arrays to detecting micro-deletions and duplications, with data based on more than 800 genomic samples run on 250k (or full 500k set) arrays, and selected samples run on Tiling arrays for breakpoint mapping. Based on these data, and using custom, highly optimized detection algorithms, we estimate that deletions exceeding 100kb can be detected with > 90% probability genomewide using the full 500k SNP chip set, with average detection resolution of 60kb, and that the Tiling arrays can effectively map deletion breakpoints with ~1 kb resolution. We also show that cell-line induced copy-number artifacts are rare, by comparing analysis of cell-line and blood-derived genomic DNA for several individuals. We conclude that the current high density SNP chips, combined with proper analystical methods, provide a highly effective tool for whole genome copy number analysis down to ~ 100kb detection resolution with high confidence, and that by selecting the best-performing probes from the tiling arrays to create an optimized copy-number detection chip, a single chip providing genomewide wide 510 kb detection resolution is feasible with existing technology.

Applications of Pedigree-Free Identity-By-Descent Mapping to Localizing Disease Genes. *S. Nelson, B. Merriman, Z. Chen, M. Ogdie, J. Stone, S. Strom* Deptartment of Human Genetics, UCLA Medical Center, Los Angeles, CA.

Risk factors for genetic disease can result in a founder effect, wherein many affected people in the population share a risk factor tracing back to a common ancestor, and thus share an interval of DNA inherited identical-by-descent (IBD) from the founder. Traditionally, such intervals are detected by establishing a detailed pedigree connecting affected individuals, and genotyping sufficient numbers of affecteds on a sufficiently dense set of markers to reliably identify the IBD intervals. The pedigree plays a key role, both in providing a priori evidence that such IBD intervals exist, and in providing for their reliable detection by tracing recombination events which occur rarely in the human genome with each generation. High density SNP genotyping(greater than 250K SNPs) now provides sufficient information to infer if large intervals of genomic DNA are inherited IBD between even distantly related affected individuals. This enables the direct comparison of affected individuals to search for shared IBD intervals, as an efficient linkage mapping approach for localizing genetic risk factors. Here we present several applications of the Pedigree-Free IBD mapping approach. First, we demonstrate it in the context of a traditional Case-Control study for ADHD, in which 150 cases and 100 controls are genotyped on, and show that IBD can be clearly detected between unrelated affected individuals, at a rate and scale that clearly exceeds the population background level, and which identifies several candidate loci genome-wide. Second, we investigate pedigree-free IBD detection under a major linkage peak for Autism, based on high density SNP typing of 250 Autism trios, and show that the unrelated affected children have ancestral IBD sharing suggestive of a founder effect. Finally, we show that within a previous successful whole genome SNP association study for a common disease, the locus identified by standard means is also highlighted by IBD between various unrelated affecteds. This latter observation also suggests that pedigree-free IBD mapping can be combined with standard association analysis to reinforce the findings of both approaches.

Association of the ERBB2 W452C Variant with Sporadic Breast Cancer. *H.L. Patney[1], R.E. Ellsworth[1], C.D. Shriver[2]* 1) Clinical Breast Care Project, Windber Research Inst, Windber, PA; 2) Clinical Breast Care Project, Walter Reed Army Medical Center, Washington, DC.

Alterations of the ERBB2 (Her2/neu) gene have been associated with poor prognosis in patients with invasive breast cancer. Aggressive behavior of breast tumors is often associated with large amplifications of the ERBB2 gene region but point mutations in ERBB2 also may be associated with deleterious effects. To determine relationships between a C->T DNA base substitution (W452C) in ERBB2 and breast pathogenesis, we genotyped 225 women (80% Caucasian, 20% African American) with invasive breast cancer and 225 age- and ethnically-matched disease-free controls. The overall minor (T) allele frequency (MAF) was 0.02, in agreement with published values, but was not observed in Caucasians. Two African American women without breast disease were heterozygous for the minor allele, while 16% of African American women with invasive breast cancer were homozygous for the minor (T) allele; these results were verified by double-stranded sequencing. The increase in frequency of the minor allele in African American cases was significant ($P<0.05$), compared to African American controls. None of the patients with the TT genotype were HER2 positive, either by FISH or by IHC analysis. Approximately 60% of the TT homozygotes were pre-menopausal at diagnosis and over half of the patients had stage I disease. These data suggest that, in addition to the traditional model of amplification and over-expression, DNA variants may contribute to breast cancer development in African American women. Determination of the functional changes associated with W452C will increase our understanding of the underlying biology of tumors from African American women and provide new targets for customized breast cancer treatments.

CFTR Mutations Panel of Persian Males with Congenital Bilateral Absence of the Vas Deferens. *R. Radpour[1], H. Gourabi[1], M.A. Sadighi Gilani[2], A. Vosough Dizaj[2], S. Mollamohamadi[3]* 1) Department of Reproductive Genetics, Reproductive Biomedicine Research Center of Royan Institute; 2) Department of Male Infertility, Reproductive Biomedicine Research Center of Royan Institute; 3) Department of Stem Cell, Reproductive Biomedicine Research Center of Royan Institute.

Congenital bilateral absence of the vas deferens (CBAVD) is a frequent cause of obstructive azoospermia and nearly 75% of Patients have at least one detectable CFTR mutation. To study the CFTR gene mutations in Persian CBAVD patients with presumed low cystic fibrosis (CF) frequency, we analyzed 112 Persian CBAVD and 7 CUAVD males from Iran with 52 fertile males as control. All 27 exons and their flanking sequences of CFTR gene was analyzed using a combination of the DGGE or by SSCP and direct DNA sequencing. Forty-six of the 112 patients with CBAVD (41.07 percent) had two mutations in the CFTR gene, 41 of them had the 5T allele (in 11 cases two allele of 5T was detected). Forty-three patients (38.39 percent) had a mutation in one copy of CFTR gene in witch 9 of them had just one 5T allele. In 23 patients (20.53 percent) no CFTR mutations were found. IVS8-5T was observed with TG12 or TG13 haplotypes, on 61 chromosomes thus confirming the association of this variant with CBAVD in Persian patients. The F508del mutation in exon 10 was uncovered on 28 chromosomes. Screening for the IVS8-5T and F508del together led to the identification of more than one-third of alleles. Exon 9 skipping was strongly joined with 5T/5T genotype, the rate of normal CFTR mRNA increased by having IVS8-9T (TG) 9-10 and IVS8-7T (TG) 10-11-12. 5T/M470 genotype was found in 21 patients, 5T/V470 was found in 3 and 5T with heterozygote form of M470V was found in 26 CBAVD patients. We could detect one novel nonsense mutation (K536X) in the NBD1 region and two novel missense mutations (Y122H & T338A) in the M2 and M6 regions of CFTR gene. The conservation of changed nucleotide and amino acid in mutated regions were analyzed by aligning with nine different species. The combination of the 5T allele in one copy of the CFTR gene with a cystic fibrosis mutation in the other copy is the most common cause of CBAVD in Persian population.

Association of Long Polyglutamine Tracts in Exon 1 of the Androgen Receptor Gene with Idiopathic Male Infertility and Impaired Sperm Production in Iranian Population. *M. Rezaee[1], R. Radpour[2], A. Tavasoly[3], A. Saleki[3]* 1) Department of Nanotechnology, Avesina Research Institute, Beheshti University; 2) Department of Reproductive Genetics, Reproductive Biomedicine Research Center of Royan Institute; 3) Department of Urology, Biomedical Research Center of Military University of Medical Sciences.

It is estimated that 10%-20% of patients with male infertility could have reduced androgen receptor function as a result of long polyglutamine tracts. To study the association of CAG trinucleotide repeats in the androgen receptor gene with idiopathic male infertility in Iranian population, we performed a case-control study of 178 Iranian males with idiopathic infertility witch were excluded for androgen receptor mutations and Y chromosome microdeletions and 152 fertile males as control. The length of the CAG repeat segment was evaluated by using PCR-sequencing in exon 1 and PCR-SSCP in exons 2-8. We were able to identify 13 different alleles in the infertile group with a range of 18-32 CAG repeats corresponding to 19-33 glutamine residues. The mean of the AR gene CAG repeat length in the infertile group was 24.13 1.64 (range 18-32), while that of fertile controls was 20.32 0.92 (range 16-25) and the difference was statistically significant (P = 0.001). The highest mean length of the AR gene CAG number in infertile group was observed in oligospermia group (24.21) but there were not significant differences between the Oligospermia and Azoospermia. In addition, the frequency of having a CAG repeat number (21) was 79% in infertile men and 27.1% in fertile controls (P = 0.001), whereas the of having a CAG repeat number (26) was 23.6% in infertile males versus 0% in fertile controls. No mutation was detected in exons 2-8 of androgen receptor gene in infertile patients. Long (26) androgen receptor CAG alleles, which are found in up to 38% of infertile males, are associated with male infertility and defective spermatogenesis in our studied population and the odds ratio for male infertility was higher for patients with 26 CAG repeat.

Associated malformations in cases with oral clefts. *C. Stoll, Y. Alembik, B. Dott, MP. Roth* Genetique Medicale, Faculté de Médecine, Strasbourg, France.

Objective: Infants with oral clefts (OCs) often have other associated congenital defects. The reported incidence and the types of associated malformations vary between different studies. The purpose of this investigation was to assess the prevalence of associated malformations in a geographically defined population.Methods: The prevalences at birth of associated malformations in infants with OCs were collected between 1979 and 2003 on all infantss born in the area covered by the registry of congenital anomalies of Northeastern France in 334,262 consecutive births. Results: Of the 651 cleft infants born during this period, 35.9% had associated malformations. Associated malformations were more frequent in infants who had cleft palate (47.9%) than in infants with cleft lip and palate (34.9%) or infants with cleft lip only (14.4%). Malformations in the central nervous system and in the skeletal system were the most common other anomalies, followed by malformations in the urogenital and cardiovascular systems. Weight, length, and head circumference of children with OCs and multiple associated malformations were lower than in controls, as was the weight of the placenta. Prenatal diagnosis was rarely done by fetal ultrasonographic examination in isolated clefts. However, even in multiple associated malformations, prenatal diagnosis by fetal ultrasonographic examination had a low sensitivity, 43.9%. Conclusion: The overall prevalence of malformations, which was one in more than three infants, emphasizes the need for a thorough investigation of infants with clefts. A routine screening for other malformations especially skeletal, central nervous system, and cardiac defects may need to be considered in infants with clefts, and genetic counseling seems warranted in most of these complicated cases.

Methylenetetrahydrofolate reductase gene polymorphisms in patients with nonalcoholic steatohepatitis (NASH).

A. Sazci[1], E. Ergul[1], C. Aygun[2], O. Senturk[2], G. Akpinar[1], S. Hulagu[2] 1) Department of Medical Biology, Faculty of Medicine, University of Kocaeli, Umuttepe, 41380, Kocaeli, Turkey; 2) Department of Gastroenterology, Faculty of Medicine, University of Kocaeli, Umuttepe, 41380, Kocaeli, Turkey.

Nonalcoholic fatty liver disease(NAFLD) is the most common cause of abnormal hepatic steatosis in the absence of alcohol worldwide. Nonalcoholic steatohepatitis (NASH) is the most progressive form of NAFLD. The aim of this study was to investigate the role of methylenetetrahydrofolate reductase gene C677T and A1298C polymorphisms (MTHFR) in the etiopatopysiology of NASH. We analysed 57 nonalcoholic steatohepatitis (NASH) patients and 100 healthy controls using a PCR-RFLP method.The diagnosis of the patients was based on liver biopsy. The following results were obtained. We studied 57 NASH patients 26 (45.6%) of whom was women and 31 (54.4%) was men. The healthy controls were 100, and 49 (49.0%)of whom was women and 51(51.0%) was men. The frequency of the 677T allele of the MTHFR gene was 25.44% in the cases and 31.00 % in the controls (Chi2=1.511;df=2;P=0.470).The 1298C allele of the MTHFR gene was 47.37% in the cases and 32.50% in the controls. The frequencies of the MTHFR C677C, C677T and T677T genotypes were 56.1%, 36.8%, and 7.0% in the cases, and 46.0%, 46.0%, 8.0% in the controls respectively. The frequencies of the MTHFR A1298A, A1298C and C1298C genotypes were 22.8%, 59.6%, and 17.5% in the cases and 43.0%, 49.0% and 8.0% in the controls. The distribution of the MTHFR 677T allele was not significant in the NASH patients compared with the healthy controls (Chi2= 1.511;df=2;P=0.470). However the distribution of the MTHFR 1298C allele was statistically significant in NASH patients compared with the healthy controls (Chi2=7.814;df=2;P=0.020). The MTHFR A1298A genotype was protective for NASH(OR=0.392; 95%CI=0.188-0.816; Chi2=6.452; df=1;P=0.011). Although the MTHFR C1298C genotype gave a 2.447 odds ratio, it lacked the power (OR=2.447; 95%CI= 0.906-6.611; Chi2=3.258;df=1;P=0.071). To conclude with, the MTHFR 1298C allele was a genetic risk factor for NASH. Presumably, the individuals carrying this genotype were predisposed to develop NASH. The MTHFR A1298A genotype, on the contrary, provided protection towards NASH in the Turkish population.

Interleukin-18 (IL-18) gene Haplotype and Allergic Dermatitis and Bronchial Asthma. *K. Yanamandra[1], D. Napper[1], P. Boggs[1], H. Chen[1], S. Ursin[1], S. Bahna[1], J.A. Bocchini Jr.[1], R. Dhanireddy[2]* 1) Dept Pediatrics, LSU Medical Ctr, Shreveport, LA; 2) Dept Pediatrics, Neonatology Section, Univ Tennessee Health Sciences Center, Memphis, TN 38163.

Interleukin (IL)-18 is involved in the regulation of TH1- and TH2-mediated immune responses, and is involved in the pathogenesis of TH1 and TH2 chronic inflammatory diseases. Allergic athma is a typical TH2-mediated disease and the serum IL-18 levels have been shown to be elevated during the acute asthmatic exacerbations, and secretion of IL-18 by peripheral mononuclear cells is increased in asthma and atopic dermatitis. Controversially, another study demonstrated that in bronchioalveolar lavage fluid IL-18 levels were reduced in asthma when compared with healthy controls. Also, there was a mention in the literature of reduced expression of IL-18 mRNA levels in atopic dermatitis. Similar conflicting results have been obtained in mouse models of allergic asthma. IL-18 stimulates TH1 or TH2 responses depending on its cytokine milieu. When IL-18 is given alone, it exhibits pro-allergic functions like stimulating IL-4 and histamine release from basophils; however, when it is given in a TH1 milieu i.e. together with IL-12, it prevents the development of allergic reactions. In view of the conflicting results on IL-18 role in inflammation, the present investigation was undertaken to study the association of IL-18 gene loci in the etiology of dermatitits and bronchial asthma. In the present investigation seventy-nine patients who presented with allergic rhinitis, dermatitis and asthma from our Northwest Louisiana region and one hundred and sixty controls were genotyped for the IL-18 gene polymorphisms. Our IL-18 haplotype data revealed no significant difference in the mutant haplotype frequency between patients and controls (0.21 vs. 0.26). Based on our data, we conclude that the IL-18 gene marker haplotype may not play a significant role in the etiology of asthma. This was the first study on the role of IL-18 gene haplotype in the etiology of asthma or dermatitis in the African American community. Data and statistics on the individual genotypes of IL-18 gene will be presented.

The First Genome-wide Scan to search for Genes predisposing to Coronary Artery Disease using 500,000 Single Nucleotide Polymorphism (SNP) marker set. *A. Stewart, R. McPherson, L. Vo, Y. Wang, J. Rutberg, G. Ewart, G. Wells, K. Williams, N. Kavaslar, H. Doelle, S. Hebert, T. Naing, R. Roberts* University of Ottawa Heart Institute, Ottawa, Ontario, Canada.

Background: Coronary artery disease (CAD) remains the number one killer in the western world and world wide by 2010. Genetics account for over 50 percent of the risk for CAD. Genetic screening and early prevention in individuals identified at increased risk could dramatically reduce CAD. Thus, the necessity to identify genes predisposing to CAD. Genes identified by the candidate gene approach have not been replicated due in part to inadequate sample size. Genome wide scan association studies have been limited by the use of thousands of markers rather than the hundreds of thousands required and hundreds of individuals rather than the thousands required (Science 2005;307:1072). Equally important is the need to replicate positive findings in an independent population. To detect a Minor Allele Frequency of 5 percent, an odds ratio for risk of 1.3, with 90 percent; power, we estimate 14,000 (9,000 affected and 5,000 control) subjects are required (Nature,2005:6;109). Methods: The Affymetrix 500,000 marker set provides a marker every 6,000 base pairs to genotype 1,000 premature CAD cases and 1,000 normals followed by replication in 8,000 cases and 4,000 controls. The phenotype is confirmed or excluded on the basis of coronary arteriograms by catheterization or multi slice CT. Results: We are averaging 4 million genotypes per day with 123 million genotypes analyzed for 99 controls and 164 cases. On average each DNA sample analyzed provided accurate and interpretable genotypes for 94 percent of the 500,000 SNPs. Where allele frequencies for cases and controls are in Hardy-Weinberg equilibrium (Chi squared, $p>0.05$), over 500 SNPs showing a difference in allele frequency ($P=0.001$) between cases and controls have been identified. Conclusions: This is the first whole genome scan for CAD genes utilizing a marker every 6,000 base pairs. Several haplotypes potentially associated with CAD have been identified.

Analysis of gene dosage of -synuclein gene in multisystem atrophy. *T. Tsunemi, K. Ishikawa, H. Jun, H. Mizusawa*
Department of Neurology and Neurological Science, Graduate School, Tokyo Medical and Dental University, Tokyo, Japan.

Recently increasing gene dosage was reported to cause Parkinsons disease or Alzheimers disease. The genetic association between multisystem atrophy (MSA) and -synuclein have been reported. MSA is pathologically characterized by glial cytoplasmic inclusions which ?-synuclein is strongly immunoreactive for anti-synuclein antibodies. Transgenic mice overexpressing human -synuclein in oligodendrocytes showed features similar to human MSA patients. To clarify whether gene dosage of ?-synuclein gene (SNCA) are altered in MSA patients, we assessed gene dosage of SNCA in 30 patients with MSA using a quantitative real time PCR method. After informed consent was obtained, DNA was prepared using standard methods. We set primers and TaqMan probes in each six SNCA exons and then compared copy number of each exon. CACNA1A was used as an endogenous reference. No genomic multiplication (duplication or triplication) was found in either exons of SNCA in our study. As far as we analyzed, SNCA gene dosage dose not seem to be altered in genomic DNA of MSA patients.

Mosaicism for supernumerary ring chromosome 17 resulting in partial trisomy of 17p11.1-17q23.3. *S.M. Purandare[1], J. Walman[1], N.J. Carpenter[2], J.J. Mulvihill[1], J.R. Seely[1]* 1) Department of Pediatrics, Division of Genetics, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma City, OK; 2) Center for Genetic Testing at Saint Francis, Tulsa, Oklahoma.

We present a case with mosaic partial trisomy 17 for the region 17p11.2-17q23.3, 47,XY+r[26]/46,XY[24].ish+r(17)(p11.1q23.3)(SMS- RARA+), due to a supernumerary ring chromosome (SRC) 17 in 52 % of cells analyzed. Clinical features included profound psychomotor delay, growth failure, feeding difficulties, microcephaly, atrial septal defect, ventricular septal defect, small hands and feet, bilateral single transverse palmar creases, partial syndactyly of 3rd and 4th toes, mild leg length discrepancy, scoliosis, bilateral inguinal hernias, hypospadias, cryptorchidism, hypotonia and other dysmorphic features including a large anterior fontanel, strabismus, malformed pinnae, broad nasal bridge and wide smooth philtrum. Other reported cases of supernumerary marker chromosome 17 involving 17q with partial trisomy of 17p11.2-17q23.3 have several clinical features similar to our patient, and those with the 17q duplication syndrome. Mosaicism and the size of the duplication likely account for the milder phenotype seen in our case. These observations further delineate the clinical features seen in partial trisomy 17q.

Insights from Three ChIP-on-chip Platforms. *D.O. Ricke[1], S. Wang[1,2], D. Cohen[2]* 1) Novartis Institutes for BioMedical Research, Inc. Genome and Proteome Sciences, Cambridge, MA; 2) Novartis Institutes for BioMedical Research, Inc. Strategic Alliances, Cambridge, MA.

Analysis of chromatin Immunoprecipation on microarrays (named chIP-on-chip) results allows new insights into regulatory networks and chromatin dynamics. These insights are affected by antibody used, experiment replicas, instrument settings (PMT), data normalization, and data analysis steps. Insights from the MIT Rick Youngs lab Hu19k platform, Affymetrix chromosome 21 and 22 platform, and Agilent 2-chip promoter platforms will be illustrated. Results can be influenced at multiple steps in the data processing. First, instrument PMT (photo-multiplier tube) settings non-linearly influence intensity measurements. Incorrect settings can lead to data saturation on one or both of the intensity channels. Second, another major source of variation can be introduced through data normalization. The number of antibody targets detected is dependent upon the biology of the antibody target. Third, for platforms that rely upon mismatch probes as controls, the PM-MM (perfect match minus mismatch) calculation introduces noise into the signal calculations. Also, the signal for half of the chips are arbitrarily discarded as PM-MM is negative for half of the probes. The introduction of this noise and loss of signal can be avoided by relying upon the PM signals in comparisons and calculations. Frequently, the experimental results from antibodies that detect large numbers of targets are often over-normalized because the normalization calculation includes the detected signal. Normalization based upon background or control signals enable improved comparisons across different antibodies. Fourth, after normalization, ratios between Cy5 and Cy3 dyes are frequently calculated. Skewed ratios often result from low Cy3 measurements. Eliminating these measurements reduces the number of false positives. Fifth, all of the platforms show good reproducibility between technical replicates. Correlation between biological replicates is influenced by the dynamics of the target protein biology. Insights from these three chIP-on-chip platforms will be illustrated and presented.

Annexin V interacts with Cystic fibrosis transmembrane conductance regulator. *P. Trouvé, M.A. Le Drévo, M. Kerbiriou, Y. Fichou, D. Gillet, C. Férec* INSERM, Brest, France.

The cystic fibrosis transmembrane conductance regulator (CFTR) which is involved in cystic fibrosis (CF) functions as a cAMP-activated chloride channel. The regulation of the CFTR function is involving protein-protein interactions. Nevertheless, the extent to which CFTR channels are regulated by interactions remains unknown. Based on the properties of Annexin V and CFTR and the overexpression of Annexin V in CF, we determine whether Annexin A5 was associated with CFTR and whether the association had implications upon the CFTR chloride channel function. Using co-immunoprecipitation and overlay experiments, we show that Annexin V is associated with the nucleotide binding domain 1 of the CFTR protein. Surface plasmon resonance was used to determine the KD values in the absence (4.3 nM) and in the presence of calcium and ATP (1.6 nM), indicating that the interaction is calcium and ATP dependant. Functional experiments were performed in A549 cells in which decreased expression of Annexin V was obtained using siRNA and was correlated to a decreased CFTR chloride channel function. The siRNA did not induce any modification in the mRNA accumulation and in the protein distribution of the CFTR protein, we concluded that Annexin V is necessary for the normal CFTR chloride channel activity via a direct mechanism. Furthermore, using confocal microscopy we show that CFTR and Annexin V are partially co-distributed in normal epithelial cells in human bronchias. In conclusion, we show for the first time that Annexin V is a CFTRs partner and is involved in the normal CFTR function.

Characterization of the *Mus musculus Tcof1* minimal promoter. *K. Shows, R. Shiang* Department of Human Genetics, Virginia Commonwealth University, Richmond, VA.

Treacher Collins syndrome (TCS) is an autosomal dominant mandibulofacial dysostosis caused by haploinsufficiency of the *TCOF1* gene product treacle. Mouse (*Mus musculus*) *Tcof1* is 74.3% identical to human *TCOF1*, and mouse Tcof1 is 61.5% identical to human treacle. Tissue-specific maximal expression of *Tcof1* mRNA is seen normally in the developing neural crest in mouse embryos; heterozygous knockout of *Tcof1* leads to severe craniofacial malformations. We have isolated the highly conserved core *Tcof1* promoter that is necessary and sufficient to direct maximal *in vitro* expression of a promoter/reporter construct in mouse P19 embryonic teratocarcinoma cells, which are of neural crest cell lineage. The putative transcription factor binding site CCAAT was shown to be essential to the maximal expression of the *Tcof1* promoter/reporter construct through transient transfection studies. In addition, the putative binding sites for transcription factors AP2-2, c-myb, and Sp1 have a modifying effect on regulation in combination with the CCAAT binding site.

High-resolution genomic profiling with Infinium Whole Genome Genotyping BeadChips. *D.A. Peiffer, T. Jenniges, F. Garcia, E. Chudin, K. Haden, E. Allen, F. Steemers, J. Le, D. Barker, R. Shen, K.L. Gunderson* Illumina, Inc., San Diego, CA.

High-density SNP genotyping technology (SNP-CGH) offers several advantages over traditional array-CGH using spotted BAC clones or oligonucleotides. Simultaneous measurement of signal intensity variations and changes in allelic ratios permits the detection of both copy number changes and copy-neutral loss of heterozygosity (LOH) events. Analysis of hundreds of thousands of SNP loci allows for chromosomal resolution of a few tens of kilobases. We demonstrate the utility of using multiple formats of high-density genotyping BeadChips (assaying 109K, 317K, and 550K SNPs) to detect chromosomal aberrations ranging in size from 90kb to several megabases in both constitutional and tumor samples. These include homozygous and heterozygous deletions, copy-neutral LOH, and amplifications. A subset of aberrations was verified using FISH, BAC array-CGH, and karyotype analysis. Genomic profiles were visualized with a genome browser displaying plots of log ratios of normalized intensities and allelic ratios along the chromosome. The browser allows expansion of the plots to any genomic region of interest, with links to genomic sequences, SNPs, and genes. The software also includes numerous other features including the ability to automatically detect and annotate aberrations. We developed two modes of quantitative analysis; one for single samples and the other for paired samples (i.e. tumor and matched normal). The single-sample mode utilizes a comparison to canonical genotype cluster data generated from ~120 reference samples. The benefits of paired-sample analysis and application of SNP-CGH arrays for profiling genomes from heterogeneous tumor samples will also be presented.

Peripheral Blood Gene Expression Signature Predicts Risk Profile of Thoracic Aortic Aneurysm. *R.R. Samaha[1], Y. Wang[1], C. Barbacioru[1], F. Chan[1], J. Blake[1], N.N. Mehmet[1], D. Shiffman[2], O. Iakoubova[2], S. Balasubramanian[3], D. Ngadimo[3], M. Tranquili[4], G. Albornoz[4], J.A. Elefteriades[4]* 1) Applied Biosystems, Foster City, CA 94404; 2) Celera Diagnostics, Alameda, CA 94502; 3) Celera Genomics, South San Francisco, CA 94080; 4) Department of Cardiothoracic Surgery, Yale University School of Medicine, New Haven, CT 06510.

Thoracic aortic aneurysm (TAA) is usually asymptomatic and associated with high mortality. Although adverse clinical outcome is preventable by surgical repair, identifying at-risk individuals is difficult. Our goal was to identify a potential gene expression signature in peripheral blood that may allow development of noninvasive screening tests to identify individuals at risk for TAA disease. Gene expression profiles of peripheral blood samples collected from 58 individuals diagnosed with TAA and 36 normal individuals were analyzed using the Applied Biosystems Expression Array Systems and Human Genome Survey Microarrays. Statistical analysis of gene expression profiles identified 1199 candidate signature genes (markedly up- or down-regulated) characterizing the TAA disease. Gene classification and biological pathway analyses of these signature genes revealed potential molecular mechanisms underlying this disease. Additionally, 30-gene prediction models for risk assessment of TAA were built for all-gender and male or female, respectively, using a training set containing 36 TAA patients and 25 controls. 10-fold cross-validation on these prediction models yield 82%, 90%, and 97% overall accuracy for each model, respectively. When these prediction models were applied on an independent testing sample set containing 22 TAA patients and 11 controls, the overall prediction accuracies for all-gender, male and female models were 79%, 70% and 77%, respectively. This study provides a comprehensive gene expression profile of peripheral blood cells from thoracic aortic aneurysm patients and normal individuals. In addition, our results also demonstrated a distinct RNA signature of aneurysm disease, setting the stage for a blood-based gene expression test that may facilitate risk assessment and early detection of thoracic aortic aneurysm disease.

Definition and Application of European Substructure Information. *M.F. Seldin[1], R. Shigeta[1], P. Villoslada[2], C. Selmi[1], L. Klareskog[3], P.K. Gregersen[4]* 1) Rowe Program Genetics, UC Davis, CA; 2) Cent Applied Med Res, Pamplone, Spain; 3) Karolinska Univ Hosp, Stockholm, Sweden; 4) North Shore-LIJ Res Inst, Manhasset, NY.

Our initial studies using over 5500 genomewide SNPs provided evidence that various cluster algorithms can distinguish northern vs. southern European(EUR)populations. To extend these studies additional samples (>1000 EUR-American subjects)were examined including most with 4 grandparent information. The samples were genotyped with 768 SNPs selected for EUR substructure information. Similar to our previous results, most individuals with ancestry from Western, Central and Northern EUR were distinguishable from those from Southern EUR. Clear membership in the corresponding north or south clusters was observed for 4 grandparent same country of origin: German, 22 subjects; mean 0.86 north; Irish 86 subjects, 0.97 north; Scandinavian, 6 subjects, 0.98 north; Italian 16 subjects mean 0.75 south; and Greek 7 subjects, mean 0.83 south. Although our initial results in this second panel of subjects showed more variability in the Eastern EUR group additional analyses suggested that most or all of the differences were explained when additional ethnic information was available. Individuals of Ashkenazi Jewish ancestry (38 individuals) clearly grouped with the southern European populations (mean =0.86 south) where as subjects with Eastern European ancestry including 16 subjects with 4 grandparent Ukrainian without Ashkenazi Jewish ancestry grouped with northern European populations (mean = 0.88 north). Finally, we examined the effect of controlling for population structure in analysis of putative RA susceptibility loci. These studies showed that significance of case control association tests were variably affected by structured association and subgroup analyses. Although most SNP candidates did not retain significance important exceptions included a confirmed disease susceptibility allele (for PTPN22) and one SNP with increased odds ratios and p values in a north only subset. These studies suggest that definition of population genetic substructure may potentially decrease both type 1 and type 2 errors.

Finemapping of a large multiplex neural tube defect (NTD) family at 2q and 7p. *D.S. Stamm[1, 2], L. Mehltretter[1], S. Slifer[1], B. Zhao[1], D. Siegel[1], T.M. George[1], J.R. Gilbert[1], M.C. Speer[1]* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Curriculum in Genetics and Molecular Biology, UNC-CH, Chapel Hill, NC.

Background: Neural tube defects (NTDs) are a complex disorder with both genetic and environmental factors implicated. To date, no major causative genes have been defined in humans despite intensive investigations. NTD family 8776 is a large, multigenerational, Caucasian family that provides a unique resource for the genetic analysis of NTDs. We have performed a high density genomewide screen to establish regions of linkage in family 8776 (Stamm et. al. 2006, in press). The regions identified are proximal to the telomeres of chromosomes 2 and 7, mapping to 2q33.1-q35 and 7p21.1-pter respectively. Both regions had maximum lod scores of ~3.0 under multipoint nonparametric methods. Preliminary haplotyping performed in regions of interest confirmed the linkage regions. **Methods**: To further refine these regions of interest we genotyped nineteen microsatellite repeat markers for 2q and six microsatellite repeat markers for 7p. Microsatellite markers were prioritized based on high heterozygosity values and spacing (~ 2 cM) within the region. In parallel, we sequenced biologically plausible candidate genes mapping to 2q33.1- q35 and 7p21.1-pter. Primers were designed to flank the exons and include the splicing region to account for splice variants. **Results**: Further haplotype analyses narrowed the minimum candidate interval for both 2q and 7p. The haplotype for chromosome 2 extends from D2S425 to D2S433 (23.8 cM) mapping to 2q32.3-2q35; and for chromosome 7 the haplotype span D7S2508 to 7pter, a 31.4 cM interval mapping to 7p21.1-pter. Sequencing of exons in candidate gene CASP8 and of exons 1, 3-9 in the PAX3 gene showed no disease associated variants. **Conclusion**: Additional genes are being sequenced. Most importantly, this family has identified two specific regions of interest that may harbor NTD susceptibility genes. Identifying a gene in this family may aid in a directed search for a disease gene for other more typical NTD families.

Genome-wide association scan for type 2 diabetes in Finns. *L.J. Scott[1], W.L. Duren[1], L.L. Bonnycastle[2], H.M. Stringham[1], A.U. Jackson[1], M.L. Erdos[2], P. Chines[2], N. Narisu[2], C.J. Willer[1], K.F. Doheny[3], E.W. Pugh[3], N.L. Riebowl[2], T.T. Valle[4], J. Tuomilehto[4], R.N. Bergman[5], K.L. Mohlke[6], F.S. Collins[2], M. Boehnke[1]* 1) U Michigan, Ann Arbor, MI; 2) NHGRI, Bethesda, MD; 3) CIDR, J.H.U., Baltimore, MD; 4) National Public Health Institute, Helsinki, Finland; 5) U Southern California, Los Angeles, CA; 6) U North Carolina, Chapel Hill, NC.

Our goal is to identify genes that increase the risk of type 2 diabetes (T2D). The FUSION study group is carrying out a genome-wide T2D association scan in 2357 first-stage samples of a two-stage study, which will ultimately include genotyping a total of ~5400 geographically matched Finnish samples. The Center for Inherited Disease Research (CIDR) has performed the sample genotyping using the Illumina HumanHap300 BeadChip. We report here an intermediate analysis of the first stage, based on of 885 T2D cases and 885 normal glucose tolerant controls and 308,231 polymorphic autosomal SNPs. In this sample, using a conservative genome-wide significance level of .05/302K = 1.6 x 10^{-7}, we have 12% or 87% power to detect an additive OR of 1.3 or 1.5 with a risk allele frequency of 0.3. The average duplicate error rate per genotype was 0.002% and the average SNP completeness was 99.6%. We flagged 5357 SNPs for future consideration based on deviation from Hardy-Weinberg equilibrium, elevated error rates, low completion rates or low minor allele frequency. We analyzed 302,874 SNPs for T2D association using dominant, recessive and additive models and adjusted the results to account for the 3 tests. Our most significant SNP had a p-value of 5.5 x 10^{-6}. We examined results around SNPs with multiple reported associations with T2D. Near PPARG Pro12Ala, TCF7L2 rs12255372, and KCNJ11 Glu23Lys, the most significant SNPs had p-values of .005, .005, and .03, and were ranked 1648^{th}, 1831^{st}, and 10321^{st}, respectively. These results suggest that other T2D susceptibility SNPs may be detected after genotyping the top 1-3% of SNPs in the full two-stage sample. To increase the power of the analysis, we will incorporate statistical weighting based on annotation information, stratify the sample by age-of-onset, and combine results across multiple T2D studies.

Psychosocial Outcomes of Bone Marrow Transplant for MPS I Hurler Disease: Patient Self Report of Personality and Personal Adjustment. *C. Pitt*[1], *C. Lavery*[1], *N. Wager*[2] 1) Society for Mucopolysaccharide Diseases, Amersham, Buckinghamshire, United Kingdom; 2) Buckinghamshire Chilterns University College, High Wycombe, Buckinghamshire, United Kingdom.

Aims: To explore the composite scores, and clinical and adaptive scales of the Behaviour Assessment System for Children: Self Report of Personality (Reynolds & Kamphaus, 1998) in terms of norms for individuals affected by Mucopolysaccharidosis I Hurler Disease (MPS IH) post-bone marrow transplant (BMT). Particular attention was given to the Personal Adjustment composite and to its contributors. Method: Eighteen MPS IH patients post-BMT participated in this investigation, along with their mothers. Patients ages ranged from 8 to 25 years. Semi-structured interviews with patients mothers were utilised, and patients were administered tests of cognitive function and the BASC-SR. Results: Hierarchical multiple regression on the Personal Adjustment composite demonstrated that 95% of the variance could be explained ($F = 18.7413,2$, $p = .051$) by patient health and disability factors, and factors associated with the mother and the family environment. In terms of the clinical and adaptive scales, no overt behavioural difficulties were observed. However, possible trends emerged, which highlighted adjustment difficulties with school and feelings of inadequacy for the 8-11 year age group; and a tendency towards inhibition and withdrawal for the 12 years and over age group. Conclusion: The findings illustrate how aspects of parenting and the family, as well as aspects of the MPS disease, require attention when providing support to these patients. They also highlight the importance of appropriate and consistent classroom support, and question whether psychosocial support should be considered within the school environment.

Tetramelic monodactyly: rare autosomal dominant condition with high rate of gonadal mosaicism. *P. Wheeler*[1], *S. Rosenthal*[1], *M. Bamshad*[2] 1) Dept Genetics, Nemours Children's Clinic, Orlando, FL; 2) Dept Pediatrics, University of Washington, Seattle, WA.

The proband is a 34 y/o female who was born with absence of all digits except the 5th digits on both her hands and feet. Radii/ulnae and tibia/fibula are normal. Radiographs show a curved 5th digit with 3 phalanges for both hands and 3 metacarpals in the right hand and 4 in the left. She has 1 metatarsal bilaterally supporting the single 5th digit on each foot. She has normal intelligence and no other anomalies. Family history is pertinent for the proband having 4 full siblings including 1 sister with no limb anomalies. That woman has had 5 children all without birth defects. The other 3 siblings (a brother and 2 sisters) all have nearly identical limb anomalies to the proband. All the affected individuals have normal facial appearance and normal intelligence. None of the individuals with the limb anomalies has chosen to have biological children. The father of the proband has no limb anomalies. The mother was born with insertional polydactyly with an extra toe between the 1st and 2nd toes of the right foot. She also had preaxial polydactyly of the left hand described as a nubbins. Both limb anomalies were surgically corrected in infancy. Tetramelic monodactyly has been described previously in a few families. The physical features are consistent between families with all individuals having a single, in-curved 5th digit on each extremity. The majority of families reported have inheritance consistent with germline mosaicism of an autosomal dominant condition. There does not appear to be significant variable expressivity in this condition except for the current family, which is unique because of the limb abnormalities present in the mother of the affected siblings. It is possible that the mother has a separate condition from what her children have or the family could have variable expression of this disorder, although this has not been reported previously. Research testing including analysis of HOXD13 is planned due to the overlap of phenotypes reported with HOXD13 mutations (specifically insertional polydactyly) and the anomalies seen in this family.

A unique rearrangement involving the BCL6, MYC, IGH and BCL2 loci in diffuse large cell lymphoma. *L. Richmond, C. Aguilar, G.S. Bezzegh, J. Skierkowski, G. Hart, C. Berger, T.C. Brown* Genzyme Genetics, Phoenix, AZ.

Chromosomal abnormalities involving t(14;18)(q32.3;q21) and 3q27 (BCL6) are common in B-cell non-Hodgkin lymphoma of germinal center cell origin. B-cell lymphoma with concurrent t(14;18) and 8q24 (c-Myc) translocations fall within the morphologic spectrum of diffuse large B-cell (DLCL) and Burkitt lymphoma. These cases are extremely rare and are associated with an aggressive clinical course and poor prognosis. It has been suggested that t(14;18) and 3q27 rearrangements are mutually exclusive in lymphoma, however, our case not only has this combination but also involves c-MYC. We believe this to be the first study to report such a combination. Cytogenetic and fluorescence in situ hybridization (FISH) studies were performed on a bone marrow sample from a 90-year old female patient who was diagnosed as having diffuse large cell lymphoma. Chromosome analysis of metaphase cells revealed an abnormal karyotype: 47,XX,t(2;3)(q11.2;q27),add(14)(q32)x2,del(18)(q22q23),+mar[20]. Metaphase FISH analysis using whole chromosome paints for chromosomes 8, 14 and 18 showed chromosome 18 material on 3q, while 8q and 14q had additional unknown material. To further identify the unknown material, FISH was performed using the IGH/BCL2 (14;18), MYC/IGH (8;14), CCND1/IGH (11;14) and MALT1(18q) probes. The interphase FISH results were positive for both the IGH/BCL2 (76% of cells) and MYC/IGH probes (77% of cells). The CCND1/IGH probe revealed no evidence of a translocation, however 68% of the cells had an extra IGH signal. The MALT1 probe results were normal, allowing localization of the breakpoint on chromosome 18 at q21.32, between the MALT1 and BCL2 genes. The BCL6 break-apart probe at 3q27 confirmed this locus was disrupted by the 18q;2q material. The combination of both chromosomal analysis and FISH were essential in identifying the complex rearrangements in this lymphoma. FISH results enabled us to further clarify the cytogenetic findings and identify the following derivative chromosomes in this patient's bone marrow sample: der(3)t(2;18;3),der(8)t(18;14;8),der(14)t(8;14)x2 and der(18)t(14;18).

Clinical and molecular findings in Fraser syndrome; Report of an Iranian consanguineous family with two affected offsprings. *G. Vakili[1], Y. Shafeghati[1], M. Zenker[2]* 1) Genetics Research Center, University of Welfare Sciences and Rehabilitation, Tehran, Iran; 2) Institute of Human Genetics, Erlangen, Germany.

Background: Fraser syndrome is a very rare autosomal recessive disorder, characterized by major malformations such as cryptophthalmos or anophthalmia, acrofacial dysmorphism, laryngeal, genitourinary tract, musculoskeletal anomalies, and mental retardation. Materials & Methods: Here, we report the clinical and pathological findings and molecular analysis of two affected patients from an inbred Iranian family. We followed the second pregnancy by ultrasound, and on the weeks 25, multiple anomalies were detected in the fetus. Parents requested to terminate the pregnancy. Results: The clinical findings on this case were similar to the first sib. The fetus was sent for karyotyping and complete postmortem study. Extra findings in autopsy were: both lungs composed of two lobes (this is a new finding in this syndrome). Esophagus was narrow in its proximal part. Bilateral renal agenesis, small and hypo plastic bladder, and agenesis of internal genitalia were detected. Chromosome study was normal. Mutation analysis on FRAS1 gene was negative, but the patient turned out to be homozygous at FREM2 locus with a homozygous mutation. The mutation IVS1+1G>A destroys the splice donor of exon 14 and most likely leads to skipping of this exon, which would be predicted to result in frameshift and a premature stop codon. We are currently trying to figure out the consequences of the mutation on the transcript level. Conclusion: We should consider this rare syndrome in any fetus with IUFD and in stillborn babies with these complex anomalies. High resolution ultrasound is a very efficient tool for detection of the affected fetuses.

Chromosomal aberrations and its association with recurrent ART failure. *R. Prabu[1], R. Dada[1], R. Kumar[2], N. Gupta[2], K. Kucheria[1]* 1) Anatomy, AIIMS, N Delhi, India; 2) Urology Department, AIIMS, N Delhi, India.

Chromosomal abnormalities and aneuploidies are found to be associated with and have a higher prevalence in infertile males than in the general population. These aberrations not only result in partial or complete spermatogenic arrest but may also result in implantation failure and consequently failure of InVitro fertilization (IVF). Assisted Reproductive Technology (ART) has revolutionised the management of infertility and allows infertile couples to procreate. Cytogenetic and molecular analysis was done in 165 infertile males and 30 couples going in for IVF. Twenty five well spread G banded metaphases were karyotyped using image analyser (Cytovision, Applied Imaging). In mosaic cases 50 metaphases were analysed. Chromosomal abnormalities were found in 46 infertile males. We found 16 cases with Klinefelter Syndrome (KFS), 20 cases were KF mosaics and 6 were mosaic variants, three cases with 46,XY 1qh+ and one case with 46,XY16h+. In 5 of the 30 couples couples opting for assisted reproduction cytogenetic analysis in the female partner revealed 46,XXq- chromosomal complement in two cases and Yq microdeletion in the AZF region in 2 cases. The AZF loci deleted was AZFc. Deletion of long arm of X chromosome(Xq-) in the female partner in two cases might have resulted in repeated failure of blastocyt development. This couple had gone in for 4 IVF cycles which had failed due to failure of blastocyst development. The male partner was cytogenetically normal and also had no Yq microdeletion spanning the AZF loci. In cases with sex chromosomal and autosomal aberrations there is probability of poor embryo development and consequently poor implantation , which may be a result of high segregation abnormalities and may negatively affect the outcome of assisted reproductive techniques. Thus these infertile couples should be counseled prior to going in for ART about the importance of genetic analysis, and how the presence of genetic anomalies results in poor IVF outcome and vertical iatrogenic transmission of these anomalies to the offspring born through ART.

COMPARISON OF FLT-1 BINDING DOMIAN OF MODELLED VEGF-C WITH VEGF-A SHEDS LIGHT ON RECEPTOR SPECIFICITY. *M. Kasap, A. Sazci* Medical Biology and Genetics, University of Kocaeli, Faculty of Medicine, Kocaeli, Turkey.

Receptor specificity determines the role of vascular endothelial growth factors (VEGF) which either induce angiogenesis via VEGFR1 and VEGFR2 receptors or lymphangiogenesis via VEGFR3 receptor. Among the VEGF proteins, VEGF-A induces angiogenesis and VEGF-C induces both angiogenesis and lympangiogenesis. However, why VEGF-C is not able to bind VEGFR1 is not known. The tertiary structure of VEGF-C protein was modelled to answer this question and examined in great detail for validity and compared with the known VEGF-A tertiary structure. The overall topology of the modelled structure highly resembled to VEGF-A and consisted of a central four stranded -sheet, three loops and two helices. An additional -helix was detected within the VEGFR2 binding site in VEGF-C model suggesting that VEGFR2 binding efficiencies may be different between VEGF-A and VEGF-C. The key residues that involve in cysteine-knot motif formation located at the same position and in an identical orientation in both proteins indicating the presence of a VEGF-A-like VEGF-C homodimer. However, a VEGF-C homodimer created via monomer docking did not superimpose well with VEGF-A homodimer. The orientation of the VEGF-C monomers within the dimer with respect to each other differed from the orientation of VEGF-A monomers indicating that the residues that help interaction between monomers in both homodimers differ from each other in identity and orientation. In overall, VEGF-C occupied a wider space than VEGF-A. Rigid docking models of VEGF-C with VEGFR1 receptor revealed that in VEGF-C-VEGFR1 complex, the receptor-protein interacting residues were not correctly oriented to induce angiogenesis via VEGF-R1. Mapping the electrostatic surface potentials to the protein surfaces revealed noteworthy amount of dissimilarity between VEGF-A and VEGF-C indicating that in overall both proteins differ in their folding properties and stability.

Inference of polyphyletic SNP-ratio by zero-distance limit of fraction of SNP paris in complete linkage disequilibrium. *R. Yamada, K. Hirosawa, A. Yoshizumi, V. Renault, M. Yamaguchi, F. Matsuda* Hum Disease Gen,Ctr Gen Med, Kyoto Univ, Kyoto, Japan.

Linkage disequilibrium (LD) mapping with common SNPs has been widely applied to studies on various phenotypes with promising successes. The further achievements are to come along with development of public database and new technologies on SNP-based LD mapping. Although alleleic association in regular LD mapping is based on the assumption that the majority of genetic variations are monophyletic, fraction of monophyletic SNPs among common variations is unclear. Because D', one of LD indices, converges to 1 at the limit of inter-SNP distance being zero for pairs of monophyletic SNPs but because it does not for polyphyletic SNPs, we introduced an index, a fraction of SNP pairs with D' of 1, fr(D'=1), as a function of inter-SNP distance and characterized its limit at distance zero with Monte-Carlo simulation under a Wright-Fisher model modified with polyphyletic mutations. The limit of fr(D'=1) at distance zero increased grossly in proportion to effective population size and it gave estimates of floor of rate of polyphyletic SNPs in population. By applying the result to the HapMap project data, we estimated $\lim_{d0}$fr(D'=1|S(d)) in SNPs of HapMap project as 0.9426 in CEU (CEPH families), 0.9218 in CHB (Han Chinese), 0.9230 in JPT (Japanese) and 0.9216 in YRI (Yoruba, Africans), respectively. These result indicated some fraction of common SNPs seemed to be polyphyletic.

Additional Report of Late-Onset Friedreich Ataxia (LOFA). *H. Roberts[1], J. Bodurtha[2]* 1) Division of Medical Genetics, Children's Hospital of The King's Daughters, Norfolk, VA; 2) Department of Human Genetics, Medical College of Virginia, Richmond, VA.

Purpose: LOFA occurs in 25% of individuals with Friedreich ataxia (FRDA). Thirteen patients with LOFA were recently published in the literature. This report describes an additional patient with LOFA who is a compound heterozygote for a GAA triplet-repeat expansion and a point mutation in the *FRDA* gene.

Methods: The patient first noted at age 26 to have balance problems leading to ataxia. She subsequently developed dysarthria, diminished sensation in her feet, and decreased tone in her lower body. Her exam was significant for diminished sensation below the knee and complete loss of vibratory proprioception below the ankle. Strength in the upper extremities was 5/5 and 4/5 in the lower extremities. DTRs were 2+ in the upper extremities. Patellar reflexes were 3+, and no Achilles reflexes were elicited. Both toes were upgoing. Romberg sign was present. Her gait was widebased and ataxic with pes cavus. Brain MRI and ENT evaluation were normal. Nerve condution studies and EMG showed mild distal lower extremity axonal sensory neuropathy. Echocardiogram, EKG and glucose tolerance tests were normal. Results of molecular testing showed compound heterozygosity for GAA expansion and G130V point mutation in the *FRDA* gene.

Summary: Most compound heterozygotes are clinically indistinguishable from typical patients with FRDA who have homozygous GAA expansions. However, compound heterozygosity for G130V or D122Y missense mutations usually results in a mild phenotype. Despite these general genotype-phenotype correlations, it is not possible to predict the specific clinical outcome in individual cases. FRDA is an autosomal recessive disorder affecting the *FRDA* gene on chromosome 9q13 which encodes the protein frataxin. Deficient frataxin results in abnormal accumulation of intramitochondrial iron, defective mitochondrial respiration, and overproduction of free radicals causing intracellular damage. Antioxidant therapy by free radical scavengers is being considered for slowing the progression of FRDA.

The CHRNA5/A3/B4 gene cluster variability as an important determinant of alcohol and tobacco initiation in young adults. *I. Schlaepfer[1,2], A. Collins[1], R. Corley[1], T. Crowley[4], J. Hewitt[1,3], C. Hopfer[4], K. Krauter[5], J. Lessem[1], S. Rhee[1,3], M. Stallings[1,3], S. Young[1], J. Zeiger[1], M. Ehringer[1,2]* 1) Inst Behavioral Genetics, Univ Colorado, Boulder, CO; 2) Dept. of Integrative Physiology, Univ Colorado, Boulder; 3) Dept. of Psychology, Univ Colorado, Boulder,CO; 4) Division of Substance Dependence, Dept. Psychiatry, Univ Colorado, School of medicine, Denver, CO; 5) Dept. Molecular Cellular and Developmental Biology, Univ Colorado, Boulder, CO.

Understanding the genetic basis of the interaction between alcohol and nicotine holds great promise for elucidating strategies for treating the dual use of the drugs. One potential site of convergence of the nicotine and alcohol actions is the family of the neuronal nicotinic acetylcholine receptors. Our study examines the genetic association between variations in the genomic region containing the CHRNA5 A3 and B4 gene cluster (A5A3B4) and several phenotypes of alcohol and tobacco use in an ethnically diverse youth sample. We tested nine individual single nucleotide polymorphisms (SNPs) and haplotypes for association with various nicotine and alcohol phenotypes, including age of initiation and measures of subjective responses to the substances in the period shortly after initiation. SNP frequency calculations revealed ethnic-specific allele distributions in Caucasians, African-Americans and Hispanics. Therefore, analysis was conducted in the full sample, including ethnicities as covariates, and in each of the three ethnic sub-samples using the statistical genetics program WHAP. Our results suggest that genetic variation in the A5A3B4 gene cluster contributes to smoking initiation and use of alcohol and nicotine in young adults. In particular, three individual SNPs were significantly associated with age of initiation for both alcohol and tobacco variables. Haplotype analysis of the SNPs revealed that a fairly common (22%) haplotype may be protective ($p<0.01$) for both alcohol and tobacco initiation in the combined sample. This is the first report of an association between the locus containing the A5A3B4 gene cluster and tobacco and alcohol-related phenotypes.

Fetal Therapy : Issues of fetal selection ; when a prenatal ' isolated ' anomaly is really a postnatal ' sequence/syndrome '. *R..D. Wilson, M.P. Johnson, M.W. Bebbington, S. Kasperski, N.S. Adzick* Ctr Fetal Diag/Treatment/Wood, Children's Hosp Philadelphia, Philadelphia, PA.

Objective : Cases are presented which illustrate the difficulty of fetal selection for fetal surgical treatment as certain structural or functional anomalies cannot be easily identified prenatally by imaging , karyotype or other functional studies alone or in combination . Case reports : Fetal therapy by thoraco or vesico amniotic shunting may be successful in draining the fluid filled space but may not correct the underlying functional anomaly . Case 1: Normal fetal karyotype at CVS due to maternal age indication . Pleural effusions (PE) initially presented at 22 weeks and increased at 30 weeks with chylothorax . A thoracoamniotic shunt was placed at 30 weeks with right sided PE resolution but preterm delivery occurred at 33 weeks . A difficult neonatal course continued with respiratory issues , generalized oedema , lymphatic obstruction above the iliac level and death at 3 months of age . A diagnosis of congenital pulmonary lymphangiectasis (CPL) was made at autopsy with possible autosomal recessive inheritance . Case 2: Prenatal lower urinary tract obstruction (LUTO) at 20 weeks with serial vesicocentesis showing preserved renal function and normal karyotype . A vesicoamniotic shunt was placed at 22 weeks with continued hydrops (bilateral PE) but empty bladder. Polyhydramnios (44cm) developed at 28 weeks with subsequent moderate bilateral PE , mild ascites , empty bladder , and normal doppler waveforms . Induction of labour at 34 weeks due to non reassuring fetal assessment with early neonatal death . Autopsy showed a possible partial urorectal septum malformation sequence with sporadic or possible X linked inheritance . Conclusion: Prenatal identification of isolated anomalies only for fetal surgery is difficult . Fetal karyotype to rule out trisomy is not enough . Pattern recognition , other specific mutation analysis (if available) and prenatal search tools are required to assist in identifying appropriate fetuses for fetal therapy so that ' right diagnosis , right treatment ' can be accomplished. Multidisciplinary evaluation and consultation is required .

Complex chromosome rearrangement t(8;21)(p21;q22.1)inv(8)(p21q22.1), a novel variant of t(8;21) in acute myeloid leukemia. *J. Xu[1], L. Mak[1], C. Richmond[1], R.C. Lohmann[2]* 1) Cytogenetics; 2) Hematology, London Health Sciences Centre and University of Western Ontario, Canada.

We report a novel variant of 8;21 translocation in acute myeloid leukemia and propose cytogenetics mechanisms for this rearrangement. This is a case study by routine karyotyping and FISH using ETO (8q22)/AML1 (21q22) dual color, dual fusion translocation probe set (Vysis). A 72-year-old female patient was diagnosed with AML and 95% of her bone marrow cells were blast cells, confirmed myeloblasts on flow cytometry. Routine cytogenetics of the bone marrow cells showed a complex karyotype with 8;21 translocation and an inversion involving the translocated chromosome 8. The detailed karyotype is 46,XX,der(8)(21qter->21q22.1::8q22.1->8p21::8q22.1->8qter),der(21)(21pter->21q22.1::8p21->8pter[24]/46,XX[1]. FISH showed that the der(8p) had yellow ETO/AML1 fusion signal whereas the der(21q) had green AML1 signal but no ETO/AML1 fusion signal. We propose that this complex karyotype is possibly a result of 3 rearrangements: inversion, translocation and deletion. It might begin with a pericentric inversion of 8p21q22.1 with the breakpoint being distal to ETO at 8q22. This inversion would have relocated the entire ETO to the der(8p), as was evidenced by absence of orange ETO signal in the der(8q). This might be followed by 8p;21q translocation, as was evidenced by the presence of the ETO/AML1 fusion signal in the der(8p). There was deletion of ETO in der(21), as was indicated by no fusion/orange signals in the chromosome. This is a new variant to a list of reported cytogenetics variants of the classical t(8;21) involving various chromosome partners identified by routine karyotyping and submicroscopic variants of ETO/AML1 detected by FISH or RT-PCR. More case reports and further cytogenomics studies will help understand clinical and prognostic significance of such variants. Our finding emphasizes that caution be exercised in interpretation of variant ETO/AML1 signal patterns in interphase and metaphase FISH.

Mitochondrial DNA depletion syndrome. *S. Seneca[1], L. Van Haute[1], R. Van Coster[2], G. Van Goethem[3], A. Löfgren[3], J. Smet[2], J. Jaeken[4], M.C. Nassogne[5], B. François[6], P. Garcia[7], W. Lissens[1], A. Meulemans[1], I. Liebaers[1], L. De Meirleir[8]* 1) Center of Medical Genetics, AZ-Vrije Universiteit Brussel, Brussel, Belgium; 2) Pediatric Neurolgy & Metabolism, UGent, Belgium; 3) Department of Molecular Genetics, Neurogenetics Group, (VIB8), UIA, Belgium; 4) Department of Pediatric Neurology, KUL & University Hospital Gasthuisberg, Belgium; 5) Service de Neurologie Pédiatrique, UCL & Cliniques St-Luc, Belgium; 6) Pimocchio Centre, Cliniques Espérence, Montegnee, Belgium; 7) Unidade de Doenças Metabolicas, Hospital Pediatrico, Coimbra, Portugal; 8) Department of Pediatric Neurology, AZ-Vrije Universiteit Brussel, Brussel, Belgium.

The mitochondrial genome (mtDNA) is a 16.5 kb DNA molecule that is normally present in multiple copies in individual mitochondria. The mtDNA depletion syndrome (MDDS) is a disorder involving a quantitative defect of mtDNA, which is inherited in an autosomal-recessive mode. Patients are born after an uneventful pregnancy and are often normal at birth, but they deteriorate in the neonatal period or early childhood. There are two main clinical presentations : myopathic and hepatocerebral. In the first group children present with devasting myopathy and neurological abnormalities. In the second condition patients suffer from early progressive hepatic failure, hypotonia, hypoglycaemia, lactic acidosis and progressive neurodegeneration as described in Alpers syndrome. We used real-time PCR to quantify the level of mtDNA in fibroblast, blood, and muscle or liver tissue of patients suspected because of clinical and biochemical abnormalities. Of all patients with clinical suspicion of MDDS, mtDNA depletion was documented in ten. Molecular analysis of nuclear predisposing genes included sequencing exons of TK2, DGUOK and polG. Two patients had DGUOK mutations, while three other patients had recessive polG mutations. Mutations in these genes count only for a fraction of MDDS cases. Recently mutations in two other nuclear genes, SUCLA2 and MPV17, were identified in MDDS patients.

Mutalyzer - a tool to improve descriptions of DNA sequence changes in mutation databases and in literature.
P.E.M. Taschner, M. Wildeman, E. van Ophuizen, J.T. den Dunnen Human Genetics, Leiden University Medical Center, Leiden, Netherlands.

Unambiguous and correct sequence variation descriptions are of utmost importance, not in the least since mistakes and uncertainties may lead to undesired errors in clinical diagnosis. We have developed the Mutalyzer sequence variation nomenclature checker (http://www.humgen.nl/mutalyzer) as the first module of a package for sequence variation effect prediction. Mutalyzer handles all mutations following the recommendations of the Human Genome Variation Society (HGVS) for mutation nomenclature. Input for Mutalyzer is a GenBank accession number, a HGCN gene symbol and the mutation. Based on this input, Mutalyzer generates an output file containing a description of the mutation at DNA level, the effect on all annotated transcripts, its deduced outcome at protein level and gains or losses of restriction enzyme recognition sites. Mutalyzer is able to handle most mutation types, including splice site and frameshift mutations. Mutalyzer facilitates uploading of reference sequence files with user-modified annotation and a batch wise sequence variation checking. The latter tool can be used to quickly check all entries in existing locus-specific mutation databases (LSDBs). To investigate their current status regarding error-free description of sequence changes as well as how they adhere to the current mutation nomenclature rules we have used Mutalyzer to analyze the content of several LSDBs. The data show that Mutalyzer can facilitate curation of both existing and new data. The mutation checker module will be linked to the Leiden Open source Variation Database (LOVD) we have developed (see http://www.DMD.nl/LOVD/).

COMPLEX CHROMOSOMAL ABNORMALITIES IN A CHILD WITH ADVANCED NEUROBLASTOMA.

H.O. Shah[1,2], N. Chen[1], Q. Tao[1], Y. Zhong[1], J.H. Lin[1,2] 1) Dept Pathology, Cytogenetics, Nassau Univ Medical Ctr, East Meadow, NY; 2) Health Science Center, State University of New York, Stony Brook, NY.

A 6 year-old girl with negative family history was admitted with proptosis of both eyes, vomiting and abdominal pain. CT scan revealed a large right retroperitoneal mass and multiple metastatic lesions to spine, lung, brain and bone marrow. Fine needle aspirate of retroperitoneal mass, and bone marrow aspirate and biopsy showed small blue cells that were negative for CD45, CD99, cytokeratin, desmin, NSE, neurofilaments and positive for CD56, synaptophysin and chromogranin. FISH performed on interphase nuclei were negative for amplification of MYCN (chromosome 2p24.1) and negative for rearrangement or loss of MLL (chromosome 11q23). Cytogenetic analysis of metaphase tumor cells revealed multiple chromosomal abnormalities with many cell-to-cell variations. The composite karyotype of tumor cells disclosed, female, 46-47,XX,add(4)(q31.1),-6,del(6)(p21.3p25),+7,add(11)(p11.2),del(11)(p11.2p15),add(19)(p13.1),+1-7mar[cp9]/89,idemx2[1]. The primary adrenal tumor was resected after four cycles of chemotherapies and the immunostain of tumor cells are positive for NSE, chromogranin and synaptophysin. Neurofilament is randomly positive in stroma and S-100 is strongly positive in Schwannian stroma. Final diagnosis is Neuroblastoma, Stage 4. In this patient, there are no N-myc amplifications nor LOH of 11q (MLL) detected. However, there are notable structural anomalies on chromosome 4, 6, 11 and 19 in this patient. The genes involved in this patients genome regions of the chromosomal structural abnormalities involve numerous factors and oncogenes reported in other malignancies, including BAK, TNFSF2, WT2, ST5, CDKN1C, NUP98 and IGF2, which may trigger this patients tumorigenesis. Various molecular and cytogenetic factors have been implicated in the pathogenesis of neuroblastoma and useful in predicting clinical behavior and outcome. Chromosomal structural changes are found in more than 50% of neuroblastomas. Therefore molecular and cytogenetic characterizations of neuroblastoma become a routine part of the clinical evaluations that influence the clinical treatment and outcome.

Evidence of extra-telomeric effects of hTERT and its regulation involving a feedback loop. *T. Tollefsbol, S.R. Lai, A.P. Cunningham, V.Q. Huynh, L.G. Andrews* Biology, University of Alabama at Birmingham, Birmingham, AL.

The human telomerase reverse transcriptase (hTERT) is the catalytic subunit of the enzyme telomerase which is responsible for telomeric maintenance and extension. Using RNA interference to knock down hTERT mRNA expression, we provide evidence that hTERT exerts extra-telomeric effects on the cell cycle and on its own regulatory proteins, specifically: p53, p21, and c-Myc. We tested our hypothesis that hTERT regulates its own expression through effects on upstream regulatory genes using transformed human embryonic kidney HEK 293 cells, p53 and p16INK4a null human ovarian cancer SKOV-3 cells, and p53-null MDA-MB-157 human mammary cancer cells. In HEK 293 cells, hTERT knock down resulted in elevated p53 and p21 transcription and a decrease in cellular proliferation. Similar results were observed in the MDA-MB-157 cell line where p21 was up-regulated, correlating with cell growth inhibition. In contrast, we observed a decrease in expression of p21 and c-Myc in SKOV-3 cells with hTERT knock down and cell growth appeared to be unaffected. These findings suggest that hTERT may be involved in a feedback loop system, thereby playing a role in its own regulation.

Knock-down Analysis of 100 KAO-NASHI Genes. *A. Shimizu, S. Asakawa, T. Sasaki, N. Shimizu* Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan.

The human genome project has provided an computer-estimation of 23,000 protein-coding genes in the human genome. However, many of these protein-coding genes are not fully proven for their existence by experimental evidence. In general, proteins with known motifs are readily classified, but substantial numbers of protein have no obvious motifs in their sequences. We designated these genes/proteins without obvious motifs as KAO-NASHI (Face-less) and initiated a project to unveil their face (kao) by comparative genomics and knock-down analysis.

We extracted 1,000 KAO-NASHI genes from human genome sequence by step-wise filtration with InterPro motif analysis, BLAST homology search and PubMed document search. A small fish medaka (Oryzias latipes) was chosen as an experimental system to knock-down medaka orthologs of human KAO-NASHI genes with morpholino-antisense oligos. As an initial study, we designed antisense oligos to target translation initiation sites of 100 medaka kao-nashi genes. When these antisense oligos were micro-injected into medaka embryos, their morphogenesis at early developmental stages was disturbed and morphological changes were observed at certain rates. Thus, we obtained initial sketchy information how these medaka kao-nashi genes are involved in the embryonic process of patterning and organ formation. About 60 genes were found to cause embryonic defects and these were further classified in terms of developmental sub-stages and expression profiles. Thus, our approach using medaka seems effective and it will eventually provide functional information on the human KAO-NASHI genes/proteins.

Elevated level of common nonsynonymous variations in human EMR1 gene is consistent with balancing selection.

J. Tan[1], M.L. Hibberd[2], R. Ong[3], E. Png[1], M. Seielstad[1] 1) Population Genetics, Genome Institute of Singapore; 2) Infectious Disease, Genome Institute of Singapore; 3) Research Computing, Genome Institute of Singapore.

The epidermal growth factor (EGF)-like module-containing mucin-like receptor, EMR1, is a member of the EGF-TM7 family of receptors that are predominantly expressed by cells of the immune system. EGF-TM7 receptors have a modular structure composed of an extracellular region containing EGF-like repeats that is joined to a seven-transmembrane membrane reminiscent of the G-protein coupled receptors. We resequenced all exons and flanking 5' and 3' regions of the EMR1 gene using DNA samples from 140 individuals of diverse geographical/ancestral origins (28 European-Americans, 28 Chinese, 28 Indians, 28 Malays and 28 Yorubans) as well as two chimpanzees. Population genetic analyses demonstrate an elevated level of nucleotide diversity in EMR1 that ranks among the most extremes of the empirical distributions, a skew in the allele frequency spectrum towards intermediate frequency alleles, positive Tajimas D values, an elevated nonsynonymous substitution rate within the human lineage, the presence of highly divergent intermediate haplotypes and a level of genetic differentiation that is lower than the global average. These data suggest that EMR1 gene does not evolve in a non-neutral fashion and is more likely to have experienced balancing selection. Because proteins containing EGF-like modules are typically involved in protein-protein interactions and the observation that 14 of the 20 nonsynonymous variations reside within the extracelullar portion of the receptor, the target of selection is probably directed against the EGF-like domain. Biological studies that seek to identify the interacting target(s) of the EMR1 receptor can shed further insight into the nature of the evolution of the gene.

Choreoathetosis gene mapping in a Native American family. *A.E. Shrimpton[1,2], J. Zeligman[2], C. Hubbell[1], J. Pellegrino[2]* 1) Clinical Pathology, SUNY Upstate Medical Univ, Syracuse, NY; 2) Pediatrics, SUNY Upstate Medical Univ, Syracuse, NY.

Blood has been collected from several members of a large four-generation pedigree of Native American extraction with non-progressive choreoathetosis (an involuntary writhing of the limbs). Onset is in infancy, is non-progressive and of variable severity with the more severely affected individuals being wheelchair-bound while less severely affected individuals remain fully ambulatory. Symptoms are not associated with any precipitating factors or improved with any specific medications or therapies. The affected individuals also have learning disabilities and are non-dysmorphic. The proband has a normal karyotype. Male to male transmission, vertical pattern of affected individuals and affected individuals of both sexes is consistent with an autosomal dominant mode of inheritance. Early onset non-progressive chorea with or without associated congenital hypothyroidism and neonatal respiratory distress has been reported in Benign Hereditary Chorea (BHC MIM 118700). A modest expansion in the CAG repeat in the Huntington's disease gene (IT15) has been reported in at least one BHC family and excluded in others. Investigation of the Huntington Disease gene (IT15) excluded CAG triplet repeat expansion as the cause of BHC in the present family. Several reports have described mutations in the TITF1 gene in several families with BHC. However a lack of linkage to 14q13 in other families indicates BHC locus heterogeneity. Missense and frameshift TITF1 mutations, as well as microdeletions, indicate TITF1 haploinsufficiency to be the cause of BHC in the 14q13-linked families. Sequencing of the TITF1 gene coding sequence, introns and promoter failed to detect an obvious pathogenic mutation, however TITF1 flanking and intragenic markers were consistent with linkage of choreoathetosis to TITF1 in this family (Maximum Lod of 1.5 at 0 cM). It is intended to collect additional family members so as to continue to investigate TITF1. Once sufficient family members have been collected and if TITF1 linkage is excluded, it is intended to use Affymetrix SNP microarrays to perform whole genome gene mapping.

Pharmacogenetic Analysis Reveals a New Role for Resistin in HIV Lipodystrophy. *K. Ranade, W. Geese, T. Delmonte, L. Hui, E. Emison, O. Flint, R. Parker, M. Noor* Pharmaceutical Research Institute, Bristol-Myers Squibb, Princeton, NJ.

Elevated lipid levels, insulin resistance and changes in body fat, collectively known as lipodystrophy, are common in HIV infected individuals on highly active anti-retroviral therapy (HAART). With the reduction in mortality resulting from HAART, the metabolic side-effects are of concern as they are well-established risk factors for cardiovascular disease. The mechanistic basis of HAART-associated lipodystrophy is poorly understood, however. For these reasons, we performed genetic analysis of 189 patients enrolled in a clinical trial of HAART. We clustered metabolic profiles of participants to identify a sub-group of patients (N = 47) who had normal mean triglyceride (176128 mg/dL), low density lipoprotein (LDL,120 30 mg/dL), total cholesterol (18233 mg/dL) and insulin resistance by homeostasis-model assessment (HOMA-IR, 21.5) at baseline but developed clinically significant elevations in mean triglyceride (+134 mg/dL, P<0.0001), LDL (+58 mg/dL, P<0.0001), total cholesterol (+81 mg/dL, P<0.0001) levels and HOMA-IR (+3, P=0.1) after 32 weeks of HAART. This high-risk cluster of patients also experienced significant body fat changes on HAART. In contrast, the normal cluster (N=142) had a similar metabolic profile at baseline and experienced clinically insignificant changes in these metabolic traits after HAART. Age, sex, race, baseline CD4 count and HIV copy number and drug treatment arm were not associated with cluster membership. Candidate gene analysis revealed that a common SNP in resistin, a gene previously implicated in obesity and insulin resistance, was highly significantly associated with clusters (P = 0.0003). The odds ratios for heterozygotes and homozygotes for high-risk cluster membership were 3 (95% C.I. 1.3-5.3) and 19 (95% C.I. 2-183) compared to wild-type, respectively. This SNP increased risk consistently in Caucasians, Hispanics and African-Americans. These results suggest a new role for resistin in HIV lipodystrophy, and demonstrate the importance of identifying less heterogeneous sub-groups prior to genetic analysis.

A Pharmacogenomic Study of Cholinergic Target Proteins in the Control of Cardiovascular Function. *A.M. Valle, K.Y. Ho, V. Mahboubi, M.T. Barragan, Z. Radic, B.K. Rana, D.T. O'Connor, P. Taylor* Depts of Pharmacology, Medicine and Psychiatry, Univ California, San Diego, La Jolla, CA.

The focus of this study is to identify polymorphisms in candidate cholinergic genes that may contribute to hypertensive disease states. Peripheral and central nervous system control of cardiovascular (CV) function mediated through the autonomic nervous system is critical in the homeostatic maintenance of blood pressure (BP) and responsiveness to exercise, postural alterations,and stress. Animal models have shown that cholinergic pathways in the spinal cord and higher brain centers modulate CV responses to influence basal BP and baroreflex pressor responses induced by external and internal stimuli. Currently we are investigating single nucleotide polymorphisms (SNPs) in acetylcholinesterase (AChE), the enzyme that regulates cholinergic neurotransmission by catalyzing the hydrolysis of acetylcholine. AChE sequence and structural makeup is relatively simple and encoded within 7.5kb. AChE can be found in blood enabling a biochemical phenotype in addition to correlating genotype with phenotypic physiologic responses.

Human whole blood samples were obtained from a twin registry of over 500 monozygotic and dizygotic twins and 80 unrelated individuals. Biochemical phenotype (AChE activity) was determined spectrophotometrically using the Ellman Assay. SNP discovery by the re-sequencing of *AChE* was performed on the unrelated panel and SNP genotyping was performed on the twin sample set. Site-directed mutagenesis was conducted to introduce non-synonymous coding SNPs that we found into a human *AChE* cDNA plasmid with subsequent transfection into HEK cells for protein expression. Protein purification was performed using affinity chromatography.

Biochemical analysis revealed over a 3-fold variance in AChE activity levels of sampled individuals. Correlation analysis showed a statistically significant relationship between enzyme activity and certain cardiovascular phenotypic endpoints. Characterization of the mutant enzymes revealed significant stability differences when compared with the wildtype AChE protein. (Supported by R37-GM18360 and U01-HL069758).

Usefulness of Buccal Smears in Rapid Diagnosis of Congenetial Myeloproliferative Disorders. *K. Patel, S. White, P. Hsu, J. Jacob, R. Kazi, AL. Zaslav* Department of Laboratory Medicine, Long Island Jewish Medical Center,the Long Island Campus of the Albert Einstein College of Medicine, New Hyde Park, NY 11040.

Neonatal myeloproliferative disorders (NMD) can represent a benign transient myeloproliferative disorder (TMD) associated with trisomy 21 Down syndrome (DS) or acute myeloid leukemia (AML) requiring aggressive management. It is important to identify true trisomy 21 so that these neonates can be treated conservatively. In NMD, the presence of trisomy 21 in peripheral blood may represent an acquired chromosome abnormality, which indicates secondary AML. Another tissue must be cytogenetically evaluated to determine this. We report two cases of NMD, in which trisomy 21 was first seen in peripheral blood. The clinical dilemma was resolved by rapidly identifying inherited trisomy 21 in epithelial nuclei from a buccal smear (BS) using FISH.

Two neonates without obvious DS phenotype or previously documented DS genotype presented with leukemic peripheral blood smears. Twenty trypsin-Giemsa banded metaphase spreads from peripheral blood revealed trisomy 21 in both cases. Fluorescent in situ hybridization (FISH) was performed on BS nuclei and peripheral blood cells using Aneu Vysion LSI 13/21 probe (Vysis, Downers Grove, ILL). In both the cases, the FISH analysis on interphase nuclei from blood and BS showed three signals for chromosome 21 in all cells indicating inherited trisomy 21. Based on the FISH results, the increased WBC count and blasts in the peripheral smear, the patients were diagnosed with DS-associated TMD and were managed conservatively. One of the two neonates showed resolution of myeloproliferative symptoms after four months of age and is disease-free one year after the initial diagnosis. The other expired at three months of age due to congenital heart defects.

This report demonstrates the use of BS in conjunction with FISH as an additional tissue to provide a quick method of determining acquired vs. inherited chromosome abnormalities. This technique was essential in assisting the clinicians with efficient, rapid, and accurate management of these cases.

Exploring gene joint effects and the clinical efficacy of morphine for cancer pain: OPRM1 and COMT gene. *C. Reyes-Gibby[1], S. Shete[1], T. Rakvåg[3], S. Bhat[1], F. Skorpen[3], E. Bruera[2], S. Kaasa[3], P. Klepstad[3]* 1) Epidemiology, U.T. M.D. Anderson Cancer Center, Houston, TX; 2) Department of Palliative Care and Rehabilitation, U.T. M.D. Anderson Cancer Center, Houston, TX; 3) Norwegian University of Science and Technology, Trondheim, Norway.

PURPOSE: The individual variation in opioid dose requirement for the treatment of cancer pain can be more than 1,000 fold, making it one of the largest observed variations in humans. Polymorphisms in genes coding for the mu-opioid receptor (A118G) and catechol-O-methyl transferase (Val158Met) may be important modulators of opioid efficacy. We assessed joint effects of OPRM1 and the COMT genes in predicting morphine dose for pain relief. PATIENTS AND METHODS: We used genotype and clinical data from a pharmacokinetic study of morphine in 207 inpatients. Patients were treated with stable morphine dose for at least 3 days by Palliative Medicine Specialists.RESULTS: Multivariate analyses showed Val158Met and A118G genotypes, months using morphine and time since cancer diagnosis as significant variables in predicting morphine dose. Significant joint effects were observed for OPRM1 and COMT genes. Adjusting for pain intensity, months using morphine and time since cancer diagnosis, carriers of the COMT Met/Met and OPRM1 AA genotype required 61% less morphine ($p<0.03$) relative to those with neither Met/Met nor AA genotypes (Met/Met and AA =92mg/24h, 95%CI=61,122; neither MetMet nor AA=150mg/24h;95%CI=109,192). CONCLUSION: Our preliminary findings suggest that genetic differences influence the clinical efficacy of morphine. Future studies with larger cohorts are needed to further characterize the role of genetic markers in predicting opioid dose. If our associations are confirmed, clinicians could potentially tailor morphine dose, based on the individuals genetic data, such that maximum effectiveness and fewer side effects could be achieved.

.

Cleft Families Have a Higher Risk of Developing Several Types of Cancer. *R. Menezes, M.E. Cooper, K.M. Bardi, C.A. Brandon, A.R. Vieira, M.L. Marazita* Oral Biology and Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA.

Individuals born with orofacial clefts have a shorter lifespan and a correlation between clefts and cancer has been proposed. The Pittsburgh Oral-Facial Cleft study begun in 1993 with the primary goal of identifying genes involved in nonsyndromic orofacial clefts and has recruited 185 families in the Pittsburgh area. Families with two or more individuals affected with orofacial clefts are preferentially recruited; therefore the study population is enriched by cleft multiplex families. Cancer history data were obtained from 168 families (75 cleft families and 93 control families) through a structured questionnaire. Out of the 75 cleft families, 70 families have two or more affected individuals. Chi-square and Fisher exact tests were used to determine statistically significant differences between cleft and control families. Overall, reported cancer history was higher in cleft families compared to control families ($p=0.0002$); further the occurrence of multiple types of cancers was also more common in the cleft families ($p=0.00001$). Among the 16 types of cancer reported in the study families, brain ($p=0.003$), breast ($p=0.009$), colon ($p=0.0009$), leukemia ($p=0.005$), liver ($p=0.02$), lung ($p=0.02$), prostate ($p=0.01$), skin ($p=0.01$), skin plus melanoma ($p=0.01$), and stomach ($p=0.04$) cancer types were found more commonly in cleft families than in control families. Our results suggest that individuals in multiplex cleft families have a higher susceptibility for specific types of cancer. Future studies will investigate the role of genes in which mutations have been associated with both cancer and clefts or other craniofacial anomalies (i.e. CDH1/E-cadherin, stomach cancer and clefts; AXIN2, colon cancer and tooth agenesis; CLPTM1, prostate and clefts). This research is supported by NIH Grants R01-DE016148, P50-DE016215, and M01-RR00084.

Dental Anomalies as an Extended Phenotype of Orofacial Clefts: Genome Wide Reanalysis of 12 Multiplex Filipino Families. *A.R. Vieira[1], G. Gamboa[2], M. Orbiso[2], T. Goldstein McHenry[1], M.E. Cooper[1], S. Daack-Hirsch[3], M.L. Marazita[1], J.C. Murray[3]* 1) Oral Biology and Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 2) Phenomics Group of The Philippines, Consolacion, Cebu, The Philippines; 3) Pediatrics, University of Iowa, Iowa City, IA.

Cleft individuals have up to 6 times more dental anomalies than individuals from the general population. We are revisiting 154 Filipino families with 2 or more cleft affected siblings that participated in previous genome wide studies and collecting complete dental information. To date, we have re-visited 12 families. One of the families was found to have an undiagnosed syndrome and was not included in this analysis. Genotypes from 390 microsatellite markers at 10cM intervals were reanalyzed in the remaining 11 families to incorporate the dental anomaly data. There were 32 affected individuals with clefts and an additional 9 people that were added as affected with the addition of the dental phenotype. In the first pass of two- and multipoint parametric linkage analysis (FASTLINK, SIMWALK2) and nonparametric two- and multipoint analysis (MERLIN), only individuals with clefts were assigned as affected. In a second pass, non-cleft-affected relatives with a dental anomaly were also assigned as affected. In the first pass, 9 chromosomes (2,3,4,7,8,13,14,16,17) presented regions with LOD>1.0. In the second pass, 9 chromosomes (1,4,7,8,9,10,14,16,18) presented regions with LOD>1.0. The most significant results in the cleft affected only scan were a LOD of 2.98 at D4S2394 (4q28.2) under a recessive model and a LOD of 2.05 at D8S592 (8q24.11) under a dominant model. When dental anomalies were added as affection status in the analysis, the most significant results were also at 4q (4q31.21, D4S1625, LOD=2.36, and 4q28.2, D4S2394, LOD=2.18). The LOD score for D8S592 dropped to 1.51. Our preliminary results confirm a candidate region for clefts at 4q and support the hypothesis that some loci may contribute to both clefts and congenital dental anomalies. Supported by NIH Grants R21-DE016718, R37-DE08559, P50-DE016215, R01-DE016148 and CIDR N01-HG-65403.

Therapy of PKU by AAV-1 based transfer of PAH and BH4-cofactor genes into skeletal muscle. *B. Thony[1], C.O. Harding[2], A. Rebuffat[1], L. Elzazouk[1], J.A. Wolff[3], Z. Ding[1]* 1) Dept Ped, Div Clin Chem/Biochem, Univ Zurich, Zurich, Switzerland; 2) Dept Ped, Dept Molec/Med Genet, Oregon Health/Science Univ, Portland, OR, USA; 3) Dept Ped, Dept Med Genet, Univ Wisconsin, Madison, WI, USA.

Phenylketonuria (PKU) is caused by an autosomal recessive deficiency of the hepatic phenylalanine hydroxylase (PAH) leading high serum Phe and irreversible damage of the brain. PAH catalyzes the hydroxylation of Phe to tyrosine with tetrahydrobiopterin (BH4) as cofactor. BH4 biosynthesis requires the consecutive action of the enzymes GTPCH and PTPS, with dihydroneopterin triphosphate as the first intermediate. Here we aimed at expressing the PAH system in skeletal muscle to degrade serum Phe, as this tissue is abundant, easy accessible, and persistent due to its post-mitotic nuclei. However, BH4 is scarce in skeletal muscle as the cofactor-synthesizing enzyme GTPCH is absent in muscle tissue, and PTPS is expressed at low levels. We first demonstrated that transgenic PKU mice that had no liver PAH and expressed coordinately PAH along with GTPCH in skeletal muscle tissue accumulated dihydroneopterin triphosphate and remained hyperphenylalaninemic unless synthetic BH4-cofactor was supplied by intraperitoneal injections. Thus, PTPS activity is definitely limiting in skeletal muscle to synthesize sufficient BH4 and to support Phe hydroxylation. A recombinant triple-cistronic AAV2-based pseudotype 1 vector expressing PAH along with the two cDNA-genes for BH4 biosynthesis, GTPCH and PTPS, was then generated. Upon single injections of 3.5x10e12 recombinant triple-cistronic AAV2/1 vector particles into each of the gastrocnemius muscles of the hind legs of the PKU mouse model Pah-enu2 resulted in long-term clearance of blood Phe, including complete phenotypic reversion. A similar therapeutic effect was achieved when a combination of two AAV2/1 vectors expressing individually PAH and GTPCH-PTPS were co-injected into the same hind leg muscles. As a control, an AAV2/1-vector expressing only PAH with GTPCH was not therapeutic. This non-invasive application is the basis to develop an efficient therapy for PKU using a triple-cistronic gene transfer into skeletal muscle.

Provisional QTL mapping of prepulse inhibition (PPI) of tactile startle response in recombinant congenic strains of mice and comparison with acoustic PPI. *A. Torkamanzehi[1], P. Boksa[2,3], R. Joober[2,3,4]* 1) Department of Cellular and Molecular Biology, University of Sistan and Baluchistan, Zahedan, Iran; 2) Douglas Hospital Research Centre, Montreal, Canada; 3) Department of Psychiatry, McGill University, Montreal, Canada; 4) Department of Human Genetics, McGill University, Montreal, Canada.

Introduction: Prepulse inhibition (PPI) of the startle response is a psychophysiological measure of sensorimotor gating believed to be cross-modal between different sensory systems. PPI has been extensively used as an endophenotype measuring sensorimotor gating which is known to be abnormal in a number of psychiatric disorders including schizophrenia. Methods: Using light as a prepulse stimulus, we analyzed the tactile startle response (TSR) and PPI of TSR (tPPI), in the mouse strains A/J and C57BL/6J and 36 recombinant congenic strains (RCSs) derived from them. We then performed a provisional QTL mapping for loci modulating TSR and tPPI using 620 SSLP markers informative for A/J and C57BL/6J. Results: Parental strains were significantly different for TSR, but were comparable for tPPI. Among the congenic strains, variation for TSR was significant in both genetic backgrounds, but that of tPPI was significant only for the C57BL/6J background. SSLP markers associated with tPPI appeared on chromosomes 2, 4, 6, 10, 11,18 and 1, 8, 11, 17, 19, 20 in the A and B backgrounds, respectively. Conclusion: Comparing mapping data from a previous study, on acoustic startle responses (ASR) and PPI of ASR (aPPI), no common markers for aPPI and tPPI were identified. However, some markers were significantly associated with both ASR and TSR, at least in one genetic background. These results indicate cross-modal genetic regulation for the startle response but not for PPI, in these mouse strains.

Impact of Cytogenetic Evaluation on Prognosis of Patients with AML. *S. Viditio[1,3], K. Zamkoff[1,3], T. Mercado[2,3], D. Gladstone[1,3], AL. Zaslav[2,3]* 1) Department of Blood And Marrow Stem Cell Transplatation Program; 2) Department of Clinical Pathology, Cytogenetics Laboratory; 3) SUNY at Stony Brook University Medical Center, Stony Brook NY 11794.

Non-random chromosome abnormalities are important, independent prognostic factors in AML. We report a study of 27 adults with AML. Cytogenetic aberrations were correlated with the median overall survival (MOS) of all patients (pts). Clinical features and outcome were examined. Cytogenetic analyses on 24, 48 and 72-hr cultures of bone marrow or unstimulated blood were performed using G-banding and/or FISH on 20 metaphase cells or 200 nuclei.

Among 27 pts, five (19%) had a normal karyotype and 22 (81%) had 1 clonal abnormalities. The pts were grouped according to the presence of a recurrent abnormality and were categorized as F, I or A risk groups.

F had six pts median age (MA) of 43 yr. Four had a t(8;21)(q22;q22) and two had a t(15;17)(q22;q22). The MOS in this group was 10.6 mo.

I had 16 pts (59%), MA of 60 yr. Five had normal karyotypes (18.5%), nine had +8 (33%). MOS was 7.8 mo. Nine of 27 had +8; and MOS of 8 mo. Five had +8 and additional abnormalities; MA of 65 yr and OS 4.9 mo. Trisomy 8 was also analyzed as a separate risk group, (nine pts). Four pts, MA of 49 yr, had only +8(15%) with MOS of 8.3 mo and five pts, MA of 65 yr, had +8, and other aberrations. MOS was only 4.9 mo. The difference in the outcomes of the two subgroups was significant. Pts with +8 and additional abnormalities had a worse MOS than patients with only +8.

A had 19 pts(70%). Ten pts had complex abnormalities. A had a MA of 63 yr and MOS 6.2 mo.

In summary, chromosome analysis is a critical independent determinant of the clinical outcome of AML. This study though limited, yielded significant data and was consistent with results from prior studies. We plan to incorporate a more aggressive approach to the use of cytogenetic data for diagnosis, treatment and prognosis in our practice.

Desmin splice variants causing cardiac and skeletal myopathy. *A. Shatunov[1], M.C. Dalakas[1], K-Y. Park[1], A. Dagvadorj[1], F. Muntoni[2], H.H. Goebel[3], L.G. Goldfarb[1]* 1) National Institute of Neurological Disorders and Stroke and National Heart, Lung, and Blood Institute, NIH, Bethesda, MD 20892, USA; 2) Dubowitz Neuromuscular Centre, Imperial College, Hammersmith Hospital, London, UK; 3) Mainz University Medical Center, D-55131 Mainz, Germany.

Desminopathy is a hereditary or sporadic cardiac and skeletal myopathy characterized by intracytoplasmic accumulation of desmin-reactive deposits in muscle cells. We characterized splice site mutations in desmin gene resulting in deletion of the entire exon 3 during pre-mRNA splicing. Sequencing of mRNA and genomic DNA from patients diagnosed with desminopathy identified 1) a heterozygous A-to-G change at the +3 position in the splice donor site of intron 3 (IVS3+3A->G) in two families and a single patient with the same (IVS3+3A->G) mutation generated de novo; 2) a G-to-A transition at the highly conserved -1 nucleotide position of intron 2 affecting the splice acceptor site (IVS2-1G->A) in two brothers affected with cardiomyopathy or a combination of cardiac and skeletal myopathy; 3) an A-to-T change at -2 nucleotide of intron 2 (IVS2-2A->T) in a patient with cardioskeletal myopathy; and 4) a G-to-A transition at the highly conserved +1 nucleotide (IVS3+1G->A) in a mother and son pair with highly aggressive illness. Aberrant splicing leads in each of the patients to an in-frame deletion of 32 codons, from 214 through 245, and is predicted to result in mutant desmin lacking 32 amino acids in the 1B segment of the alpha-helical rod. None of the 150 tested control individuals carried a splice variant distinct from the wild type desmin gene sequence. Expression of genomic DNA fragments carrying the IVS3+3A->G and IVS2-1G->A mutations in SW13 (vim-) cells confirmed that these mutations cause exon 3 deletion. Functional analysis of the mutant desmin lacking the 32 amino acids in SW13 (vim-) cells demonstrated aggregation of abnormal coarse clumps of desmin-positive material dispersed throughout the cytoplasm.

Ryanodine Type 1 Receptor mutations in Neuromuscular Disorders. *N. Sambuughin[1, 2], S. Muldoon[2], B. Brandom[3], T. Nelson[4], L. Goldfarb[1]* 1) NINDS/NIH, Bethesda, MD; 2) USUHS, Bethesda, MD; 3) Children's Hospital, Pittsburgh, PA; 4) Wake Forest University of Medicine, Winston Salem, NC.

The Ryanodine Receptor 1 (RYR1) is skeletal muscle specific intracellular calcium channel which plays a central role in muscle contraction. The RYR1 receptor is localized at the terminal cisternae of the sarcoplasmic reticulum and regulates calcium release into myoplasm. Mutations in the RYR1 gene have been identified in several neuromuscular disorders with underlying pathophysiology involving calcium regulation in skeletal muscle. To date, more than 120 mutations in the 15,117bp coding region of the RYR1 gene have been found to segregate with Malignant Hyperthermia (MH) and Central Core Disease (CCD), while a few of these mutations are also associated with Multiminicore Disease (MmD). MH is a life-threatening hypermetabolic crisis occurring in susceptible individuals as a result of exposure to inhalational anesthetics or depolarizing muscle relaxants. CCD and MmD are congenital myopathies characterized by the presence of cores in muscle. Clinical presentations of CCD and MmD may overlap and differential diagnosis is based on the nature of the cores and the type of affected muscle fibers. The majority of RYR1 mutations appear to be clustered into three regions or mutational hot spots: N-terminal, Central and C-terminal. The functional role of the first two regions is unclear, while the C-terminal region of RYR1 forms the transmembrane channel. We have screened the entire coding region of the RYR1 gene in 30 MH individuals from North America. Nine previously reported and nine novel RYR1 mutations have been identified accounting altogether for 70% of screened patients. Some of the new mutations were located outside of the known mutational hot spots, suggesting that RYR1 contains previously unknown mutation-prone areas requiring further analysis. The North American MH population exhibits notably different RYR1 mutational pool compared to the European MH populations and is characterized by a higher RYR1 allelic heterogeneity.

Haplotype and copy number variation in the low affinity Fc receptor 3B in the Pima Indians of Arizona. *K.M. Schroeder, V.M. Ossowski, L. Baier, C. Bogardus, M. Prochazka* PECRB, NIDDK, Genomics Unit, Phoenix, AZ.

The Pima Indians of Arizona have the worlds highest reported prevalence rate of type 2 diabetes (T2D), and our prior genetic linkage study indicated a susceptibility locus for this disease on Chr1q21-q25. As part of ongoing positional candidate gene analysis within this region of linkage, we analyzed the low affinity Fc receptor 3B (FCR3B), located within 2 Mb centromeric to the peak of linkage. FCR3B contains a well-validated haplotype system whose predominant alleles, FCR3B*1 and FCR3B*2 (formerly referred to as NA1 and NA2, respectively), are associated with a number of immune-related diseases. FCR3B can also vary in copy number, and a lower number was recently shown to be associated with predisposition to lupus nephritis. To genotype the FCR3B*1/*2 system in Pima Indians, genomic DNA from 208 subjects who contributed to the linkage was directly sequenced using allele-specific primers. Genotype frequencies for the 186 subjects for whom product was obtained indicated an excess of heterozygosity (0.80) and deviation form Hardy-Weinberg equilibrium (HWE; $p < 0.001$), suggesting higher copy numbers. Consistent with this, sequencing revealed an intronic single nucleotide polymorphism using either of the allele-specific primer sets. Based on heterozygosity at this site, 39 % of the Pima subjects had at least three alleles, in contrast to a Caucasian sample ($n = 49$) where only 4 % of subjects had more than two alleles, and where genotype frequencies did not deviate from HWE ($p = 0.85$). Our results show that Pima Indians, unlike most other populations studied to date, show excess FCR3B*1/*2 heterozygosity that can be attributed to higher gene copy numbers. We are currently attempting to measure copy number of each of the two haplotypes using quantitative real-time PCR to determine whether haplotype copy number contributes to susceptibility to T2D in Pima Indians.

Recessive alleles and Longevity among Kurichians: a tribal population of Kerala, India. *P.K.R. Thavanati[1], K.R.R. Kanala[2], A. Escoto de Dios[3], P.R. Alaharai[2], M.G. Lopez Cardona[1], N.O. Davalos Rodriguez[1], J.M. Cantu Garza[1]* 1) Instituto de Genetica, Departamento de Biologia Molecular y Genomica, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, 950 Sierra Mojada, Col. Independencia, Guadalajara. Jal. 44340,Mexico; 2) Department of Anthropology, School of Biological & Earth Sciences, Sri Venakateswara University, Tirupati - 517 502. Andhra Pradesh. India; 3) Genetica, Centro de Investigacion Biomedica de Occidente, IMSS, 900 Sierra Mojada, Col. Independencia, Guadalajara. Jal. 44340,Mexico.

Recessive lethal/semi-lethal genes will be eliminated at a faster rate from the population that maintains higher rate and prolonged practice of inbreeding wherein, the deleterious genes are effective in post-natal stages of life. The present study is aimed to evaluate the levels of inbreeding and its effects including the ancestral consanguinity effect, along with the levels of lipid peroxidation and DNA damage among Kurichias, a tribal population of Kerala, India to understand their structure who are leading a healthy long life. Personal interview method has been done on 300 families of Kurichian tribe of Kerala, using a questionnaire alongwith 10 ml intravenous blood sample (healthy 600: 404 males and 196 females) for the analysis of lipid peroxidation and DNA damage. The high levels of inbreeding among Kurichians would have been eliminating the deleterious genes, and under interaction with living conditions, such high inbreeding leading to increase in homozygosity of many of the genes that might have adapted to those conditions would explain the increased survivial of the individuals under inbreeding. Further, the effects of parental consanguinity of both the parents of the couples suggest the practice of inbreeding had already reduced the burden of deleterious genes. The values of lipid peroxidation and the DNA damage explains less susceptibility to oxidative stress leading to many degenerative diseases resulting to mortality. Therefore, inbreeding under favourable heredity does not reduced the level of longevity, where healthy aged and centenarians are found in the study population.

Large-scale blinded comparison of a commercially available array CGH platform to FISH for the analysis of subtelomeric abnormalities. *E. Thorland, T. Gliem, P. Gonzales, A. Wiktor, R. Ketterling* Cytogenetics, Dept of Lab Medicine & Pathology, Mayo Clinic, Rochester, MN.

Array comparative genomic hybridization (aCGH) allows the detection of copy number differences at varying sensitivity across the genome, depending on the number and density of probes utilized. aCGH chips targeting clinically defined loci that are recurrently deleted or duplicated are quickly becoming a clinical tool used for testing patients with unexplained mental retardation, developmental delay, or congenital anomalies. While this technology is not likely to replace standard chromosome analysis in this patient group, it may substitute for the numerous FISH tests that are often performed in an attempt to make a diagnosis, including FISH for the 41 clinically relevant subtelomeric sites which is very labor intensive and expensive. We have utilized our extensive clinical database of patients with previously defined subtelomere abnormalities, representing deletions and duplications of the majority of the 41 clinically relevant sites, to initiate a blinded study using the Spectral Genomics Constitutional Chip 3.0. This will allow a determination of the sensitivity and specificity of this aCGH platform compared to standard subtelomere analysis by FISH. The Spectral chip contains multiple BAC clones at all of the subtelomeric regions, in addition to clone coverage at numerous other clinically relevant loci. Patient samples that were normal by chromosome analysis or had subtle chromosomal rearrangements that necessitated further confirmation by subtelomere analysis were preferentially chosen for the blinded study. This strategy minimizes detection bias by limiting the number of abnormal proximal, non-subtelomere clones that could artificially enhance the ability of the aCGH chip to detect dosage diffences in this patient subgroup. To our knowledge, this is the most comprehensive comparison of subtelomere FISH to any aCGH platform that has been reported. This study will provide data as to the efficacy of aCGH as a replacement for subtelomeric FISH studies in a clinical setting.

Associated malformations in cases with neural tube defects. *m-p. roth, y. alembik, b. dott, c. stoll* genetique medicale, faculte de medecine, strasbourg, France.

Objective: Infants with neural tube defects(NTD)may have other associated con¬genital defects. The reported incidence and the types of associated malfor¬mations vary between different studies. The purpose of this investigation was to assess the prevalence of associated malformations in a geographically de¬fined population. Method: The prevalences at birth of associated malformations in infants with NTD were collected between 1979 and 2003 on all infantss born in the area covered by the registry of congenital anomalies of Northeastern France in 334,262 consecutive births. Results: Of the 295 infants with NTD born during this period, 18,6% had associ¬ated malformations. Associated malformations were more frequent in infants who had encephalocele(24,2%) than in infants with anencephaly(18,8%) or infants with spina bifida(12,5%). Malformations in the cardiovascular system and in the skeletal system were the most common other anomalies, fol¬lowed by oral clefts and malformations in the digestif system. Weight, length, and head circumference of children with NTD and multiple associated malformations were lower than in controls, as was the weight of the placenta. Conclusion: The overall prevalence of malformations, which was one in more than six infants, emphasizes the need for a thorough investigation of infants with NTD. A routine screening for other malformations especially skeletal, and cardiac defects may need to be considered in infants with NTD,and genetic counseling seems warranted in most of these complicated cases.

Empirical evaluation in 8 diverse populations reveals that common variation is well-captured by transferred tags, but tag combinations are highly divergent from specified tests. *E. Zeggini, N.W. Rayner, L.R. Cardon, M.I. McCarthy for the International Type 2 Diabetes 1q Consortium* WTCHG, University of Oxford, UK.

Universal applicability of the HapMap relies on tag SNP portability across populations. We addressed the issue of tag transferability by studying 3304 SNPs across 21 Mb of chromosome 1q, a replicated region of linkage to type 2 diabetes (T2D), in 8 case-control sets from diverse populations (4 European-descent, 2 East Asian, 1 African-American and 1 Native-American). Sample sizes were standardized to 64 (controls for training and cases for test sets). Tags were selected from each population and capacity to capture variation was tested in all 8. Tag method (pairwise or aggressive) was consistent between selection and evaluation steps. Importantly, neither pairwise nor multimarker tests were specified for the evaluation stage, thus permitting full use of the underlying LD structure. To reflect realistic genotype success rates, random 10% tag subsets were dropped from each set and capture was re-evaluated. Irrespective of tagging method, tags were portable across datasets (63%-97% common SNPs captured), but with a marked decrease in capture when evaluated in African-Americans (45%-69%). The average drop in observed common SNP capture with 90% of tags at $r^2>0.8$ was substantial (>7%) and overall comparable between pairwise and multimarker-defined tags. Only 20.6% of aggressively-captured variation was tagged by the SNP combination specified at the selection stage ($r^2>0.8$, with similar results for $r^2>0.5$). Interestingly, up to 12% (16.9% for 90% tag subset) of tests do not match the specified tests for pairwise-defined tags. We demonstrate that common SNP tags are transferable across most of the diverse populations studied, but that variation capture can decline substantially when even a small proportion of tags is not successfully genotyped, or when downstream analyses are restricted to specified tests.

A Genome-Wide High Ancestry Informative SNP panel for African American Admixture Mapping. *C. Tian*[1], *D.A. Hinds*[2], *R. Shigeta*[1], *R. Kittles*[3], *D.G. Ballinger*[2], *M.F. Seldin*[1] 1) Rowe Program in Human Genetics, Univ California Sch Medicine, Davis, CA; 2) Perlegen Sciences, Mountain View, CA; 3) Comprehensive Cancer Center, Ohio State Univ, Colombus, OH.

Admixture mapping requires a genome-wide panel of relatively evenly spaced markers that can in admixed individuals distinguish the ancestral origins of chromosomal segments. Using the results of the HapMap study (including over 3.5 million SNPs) and specific selection criteria the current study has examined the ability of selected SNPs to extract continental ancestry information in African American subjects and to explore parameters for admixture mapping. Genotyping of two disparate African populations (Bantu speaking and Nilo-Saharan ethnic groups), European Americans and African Americans with 5300 SNPs validated a genome-wide set of 4222 SNP ancestry informative markers (AIMs) with mean and median Fst values > 0.59 and mean and median Fishers information content >2.5. In contrast, the intra-African and intra-European mean Fst values were < 0.02. This set of AIM SNPs extracted a larger amount of ancestry information in the African American than previous reported SNP panels and provides more uniform coverage of the genome. ADMIXMAP was used to examine the admixture information in the genotyped African American samples (96 samples from Coriell set). When considering an interpolated genome-wide Decode map, the 4222 SNP AIMs extract >60% of the admixture information for over 98% of the genome, >70% for over 90% of the genome, and >80% for >66% of the genome. Moreover, simulations using different marker sets show that this more informative AIMs panel can improve power for admixture mapping in African Americans compared with smaller AIMs panels. This is particularly evident when the ethnicity risk ratio was below 1.75. This may have practical importance in the application of admixture mapping in complex genetic diseases in which the individual ethnicity risk ratios of many relevant susceptibility genes are unlikely to be very great.

The study of DNA hypervariability detected by DNA of phage M13 with the purposes of ecological monitoring.

S.N. Petrova[1], E.V. Shabrova[2], S.N. Ardashova[1], S.A. Limborska[2], E.K. Khusnutdinova[3] 1) Department of Health, Research Genetic Laboratory, Sterlitamak; 2) Institute of Molecular Genetics of the Russian Academy of Sciences, Moscow, Russian Federation; 3) Institute of Biochemistry and Genetics of Ufa Scientific Centre, Russian Academy of Science, Ufa, Russian Federation.

Ecological intensity in industrial regions conducts to contact of the population with potentially harmful polluting factors of environment, which can enhance the mutation influence, can damage a genome in gametes and somatic cells of the man. Sterlitamak is large industrial city of the Bashkir Republic, where are submitted the potent chemical industry and oil processing. The bank DNA of the townspeople is being created, which now contains 397 samples. The experimental group include of the members 53 families (both of parents and them children), selected with allowing for professional contact with toxic materials even of one of the parents during not less half-year up to a conception of the child. The control group - 30 families, where the parents by virtue of the professional work had no similar contact. The fingerprints with DNA of phage M13 of the members 14 experimental and 6 control families is carried out. The fields of 11 radioautographs with lengthes from 2027 up to 21226 p.n. were used for visual comparison. We believed that the bands is identical, if in an electrophoretic profile the bands differed less, than on 1 mm. We were considering as mutation events the absence of fragment in a profile of child in comparison with the strip at the level of parents strips and presence at him of the restriction fragment which is not conterminous on molecular weight with the strips of the parents. Amount of bands in a profile of children, which were not referred to parents, was unexpectedly above the concerning similar researches: 1,55 new bands for the child in experimental group and 3,10 - in monitoring. This fact can be conditioned as by methodological features of the given research, so by actual effect on gametes of high concentrations of mutagenes of environment.

Short isoform of Myoclonin1/EFHC1 in human and monkey but not in mouse. *T. Suzuki[1, 2], A. Delgado-Escueta[3], K. Yamakawa[1]* 1) Lab. for Neurogenetics, RIKEN Brain Science Institute, Saitama, Japan; 2) Special Postdoctoral Researchers Program; 3) Epilepsy Genetics/Genomics Laboratories, Comprehensive Epilepsy Program, David Geffen School of Medicine, UCLA, and VA GLAHS-West Los Angeles Epilepsy Center of Excellence, Los Angeles, California, USA.

Juvenile myoclonic epilepsy (JME) is a life-long disorder accounting for 10-20% of all epilepsies. In 2002, we mapped a JME gene on chromosome 6p12-p11 (EJM1) and in 2004 we identified JME causing mutations in a novel gene myoclonin1/EFHC1. Myoclonin1/EFHC1 encodes 640 amino acids protein (isoform A) and 278 amino acids protein (isoform B). EFHC1 revealed five missense mutations in isoform A co-segregating with 21 affected members of six JME families that did not appear in 382 healthy control individuals. Recently, we screened 111 new JME families from Mexico, Honduras and Japan for mutations. We identified additional novel heterozygous missense mutations in isoform A, and frameshift and nonsense mutations in specific regions of isoform B. Because mutations of isoform B appear in three JME families, we further characterized Myoclonin1/EFHC1 isoform B in mice and monkeys. Northern blot analysis of mouse multiple tissues including brain at various developmental stages was performed with 3' end (nt 1670-1990) of Efhc1 as a probe. A ~2.3 kb transcript appeared in multiple tissues including brain but most strongly in lungs. Hence, the mouse either does not have isoform B or it is expressed at levels below that detectable by Northern blots. Northern blots of monkey Efhc1 showed multiple size transcripts (~2, 3, 4.4 and 6 kb) in cerebellum. The 3 and 6 kb transcripts were detected by human isoform B specific probe. We also isolated monkey Efhc1 cDNA clones by RT-PCR. These cDNA clones contained several forms of Efhc1 including isoform B. Further studies on monkey isoform B may advance understanding of the pathophysiology of seizures in human JME.

A Japanese patient with a mild variant of Lenz-Majewski syndrome. *D. Sumito[1], T. Kondoh[1], G. Nishimura[2], K. Motomura1[1], K. Yoshiura[3], A. Kinoshita[3], H. Kuniba[1], Y. Koga[4], H. Moriuchi[1]* 1) Dept Pediatr, Nagasaki University, Nagasaki, Japan; 2) Dept Radiol, Tokyo Metropolitan Kiyose Childrens Hospital, Tokyo, Japan; 3) Dept. Hum Genet, Nagasaki University, Nagasaki, Japan; 4) Dept. Dev and Reconstr Med, Nagasaki University, Nagasaki, Japan.

Lenz-Majewski syndrome (LMS) is a rare skeletal dysplasia comprising progressive skeletal sclerosis, mental retardation, failure to thrive, enamel hypoplasia and loose atrophic skin with prominent cutaneous veins, and its prognosis is considered to be poor. Here we report a 17-year-old Japanese boy with a mild variant of LMS. He showed cutis laxa and prominent scalp veins in infancy. Dentition started at age 2 years; however, permanent teeth of the upper jaw had not been erupted. At the age of 13 years, he was admitted to our hospital for purpose of jaw reconstruction. Facial appearance was peculiar with progeroid-looking, sparse hair, large auticles, maxillar hypoplasia, high-arched palate and severe enamel dysplasia. He had mild mental retardation of 60 intelligence quotients. His skin was loose with prominent veins in abdominal wall. His extremities lacked major anomaly except for interdigital webbing and mild cubitus valgus, and his motor function was entirely normal. He had neither hearing impairment nor impingement on other cranial nerves. Skeletal roentgenograms demonstrated symmetric hyperostosis of calvaria, skull base, vertebrae, pelvis, carapals, and long bones, which were pronounced in epiphysis. At the age of 17 years, clinical findings appeared stable, but radiological abnormality was slowly progressive. No abnormality was detected in his TGFB-1 and LRP5 genes, which are candidate genes of two similar disorders, Camurati-Engelmann disease and endosteal hyperostosis, respectively. Clinical features and radiological findings of our patient were overlapped with those of LMS, but milder and less progressive than those of the previously reported LMS patients. It is suggested from our experience that LMS may be phenotypically variable. Further investigation is required to better understand etiology and pathogenesis of LMS and related disorders.

Voiding dysfunction - a previously unrecognized but surprisingly frequent complication of Down syndrome. *A. Tanaka[1], T. Kondoh[1], M. Noguchi[2], T. Hatada[2], S. Tohbu[2], T. Matsuo[2], M. Matsuo[2], H. Kanetake[2], H. Moriuchi[1]* 1) Dept Pediatrics, Nagasaki Univ, Nagasaki, Japan; 2) Dept. Urology, Nagasaki Univ, Nagasaki, Japan.

Genitourinary anomalies such as small penis and small scrotum have been associated with Down syndrome (DS) patients; however, voiding function has not been precisely evaluated in DS patients. We therefore investigated voiding function in 74 DS patients (36 women and 38 men), aged 2-39 years. Voiding function was evaluated by urinary frequency/volume chart for 3 consecutive days, uroflowmetrical examination by the uroflowmeter, residual urinary volume after micturition by ultrasonography, urinalysis and checking their history of voiding status. We divided the subjects into three groups: group A (23 patients younger than 10 years old), group B (14 patients aged 10-15 years), and group C (37 patients older than 15 years old). According to their voiding history, 52 (70%) and 10 (14%) patients reported normal and reduced desire to urinate, respectively. Seventeen patients (23%) presented with urinary incontinence. Urinary incontinence was infrequent in group C patients, as compared to other groups. On the other hand, 16% of group C patients had significant amount of residual urine, while group A patients had no residual urine. The urine frequency in 24 hours was lower and mean voided volume per one time was larger in group C patients than in group A or B patients. Uroflowmetrical analyses were informative in 40 of 74 patients. Maximum and average flow rates were highest in group B and lowest group C patients. Twenty nine (73%) DS patients presented with abnormal flow pattern such as straining to void. Thus, voiding function of DS patients is characterized by decrease in urinary frequency and flow rate as well as increase in residual urinary volume with aging. In other words, the bladder of DS patients tends to retain urine with aging, ultimately resulting in detrusor dysfunction. In conclusion, surprisingly many DS patients are affected by voiding dysfunction, which should decrease quality of their lives. We should recognize such important complication and monitor their voiding function regularly.

Multi Information for Testing Association of Gene-Gene Interaction Networks with Disease. *M. Xiong, L. Luo*
Dept Human Genetics, Univ Texas Health Science, Houston, TX.

Complex diseases are caused by multiple genes, primarily through nonlinear gene interactions and gene-environment interactions. Complex gene interactions are organized into networks. It has been found that the number of interactions per gene varied from 1 to hundreds, with average of 34 interactions in some model organisms. Genetic interaction networks must be ubiquitous in common diseases. A major challenge is to develop quantity for characterization of the genetic interaction networks which take high order gene-interaction into account and statistics for testing association of the genetic interaction networks with diseases. In this report, we present novel concept of multi information that is the extension of the mutual information or correlation between two random variables in formation theory to the multiple variables and the network and reveal the relationship between multi information and linkage disequilibrium at multiple loci. We study the distribution of multi information and develop a novel statistic based on multi information to test association of the genetic interaction networks or biochemical pathways with the diseases. The null distribution and power of the statistic are evaluated. The proposed statistic is applied to the genetic studies of atherosclerosis where overall 1518 SNPs from 123 candidate genes in inflammatory pathway, antioxidant pathway, coagulation pathway and lipoprotein metabolic pathway in 916 samples (492 atherosclerosis patients and 424 controls) were typed and identify a genetic interaction network with total 84 interactions within the pathway and 36 interactions between the pathways associated with atherosclerosis. The development of the multi information theory will provide a general framework for study of gene-gene and gene-environment interaction.

Genome-wide association mapping under the Malecot model and composite likelihood. *W. Zhang[1], A. Collins[1], W. Jia[2], C. Hu[2], N.E. Morton[1]* 1) Human Genetics Div, Univ Southampton, Southampton, United Kingdom; 2) Shanghai Diabetes Institute, Shanghai Jiaotong University Affiliated Sixth Peoples Hospital, Shanghai, 200233, China.

The combination of the evolutionary model of the Malecot and composite likelihood has been successfully applied to candidate gene association mapping. Here, we extended our method to genome-wide scans. The underlying logic is that a chromosome (a unit of the genome) is divided into segments according to the LD map expressed in linkage disequilibrium (LD) unit (LDU), a metric of genetic distance between markers monotonic to cM in a linkage map. Tentatively we defined 10 LDUs as the length of a segment assumed to have extensive LD that is useful for association mapping and minimum of 30 SNPs in a segment. The observed association between the phenotype and a marker SNP was calculated from the data. The expected association was predicted by the Malecot model, which is a function of the distance in LDU or kb between the hypothesized disease variant and the marker and a few other parameters. Composite likelihood was applied to combine association at multiple loci, substantially reducing the burden of multiple testing encountered in single SNP tests. By fitting the Malecot model and maximizing the composite likelihood, we can detect association and if there is an association, to estimate the location of the disease variant and its confidence interval. Starting with a case-control sample with thousands of SNPs for a large region, we simulated the case/control status based on genotypes of a randomly chosen causal SNP in a segment with some constrains. We estimated the significance levels empirically through simulation under the null hypothesis of no association by randomly shuffling the case/control status, and assigned a P value for each segment in a replicate according to the rank order of the statistic to ensure uniform distribution. We explored three association statistics by contrasting different hierarchical models. We demonstrate that our method is both practical and efficient for whole genome association scans and we also discuss other issues, such as the false discovery rate and meta-analysis.

Expression profiling supports peroxisome proliferator-activated receptor alpha (PPAR) activation in livers of 70kDa Peroxisomal Membrane Protein (PMP70) deficient (*Abcd3*-/-) mice. *I. Silva-Zolezzi*[2,3], *S. Bradley*[1], *D. Valle*[1], *G. Jimenez-Sanchez*[2] 1) McKusick-Nathans Institute of Genetic Medicine and Howard Hughes Medical Institute, Johns Hopkins University, School of Medicine, Baltimore, MD; 2) National Institute of Genomic Medicine, Mexico DF, Mexico; 3) Ph.D. Program in Molecular Biomedicine, CINVESTAV-IPN, Mexico.

There are 4 known human half ABC transporters in the peroxisomal membrane: ALD, ALDR, PMP70 and P70R, encoded by *ABCD1, 2, 3*, and *4*. Mutations in *ABCD1* cause X-linked adrenoleukodystrophy while the function and disease associations of the other three are unknown. PMP70 is thought to be a transporter for very long chain branched chain fatty acids into peroxisomes. *Abcd3*-/- mice have reduced hepatic glycogen, dicarboxylic aciduria, secondary carnitine deficiency and cold intolerance. Despite these metabolic alterations, mice are healthy and have a normal lifespan. In order to understand the molecular mechanisms underlying this metabolic phenotype, we evaluated the role of (PPAR) activation by surveying hepatic gene expression using murine U74Av2 Affymetrix arrays. In pooled samples of liver total RNA of *Abcd3*-/- and *Abcd3*+/+ mice, we identified 221 transcripts, with an AFC in mRNA level of at least 1.7. Of these, 97 were increased and 124 were decreased. Using designations of Gene Ontology and information from public resources, we organized genes into 13 categories. Our results show expression changes in genes of lipid metabolism, inflammation and cell growth similar to those observed when PPAR is activated. In addition, 65% of the altered genes have not been reported to be affected by PPAR activation, some of these may be novel PPAR targets, while others may represent downstream effects. Interestingly, we found reduced expression of two genes lipocalin 2 (*Lcn2*) and serum amyloid P-component (*Apcs*), both reported to be increased in hepatocellular carcinomas (HCCs) from *Acox1*-/- mice, a peroxisomal -oxidation enzyme, and in mice subjected to long term exposure to PPAR synthetic agonists. Our results are consistent with our hypothesis that *Abcd3*-/- metabolic phenotype is a consequence of inappropriate and chronic PPAR activation.

Expression of cAMP-responsive element modulator (CREM) in Rat Testes Following the Root of *Panax ginseng* Treatment. *W.M. Yang, D.Y. Shin, B.H. Lee, W-N. Kim, D.R. Kim, W. Park, S.K. Park* Prescriptionology, Kyung Hee Univ. College of Oriental Medicine, Seoul, Korea.

Ginseng Radix (GR), the root of *Panax ginseng* has been used as a tonic in Asia for more than 2,000 years, and is now widely used around the world. Previous reports have shown GR to improve survival rate and sperm quality; inhibit lipid peroxidation; protect against testicular toxicity. However, few studies have used rat testes to examine the effects of GR on male reproductive functions. After Rats were treated GR for 56 days consecutively. Total RNA was extracted from rat testes using Trizol method. Then we carried out Western blotting assay using anti-CREM antibody. CREM mRNA levels were significantly increased in testes from the rats treated with GR (p 0.05). The relative expression of CREM mRNA in the GR treated group was 174% than that in the normal group. There was significantly enhanced expression of CREM-immunoreactive bands in the GR treated group compared to the vehicle treated group (p 0.05). The relative expression of CREM in the GR treated group was 108% than that in the normal group. In this study, GR has the enhancing effect of CREM expression in rat testes especially at mRNA level. These findings suggest that GR may have a role of improving male infertility related with the sperm alterations and proliferating or differentiating of germ cells closely related with CREM gene expression.

Leptin and adiponectin in Gaucher disease. *A. Rosenberg[1], G. Litvin[1], G. Altarescu[2], A. Zimran[1], D. Elstein[1]* 1) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Genetic Unit, Shaare Zedek Medical Center, Jerusalem, Israel.

Although genotype may be predictive of phenotype in a broad sense in type I (non-neuronopathic) Gaucher disease, there is considerable phenotypic variability. Research suggests that adipose tissue may secrete hormones that take part in energy metabolism and have anti-atherogenic and anti-inflammatory properties since adipocyte products such as leptin and adiponectin have been implicated in pathological processes in liver, spleen, bone, lung, and brain. The purpose of this study was to ascertain whether either or both of these hormones are predictive of various disease specific parameters, including hematological and bone markers, body mass index, inflammatory indices, lipid profiles, and glucose levels. All adult patients arriving at the Gaucher Clinic for routine follow-up during January-June 2005 and for whom laboratory tests were available, were included. There were 99 patients (45 men, 54 women). Mean values for leptin in male patients only showed borderline higher values than controls (p=0.082). There were no other statistically significant correlations between leptin and any of the other parameters, nor with adiponectin. Patients with Gaucher disease had statistically significant lower values of adiponectin (p=.0007 and p=.0001 for men and women, respectively) with a trend to a statistically significant difference between men and women (p=.06). Adiponectin was not correlated with any of the other disease parameters. There was no significant difference in leptin levels or in adiponectin levels between patients with the N370S/N370S genotype versus other genotypes or between patients treated with enzyme replacement therapy versus untreated patients. We speculate that Gaucher-induced liver pathology even if not clinically overt may be related to adiponectin levels as in other liver diseases. However, we cannot explain why lipid accumulation in Gaucher disease is correlated with abnormally low adiponectin values, albeit without clinical evidence of insulin resistance.

Correlation between inflammatory cytokines genes polymorphisms and Mainz Severity Score Index (MSSI) in patients with Fabry disease. *R. Safyan[1], C. Whybra[2], D. Elstein[3], G. Chicco[3], M. Beck[2], G. Altarescu[1]* 1) Genetic Unit, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Universitäts- Kinderklinik2, Mainz, Germany; 3) Gaucher Clinic,Shaare Zedek Medical Center, Jerusalem, Israel.

Fabry disease is an X-linked disorder associated with early-onset stroke, cardiomiopathy, and progression to end-stage renal failure. Correlations between IL-6 inflammatory cytokine gene polymorphisms and MSSI scores have been shown. Therefore, polymorphisms of other key pro- and anti-inflammatory cytokines and correlation to clinical manifestations (MSSI scores) were attempted in order to build haplotype descriptions for Fabry disease. Genotyping for IL-10[819C/T; -592C/A]; IL-1beta[+3954 C/T; -511C/T]; IL-1alpha[-889C/T]; and TNF-alpha[-308G/A] was performed in 76 patients and correlated with MSSI sub-scores and with enzyme (alpha-galactosidase A) levels. Fifty normal volunteers, age- and sex-matched, were also genotyped. Of 76 patients, 31(41%) were males and 45(59%) were females. There was no correlation between enzyme levels and any cytokine polymorphisms. Statistically significant differences were found in prevalence of TNF-alpha[-308G/A] genotypes: 84%GG in patients versus 63%GG in controls ($p=0.038$) and for IL-1alpha[-889C/T] genotypes: 94%CC in patients versus 21%CC in controls ($p<0.001$). Statistically significant differences were found in ratio between the two polymorphisms of IL-10 ($p<0.0001$), between the two polymorphisms of IL-1beta ($p=0.001$); between IL-1alpha[-889C/T] and IL-1beta [3954C/T] ($p=0.002$); and between IL-10[-592C/T] and IL-1beta [3954C/T] ($p=0.041$). Correlations between TNF-alpha[-308G/A] and both kidney and neurological MSSI sub-score (both: $p=0.06$) and between IL-10[-819C/T] and the MSSI neurological score ($p=0.03$) were noted. We speculate that sequence variations in regulatory DNA of genes coding for important members of the interleukin inflammatory family are associated with differential effects in Fabry disease and with increased sample size, haplotype blocks might be constructed.

Nosology and Classification of Genetic Skeletal Disorders. *A. Superti-Furga[1,3], S. Unger[2,3], and the ISDS Nosology Group* 1) Dept of Pediatrics, Univ of Freiburg, Germany; 2) Inst of Human Genet, Univ of Freiburg, Germany; 3) ISDS International Skeletal Dysplasia Society, www.isds.ch.

Objectives - Revision of the Nomenclature of Genetic Disorders of Bone to incorporate newly recognized disorders and to reflect new molecular and pathogenetic concepts.

Methods -Criteria for inclusion of disorders were (1) significant skeletal involvement corresponding to the definition of skeletal dysplasias, metabolic bone disorders, dysostoses, and skeletal malformation and/or reduction syndromes, (2) publication and/or MIM listing, (3) genetic basis proven or very likely, and (4) nosologic autonomy confirmed by molecular or linkage analysis and/or distinctive diagnostic features and observation in multiple individuals or families.

Results - 370 different conditions were included and placed in 37 groups defined by molecular, biochemical and/or radiographic criteria. Of these conditions, 213 were associated with one or more of 138 different genes. Nosologic status ranged from final (mutations or locus identified) to probable (pedigree evidence) to bona fide (multiple observations but no pedigree or locus evidence yet).

Discussion - The number of recognized genetic disorders with a significant skeletal component is growing and the distinction between dysplasias, metabolic bone disorders, dysostoses, and malformation syndromes is blurring. Clinical and radiographic evaluation remains essential. Molecular evidence leads to confirmation of individual entities and to constitution of new groups, but also allows for delineation of new entities and indicates an unsuspected heterogeneity of molecular mechanisms; thus, molecular evidence does not necessarily simplify the Nosology, and a further increase in the number of entities and growing complexity is expected.

Conclusions - By providing an updated overview of recognized entities with skeletal involvement, the new Nosology can provide practical diagnostic help, facilitate the recognition of new entities, and foster research in skeletal biology and genetic disorders.

Identification of a novel role of excess copper in enhancing apoptotic potential of Arg72 variant of p53: New insights into molecular pathophysiology of Indian Childhood Cirrhosis. *R. Prasad[1], N. Sharma[1], B.R. Thapa[2], G. Kaur[3]* 1) Biochemistry, PGIMER, Chandigarh, India; 2) Pediatric Gastroenterology, PGIMER, Chandigarh; 3) Physiology, Government Medical College, Chandigarh.

We purified a major copper binding protein (MCuBP ~50 kDa) from ICC patients. N-terminal sequencing of this protein matched to p53. Cloning of MCuBP gene was accomplished by polysome isolation, immubolization of polysome-antibody (pantropic p53) complex, elution of specific MCuBP mRNA, dscDNA synthesis, annealing of dC tailed cDNA with dG tailed pBR322 and transformation of competent E.coli dH5 with recombinant plasmid. Sequence of plasmid DNA bearing MCuBP gene matched to p53 cDNA. C residue at nucleotide position 350 was substituted by G, resulting in Argnine instead of Proline at position 72. Using gene specific primers, approximately 1.2 kb p53 cDNA was synthesized by RT-PCR. Sequence analysis confirmed Arg72 polymorphism in p53 gene of ICC patients. The p53 Arg72 was cloned into pcDNA 3.1 vector for expression studies which showed increased expression of p53 mRNA by RT-PCR analysis and increased p53 staining intensity on immunocytochemical analysis with increasing concentrations of copper. Western blot analysis showed p53 protein in liver and p53 antibodies in plasma of ICC patients. Exon 4 was amplified from the genomic DNA of 11 ICC patients, 8 were homozygous and 3 were heterozygous for Arg at position 72. We demonstrated an increased expression of CD95 in ICC liver by immunoblot and RT-PCR. We conclude that in ICC, consumption of milk in brass/copper utensils results in hepatocytes death by increased tumor suppressor activity of Arg72 form of p53 through activation of CD95. Role of copper in transcriptional or translational regulation of Arg72 p53 deserves further investigations.

Two novel bi-allelic MMR gene mutations: further evidence for a distinct syndrome with constitutional inactivation of DNA mismatch repair system. *Q. Wang[1,4], J. Auclair[1], D. Leroux[5], F. Desseigne[2], J-C. Saurin[6], C. Lasset[3], V. Bonadona[3], S. Pinson[4], M-O. Joly[7], G. Montmain[1,4], A. Puisieux[1]* 1) Dept Oncologie Moleculaire,Centre Leon Berard,; 2) Dept de médecine, Centre Leon Berard,; 3) Dept de Santé Public, Centre Leon Berard, Lyon, France; 4) Plateforme Mixte de Génétique Constitutionnelle HCL-CLB, Lyon, France; 5) Service de génétique, CHU Grenoble, Grenoble, France; 6) Service d'Hépato-Gastroentérologie, Centre Hospitalier Lyon-Sud, France; 7) Laboratoire Central d'Anatomie et de Cytologie Pathologiques, Hôpital Edouard Herriot, Lyon, France.

Hereditary nonpolyposis colon cancer (HNPCC) is characterized by early onset of colorectal cancer and certain extracolonic cancers, caused by a heterozygous germline mutation of one of the DNA mismatch repair genes (MMR). Such mutations are also implicated in HNPCC-related syndromes, i.e. Muir-Torre syndrome associated with skin malignancies and Turcot syndrome associated with tumors of central nervous system. Recent studies suggested the existence of a distinct HNPCC-related syndrome caused by a bi-allelic germline mutation of MMR genes. A total of 18 cases have been reported so far, involving either MLH1, MSH2, MSH6 or PMS2. Mutation carriers developed frequently, in their early childhood, brain tumors and haematological malignancies, with the presence of café-au-lait spots (CALS). Microsatellite instability was often observed indicating a MMR deficiency. Herein we reported two novel compound heterozygous mutations in respectively MSH6 and PMS2 gene from families not suggestive for HNPCC. In addition to CALS, mutation carriers displyed early onset of brain tumor, colorectal neoplasia, and endometrial carcer. However, no deleterious mutation was detected in NF1 gene. Our observation further evidence the existence of this distinct, although rare, HNPCC syndrome variant with recessive inheritance. The phenotype and genotype of all similar cases are compared, in an attempt to draw a profile of this syndrome which will be of great help for genetic counselling for those families.

A novel HEXB gene mutation producing a dual pathogenic mechanism results in the Sandhoff motor neuron phenotype. *M. Santoro[1], G. Silvestri[1], A. Modoni[1], M. Sabatelli[1], F. Piemonte[2], E. Ricci[1], P. Tonali[1]* 1) Neuroscience, Catholic University, Rome, Italy; 2) Laboratory of Molecular Medicine Bambino Gesù Hospital, Rome, Italy.

GM2 gangliosidosis type Sandhoff(MIM 268800) is an inherited lysosomal storage disorder caused by mutations in the HEXB gene, encoding the beta subunit of Hexosaminidase (Hex). We report a novel HEXB gene mutation associated with a familial, chronic Sandhoff lower motor neuron (LMN) phenotype. HEX activity in leukocytes was done by spectrophotometric assays. HEXB gene sequencing and PCR-RFLP analysis for the c.1556A>G transition were performed on DNA, and RT-PCR studies on RNA extracted from leukocytes. Data were analysed by ESE-finder, RESCUE-ESE, BLASTP and Cn3D 4.1 softwares. The biochemical diagnosis of Sandhoff disease was made in two affected family members showing a reduction of total HEX,lack of Hex-B and near normal Hex-A activity; an unaffected member showed total HEX and Hex-B enzyme activities compatible with heterozigosity.HEXB gene sequencing documented a novel c.1556 A>G transition in exon 12, homozygous in the two affected individuals and heterozygous in the unaffected one. The mutation, not detected in 100 Italian controls, changes a highly conserved aspartic acid to glycine at position 494 (D494G). The mutation does not affects Hex cathalitic domain, but it is part of the interface I,which regulates Hex dimers assembly and their affinity for the natural substrate,GM2-activator complex. Moreover, amplification of a cDNA fragment including exon 12 from the RNA extracted from leukocytes of the two affected family members showed a normal 538 bp and a shorter 447 bp fragment, corresponding to an aberrantly spliced RNA in which skipping of exon 12 had occurred, producing a frame-shift with stop codon 78 nucleotides downstream from exon 11. ESE-finder and RESCUE-ESE analyses revealed that the mutation disrupts an ESE motif in exon 12 for human SR proteins SC35 and SRp55. Conclusions: Analysis of clinical, biochemical and molecular data in this family suggest that the D494G mutation would affect HEXB gene expression both at the transcriptional and the post-traductional level.

Cryptic ins(4;11)(q21;q23q23): a variant of t(4;11)(q21;q23) in an infant with an immature B-ALL. *C.A. Tirado[1], A.M. Meloni-Ehrig[1], T. Edwards[1], J. Scheerle[1], K. Burks[1], C. Repetti[2], J.C. Kelly[1], N.C. Christacos[1], J. Grenberg[3], C.D. Croft[1], D. Heritage[1], P.N. Mowrey[1]* 1) Cytogenetics, Quest Diagnostics Nichols Institute, Chantilly, VA 20151; 2) Flow Cytometry, Quest Diagnostics Nichols Institute, Chantilly, VA 20151; 3) Arlington-Fairfax Hematology-Oncology, Arlington, VA.

We report on a 4-year-old female with a WBC of 120,000 and thrombocytopenia. The blood findings revealed a Hb of 10 g/dL, a hematocrit of 29%, and a platelet count of 47 K/L. The flow cytometry report identified abnormal blasts which were CD10-, CD19+, partial dim TdT, HLA-DR +, and CD15+ consistent with an immature B-cell lineage acute lymphoblastic leukemia. Routine chromosome analysis detected an isochromosome 7q resulting in loss of the short arm and gain of the long arm of chromosome 7, as well as a possible loss of material from 11q23. FISH studies on both interphase nuclei and metaphase cells using the LSI MLL Dual Color, Break Apart Rearrangement probe (Abbott Molecular, Inc.) were instrumental in the characterization of an *MLL* gene rearrangement, which was cryptic by conventional cytogenetic analysis. Specifically, the FISH pattern was consistent with an insertion of the 5' region of the *MLL* gene into one chromosome 4 at band q21. Insertions of the *MLL* gene into various partner chromosomes have been reported previously. To our knowledge, this particular insertion of the MLL gene into chromosome 4 has only been reported once. We assume that this cryptic insertion results in the fusion of the 5' portion of the *MLL* gene with the *AF4* gene at 4q21, as is seen in the typical t(4;11)(q21;q23). This translocation has been reported mostly in very young children (1-2 years of age, 50% are under 4 years), as well as adults and it is usually associated with an unfavorable prognosis. The presence of the i(7q), which is an additional abnormality seen in approximately 10% of ALL cases with t(4;11)(q21;q23), strengthens the possibility that this insertion is a variant of the typical t(4;11)(q21;q23). This case exemplifies the importance of FISH in the further characterization of cytogenetic abnormalities in hematologic oncology cases.

Genetic and reproductive knowledge among adolescents and adults with cystic fibrosis. *N.H. Robin[1,2], G.H. Houser[1], H. Gutierez[2], J.P. Clancy[2], K.R. Young[3], C. Holt[3]* 1) Dept Genetics; 2) Pediatrics; 3) and Medicine, Univ Alabama at Birmingham, Birmingham, AL.

Cystic fibrosis (CF) is now becoming a disease of adulthood. In 2002, 40% of the 30,000 CF patients in the United States were over 18, and it is expected that in the next 10 years over 50% of CF patients will be adults. Therefore, issues of transition care are becoming more important. One such issue is reproduction. Many studies have shown that CF patients have a good understanding of the medical issues of CF, but a poor understanding of the genetics. No study has looked at their knowledge of reproductive options. This is because, until recently, issues of genetics and inheritance were not relevant. Most CF patients died very young, older male patients were almost all sterile, and women had also had diminished fertility. However, these issues are now very important, as improving health and advances in assisted reproductive technology have made reproduction a viable option for many CF patients. We conducted structured interviews with 18 CF patients age 16-25 yrs., 7 male and 11 female. All had a good understanding of the medical issues of CF, such as common symptoms, organs affected, and complications, and all knew genes were somehow involved in causing CF. However, there was poor understanding of inheritance. Only 4/18 could explain that their parents each carried a CF allele, and that that they had a 25% chance of having a CF child; 6/18 did not know they inherited a CF mutation from each parent; 15/18 did not know their risk for having a child with CF; and 15/18 responded incorrectly to basic questions about the genetics of CF. Only 12 (5 males, 7 females) knew that males are sterile, and 9/12 (3 males, 6 females) did not know why. There was also confusion concerning female reproductive capabilities. Finally, 9/18 (2 males, 7 females) did not know that there are reproductive options available if they do want to have children in the future. Based on these results, genetic and reproductive education should be incorporated into the transitional care of adolescents and young adults with CF.

A-Richness and the Repression of L1 Protein Expression. *N. Wallace, P. Deininger* Epidemology, Tulane University, New Orleans, LA.

Long interspersed element-1 or L1 composes approximately one-fifth of the average mammalian genome. It is necessary to constrain the activity of this retroelement in order to minimize genomic damage. The repression of L1 expression and subsequent retrotransposition has been shown to occur through multiple cellular mechanisms. It has been demonstrated that premature polyadenylation, and improper splicing function to suppress the expression of human L1 proteins. In addition to these ways, the use of very A-rich open reading frames (ORFs) may play a suppressive role, as well. This excessive A-richness results in extremely suboptimal codon use in each of the two L1 proteins, ORF1p and ORF2p. In addition to poor translation efficency, the A-richness may also result in altered RNA production, transport or stability. We have demonstrated that removing the A-richness found in the ORF1 region results in an increase in RNA production, and a dramatic increase in protein production. Similarly, the removal of the ORF2 A-richness results in increased RNA levels. Orf2p levels, as measured via a functional assay, also increase. These findings are consistent with our hypothesis that the A-richness of the L1 ORFs contributes negatively to the translation as well as transcription of L1.

Mortality in Achondroplasia study: A 40 year follow-up. *J. Wynn[1], M.J. Gambello[1], T.M. King[1], A. Scott[3], K. Waller[2], J.T. Hecht[1]* 1) Department of Pediatrics, The University of Texas Health Science Center at Houston, Houston, TX; 2) The University of Texas School of Public Health, Houston, TX; 3) Houston Shriners Hospital, Houston, TX.

Achondroplasia (ACH) is a well-studied, common dwarfing condition that affects approximately 12,000 persons in the US. In studies of the natural history, an increase in overall mortality, age specific mortality up to age 34 years and cardiovascular disease related mortality was identified in a large cohort of ACH individuals. Concern about premature death, particularly in young adults, has continued to be a worry in the ACH population. This study was undertaken to follow up the original ACH mortality study to assess the patterns of mortality in a more contemporaneous population. Seven hundred eighteen ACH individuals from the original study and 75 new ACH individuals ascertained through the University of Texas Medical School at Houston were assessed for vital status using the National Death Index, Social Security Administration Death Master File and the Little People of America list of deceased members. The results showed that the overall mortality and age specific mortality at all ages remains significantly increased. Rates of death were similar in the first and second 20 years of follow-up suggesting that higher death rates were still occurring in this ACH population. Accidental, neurological, and cardiac deaths were all significantly increased in adults. Cardiovascular disease related mortality, in ACH individuals between ages 25 to 35, was more than 10 times higher than the general population. Overall survival and the average life expectancy were decreased by fifteen years for this ACH population. This study demonstrates that despite advances in the knowledge of the natural history of ACH and health care of this population, mortality remains significantly increased. The high rate of cardiovascular related deaths illustrates the need for risk factor assessment in the ACH population to identify specific risk factors and to develop treatment interventions.

A Novel Approach To Detect Parent-Of-Origin Effects From Pedigree Data. *S. Shete[1], R. Elston[2], Y. Lu[1]* 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH.

The parent-of-origin phenomenon in humans is now well recognized, and the deregulation of imprinted genes has been implicated in a number of human diseases. Recently, several linkage analysis methods have been developed to allow for parent-of-origin effects in the analysis of pedigree data. However, in general, one does not know a priori if disease-causing loci are imprinted or not. Linkage methods that allow for imprinting can lose power if there is no imprinting. Conversely, linkage methods that do not allow for imprinting will lose power if there is imprinting because of penetrance values not being correctly specified. Therefore, it is important to know whether imprinting is a possible mode of disease inheritance before performing linkage analyses. In this paper, we describe a simple covariate-coding scheme to test for the presence of parent-of-origin effects and provide a formula for calculating parent-specific penetrance values prior to any linkage analysis. Our coding scheme was successful in detecting parent-of-origin effects and in leading to more accurately estimated penetrance values. The use of accurate penetrance values in a linkage analysis that allows for imprinting can provide higher power in the case of a disease locus that is imprinted.

Analysis of the dopamine hypothesis in schizophrenia reveals significant main effects and interactions between the dopamine transporter and dopamine D3 receptor genes. *M.E. Talkowski, K. Chowdari, H. Mansour, J. Wood, B. Shirts, B. Devlin, V.L. Nimgaonkar* Departments of Human Genetics and Psychiatry, University of Pittsburgh Graduate School of Public Health and School of Medicine.

We investigated the genetic basis for the dopamine (DA) hypothesis of schizophrenia (SZ) in a two-stage design using the intersection of functional biology and SZ linkage to prioritize our analyses. We first analyzed functional DA genes using database SNPs. We then conducted comprehensive tag SNP analyses of associated genes and genes localized to linked regions based on a published meta-analysis of SZ linkage.

In phase I, 18 DA genes were evaluated among 150 SZ trios and 280 controls. Two genes met suggestive criteria for associations after corrections for multiple testing ($p<0.0028$; *SLC6A3* (DAT) and *DRD3*). Phase II involved follow-up analyses in an enlarged case sample (n=478) and new control sample (n=500). We included the four DA genes localized to linked regions (*COMT, DRD2, VMAT1*, *NR4A2*), as well as *SLC6A3* and *DRD3*. Tag SNPs ($r^2>0.8$ between loci) were derived using HapMap data alone (*DRD2, NR4A2, VMAT1, SLC6A3*; 148 total SNPs/58 tags) or in combination with novel SNPs detected by sequencing known functional regions (*COMT*; 58 SNPs/20 tags). At *DRD3*, we sequenced the entire gene to identify all common variation and determine LD patterns (69 total SNPs detected, 15 novel SNPs, 20 tags). A genomic control panel was also evaluated.

Phase II results continued to implicate *SLC6A3* and *DRD3* ($p<0.05$: 6 SNPs and 5 SNPs associated, respectively). The associations could not be attributed to population substructure and were detectable using different analytic designs. Post-hoc logistic regression with 6 SNPs at these two genes detected significant interactions between two locus pairs ($p<0.05$). A previously reported interaction between COMT polymorphisms and gender in both SZ and Alzheimer's disease was significantly replicated in this cohort (rs737865; $p<0.01$ in females). These analyses represent a novel evaluation of dopaminergic genes in SZ genesis. .

Simultaneous Preimplantation Genetic Diagnosis (PGD)for Tay Sachs and Gaucher Disease. *P. Renbaum[1], B. Brooks[2], E.J. Margalioth[2], T. Eldar-Geva[2], M. Patt[1], Y. Kaplan[1], E. Levy-Lahad[1], G. Altarescu[1]* 1) Zohar PGD Lab, Genetic Unit, Shaare Zedek Medical Center, Jerusalem, Israel; 2) IVF Unit, Shaare Zedek Medical Center.

PGD for single gene defects is presented for a family in which each parent is a carrier of both Tay Sachs (TS) and Gaucher disease (GD). This childless couple were both compound heterozygotes for the GD-GBA and TS-HEXA genes (N370S/ IVS2+1G>A and IVS12+1G>C/ Gly269Ser respectively). We developed a multiplex fluorescent PCR protocol simultaneously amplifying all four familial mutations and 10 (2 sets of 5) closely spaced, highly polymorphic informative microsatellite markers surrounding these genes, to be used in polar body or blastomere based PGD. In one cycle of PGD, blastomeres from 7 embryos were analyzed for both diseases using the 10 informative markers (while mutation analysis was informative for polar body analysis, due to possible allele drop out none of the mutations were fully informative in blastomere analysis). Amplification was observed in all 7 blastomeres, and a conclusive diagnosis for both TS and GD was reached in 6/7 embryos, based on a minimum of 4 markers encompassing each gene. We observed ADO in 3 of 34 reactions (8% ADO rate). Of the 6 diagnosed embryos, one was wild type for both TS and GD, while another three were wild type for GD and carriers of TS. The two remaining embryos were compound heterozygotes for TS. While both of these embryos were wild type for GD, one showed recombination in the GD-linked markers. Only 2 of the 4 transferable embryos developed into blastocysts (wt/wt and wt/TS car) and both were transferred on day 5. This single cycle of PGD resulted in an ongoing singleton pregnancy. The occurrence of allele drop-out in single cell analysis and undetected recombination events (when mutation testing is either unavailable or non-informative) are primary causes of misdiagnosis in PGD. These obstacles emphasize the necessity of using multiple polymorphic markers flanking both sides of the gene/mutation in order to prevent misdiagnosis. To our knowledge this is the first report of concomitant PGD for two frequent Ashkenazi Jewish recessive disorders.

LOC387715 is associated with increased risk of neovascular age-related macular degeneration in the Utah population. *Z. Yang[1, 2], Z. Tong[1], Y. Zhao[1], A. Praggastis[1], E. Brinton[1], J. Baird[1], Y. Chen[1], D.J. Cameron[1], E. Pearson[1], P.S. Bernstein[1], G. Brinton[3], C. Wang[1], K. Howes[1], N.J. Camp[4], K. Zhang[1]* 1) Ophthalmology Research, EIHG, Salt Lake City, UT; 2) Sichuan Medical Science Academy & Sichuan Provincial Peoples Hospital, Sichuan 610071, Peoples Republic of China; 3) Retina Associates of Utah, Salt Lake City, Utah 84103; 4) Division of Genetic Epidemiology, Department of Biomedical Informatics, University of Utah School of Medicine, Salt Lake City, UT 84108.

Purpose Age-related macular degeneration (AMD) is the most common cause of irreversible vision loss in the developed world. Recently, it has been proposed that a second locus at 10q26.13 increases the risk for AMD. The precise gene involved at this locus has not been determined. The purpose of this study is to confirm the association at 10q26, determine the principal variant which explains this association, and to determine its contribution to wet AMD risk. Additional we examined the risk at 10q26 in the context of risk attributed by CFH at 1q31.3. Methods We genotyped 260 Utah patients with wet AMD, and 297 age and ethenity matched control subjects. Three single nucleotide polymorphism (SNPs) at 10q26.13, LOC387715 rs10490924, PLEKHA1 rs2421016, and PLEKHA1 rs4146894, in addition to CFH Y402H were genotyped and analyzed. Results We showed that the A69S (rs 10490924) in LOC387715 was significantly associated with wet AMD. In addition we showed that the association for LOC388715 rs10490924 was the principal variant for 10q26.13, and that it drives the secondary associations found for PLEKHA1 rs2421016 and PLEKHA1 rs4146894. Association analyses for genotype at LOC388715 rs10490924 conditional on genotype at CFH Y402H also demonstrated significant association indicating its independence effect from that of CFH. We showed that the interaction term was non-significant and that the risk of wet AMD at LOC387715 was independent and additive with CFHY402H. Conclusions Our results confirm the findings of Rivera et al (2005) suggesting that LOC387715 as the second major susceptibility locus for wet AMD. Together with CFH, they represent a major risk for AMD.

Beneficial effects of oral miglustat on skeletal symptoms in Type 1 Gaucher disease: meta-analysis of a 2-year clinical trial follow-up. *G.M. Pastores[1], D. Elstein[2], M. Hrebicek[3], A. Zimran[2]* 1) Department of Neurology and Paediatrics, New York University School of Medicine, New York, USA; 2) Gaucher Clinic, Department of Medicine, Medical Centre, Jerusalem, Israel; 3) Institute of IMD, Prague, Czech Republic.

Bone disease has a substantial impact in patients with Type I Gaucher disease (GD1). The aim of this study was to assess the effectiveness of oral miglustat (Zavesca) on skeletal complications in GD1 over two years. Prevalence and incidence of bone pain (BP), bone crises (BC), pathologic fractures, and avascular necroses (AVN) were assessed. Bone mineral density (BMD) measurements were performed at the lumbar spine and/or hip at 6 months, then annually. 72 patients (49% females) were included in the study. Mean age SD was 41.213.2 years. Mean miglustat exposure SD was 20.53.6 months. 57% of patients had been previously treated with enzyme replacement therapy (ERT) for a mean duration SD of 6424 months. At baseline 63% of patients had BP and 15% had a recent history of BC. AVN had occurred in 12.5% of patients. 68% of patients were classified as osteoporotic and 7% were receiving bisphosphonates. Among those who had BP at baseline, only 14.6% and 7.3% had new BP in the first and second years after treatment with miglustat, respectively. There were no differences in the incidence of new BP between treatment-naive and former ERT-treated patients. Amongst patients without BP at baseline, 8.3% developed new BP in the first year and none in the second year. No cases of BC, AVN and pathologic fractures occurred over the 2-year follow-up period. Spine and hip BMD measurements in patients (excluding those taking bisphosphonates) revealed increased BMD. Amongst naive patients, spine and hip BMD increased in 29% and 43% of patients at 6 months, and in 77% and 73% at 24 months. In former ERT users, spine and hip BMD increased in 48% and 83% of patients at 6 months and in all patients at 24 months. This study demonstrates that miglustat treatment is associated with early improvement in bone manifestations and increased bone density in GD1 patients.

***CYP2D6* worldwide genetic variation shows high frequency of altered activity variants and no continental structure.** *J. Sistonen[1], A. Sajantila[1], O. Lao[2], J. Corander[3], G. Barbujani[4], S. Fuselli[1,4]* 1) Department of Forensic Medicine, University of Helsinki, Helsinki, Finland; 2) Department of Forensic Molecular Biology, Erasmus University Medical Center, Rotterdam, The Netherlands; 3) Department of Mathematics and Statistics, University of Helsinki, Helsinki, Finland; 4) Department of Biology, University of Ferrara, Ferrara, Italy.

CYP2D6, a member of the cytochrome P450 superfamily, is responsible for the metabolism of about 25% of the commonly prescribed drugs. Its activity ranges from complete deficiency to excessive activity, potentially causing toxicity of medication or therapeutic failure with recommended drug dosages. Here we report on global variation at the *CYP2D6* locus, on the basis of 52 worldwide-distributed populations, typed at 12 highly informative variable sites, as well as for gene deletion and duplications. Phenotypes were predicted on the basis of haplotype combinations. Our study shows that (1) *CYP2D6* diversity is far greater within than between populations and groups thereof, (2) null or low-activity variants occur at high frequencies in various areas of the world, (3) linkage disequilibrium is lowest in Africa and highest in the Americas. Patterns of variation, within and among populations, are similar to those observed for other autosomal markers (e.g. microsatellites and protein polymorphisms), suggesting that the diversity observed at the *CYP2D6* locus reflects the same factors affecting variation at random genome markers.

Oral miglustat in Niemann-Pick type C (NPC) disease: a 1-year interim analysis. *M.C. Patterson[1], D. Vecchio[1], H. Prady[2], L. Abel[3], N. Ait Aissa[4], J.E. Wraith[2]* 1) Departments of Neurology and Paediatrics, Columbia University, New York, USA; 2) Royal Manchester Children's Hospital, Biochemical Genetic Unit, Manchester, UK; 3) Department of Optometry and Vision Sciences, University of Melbourne, Melbourne, Australia; 4) Actelion Pharmaceuticals Ltd., Allschwil, Switzerland.

NPC is an inherited neurodegenerative disorder characterised by an intracellular lipid-trafficking defect with secondary pathological storage of glycosphingolipids (GSLs). Oral miglustat (Zavesca) reversibly inhibits glucosylceramide synthase, which catalyses the first committed step of GSL synthesis. Due to its physicochemical properties, miglustat is able to cross the blood-brain barrier. Adult and juvenile NPC patients (n=29, age12 yrs) were randomised to receive miglustat, 200 mg t.i.d. (n=20) or standard care (n=9). Patients were then treated with miglustat for an additional year. Twelve paediatric patients (age<12 years) were included in a separate substudy: all received miglustat at a dosage adjusted for body surface area. Changes in horizontal saccadic eye movement was the primary study endpoint, based on the correlation between the severity of supranuclear gaze palsy and NPC disease progression. At baseline, nearly all individuals suffered from cognitive impairment, as shown through extensive cognitive measurements including mini-mental state examination (MMSE) scores. At 1 year, saccadic velocity improved in treated adult-juvenile patients vs. controls; results were statistically significant when patients taking benzodiazepines (a known confounder) were excluded (p=0.03). Improvements in swallowing capacity, auditory acuity and MMSE scores were also observed. A beneficial effect on horizontal saccades was also shown at 1 year in the paediatric cohort. The safety profile of miglustat was consistent with previous trials in Type I Gaucher disease, where half the dose was used. In conclusion, these findings suggest that miglustat may induce some degree of restoration of neuronal function after 1 year of treatment. These preliminary data suggest that miglustat may represent a major advance in the clinical management of NPC disease.

The first association study between G72/G30 and unipolar depression in a large sample of patients and controls of German descent. *T.G. Schulze[1], A. Georgi[1], F. Schirmbeck[1], A. Karpushova[2], S. Hoefels[3], R. Abou Jamra[4], J. Schumacher[4], W. Maier[3], L. Beckmann[5], P. Propping[4], M.M. Nöthen[2], S. Cichon[2], F. Henn[6], M. Rietschel[1]* 1) Division of Genetic Epidemiology in Psychiatry, Central Institute of Mental Health, Mannheim, Germany; 2) Dpt. of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 3) Dept. of Psychiatry, University of Bonn, Bonn, Germany; 4) Institute of Human Genetics, University of Bonn, Bonn, Germany; 5) Division of Genetic Epidemiology, German Cancer Research Center (DKFZ), Heidelberg; 6) Dpt. of Psychiatry and Psychotherapy, Central Institute of Mental Health, Mannheim, Germany.

G72/G30 is considered a strong susceptibility gene for both schizophrenia (SZ) and bipolar disorder (BD). We recently reported association between identical G72/G30-haplotypes and SZ, BD and panic disorder (PD). An association study on major depression has not yet been conducted. We studied a German sample of 500 MD patients and 1030 population-based controls. We were interested whether our previously identified risk haplotype of markers M22, M23, and M24 was also associated with MD. To further explore any relationship between G72/G30 and MD, we genotyped 9 additional SNPs highlighted in other studies. The haplotype C-C-T was significantly more frequent in MD patients than in controls (40.5 % vs. 36.1 %; p=0.027; OR=1.2). The exploratory analysis on 9 further G72/G30 SNPs of interests yielded significant associations for M12 (p=0.038), M14 (p=0.046), while M15 (p=0.090) and rs1935062 (p=0.055) did not reach significance. Permutation analysis adjusting for the 9 SNPs yielded a global p=0.176 This is the largest case-control study on G72/G30 and MD to date. We found an association between MD and the same risk haplotype that we previously found associated with SZ, BD, or PD. We also found suggestive associations with other variants. Given that depressive symptoms are present across these diagnostic groups, G72/G30 might predispose to core symptoms prevalent in all four disorders. Further studies will be needed to elucidate these core symptoms.

Heritability of carotid intima-media thickness: A twin study. *J. Zhao[1], F. Cheea[1], J. Bremner[1], J. Goldberg[2], S. Su[1], H. Snieder[3], C. Maisano[1], L. Jones[1], N. Murrah[1], V. Vaccarino[1]* 1) Dept. of Medicine,Emory University, Atlanta, GA; 2) VETR, Seattle, WA; 3) Georgia Prevention Institute, August, GA.

Carotid intima-media thickness (IMT) is widely used as a surrogate marker for atherosclerosis. Several studies reported the heritability estimates of carotid IMT using family studies, however, these estimates may be biased due to confounding factors in unmatched samples. The twin study design totally eliminates these confounding effects due to the exact match for demographic and early environmental influences (if the twins are raised together), thus is ideal for heritability estimation. In this study, we report the results of heritability estimation of carotid IMT using 98 middle-aged male twin pairs (55 monozygotic [MZ] and 43 dizygotic [DZ]) from the Vietnam Era Twin Registry. All twins were free of overt cardiovascular disease. Carotid IMT was measured by ultrasound. Bivariate and multivariate analyses were used to determine the association of traditional cardiovascular risk factors with carotid IMT. Intraclass correlation coefficients and structural equation modeling were used to determine the relative contributions of genes and environment to the variation in carotid IMT. We found that age, systolic blood pressure (SBP), diastolic blood pressure (DBP) and high-density lipoprotein (HDL) were strongly associated with carotid IMT in bivariate analysis. In multivariable analysis, age, SBP and HDL were significantly associated with carotid IMT. The intraclass correlation coefficients for carotid IMT were 0.66 (95% CI, 0.62-0.69) in MZ and 0.37 (95% CI, 0.29-0.44) in DZ twins, suggesting a genetic influence. After adjusting for traditional cardiovascular risk factors, the heritability of carotid IMT was 0.66 (95% CI, 0.48-0.78). This classic twin study demonstrates that genetic factors account for a significant proportion of variation in carotid IMT.

Alcohol dependence is associated with the *ZNF699* gene, a human locus related to *Drosophila hangover*, in the Irish Affected Sib Pair Study of Alcohol Dependence (IASPSAD) sample. *B. Riley[1,2], G. Kalsi[1], P.-H. Kuo[1], V. Vladimirov[1], D.L. Thiselton[1], J. Vittum[1], B. Wormley[1], M.S. Grotewiel[2], D.G. Patterson[3], P.F. Sullivan[4], E.J. van den Oord[1], D. Walsh[5], K.S. Kendler[1,2], C.A. Prescott[6]* 1) Dept. of Psychiatry, Virginia Commonwealth University, Richmond, VA; 2) Dept. of Human Genetics, Virginia Commonwealth University, Richmond, VA; 3) Shaftesbury Square Hospital, Belfast, Northern Ireland; 4) Dept. of Genetics, University of North Carolina, Chapel Hill, NC; 5) Health Research Board, Dublin, Ireland; 6) Dept. of Psychology, University of Southern California, Los Angeles, CA.

Because tolerance is an important aspect of alcohol dependence (AD) in humans, recent evidence showing that the *Drosophila* gene *hangover* is critically involved in the development of alcohol tolerance in the fly suggests that variation in related human loci might be important in the etiology of alcohol-related disorders. The orthology of hangover in mammals is complex, but a number of human gene products (including ZNF699) with similar levels of amino acid identity (18-26%) and similarity (30-37%), are consistently identified as the best matches with the translated hangover sequence. We tested for association between the dichotomous clinical phenotype of alcohol dependence and seven single nucleotide polymorphisms (SNPs) in *ZNF699* in our sample of 565 genetically independent cases and 496 siblings diagnosed with AD, and 609 controls. In analyses of genetically independent cases and controls, four of the seven single markers show strong evidence for association with AD (Fishers exact p=0.00003-0.001), and the most significant single marker, rs7254880, tags an associated haplotype with frequency 0.071 in cases compared to 0.034 in controls (chi-square 15.563, p<0.00008, 5000 permutation p<0.001, OR 2.17); inclusion of affected siblings gives similar results. Expression analyses conducted in independent postmortem brain samples show that expression of *ZNF699* mRNA is significantly reduced in the dorsolateral prefrontal cortex of individuals carrying this haplotype compared with other observed haplotype combinations.

Genotype-phenotype correlation for age of onset in patients with nephrotic syndrome and *NPHS2* mutations.

C.N. Vlangos[1], B.G. Hinkes[1], B. Mucha[1], R.A. Gbadegesin[1], F. Ozaltin[2], A. Bakkaloglu[2], J.H. Liu[1], K. Hasselbacher[1], F. Hildebrandt[1,3] 1) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 2) Department of Pediatrics, Hacettepe University, Ankara, Turkey; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Nephrotic syndrome (NS) is defined by proteinuria, edema, hypoalbuminemia, and hyperlipidemia which can progress to end-stage renal failure. Genetic causes for pediatric cases of NS have been elucidated and include autosomal recessive mutations in *NPHS1* (nephrin), *NPHS2* (podocin), and *LAMB2*; as well as autosomal dominant mutations in the *WT1* gene. Approximately 28% of NS cases are caused by mutations in *NPHS2*. Standard treatment for NS includes administration of steroids. We have previously described that patients with mutations in *NPHS2* exhibit steroid resistant nephrotic syndrome (SRNS)(1). In order to study a possible genotype-phenotype correlation for age of onset in SRNS we examined a worldwide cohort of 433 children with SRNS for *NPHS2* mutations. The *NPHS2* mutations were grouped into 4 classes: A) 2 mutations, at least one of which is truncating (stop codon, frame shift, or obligatory splice site); B) homozygous R138Q mutation (founder mutation); C) 2 missense mutations, and D) single heterozygous mutations only. Within this group we confirmed a total of 112 out of 433 (26%) individuals had mutations in *NPHS2*. We found that the 4 groups ranked as follows in increasing age of onset: A, 1.0 yr; B, 1.7 yrs; C, 4.2 yrs; D, 7.2 yrs. Age of onset (overt nephrosis or significant proteinuria) was significantly different between all groups of mutations, with the exception of groups A) vs. B). These data confirm the previously described strong pathogenic role of R138Q mutations. Additionally, truncating mutations of *NPHS2* also lead to early onset of SRNS. We demonstrate a statistically significant genotype-phenotype correlation regarding age of onset in children with SRNS due to different *NPHS2* mutations.

Increased nuchal translucency necessitates full chromosome analysis. *M.H. Quigg, A. Decker, A. Adeyinka, J. Roberson, B. Wolf* Dept Medical Genetics, Henry Ford Health System, Detroit, MI.

Increased nuchal translucency (NT) in the first trimester and increased fetal nuchal fold measurement in the second trimester of pregnancy are associated with fetal chromosome abnormalities. Measurement of these parameters has been incorporated into screening for Down syndrome, trisomy 13 and 18, and sex chromosome abnormalities. There is growing sentiment that it is cost-effective to assess these pregnancies by performing only aneuploidy FISH analysis We report a fetus with increased NT that was found to have an unbalanced translocation that would not have been ascertained if only aneuploid FISH assessment was performed.

The mother is a 25-year-old female who had a fetus in a previous pregnancy with multiple fetal anomalies and IUGR.This fetus was found to have an unbalanced translocation, 46,XY,der(7)t(4;7)(q33;q34)pat producing a functional partial monosomy 7 and a partial trisomy 4. The father was a carrier of a balanced translocation, 46,XY,t(4;7)(q33;q34). This fetus expired shortly after birth.

In the current pregnancy, the mother had a CVS at 11 weeks gestation. NT was abnormal at 4.7 mm. Aneuploidy FISH analysis was normal. Chromosomal analysis found that the fetus had an unbalanced translocation, 46,XX,der(4)t(4;7)(q33;q34).ish der(4)t(4;7)(qter-,qter+)pat producing a partial monosomy 4 with partial trisomy 7. Fetal demise occurred two weeks after the CVS.

Unbalanced chromosomal translocations may be associated with increased NT. Although the risk for an unbalanced translocation was known in advance in this case, it is frequently not known until after prenatal diagnosis. Aneuploidy FISH analysis as the sole method of assessing pregnancies with increased NT would not have detected this abnormality. Caution should be given when informing a family about normal aneuploid FISH results in a pregnancy with increased NT.

SOD2 association with Alzheimers disease: False positive, or the result of non-monotonic genotypic risk? *H.W. Wiener[1], R.T. Perry[1], G. McGwin[1], L..E. Harrell[2], R.C.P. Go[1]* 1) Epidemiology, University of Alabama at Birmingham, Birmingham, AL; 2) Neurology, University of Alabama at Birmingham, Birmingham Alabama.

Lack of replication of association results in genetic studies is a widely recognized phenomenon. We propose a non-monotonic genetic model as one possible explanation for such results. When the genetic model has this form, we show that the results of association studies can vary with allele frequency at the affective locus, and even show diametrically opposed results for different allele frequencies. As a possible example of this type of genetic model, we present results from an association study of superoxide dismutase 2 (SOD2) with Alzheimers Disease (AD). The gene for this enzyme is located within a region on 6q where evidence of linkage to AD has been reported. We genotyped four SNPs in SOD2 in three different populations: probands and families of the NIMH AD Genetics Initiative, a sample of African American AD cases and age-matched controls, and a set of Caucasian controls from a study of age related macular degeneration. One SNP, which lies in intron 3 of SOD2, was significantly associated with onset of AD in all three samples. A conditional logistic regression analysis for development of AD versus genotypes at this locus showed significant excess risk for the heterozygotes. The allele that was transmitted in excess to individuals with AD in the NIMH dataset was protective against AD in both the African American case/control dataset and in the comparison of NIMH cases versus Caucasian controls Similar results were noted at the other genotyped loci. While the association results seen here could be explained by chance, the data is consistent with a non-monotonic disease model.

Improving Estimates of Linkage Maps by Combining Information over Studies. *W.C.L. Stewart* Department of Biostatistics, Center for Statistical Genetics, School of Public Health, University of Michigan, Ann Arbor, MI.

In parametric multipoint linkage analysis, map misspecification leads to a loss in power when linkage is present and can lead to an increase in type 1 error when linkage is not present (Daw et al. 2000 Genet Epidemiol **19**, 366-380). To improve the accuracy of existing maps, a meta-analysis of map estimates is an attractive approach. It has the potential to reduce sampling error by incorporating information from multiple studies, and since the sampled genotypes are not needed, it avoids the difficulties associated with the sharing of human-subjects data. Also, when data sets have study specific parameters and missing data, it can yield more accurate estimates than existing methods which analyze the pooled data.

I present an efficient estimator of the linkage map that combines map estimates from different studies using weights that vary inversely in proportion to the variance of each map estimate. I apply the proposed estimator to simulated marker data on nuclear families, three-generation families, and 239 families modelled after the large linkage study of Abkevich et al. (2003, Am J Hum Genet **73**, 1271-1281). I compare it to two estimators that analyze the pooled genotypic data directly: the maps estimated by the programs LM_MAP and CRIMAP.

The results indicate that when the constituent map estimates share a a common panel of markers, the proposed estimator and the maximum likelihood estimator have similar performance in terms of absolute bias and variance. Furthermore, in the presence of missing data, both estimators outperform CRIMAP. Also, the results demonstrate that the weights can be used to estimate accurately the variance of the proposed estimator. Remarkably, when the constituent map estimates do not share a common marker panel, the proposed estimator performs at least as well as CRIMAP.

Addiction molecular genetics: 639,401 SNP whole genome association reveals many "cell adhesion" gene variants. *G.R. Uhl, Q.R. Liu, T. Drgon, D. Walther, C. Johnson* Molecular Neurobiology, NIH IRP, NIDA, Baltimore, MD.

Addictions are substantially-heritable complex disorders. We now report whole genome association studies that identify 89 genes that are likely to contain variants that contribute to vulnerability to addictions. These studies follow validation of pooling methods for early acvess versions of affymetrix 100 and 500k arrays. These genes are identified since each contains clustered single nucleotide polymorphisms (SNPs) that display significant allele frequency differences between abusers and controls in each of two samples (n = 1460) studied with 639,401 autosomal SNP Affymetrix array sets and confirmatory SNPs from each of two other abuser/control samples (n = 450) studied using 100,000 SNP Afymetrix arrays. Primary data analyses use Monte Carlo simulations and secondary analyses use permuation and false discovery rate approaches. Each indicates that these results are very unlikely to be due to chance. The genes identified here are implicated in interesting functions. We focus on genes that contribute to "cell adhesion" processes that help to establish and maintain neuronal connections of special relevance to addiction's memory-like features. These genes are all expressed in the brain, with most displaying striking expression in hipposampus, cerebral cortex, and other memory-associated areas. Most of these genes display rich patterns of alternative splicing and alternative transcriptional start site variations and individual differences in these expression patterns in studies of cDNA prepared from postmortem brain samples. These observations support polygenic contributions of evolutionarily old allelic variants to human addictions to substances in several different chemical classes. They support the idea that the brains of indiduals at most risk for addiction are likely to differ from those at less risk.

Distant Relative Identical-By-Descent Mapping in Autism. *S. Strom* Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

Autism Spectrum Disorder (ASD) is a set of complex neurological disorders presenting with a range of deficits in social and language development and repetitive behaviors. ASD exhibits a complex inheritance pattern, and there are likely many genetic and environmental risk factors. While little is known of the molecular or genetic mechanisms underlying this disorder, twin concordance studies have strongly implicated heredity as a major risk factor.

Using an effected cousin pair strategy, analyzing high-density single nucleotide polymorphisms (SNPs) across the genome in related probands allows the determination of shared genomic regions. Relatives share large blocks of regions identical-by-descent (IBD), which can be readily identified with a dense marker set. Regions shared at a significantly increased rate in probands may be linked to the disease. This method potentially allows for the mapping of disease genes or risk alleles without the need for phase information. While observation of IBD between unrelated individuals is rare, observing an elevated rate of IBD sharing in these comparisons may identify regions of ancestral IBD.

Many groups are utilizing high-density marker sets to perform whole-genome association, which rely on trios. Distant relative IBD analysis provides a convenient and cost-effective alternative that produce similar results to whole-genome association while testing fewer individuals. Additionally, there may be specific genetic risk factors enriched in such families. Such factors would likely be either strong or common due to the influx of new genetic material via married-in parents. Importantly, this technique may demonstrate the potential for a novel usage of high-density SNP genotyping in identifying genomic regions of interest for complex traits and diseases.

The Genetic Basis of Lactase Persistence in Africa; Evidence for Convergent Adaptation Due to a Shared Cultural Trait in Europeans and Africans. *S.A. Tishkoff[1], F.A. Reed[1], A. Ranciaro[1,2], B.F. Voight[3], C.C. Babbitt[4], J.S. Silverman[4], K. Powell[1], J.B. Hirbo[1], H. Mortensen[1], M. Osman[5], M. Ibrahim[5], S.A. Omar[6], S. Bumpstead[7], J.K. Pritchard[3], G.A. Wray[4], P. Delouckas[7]* 1) Dept. of Biology, Univ of Maryland, College Park, MD; 2) Dept. of Biology, Univ of Ferrara, Ferrara, Italy; 3) Dept. of Human Genetics, Univ of Chicago, Chicago, Illinois, USA; 4) Dept. of Biology and Inst. for Genome Sciences & Policy, Duke Univ, Durham, NC 27708, USA; 5) Dept. of Mol. Biol., Inst. of Endemic Diseases, Univ of Khartoum, Khartoum, The Sudan; 6) KMRI,(CBRD) Nairobi, Kenya; 7) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, CB10 1SA, UK.

The ability to digest milk as adults (lactase persistence, LP) is a cis-regulated genetic trait. Although a mutation associated with LP was previously identified in Europeans, the genetic basis of LP in African populations remained unknown. We collected phenotype data from 470 individuals originating from 43 populations in Tanzania, Kenya, and the Sudan using a Lactose Tolerance Test (LTT). We have identified two novel SNPs located ~14 kbp upstream of the lactase gene (*LCT*) that are significantly associated with the LP trait; one common in Tanzanian and Kenyan pastoralist populations and the other common in the Beja from northern Sudan. Expression assays indicate that the Kenyan/Tanzanian LP-associated SNP enhances transcription from the *LCT* promoter *in vitro*. Genotyping of 122 SNPs across a 3 Mbp region in these populations demonstrated that these African LP-associated mutations exist on haplotype backgrounds that are distinct from the European LP-associated mutation and from each other. In addition, we observe haplotype homozyogisty extending > 1.8 Mbp on chromosomes with the LP-associated mutation most common in Kenya/Tanzania, consistent with an ongoing selective sweep over the past 12,000 years (time of origin of this mutation ranges from ~2000 - 12,000 ybp). These data indicate a striking example of convergent evolution due to strong selective pressure (selection coefficients range from .05 - .13) resulting from shared cultural traits (*e.g.* cattle domestication and adult milk consumption) in Europeans and Africans.

Changing neurocognitive outcomes in Hurler syndrome with advancements in therapy. *E. Shapiro, K. Bjoraker, P. Orchard, L. Charnas, C. Doyen, C. Whitley* Dept Pediatrics, Univ Minnesota, Minneapolis, MN.

Hematopoietic stem cell transplant (HSCT) halts decline in rate of cognitive growth in Hurler syndrome. Without treatment, cognitive development slows by age 2 with decline in developmental quotient (DQ), eventual loss of skills after age 3, and the mean age of death is 5 years. At the Univ. of Minnesota, the first bone marrow transplant (BMT) for Hurler syndrome was performed in 1983. Initially only HLA matched siblings were donors for BMT, then unrelated donors. New protocols decreased risk and improved mortality. In 1998, umbilical cord (UCB) started to be used with routine use in 2001. In 2004 combination of ERT and HSCT began. While mortality has improved, we explore the change in morbidity associated with advancement in therapies. Data for 49 children who are alive, engrafted and have 1 or 3 years of follow up data after HSCT are presented; 24 prior to 1997, 16 from 1995-2002, and 9 after 2002. Within this data set, 10 who had UCB were matched with 10 with BMT. Of children seen before 1997 median DQ was 85, receptive language (RL) was 73 and expressive language (EL) was 82 (normal 8515). Of the 18 children seen between 1997 and 2002, median DQ was 90 and RL and EL were both 85 with a correlation of 0.52 between DQ and HSCT date. One year post-HSCT, the median loss of DQ points was one standard deviation (15 points) for all HSCT types. Between one and three years after HSCT no change in developmental quotient and RL was seen, but improved EL was found in those transplanted more recently. No difference in outcome was found between UCB and BMT. We conclude that all children show a decline of one standard deviation over the 1st year post transplant and stability thereafter. DQs and language quotients of children seen more recently are more intact due to a variety of factors 1) children are being diagnosed slightly earlier and 2) they are physically healthier at baseline with better DQs and language (partly because of increased use of early intervention and therapies). No difference was found in outcome by source of cells. The challenge is to find methods to prevent the cognitive decline during the first year post transplant.

Age-at-Onset Anticipation in Intracranial Aneurysms: An Analysis of 103 Finnish Families. *S. Wills[1], H. Kuivaniemi[1,2], A. Ronkainen[3], K. Helin[3], M. Niemelä[4], J.E. Jääskeläinen[3], J. Hernesniemi[4], G. Tromp[1]* 1) Center for Molecular Medicine and Genetics, Wayne State University,School of Medicine, Detroit, MI; 2) Department of Surgery, Wayne State University,School of Medicine, Detroit, MI; 3) Department of Neurosurgery, University of Kuopio, Kuopio, Finland; 4) Department of Neurosurgery, University of Helsinki, Helsinki, Finland.

Age-at-onset (AO) anticipation (AOA) occurs when the AO of a disease decreases or disease severity increases with successive generations or both. The goal of the study was to determine if AOA exists for familial intracranial aneurysms (IA) in the Finnish families. Families with two or more members having verified diagnoses of spontaneous rupture of IA and vertical transmission were recruited from the Kuopio and Helsinki IA registries in Finland. Families having heritable disorders associated with IA were excluded. Birth year, AO of spontaneous rupture, and generation data were collected. Statistical analysis for AOA was performed using the method reported by Vieland and Huang (Am J Hum Genet. 1998; 62:1212-1227) with an implementation of their algorithm by Dr. Huang and R, an open-source statistical computing environment. The algorithm was run for 1000 iterations with change criterion of 0.000001. We identified 103 (24.4%), IA families with vertical transmission in this collection of 422 Finnish families, in which AO information was available. There were 224 individuals with spontaneous rupture of IA. The mean AO in the 224 individuals was 49.3 13.9 years which is the same as that of the overall Finnish estimates for AO in the population. We found strong evidence for AOA ($P < 4.2 \times 10\text{-}6$). Truncation has a profound effect on AO of disease between parent-child pairs; however, with an appropriate statistical test correcting for truncation, our results show the existence of anticipation in Finnish IA families. This is the largest collection to date reporting on AOA in familial IAs. Anticipation suggests trinucleotide repeats may be involved in the disease. Our findings also suggest that screening at a younger age may be necessary in cases with a family history.

In preeclampsia invasive cytotrophoblasts have a lower rate of hyperdiploidy. *J. Weier[1, 2], C. Ferlatte[1], C. Jung[3], Y. Zhou[3], V. Winn[3], H. Nguyen[1], H. Weier[2], R. Romero[4], K. Bianco[4], S. Fisher[1,3,5]* 1) Dept OB/GYN & Repro Sci, University of California, San Francisco (UCSF), CA; 2) Life Sciences Division, University of California, E.O. Lawrence Berkeley National Laboratory, Berkeley, CA; 3) Dept Cell and Tissue Biology, UCSF, CA; 4) Perinatology Research Branch, NICHD, Wayne State University/ Hutzel Hospital, Department of Obstetrics and Gynecology, Detroit, MI; 5) Dept Anatomy & Pharm Chem, UCSF, CA.

Preeclampsia is associated with defects in the (placental) cytotrophoblast (CTB) differentiation pathway that leads to uterine invasion. Anchoring villi and invasive CTBs from patients with preeclampsia show specific morphological alterations: endovascular invasion is consistently shallow, and fewer spiral arteries are modified. Using a molecular cytogenetic method [i.e., fluorescence in situ hybridization (FISH)], we found that in normal pregnancy more than 50% of invasive CTBs were hyperdiploid without evidence of endoreduplication (Weier et al., Dev. Biol. 279:420-432, 2005). These data suggest that hyperdiploidy is an important component of normal placentation, perhaps limiting the proliferative and invasive potential of CTBs. Here we tested the hypothesis that preeclampsia is associated with a shift in the normal hyperdiploid state of these cells. Accordingly, we used FISH and immuno¬staining to study the aneuploidy rates of CTBs in placental tissues obtained from patients with preeclampsia. The results showed lower overall rates of hyperdiploid CTBs as compared to normal control samples. Specifically, the average rate of hyperdiploid CTBs involving chromosomes X, Y and 16 in preeclampsia samples was not significantly different from that of normal controls [36.5% (PE) vs. 40.2% (control)]. However, scoring of chromosomes 13, 18 and 21 showed significantly fewer hyperdiploid cells [11.7% (PE) vs. 44.7% (control), $p < 0.01$]. In conclusion, the results of this study offer genetic evidence that corroborates an association between preeclampsia and incomplete CTB differentiation along the pathway that leads to uterine invasion. Furthermore, these data support the concept that abnormal CTB differentiation proceeds the onset of the clinical syndrome.

Sequence divergence between *Mus Spretus* and *Mus Musculus* across a 13Mb region on chromosome 12. *A.E. Toland[1,2,5], K.L. Cooper[1,5], A. Dworkin[1,3,5], N.P. Gladman[6], H.-Y. Cho[4,5], J.-H. Mao[7], A. Balmain[7]* 1) Molecular Virology, Immunology & Medical Genetics, Human Cancer Genetics; 2) OSU Comprehensive Cancer Center, Department of Internal Medicine; 3) Integrated Biological Science Graduate Program; 4) Molecular, Cellular, & Developmental Biology Program; 5) The Ohio State University, Columbus, OH; 6) Wittenberg University, Springfield, OH; 7) UCSF Comprehensive Cancer Center,University of California, San Francisco, CA.

Mus. spretus and *Mus. musculus* diverged from each other approximately 1-3 million years ago and are estimated to have an average of one single nucleotide polymorphism (SNP) every 50bp. In addition to a high degree of sequence diversity, *spretus* and *musculus* show a high degree of phenotypic variability and have been used for QTL mapping for cancer susceptibility and inflammation. Using 3 different *spretus* x *musculus* F1 backcrosses, we mapped 13 loci for skin cancer susceptibility. One locus on chromosome 12, *Skts5*, shows linkage for skin cancer susceptibility in all three crosses. To determine the degree of genetic diversity between *musculus* and *spretus* derived strains at *Skts5* and to identify potential candidate genes for cancer susceptibility, we sequenced all 51 named and unnamed genes mapping to the peak area of linkage in *Spret/EiJ* and *FVB/NJ*. Regions housing polymorphisms between the strains were sequenced in the other strains used for linkage analysis: *outbred spretus*, *SEG/PAS* and *NIH/Ola*. All 51 genes contained at least one polymorphism between *spretus* and *musculus*. The majority of changes were synonymous or located in 5 or 3UTRs. Of interest, we identified 69 amino acid substitutions in 25 genes. To determine the potential significance of the amino acid substitutions identified, protein alignments between *Mus. musculus* (*FVB/NJ*, *NIH/Ola*), *Mus. spretus* (*Spret/EiJ*, outbred *spretus*, and *SEG/PAS*), other mouse strains for which sequence was available, and a minimum of 8 additional species were completed. A few amino acids that differ between musculus and spretus at *Skts5* are highly conserved across taxa; these will be considered as candidate polymorphisms for cancer susceptibility.

Haplotype inference for absent-present genotype data for clustered genes using identified haplotypes and/or sub-haplotypes. *Y. Yoo[1], J. Tang[2], R.A. Kaslow[2,3], K. Zhang[1]* 1) Departments of Biostatistics; 2) Medicine; 3) Epidemiology, UAB, Birmingham, AL, 35294.

The majority of killer cell immunoglobin-like receptor (KIR) genes are detected as either present or absent using locus-specific genotyping technology. This detection scheme leaves missing data: whether a detected gene is present on one or both chromosomes remains unknown. Thus, the performance of methods for haplotype inference (e.g., PHASE) for KIR genes may be compromised. To accommodate this, we developed an EM-based method for haplotype inference by incorporating previously identified haplotypes and/or sub-haplotypes. Specifically, a set of reported haplotypes is used and then extended to resolve as many as possible samples using a greedy algorithm. Haplotype is then inferred on he basis of this extended set of haplotypes via the EM algorithm. We compared our method with HAPLORE and PHASE based on three measures: 1) SAD, the sum of absolute difference between the true and estimated haplotype frequencies; 2) IE, the portion of individuals whose estimated haplotypes are not correct, and 3) SE, the Hamming distance between the true and estimated haplotypes in an individual. Our method outperformed the two other techniques by all three measures when at least 60% of known haplotypes were incorporated and by SAD even when only 25% were known (Table). From these results, our method appears more useful than existing techniques in assigning haplotypes for genes detected only as present or absent.

Table - Comparison of three methods for haplotype inference for KIR genes designated present or absent

	EM Using 100% known haplotypes	EM Using 60% known haplotypes	EM Using 25% known haplotypes	HAPLORE	PHASE
SAD	0.11	0.13	0.18	0.31	0.86
IE	0.17	0.20	0.34	0.29	0.64
SE	0.02	0.03	0.13	0.03	0.09

.

Quantitative analysis using decreasing amounts of genomic DNA to assess the performance of the Agilent oligo comparative genome hybridization microarray system. *S. SONG, D. Ilsley* Genomics Division, Agilent Technologies Inc., Santa Clara, CA.

Comparative genomic hybridization (CGH) is a technique for studying chromosomal changes in cancer. As cancerous cells multiply, they can undergo dramatic chromosomal changes, including chromosome loss, duplication, and the translocation of DNA from one chromosome to another. Chromosome aberrations have previously been detected using optical imaging of whole chromosomes, a technique with limited sensitivity, resolution, quantification, and throughput. Efforts in recent years to use microarrays to overcome these limitations have been hampered by inadequate sensitivity, specificity and flexibility of the microarray systems. The Agilent oligonucleotide CGH microarray system overcomes several scientific hurdles that have impeded comparative genomic studies of cancer. This new system can reliably detect single copy deletions in chromosomes. The system includes a whole human genome microarray, genomic DNA Labeling kit for sample preparation, an optimized microarray processing protocol, and software for data analysis and visualization. In this study, we determined the sensitivity, accuracy and reproducibility of the new system. Using this assay, we find that the performance of the complete system was maintained over a range of input genomic DNA (non-amplified) from 5 ug down to 0.2 ug with the array signal to noise ratio higher than 70:1.

Mutation screening and phenotype analysis is 48 patients with a clinical diagnosis of CFC or Costello syndromes and no mutation in PTPN11 and HRAS. *A. Verloes[1], C. Nava[1], M. Gérard-Blanluet[1], C. Baumann[1], T. Niihori[2], Y. Narumi[2], Y. Aoki[2], Y. Matsubara[2], B. Arveiler[3], D. Lacombe[3], H. Cavé[1]* 1) Department of Genetics, AP-HP Robert Debre University Hospital, Paris, France; 2) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 3) Department of Genetics, CHU Pellegrin, Bordeaux, France.

CFC syndrome is a serious clinical condition clinically related with Noonan syndrome, which has been very recently linked to mutations in 4 genes from the RAS signalling pathway. We performed mutation analysis for KRAS, BRAF, MEK1, MEK2 in 19 patients with CFC syndrome referred to our lab for molecular screening of PTPN11, and a clinical diagnosis of CFC, and 16 patients from the french Costello family support group without HRAS mutations. We further incorporated in this presentation the 13 CFC patients initially analysed by Niihori & al, and already published in Nature Genetics, as their were a part of our French/Belgian Noonan-CFC pool. Direct bidirectional sequencing of KRAS (exons 1, 2, 3, 4a, 4b), BRAF (exons 6, 11, 12, 14, 15), MEK1 and MEK2 (exons 2, 3). We found a) 20 mutations in BRAF: 13/32 CFC patients (40,6%) and 7/16 Costello HRAS-neg patients (44%) - b) 2 mutations in KRAS 1/32 CFC (3%) and 1/16 (6%) Costello HRAS-neg. c) 6 MEK1 mutations : 2/32 CFC (6%) and 4 / 16 (25%) Costello HRAS; d) at least 2 MEK2 mutations : CFC : 2/13 (analysis still ongoing.) We will present the molecular and clinical data related to this series, and possible genotype/phenotype correlations. Although most patients have been sent by trained clinical geneticists, it clearly appears that distinction between CFC and Costello, and to a lesser extend between CFC and Noonan remains difficult, at least in younger children.

Physician Survey on Asthma Genotyping. *I.W. Yu[1], T. Stith[1], A. Ferreira-Gonzalez[2], L.B. Schwartz[3], A-M. Irani[4], B.L. Bukaveckas[1,2]* 1) School of Pharmacy; 2) Department of Pathology; 3) Division of Rheumatology, Allergy and Immunology, Department of Internal Medicine; 4) Division of Rheumatology, Allergy and Immunology, Department of Pediatrics at Virginia Commonwealth University, Richmond, VA.

Our aim was to test physician understanding of and perceived utility for a new lab assay described on a reference card. The test is for position 16 ArgGly in the 2 adrenoceptor gene (ADRB2). Asthmatics with the Arg/Arg genotype (20-25% of the population) have decreased lung function from long-term, regular use of 2 agonist bronchodilators. To aid clinicians we developed an ADBR2 test information card with steps to avoid future decreased lung function in asthmatics based on test results. **Methods**: We distributed a reference card and questionnaire to 81 physicians in the VCU Health System, Richmond, VA. There were five multiple choice comprehension questions as well as seven visual analog scale response questions. Scalar responses were converted to continuous variables prior to analysis, and are reported here as (mean standard deviation %). **Results**: 17 physicians returned surveys (21% response rate). More than 80% had correct answers for all comprehension questions. The physicians agreed (76, 18.9%) that the goal of the test was significant to asthmatics, and did not think the test without utility (77.6, 23.4%). Physicians were also in agreement with the benefit of the test for physicians and patients, (72.2, 22.2% and 78, 15.7% respectively). There was strong agreement that the test would result in better treatment for asthma patients (78.4, 16.4%), and that using the test was a straightforward process (81.6, 13.2%). Perhaps most telling is that almost 2/3 of the physicians plan to use the test (62.9, 26.7%). The results of the survey are limited and potentially biased by respondent self-selection. **Conclusion**: Our survey demonstrated that physicians understand and concur with the content and intent of the ADBR2 assay pocket reference card. The card was an aid to comprehension and acceptance of the ADBR2 test. Ms. Stith was supported by the VA-Nebraska Alliance during this project.

Universal detector assay for measuring DNA copy number changes. *A.R. Tobler, A.J. Broomer, R.T. Koehler, D.C. Merrill, K.J. Guegler, C. Chen* Molecular and Cell Biology R&D, Applied Biosystems, Foster City, CA.

Understanding the genetic basis of human phenotypic differences requires the study of an increasing variety of human genetic variations. Detection of single nucleotide polymorphisms (SNPs) has been at the center of efforts to characterize the genetic components of diseases and traits. However, emerging evidence suggests that intermediate and large-scale DNA copy number changes in a genome are prevalent and account for an important source of genetic variation between individuals. Several methods have been developed to measure DNA copy number changes. Most methods require the enzymatic manipulation of genomic DNA and the analysis of fluorescently labeled DNA fragments by either array hybridization or capillary electrophoresis. For the analysis of a small number of loci, conventional TaqManÒ assays can be designed as well. We report here a new assay called Universal Detector (UD) for accurately measuring copy number changes. The UD assay utilizes a 96-plex oligonucleotide ligation assay (OLA) followed by 48 duplex TaqManÒ assays for analyzing up to 96 genetic loci. Our results show accurate identification of duplicated sequences in samples with known chromosome duplications. We further tested DNA samples for copy number changes in drug metabolizing enzyme genes, and for a 1.5 MB duplication responsible for a neurodegenerative disease. Samples with gene duplications and deletions were identified. The UD assay can be completed in less than a day and is suitable for genetic studies requiring a low to medium sample throughput. UD is a powerful, new tool for accurately measuring DNA copy number changes.

Prevalence of 47,XXX, 47,XXY and 47,XYY in prenatal diagnosis. *M. Thangavelu, B. Huang* Genzyme Genetics, Orange, CA.

Trisomy for chromosomes 13, 18 and 21 and monosomy X are the chromosome abnormalities most frequently observed during prenatal diagnosis and are associated with an "adverse" phenotype in the fetus. Unlike these abnormalities, 47,XXX, 47,XXY and 47,XYY are not associated with advanced maternal age, abnormal maternal serum screen or ultrasound abnormalities. Because of the mild and variable phenotypes, they come with their own challenges of counseling for the clinical team and decision making for the patients. We attempted to estimate the prevalence of these sex chromosome anueploidies for groups of patients with different indications during prenatal diagnosis. A data base of 306,487 prenatal specimens was analyzed for the incidence of sex chromosome polysomies compared to trisomy for chromosomes 13, 18 and 21 and monosomy X for various clinical indications was estimated. The combined incidence of +13, +18, +21 and XO was 2% for advanced maternal age, 3% for abnormal maternal serum screen and 20.6% for abnormal ultrasound. The combined incidence for XXX, XXY and XYY was 0.1% for each of the groups, irrespective of clinical indication. Of the three aneuploidies, 47,XXY, a karyotype associated with infertility was the most frequent (46.7%), followed by 47,XXX (35.5%) and XYY (17.8%). Uniform prevalence of these sex chromosome aneuploidies in the different groups is not surprising, as these abnormalities are not associated with either maternal age (as a factor in their etiology) or anatomical abnormalities detectable on prenatal ultrasound evaluation.

Validation of a molecular technique (MLPA) for prenatal screening in amniotic fluid. *M.M. Weiss, L. Vijfhuizen, M.J.V. Hoffer, C. Ruivenkamp, E.M.J. Boon, N. denHollander, E. Bijlsma, E. Bakker, M.H. Breuning* Clinical Genetics, Leiden University Medical Center, Leiden, Zuid-Holland, Netherlands.

Diagnosis of chromosomal abnormalities on amniotic fluid samples by karyotyping or FISH is time consuming and labor intensive. It can be expected that a DNA-based technique will replace the FISH test and karyotyping in those prenatal cases where there strictly is no indication for karyotyping, for example, advanced maternal age with no structural abnormalities of the fetus. We are currently validating Multiplex Ligation dependent Probe Amplification (MLPA) for advanced maternal age in a national collaboration with the other cytogenetic laboratories in The Netherlands. Therefore, we performed a prospective study on 1296 amniotic fluid samples by analysing these both with MLPA and karyotyping. The commercially available kit (P095, MRC Holland, The Netherlands) contains eight probes for each of the chromosomes to be tested (13, 18, 21, X), as well as four probes on chromosome Y. There were 1133 conclusive MLPA tests. In 1113 test, results were concordant with those of karyotyping. The twenty disconcordant cases were all cases that could theoretically not be detected with this MLPA kit. Of these twenty cases only five were referred for advanced maternal age, the fifteen others were screened because of a high-risk based on ultrasound abnormalities, or serum screening and/or nuchal translucency measurement or because of a familial chromosomal translocation. After collecting follow-up data (from four cases), two healthy children were born, one pregnancy resulted in IUD, and one was considered a culture artefact after re-analysing a 2nd amniotic fluid by karyotyping. We correctly identified all 33 autosomal trisomy cases, and 11 sex chromosomal copy number aberrations (45,X; 47,XXX; 47,XXY; 47,XYY). In conclusion, in this study, for advanced maternal age, no chromosomal aberrations would have been missed by MLPA that would have consequence for the fetus. In a clinical setting, MLPA can be used for a rapid and reliable determination of common chromosomal aneuploidies in uncultured amniocytes for advanced maternal age.

Mutations of PRSS1 and SPINK1 Genes in Korean Patients with Idiopathic Recurrent or Familial Pancreatitis.

H-W. Yoo[1, 2, 3], J.M. Ko[3], S.K. Lee[4], M-H. Kim[4], G-H. Kim[1, 2] 1) Medical Genetic Clinic & Lab; 2) Genome Res Center for Birth Defects & Genetic Disorders; 3) Dept Pediatrics; 4) Dept Internal Medicine, Asan Medican Center, University of Ulsan College of Medicine, Seoul, Korea.

BACKGROUND: Hereditary pancreatitis (HP) is a rare inherited disorder, characterized by recurrent episodes of pancreatitis often beginning in early childhood. It has been found that mutations of cationic trypsinogen gene (PRSS1) and serine protease inhibitor, Kazal type 1 gene (SPINK1) increase the susceptibility of chronic pancreatitis (CP) and pancreatic cancer. We investigated the genotype of PRSS1 and SPINK1 genes and clinical characteristics in idiopathic recurrent or familial pancreatitis with PRSS1 or SPINK1 mutations in Korea. METHODS: Clinical data was obtained from 19 patients with a family history (2 or more family members) of pancreatitis or with early-onset (40 years of age or younger) idiopathic recurrent acute pancreatitis (AP) or CP. Entire coding regions with intron-exon boundaries of the PRSS1 gene and SPINK1 gene were sequenced by PCR-direct DNA sequencing RESUTLS: Six patients were heterozygote for PRSS1 (p.R122H: 5, p.D20G: 1, p.G208A: 1) mutations and 4 of them had a family history of early-onset pancreatitis. Mutations in SPINK1 (c.194+2T>C: 5, p.N34S: 1) were identified in 6 patients, and 2 of them had a family history of early-onset pancreatitis. The median age at diagnosis in patients with PRSS1 mutation was 10 years of age, 26 years with SPINK1 mutation, and 29 years in mutation negative patients. Mean peak serum amylase and lipase level, the male to female ratios and the frequency of complications of the patients with mutations were not significantly different compared with the patients without mutations. Median age at diagnosis of pancreatitis is younger (P=0.04) and pancreatic duct stones are more frequently observed in mutation positive patients. CONCLUSIONS: PRSS1 and SPINK1 mutations are related to the development of idiopathic recurrent or familial pancreatitis in Korea. HP caused by PRSS1 or SPINK1 mutations is considered as an etiology of early-onset idiopathic recurrent AP or CP, especially when a family history is present.

Evolution of the Y chromosome *AZFc* region in the great ape lineage. *P. Yen[1], Y.-H. Yu[1], Y.-W. Lin[1], W. Schempp[2]*
1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Institute of Human Genetics and Anthropology, University of Freiburg, Germany.

The *AZFc* region on the long arm of the human Y chromosome is one of the least stable regions in the human genome. It consists of several very long repeats (amplicons) and is prone to rearrangement. Numerous *AZFc* architectures have been identified, and deletion of the entire *AZFc* region is present in about 10% of azoospermic men and is a major genetic cause of male infertility. Within the *AZFc* region are four *DAZ* genes that encode RNA-binding proteins with one, two, or three RNA-binding motifs (RBMs) and 8-24 copies of the DAZ repeat. *DAZ* orthologs are present only on the Y chromosomes of Old-World monkeys, great apes and humans, whereas its two autosomal paralogues, *BOULE* and *DAZL*, are found in all vertebrates. It has been proposed that the Y-linked *DAZ* genes arose from the autosomal *DAZL* gene by duplication and translocation. We used Southern analyses to study the evolution of the *AZFc* region in the great ape lineage. We found that Bonobos (*Pan paniscus*), chimpanzees (*Pan troglodytes*) and gorillas (*Gorilla gorilla*) have two *DAZ* genes encoding various copies of RBMs, whereas orangutans (*Pongo pygmaeus*) have at least 6 *DAZ* genes encoding a single RBM. The results suggest that the ancient Y chromosome of the great ape lineage had only two *DAZ* genes, and subsequent duplication of the *DAZ* gene pair occurred independently in the human and the orangutan branches to give rise to the present day structural spectrum of the *DAZ* genes. We also found that all great apes have the "red" and the "green" amplicons, but not the "gray" amplicon within their *AZFc* regions, indicating that the "gray" amplicon was translocated from an autosome to the human Y chromosome after the separation of the human and the chimpanzee lineages.

Acquired microcephaly: patterns, causes & effects. *A.S. Rigby[1], P. Baxter[2], M. Rotsaert[2], B. Steele[2], I. Wright[3]* 1) Academic Cardiology, University of Hull, Hull, UK; 2) Sheffeld Children's Hospital, Sheffield, UK; 3) Department of Psychology, University of Sheffield, UK.

Acquired microcephaly is a condition where a child's head circumference is within the normal range at birth but then does not increase as fast as normal and falls below the 2nd centile. There is a lack of literature on this acquired form of microcephaly. Retrospective study of 58 children (29 M) aged 0.7-11.3 years (median 4.5 years) referred over a 10 year-period. Measurements included neonatal discharge examinations and community measurements. Centile charts/growth data were based on a UK reference sample. Cause was judged from standard assessments including head size in the immediate family. Growth pattern was made by inspection of centile charts by 2 independent observers. 34 families agreed to further assessments including: IQ, BSID-II, WPPSI-R, WISC-III, literacy, numeracy, specific abilities and behaviour (WORD, WOND, NEPSY,CBCL). Causes were divided into following: idiopathic (n=8) - no specific cause; familial (n=15) - parent/sib had a head circumference below 2nd centile; syndromic (n=15) - with associated other anomalies; symptomatic (n=16)- following a pathologic event; other (n=4). In the familial group affected relatives were mainly mothers (n=12) and brothers (n=8). In the syndromic group 5 had recognised symptoms including Rett (n=2) and Angelman (n=1). In the symptomatic group causes included EBV infection, trauma and failure to thrive. Growth patterns could be classified into 4 types: type A (n=36) - initial fall below 2nd centile then parallel to the centiles; type B (n=12) - continued fall across all centiles; type C (n=5) - later recovery after falling below normal range; type D (n=10) - insufficient data to classify. More symptomatic cases had type B (6/12) than type A (9/26) but type B could occur in all causal groups. Idiopathic had mainly type A (6/8). Final Z-scores were strongly related to initial Z-scores ($p<0.001$). There was no correlation between IQ and final Z-scores. Parents can be advised that there are 4 main causal groups. Some of these may have genetic implications. There was poor correlation between causes and patterns.

5-aza Cytidine mediated CAG expansion in vitro. *Ravindra. Varma[1,2], K. Sreelatha[1], V. Sharmila[2], Sudharthi[2], Gita Sharma[2], Zacharia Mathew[2], Qurratulain Hasan[1]* 1) Department of Genetics, Kamineni Hospitals, Hyderabad, India; 2) Assay Development Unit, MAGENE Lifesciences, Hyderabad, India.

Spinocerebellar ataxias (SCAs) are a heterogeneous group of neurodegenerative disorders, inherited in an autosomal dominant manner. CAG repeat expansion in the causative genes has been identified as the basic cause of most types of SCAs. Studies from different groups have identified cis-elements, such as tract length, sequence purity and orientation relative to replication origins and trans-acting factors, such as DNA repair and replication proteins as agents that can critically affect the stability of repeats. Nevertheless, the mechanisms by which such agents collaborate to bring about intergenerational repeat instability remain unclear. AIM: The main aim of these experiments was to determine if exogenous agents play a role in modifying the somatic mutational dynamics of expanded CAG repeat sequences. We tested a genotoxic agent, 5-aza Cytidine that is known to have an effect on DNA. METHODS: Two stable cell lines with 17 CAG repeats (Q17) and 65 CAG repeats (Q65) were developed using HEK293 cell lines. Both the cell lines were grown in triplicates for 90 days in presence of 10uM 5-aza Cytidine. Control cultures were also maintained through out the experiments with no chemicals added. RESULTS: We identified that 5-aza Cytidine significantly enhanced the CAG repeat number in case of Q65 cells where as no change in repeat number was observed in Q17 cells treated with the same chemical. CONCLUSION: Although much progress had been made in understanding the molecular and cellular mechanisms that underlie diseases with CAG repeats, cause for their instability is unknown. Our results indicate that 5-aza Cytidine plays a role in triggering expansion at the CAG repeat size beyond a certain length. Methylation may be the critical mechanism in triggering expansion. The system we have developed offers the potential to investigate the role of other exogenous agents that mediates somatic expansions by interfering with specific aspects of DNA metabolism.

Mitotic recombination as evidence of alternative pathogenesis of gastrointestinal stromal tumors (GISTs) in neurofibromatosis type 1. *D.R. Stewart[1], C.L. Corless[2], B.P. Rubin[3], M.C. Heinrich[2], L.M. Messiaen[4], L.J. Kessler[5], P.J. Zhang[6], D.G. Brooks[7]* 1) NHGRI/NIH, Bethesda, MD; 2) OHSU, Portland, OR; 3) U. Washington Medical Center, Seattle, WA; 4) UAB, Birmingham, AL; 5) U. Pennsylvania, Dept. Medical Genetics, Phila, PA; 6) U. Pennsylvania, Dept of Pathology, Phila, PA; 7) Merck and Co, Whitehouse Station, PA.

Background: Neurofibromatosis type 1 (NF1) is a neurocutaneous disorder resulting in the growth of a variety of tumors and is inherited in an autosomal dominant pattern. Gastrointestinal stromal tumors (GISTs) are mesenchymal tumors that commonly harbor oncogenic mutations in KIT or PDGFRA and are thought to arise from the interstitial cells of Cajal (ICC; the pacemaker cells of the gut). We characterize two patients with NF1 and GISTs. Methods: Both patients were genotyped for germline mutations in NF1. GIST tumors from both patients were genotyped for somatic mutations in KIT and PDGFRA. Loss of heterozygosity (LOH) of NF1 in one GIST tumor was assessed by genotyping seven microsatellite markers spanning 2.39 Mb of the NF1 locus in the tumor and in genomic DNA. The known germline mutation in NF1 was confirmed in GIST tumor DNA by sequencing. The copy number of the mutated NF1 allele was determined by MLPA. Results: GIST tumors from both patients were wild-type for mutations in KIT and PDGFRA. In the one GIST tumor with adequate DNA, all seven markers were informative and showed a loss of heterozygosity (LOH) at the NF1 locus; sequencing of NF1 from that GIST showed no wild-type sequence, suggesting it was lost in the tumor. The MLPA analysis showed that two copies of all NF1 exons were present. Conclusions: This is the first evidence of mitotic recombination resulting in a reduction to homozygosity of a germline NF1 mutation in an NF1-associated GIST. The LOH of NF1 and lack of KIT and PDGFRA mutations are evidence of an alternative pathogenesis in NF1-associated GISTs. The significant clinical differences between sporadic and NF1-associated GISTs are compatible with the proposed alternative pathogenesis.

An Age-Related Macular Degeneration Susceptibility Locus on Chromosome 16p12. *K. Spencer[1], S. Schmidt[2], M.A. Hauser[2], W.K. Scott[2], L.M. Olson[1], P. Gallins[2], N. Schnetz-Boutaud[1], A. Agarwal[3], E.A. Postel[4], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Human Genetics and Department of Medicine, Duke University Medical Center, Durham, NC; 3) Vanderbilt Eye Institute, Vanderbilt University Medical Center, Nashville, TN; 4) Duke University Eye Center and Department of Ophthalmology, Duke University Medical Center, Durham, NC.

Age-related macular degeneration(AMD) is a complex disease caused by both genetic and environmental risk factors. As the disease progresses from the presence of large, soft drusen to geographic atrophy and/or choroidal neovascularization, legal blindness may result. The risk associated with the Y402H variant in the complement factor H gene on chromosome (chr) 1 and a variant in the LOC387715 gene on chr.10 have been well-documented. Consistent with the results of several genomic screens, we also have evidence of another AMD susceptibility locus that resides on chr.16p12. We genotyped 312 SNPs across chr. 16 in a dataset of 127 multiplex families as part of a genome-wide screen. In an independent dataset of 584 cases and 248 unrelated controls we genotyped a subset of 137 SNPs that are concentrated between 10-31 Mb to follow up on linkage results in this region. Our peak multipoint nonparametric LOD* score of 1.33 occurred at 22.8 Mb. Ordered Subset Analysis (OSA) considering smoking, the proportion of risk alleles in affecteds for Y402H or the rs10490924 variant in LOC387715 did not significantly change the LOD score. Using the association in the presence of linkage APL method in the family-based dataset and tests of allelic and genotypic association in the case-control dataset, a cluster of SNPs between 28 and 30 Mb were significant at <=0.01 level. Stratifying by Y402H or rs10490924 risk alleles did not have a large impact on the association results in the case-control dataset, consistent with the family-based OSA analysis. The association results in the independent case-control dataset confirm the linkage data and further localize the risk gene to a 2 Mb region.

Human genetic association study of 232 osteoarthritis candidate genes in patients with radiographically confirmed knee OA. *J. Richmond[1], L. Wood[1], K. Durham[2], S. Yocum[3], D. Aguiar[4], A. Seymour[1]* 1) Pharmacogenomics, Pfizer, Groton, CT; 2) Statistics, Pfizer, New London, CT; 3) Inflammation, Pfizer, Ann Arbor, MI; 4) Molecular Pharmacology, Pfizer, St Louis, MO.

Osteoarthritis (OA) is the most common form of arthritis with 1 in 3 people expected to have radiographic evidence of joint destruction by age 75. While the multifactorial nature of OA is well recognized, genetic factors comprise an essential component of the etiology of the disease. The genetic component of OA has been estimated via familial aggregation and twin studies with heritability ranging from 20 to 65%. A human genetic approach to identify associations between biologically relevant candidate genes and OA can provide early confidence in these genes as drug targets. Multiple genome wide linkage and candidate gene association studies have identified several loci contributing to the disease, confirming the complex heterogeneity of this disease.

We have extended genetic studies to also include RNA work to focus on particular candidate genes. 232 candidate genes, selected on the basis of differential RNA expression in cartilage tissue, were tested for genetic association in a large OA cohort. 422 subjects with clinical and radiographic knee OA and 437 age and gender matched controls were screened for 636 SNPs using a pooled approach on the Sequenom Mass Spectrometer. 104 SNPs representing 68 genes were selected from the pool based on a first pass allelic association of p0.05. These 104 SNPs were then genotyped across each subject individually to test for allelic and genotypic associations. The results of this study identified twelve putative candidate genes (NR1D1, SPARCL, LMOD1, PPAP2B, CXCR4, CLIC5, BMP6, PECAM1, RS6K2, SERPINE1, STK39, and HIST1H2A1) for follow-up evaluation based on a combination of gene expression and genetic association data. These results provide preliminary evidence of genetic association in a human knee OA population. However, as with any genetic association study, further validation in an independent population is warranted to better assess the role these genes play in disease risk.

Chediak Higashi syndrome: a genotype-phenotype correlation. *W. Westbroek[1], D. Adams[1], A. Koshoffer[2], H. Dorward[1], A. Helip-Wooley[1], M. Huizing[1], J. Parkes[1], R. Kleta[1], R. Boissy[2], W.A. Gahl[1]* 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Univeristy of Cincinatti College of Medicine, Cincinnati, OH.

Chediak Higashi syndrome (CHS) is a rare autosomal recessive disorder caused by mutations in the CHS1 gene. Clinical characteristics include skin, hair and eye hypomelanosis, recurrent infections, a mild bleeding diathesis and late-onset progressive neurological impairment. We report two unrelated patients, CHD4 and CHD6, with vastly different clinical presentations. CHD4 had severe symptoms in early childhood and carried two truncating CHS1 mutations; a nonsense (p.R514X)) and a frameshift mutation (p.F3298fsX3304). CHD6 had mild adult-onset neurological symptoms and carried a truncating frameshift (p.E805fsX) and a relatively milder missense mutation (p.N3376S) located in the BEACH domain of CHS1. Whole mount electron microscopy of normal and patients platelets revealed absence of dense bodies in most platelets of CHD4 and few dense bodies for CHD6. Laser scanning confocal microscopy and electron microscopy on cultured melanocytes showed that CHD4 had huge melanosomes restricted to the perinuclear area, while melanosomes in CHD6 were much smaller, with a normal dendritic distribution. Both CHD4 and CHD6 melanocytes showed some focal pigment deposits in melanosomes. Fibroblasts stained with the lysosomal markers LAMP1, LAMP2 and CD63 showed a perinuclear distribution of a few large lysosomes in CHD4 cells, while CHD6 fibroblasts contained slightly enlarged lysosomes in the perinuclear area, and slightly less than the normal contingent in the periphery. The relatively mild findings in CHD6 might be attributable to the CHS1 missense mutation, with residual CHS protein expression. These studies illustrate that genotype-phenotype correlations span the clinical, molecular and cell biological spectra. These two melanocyte cultures also allow for comparative investigations into the possible role of the CHS1 protein in intracellular organelle trafficking.

Severe cystic fibrosis with R117H/DF508 and 7T/9T polymorphism : difficulties in genetic counselling after newborn screening. *C. Thauvin-Robinet[1], S. Pérez-Martin[2], A. Masurel-Paulet[1], A. Contrain[1], I. Sermet-Gaudelus[3], F. Chevalier-Porst[4], L. Faivre[1], F. Huet[2]* 1) Ctr de Genetique, Hosp d'Enfants, Dijon, France; 2) Service de Pédiatrie 1, Hosp d'Enfants, Dijon, France; 3) Service de Pédiatrie, Hosp Necker-Enfants Malades, Paris, France; 4) Laboratoire de Biochimie Pédiatrique, Hosp Debrousse, Lyon, France.

Over 1000 CFTR mutations have been reported with cystic fibrosis, congenital bilateral absence of the vas deferens (CBAVD), chronic pancreatic insufficiency, rhinosinusitis and allergic broncho-pulmonary aspergillosis. The presence of the R117H/DF508 on a background of 5T is associated with borderline or elevated sweat test, mild to moderate lung disease, pancreatic exocrine sufficiency and CBAVD. The genotype of R117H/DF508 in association with 7T/9T is associated with a normal, borderline and rarely elevated sweat test with a broad phenotype ranging from no symptoms, CBAVD to mild lung disease. Here, we report on a 1-year-old female case with R117H/DF508 and 7T/9T identified in the newborn screening. Sweat test showed normal chloride concentrations (19 mEq/l and 30 mEq/l). Follow-up revealed recurrent respiratory infections since 1 month of life, with Staphylococcus aureus and Haemophilus influenzae, and chronic diarrhoea secondary to pancreatic exocrine insufficiency, leading to the diagnosis of severe cystic fibrosis. Significant growth failure (-2.5 SD) required gastrostomy for hypercaloric enteral nutrition. Nasal potential difference was characteristic of classical cystic fibrosis. The possibility of the presence of another rare severe mutation that could better explain the severity of the clinical phenotype was ruled out by direct sequencing of the overall CFTR gene. This observation presents the very rare association of severe cystic fibrosis with R117H/DF508 and 7T/9T genotype, showing to difficulties in genetic counselling after R117H/DF508 carrier detection by newborn screening. A survey of the phenotype of such patients is needed on a large series of patients.

Identification of Na/K ATPase 1 subunit as an interacting partner of WFS1. *M. Zatyka[1], C. Ricketts[1], J.A.L. Minton[1], S. Fenton[1], G. daSilvaXavier[2], S. Hofmann[3], C. McConville[1], G.A. Rutter[2], T.G. Barrett[1]* 1) Med & Molec Genetics, University of Birmingham, Birmingham, UK; 2) Dept of Biochemistry, University of Bristol, UK; 3) Istitut fur Diabetesforschung, Muenchen, Germany.

Wolfram syndrome is a monogenic disorder characterised by the juvenile onset of diabetes mellitus, progressive optic atrophy, sensorineural deafness, diabetes insipidus, and psychiatric illness. The product of the gene responsible for this disorder (WFS1 or Wolframin) localises to the Endoplasmic Reticulum (ER) membrane and is important in the regulation of calcium homeostasis and the ER stress response. To gain insight into WFS1 function we performed a yeast two hybrid assay to identify WFS1 interacting partners. Among interacting clones we identified the 1 subunit of sodium pump (Na/K ATPase). This interaction was confirmed in Cos7 cells using Myc-tagged WFS1 and HA-tagged 1, and subsequently confirmed endogenously in placental JEG3 cells, neuroblastoma cell lines and fibroblasts expressing different levels of WFS1. Mapping of interacting domains revealed that WFS1 interacts with the 1 subunit via its C-terminal domain and another interacting domain present in the transmembrane region, whereas the WFS1 N-terminal domain does not interact with the 1 subunit. Our mapping data suggests that this interaction probably takes place in the ER lumen. The sodium pump is inserted into the plasma membrane but undergoes maturation and assembly in the ER, with the 1 subunit acting as a chaperone for the proper membrane insertion of the subunit. Our findings are consistent with the proposed WFS1 involvement in protein folding and processing. Experiments are underway to establish the role of this interaction.

Towards delineating cell types in the mouse central nervous system: a genome-scale high resolution expression map of the adult mouse brain. *S. Sunkin, C. Dang, M. Hawrylycz, J. Hohmann, E. Lein, P. Wohnoutka, A. Jones* Allen Institute for Brain Science, Seattle, WA.

Several techniques to study large-scale gene expression (microarrays and serial analysis of gene expression) have been applied to large brain structures; however, these techniques lack spatial specificity in the resulting expression profile. A high-throughput colorimetric in situ hybridization platform has been developed to generate cellular resolution gene expression maps of the adult mouse brain. The goal of the Allen Brain Atlas (ABA) is to map the expression of ~20,000 genes in C57BL/6J. Currently, over half a million high resolution images of expression patterns for 18,500 genes are in the ABA database (www.brainatlas.org), which contains ~500 terabytes of data. To assist in the search, visualization, and analysis of expression patterns, informatics tools allow the user to query the database by anatomic structure in combination with expression coverage, intensity, and pattern. Approximately 80% of the genes assayed are expressed in the adult brain. While many of the expressed genes have widespread or non-restricted expression, only ~25% display regional and/or cell type specificity. Of these genes, it is rare to find highly localized expression or expression in only one structure. Another striking finding is that gene expression is heterogeneous in known anatomical regions, such as the hippocampus, suggesting further functional divisions within defined cytoarchitectural units. In the cortex, gene expression subdivides both the laminar and functional organization. Major cell types in each brain region can be defined by panels of genes. Overall, the expression patterns show a tremendous diversity of cell types. It has been estimated that there are ~1,000 cell types in the brain; however, few of these have been defined transcriptionally. The ABA database is a resource that will assist in more global approaches to redefine functional cellular neuroanatomy in the mouse central nervous system. In addition, this high-throughput in situ hybridization platform can be applied to investigate gene expression in various models of nervous system disease.

Left-Sided Cardiac Defects and Genetic Variants of the Folate-Homocysteine Metabolic Axis. *P.C. Paluru[1], M. Mei[3], W. Huang[1], J. Garbarini[1], L.E. Mitchell[3], E. Goldmuntz[1,2]* 1) Division of Cardiology, Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, School of Medicine, Philadelphia, PA; 3) Institute of Biosciences and Technology, Texas A&M University System Health Science Center, Houston, TX.

Congenital heart disease (CHD) is the most common major birth defect. Left-sided cardiac defects (LSCD) account for at least 10% of all CHD recognized at birth, and include valvar aortic stenosis, coarctation of aorta, and hypoplastic left heart syndrome. The etiology of LSCD is poorly understood but is likely to result from complex interactions between environmental and genetic factors. Several studies suggest that maternal periconceptional intake of folic acid decreases the risk of CHD, but relatively few studies have evaluated the contribution of common variants in genes in the folate-homocysteine metabolic axis to the etiologic risk of LSCD. We hypothesized that such variants would be associated with the risk of LSCD and that such variants could exert their effect through either the maternal or the embryonic genotype. Consequently, we performed family-based association studies to determine whether five common variants in four genes whose products participate in the folate-homocysteine methylation process are associated with the risk of LSCD. We genotyped 367 probands with LSCD and one or two parents for the C667T and A1298C variants of MTHFR (5,10-methylene tetrahydrofolate reductase), A2756G variant of MTR (methionine synthase), A66G variant of MTRR (methionine synthase reductase) and 844Ins68 variant of CBS (cystathionine -synthase). A log-linear approach was used to test for associations between LSCD and both the maternal and embryonic genotypes for each variant. Only one of these variants was found to be significantly associated with the LSCD. Specifically, the maternal MTR genotype was significantly associated with the risk of LSCD in offspring (uncorrected p-value = 0.01). This finding warrants further investigation in larger and independent samples. The association between LSCD and additional genetic variants of the folate-homocysteine metabolic axis is under further investigation.

A genealogical assessment of heritable predisposition to asthma mortality. *C.C. Teerlink, L.A. Cannon-Albright*
Dept Biomedical Informatics, University of Utah School of Medicine, Salt Lake City, UT.

Asthma is a multi-factorial disease; genetic factors are suggested but poorly defined. We have studied an extreme asthma phenotype (defined as death as a result of asthma) and describe the familiality of Utah asthma deaths observed. We examined evidence for a heritable component to asthma mortality using a unique data resource consisting of Utah death records (1904-present) linked to a Utah genealogy. Cases were defined as individuals with death records listing asthma as a cause of death (n = 1,436), who also had at least 3 generations of genealogy data. The genealogical index of familiality (GIF) statistic was used to compare the average relatedness of individuals dying from asthma to the expected relatedness in the population. Expected relatedness was estimated in 1000 sets of randomly selected, matched controls. We observed a significantly higher than expected average relatedness in individuals dying from asthma ($p < 0.001$). The excess relatedness had contributions from close relatives and from relatives as distant as second cousins. We also estimated the relative risk of asthma death in relatives of individuals dying from asthma. We observed a significantly increased risk of asthma death for first-degree relatives of cases (RR = 1.55, $p = 0.006$) and for second-degree relatives of cases (RR = 1.30, $p = 0.011$). These results suggest a heritable component to asthma mortality, in addition to an environmental component.

Comprehensive genetic study of an SRY-negative, XX male. *Y. Wang[1], J.E. Martinez[1], T.-L. Lee[2], R. Quimbo[3], C. Tuck-Muller[1], W.-Y. Chan[2], C. White[4], R. Del Fierro[5], W. Wertelecki[1], T.-J. Chen[1]* 1) Dept. Med. Genetics, University of South Alabama, Mobile, AL; 2) Laboratory of Clinical Genomics, NICHD, NIH; 3) Division of Pediatric Pathology, SUNY Downstate Med Center, NY; 4) Urology Associates of Mobile, Mobile, AL; 5) Mobile Diagnostic Center, Mobile, AL.

SRY is a well-known sex-determining factor but the pathway downstream from SRY remains largely mysterious. Several genes have been proposed for this function, including SOX9, SOX10, and DAX1. Comprehensive genetic analysis of the rare SRY-negative, XX male patients may yield clues to dissecting this pathway. The patient in this study is a 20 yr old WM who was born with hypospadias. Several surgical procedures were needed to repair this abnormality. Physical examination showed evidence of hypogonadism. The right testicle appeared small and the left had some degree of epididymal tenderness. A left testicular biopsy revealed malformed seminiferous tubule without spermatogenesis or germ cells. Ovarian-type stroma with a rare focus of luteinized stromal cells was also noted. No disproportions or dysmorphisms were noted. Chromosome analysis showed a 46, XX karyotype. A Y chromosome painting probe was used to detect the translocation of Y material to another chromosome. Fluorescent signals were only present on the distal Xp arms in pseudoautosomal regions, but not on other chromosomes. PCR analysis of SRY and AZF regions was negative from DNA samples isolated from blood and paraffin-embedded gonadal tissue. The combined results from FISH and PCR analysis confirmed the patient to be an SRY negative, XX male and ruled out gonadal mosaicism. X-chromosome inactivation studies on blood DNA showed a random inactivation pattern similar to normal female controls. No duplication was found on the 17q23-25 and 22q11-13 regions containing the SOX9 and SOX10 genes using STR markers. No mutation was detected in the entire coding region of DAX1 gene by direct sequencing. These results suggest that development of the male phenotype in this patient may result from defects in other as yet unknown genes in the sex-determining pathway. Further genetic analysis of the expression profiling is undergoing.

High-density QTL mapping for loci influencing gene expression patterns in entire biochemical pathways. *M.A. Zapala, J. Wessel, N.J. Schork* Polymorphism Research Laboratory, Department of Psychiatry, UCSD School of Medicine, La Jolla, CA.

Associating a set of SNPs to gene expression levels as phenotypes has been useful in identifying transcriptional regulatory networks. However, these studies suffer from two potential drawbacks. The first concerns the number of test statistics performed, since thousands of gene expression signals are being tested against thousands of SNP markers creating a potential for false-positive results. The second issue is that the biological meaning of a cis or trans association is difficult to discern. We have taken a multivariate approach to gene expression SNP associations in which the similarity/dissimilarity of the gene expression of a group of genes related to the same pathway are associated with the SNP markers. In this way, SNPs that perturb the expression of an entire pathway are identified. We have adapted and applied a novel analysis technique developed by us for use in other gene expression analysis contexts to whole genome association studies of pathway gene expression data. To showcase the method, we analyzed publicly-available gene expression data gathered on hematopoetic stems cells isolated from 22 recombinant inbred BXD mice on which 1093 unique SNPs from the Wellcome Trust CTC mouse strain SNP genotype set are available. Genes were grouped into KEGG pathways based on their Entrez ID. The pathway showing the lowest p-value ($p\text{-value} < 0.000001$) and largest proportion of variation explained (0.64) was the Complement and Coagulation Cascade. The association peak was located on Chromosome 13 at the Factor II receptors (*F2r* and *F2rl2*) locus, also known as the Thrombin receptors (PAR-1 and PAR-3), which play absolutely critical roles in the signal transduction of the coagulation cascade. This pathway-oriented approach to gene expression SNP associations reduces the number of test statistics and identifies genetic variation that may have effects throughout an entire pathway.

Mutation Positive and Mutation Negative Cowden and Bannayan-Riley-Ruvalcaba Syndrome Patients and Normal Controls Defined by Distinct 10q-Haplotypes. *M.G. Pezzolesi[1], Y. Li[2], X.P. Zhou[1,3], R. Pilarski[3], L. Shen[2], C. Eng[1]* 1) Cleveland Clinic Genomic Med Inst, Cleveland, OH; 2) Div of Biostats, The Ohio State Univ, Columbus, OH; 3) Hum Cancer Genetics, The Ohio State Univ, Columbus, OH.

PTEN is a tumor suppressor gene frequently mutated in sporadic and heritable human cancers. Germline mutations are associated with a number of clinically distinct heritable cancer syndromes referred to as the *PTEN* Hamartoma Tumor Syndrome (PHTS). Despite a lack of genetic heterogeneity, specific germline *PTEN* mutations have yet to be identified in 15% to 50% of PHTS patients. In order to better understand the genetic contribution of this locus, we set out to characterize its haplotype architecture utilizing a case-control haplotype-based approach in 94 normal control and 353 PHTS samples with various germline *PTEN* mutation status. We found the *PTEN* locus to be characterized by 3 distinct haplotype blocks of length 33kb, 65kb, and 43kb, respectively. Comparisons of the haplotype distributions for all blocks differed significantly among PHTS patient groups and controls ($P = 0.010$, <0.001, and <0.001, respectively). Rare haplotype blocks and extended haplotypes account for 2- to 3-fold more PHTS chromosomes compared to control chromosomes. *PTEN* mutation negative patients were strongly associated with blocks spanning upstream of *PTEN* and including the genes first intron ($P = 0.0066$). One rare block spanning this region was only observed in 8 patient samples, including 7 with previously undetected mutations. Additionally, the haplotype profiles of PHTS patients with known mutations/variations appear to contribute to the phenotypic complexity of this syndrome. Our efforts also enabled us to identify the first germline *PTEN* deletion in a patient with a clinical diagnosis of Cowden Syndrome (previously only observed in patients with Bannayan-Riley-Ruvalcaba Syndrome). Taken together, these data suggest that specific *PTEN* haplotypes and rare alleles can underlie the disease etiology in these patient populations, constitute low-penetrant, modifying loci, and may harbor pathogenic variant(s) which have escaped detection by standard *PTEN* mutation scanning methodologies.

Unequal Distribution Of DNA Methylation Within A DNA Repeat Array Linked To Facioscapulohumeral Muscular Dystrophy. *L. Qi, K. Jackson, M. Ehrlich* Department of Biochemistry, Tulane University, New Orleans, LA.

The D4Z4 array, which is associated with facioscapulohumeral muscular dystrophy (FSHD), consists of tandem 3.3-kb repeat units at 4q35 and 10q26. It usually contains 10-100 repeat units, and when an array at 4q35 has less than 10 units, FSHD almost always results. We studied methylation of three types of CpG-containing sites, *Hpy*CH4IV (6 sites per 3.3 kb), *Bst*UI (37 sites per 3.3 kb), and *Hpa*II (71 sites per 3.3 kb) within the whole array *vs*. at the proximal end of the array by blot hybridization. First, we used a D4Z4 hybridization probe under conditions that monitor all the D4Z4 repeat units, but not cross-hybridizing sequences. The examined sites were largely, but incompletely, methylated within the bulk of the array in normal somatic tissues and hypermethylated or hypomethylated in many ovarian carcinomas and Wilms tumors. We next tested methylation of these sites just at the proximal end (within the terminal 0.9 kb) of the D4Z4 array by using a probe from a sequence adjacent to the beginning of the array (p13E-11). Surprisingly, the end of the array exhibited much less methylation than the bulk of the array in somatic controls. Even cancers that were very hypermethylated at examined sites within the array (more than 97% of the sites methylated) displayed no hypermethylation at the proximal end of the array and were mostly unmethylated there. This D4Z4 position-dependent methylation cannot be attributed to differences in sequence because D4Z4 has an extremely conserved sequence throughout the array including at its proximal end. Therefore, the position-dependent differences in methylation in D4Z4 in both control tissues and cancers are likely to reflect an effect of chromatin conformation on the DNA methylation apparatus. These results give us new insight into the establishment of DNA methylation patterns in normal and malignant tissues. Our study may also help elucidate the relationship of D4Z4 chromatin structure to FSHD. (Supported in part by NIH grant R01 NS048859).

A Trans-Splicing strategy corrects the defective splicing of the Spinal Motor Neuron 2 (SMN2) transcripts. *M. Shababi[1], T.H. Coady[1], G. Tullis[2], C.L. Lorson[1,3]* 1) Veterinary pathobiology, University of Missouri, Columbia, MO; 2) Ophthalmology, Boston university; 3) Molecular Microbiology and Immunology, university of Missouri, Columbia.

Spinal Muscular Atrophy (SMA) is an autosomal neurodegenerative disorder characterized by loss of the motor neurons in the spinal cord. SMA is caused by the homozygous deletion or mutation of the Survival Motor Neuron 1 (SMN1) gene. A nearly identical homolog of SMN1 (SMN2) exists only in humans; however, it cannot compensate for the loss of SMN1 due to a single nucleotide exchange at the beginning of exon 7 that alters its splicing pattern. SMN1 predominantly produces full-length transcript resulting in functional SMN protein, whereas SMN2 expression gives rise to exon 7-deleted transcripts and therefore a truncated and unstable SMN protein. Since, SMN2 has the same protein coding capacity as SMN1 and is retained in all SMA patients, this disease is desirable for therapeutic strategies that target SMN2 and correct its splicing defect. Here, we have developed a trans-splicing strategy to increase incorporation of exon 7 in the SMN2-derived transcripts. Trans-splicing system involves exogenously delivering a trans-splicing RNA molecule that can interact with the defective pre-mRNA and alter its splicing. This molecule contains an anti-sense sequence binding to the target, a trans-splicing domain to interact with the mutant pre-mRNA, and intact coding sequence of exon 7 that will be incorporated in the SMN2 transcript. Several trans-splicing RNA molecules were initially delivered and expressed from a plasmid backbone. The introduction of these plasmids into the cells re-directed the splicing of SMN2 from a SMN2 mini-gene as well as the endogenous transcript. These plasmids were eventually developed into recombinant AAV vectors and introduced into SMA patient cells. Infection of the severe SMA patient cells with these vectors, expressing the trans-splicing RNA, increased the levels of the full length SMN transcript and elevated the level of the total SMN protein.

A new autosomal dominant distal arthrogryposis syndrome characterized by plantar tendon contractures in large Utah kindred maps to 2q. *D.A. Stevenson[1], R. Toydemir[2], K. Swoboda[1, 3], H. Coon[4], M. Bamshad[5]* 1) Dept of Pediatrics, University of Utah, Salt Lake City, UT; 2) Dept of Human Genetics, University of Utah, Salt Lake City, UT; 3) Dept of Neurology, Univeristy of Utah, Salt Lake City, UT; 4) Dept of Psychiatry, Neurodevelopmental Genetics Program, University of Utah, Salt Lake City, UT; 5) Dept of Pediatrics, University of Washington, Seattle, WA.

The distal arthrogryposis (DA) syndromes are a distinct group of disorders characterized by contractures of two or more different body areas. More than a decade ago, we revised the classification of DAs and distinguished several new syndromes. This classification facilitated the identification of nearly half a dozen genes (i.e., *TNNI2*, *TNNT3*, *MYH3*, *MYH8*, and *TPM2*) that encode components of the contractile apparatus of fast-twitch myofibers and when defective cause DA. We now report the characterization of a novel DA disorder in a large five-generation Utah family in which plantar tendon shortening was transmitted among 14 affected individuals in an autosomal dominant pattern. Contractures of hips, elbows, wrists, and fingers varied in severity among affected individuals. All affected individuals had normal neurological examinations; electromyography and creatinine kinase levels on selected individuals were normal. We have tentatively labeled this condition distal arthrogryposis type 10 (DA10). A genome-wide linkage scan showed a maximum LOD score of 3.96 at marker D2S364 on chromosome 2q near a region containing several genes that encode contractile proteins.

The effect of enzyme replacement therapy with imiglucerase on bone mineral density in type 1 Gaucher disease.

R. Wenstrup[1], K. Kacena[2], P. Kaplan[3], G. Pastores[4], A. Prakash-Cheng[5], A. Zimran[6], T. Hangartner[7] 1) Cinn Child Hosp, OH; 2) Genzyme Corp, MA; 3) Univ Penn Sch Med, PA; 4) NYU Sch Med, NY; 5) Mt Sinai Sch Med, NY; 6) Shaare-Zedek Med Ctr, Israel; 7) Wright State Univ, OH.

Purpose: To determine the effect of enzyme replacement therapy (ERT) with imiglucerase on bone mineral density (BMD) in patients with type 1 Gaucher disease (GD) and assess fracture prevalence. **Methods:** Lumbar spine BMD data as assessed by dual energy x-ray absorptiometry (DXA) from all males 18-70y and females 18-50y with type 1 GD enrolled in the ICGG Gaucher Registry were analyzed; 160 untreated patients and 342 patients treated with ERT were included. Linear mixed effects models were used to analyze Z-scores over time and assess dose-response relationships. The reported prevalence of fractures and estimated prevalence of osteoporosis by age and sex were calculated. **Results:** DXA Z-scores in the untreated group were below normal at baseline (y intercept = -0.80 Z-score units, $p<0.001$) and remained about one standard deviation below normal over time (slope = -0.010 Z-score units/year, $p=0.68$). DXA Z-scores for patients on ERT were below normal at baseline (y-intercept = -1.17 Z-score units, $p<0.001$), but improved significantly over time (slope= +0.132 Z-score units/year for ERT 60U/kg/2wk, $p< 0.001$). A significant dose-response relationship was noted for ERT, with the slopes for 15, 30, and 60 U/kg/2wk of +0.064, +0.086, and +0.132 Z-score units/year, respectively. The BMD of patients with GD treated with ERT increased to within -0.12 (60U/kg/2wk), -0.48 (30U/kg/2wk) and -0.66 (15U/kg/2wk) standard deviations of the reference population after approximately 8 years. Estimated prevalence of osteoporosis of this GD population, if left untreated, ranged from about 10 to 30% in females, and 10 to 25% in males. Patients with GD had a much higher prevalence of fractures than expected, with >50% of women with GD at age 50 and men with GD at age 70 reporting the presence of vertebral fractures. **Conclusions:** ERT with imiglucerase significantly improves BMD in patients with GD. A normal (age- and sex-adjusted) BMD should be a therapeutic goal for patients with type 1 GD.

Identification of copy number variants in non-isolated congenital diaphragmatic hernia (CDH+). *D.A. Scott[1], M. Klaassens[3,4], A. Holder[1,6], K.P. Lally[5], C. Fernandes[2], A. de Klein[3], D. Tibboel[4], B. Lee[1,6]* 1) Dept Mol & Hum Genet, Baylor Col Med, Houston, TX; 2) Dept Peds, Baylor Col Med, Houston, TX; 3) Dept of Clin Genet, Erasmus Med Cent, Rotterdam, the Netherlands; 4) Dept of Paed Surg, Erasmus Med Cent, Rotterdam, the Netherlands; 5) Dept of Ped Surg, Univ of Texas Med School, Houston, TX; 6) Howard Hughes Medical Institute.

Non-isolated congenital diaphragmatic hernia (CDH+) is a common cause of severe newborn respiratory distress and is associated with high mortality and significant morbidity. The development of improved methods for identifying copy number variants in CDH+ is of particular importance since many chromosomal anomalies may not be detected using current screening methods and detection of a chromosome anomaly can impact prognosis, the selection of additional screening tests, treatment decisions, and recurrence risk counseling. Identifying more subtle copy number variation will also be an increasingly important approach to studying disease causality and susceptibility. To determine if the combination of oligonucleotide-based array comparative genome hybridization (aCGH) and quantitative real-time PCR is an effective method of identifying and confirming clinically relevant chromosomal deletions and duplications we screened a cohort of 26 CDH+ patients for de novo copy number variants. Critical breakpoints were also mapped using this combination of techniques. aCGH identified 105 putative copy number changes. Sixty-one of the 105 changes (58%) had been previously described in normal controls. Twenty of the remaining 44 changes (45%) were confirmed by real-time quantitative PCR or standard cytogenetic techniques. Seven de novo changes were identified in five patients, two of whom had previously normal G-banded chromosome analyses. We conclude that combination of oligonucleotide-based aCGH and quantitative real-time PCR is an effective method of identifying, confirming, and mapping clinically relevant copy number changes in patients with CDH+. This method is more sensitive than G-banded chromosome analysis and may find wide application in screening patients with congenital anomalies and/or mental retardation.

Unusual Presentation of Epidermal Nevus syndrome. *Y. Zarate, R. Hopkin* Div Hum Genetics, Cinn Children's Hosp Med Ctr, Cincinnati, OH.

A 35 year old female with a diagnosis of Neurofibromatosis type I since age 17 presented for a second opinion. At birth multiple café au lait spots were noted with lesions on the face and trunk. The skin lesions had evolved with increasing pigment and developing a raised verruciform surface. Multiple cosmetic surgeries resulted in little improvement as the lesions continued to progress. She developed pain in her hands and wrists eventually requiring surgery for carpel tunnel. She had also been diagnosed with spinal canal stenosis. Radiographs demonstrated multiple lucent lesions of the right ulna, and 3rd and 4th metacarpal bones. There was a 2 X 0.5 cm raised lesion on the anterior surface of the tongue. Skin examination in adulthood revealed multiple verruciform lesions with variable hyperpigmentation in addition to areas with multiple lentigines, but there were no typical café au lait spots. The lesions tended to follow the lines of Blaschko and were bilateral with some areas that crossed the midline. The final diagnosis is Epidermal Nevus Syndrome. There are no previous reports of carpel tunnel or spinal stenosis with this syndrome. Furthermore, we emphasize the overlap with Neurofibromatosis I, LEOPARD syndrome, and other phacomatosis especially early in disease progression.

Molecular Identification of Individuals with Spinal Muscular Atrophy through Newborn Screening to Benefit Clinical Trial Efficacy. *R.E. Pyatt, D.C. Mihal, T.W. Prior* Dept Pathology, Ohio State Univ, Columbus, OH.

Clinical trials are currently underway evaluating the first wave of potential therapeutics for Spinal Muscular Atrophy including phenylbutyrate and valproic acid. With the clinical course leading to the degeneration of anterior horn motor neurons, the window of time for effective administration of these agents may be short. Enrollment of children into these two trials is based on clinical diagnosis followed by confirmation of deletions status and determination of SMN2 copy number in our laboratory. However the time required for clinical and molecular diagnosis may exceed the lifespan of anterior horn cells particularly in individuals with Type I disease creating a cohort for therapeutic validation who may not be within that treatment window. We sought to examine then if new methodologies could be created for the detection of affected individuals in a more timely fashion. This would involve identification at birth and consequently necessitate that diagnostic testing be incorporated into newborn screening programs. We defined an assay to detect the 95% of affected individuals with homozygous deletions in SMN1 exon 7 using the Luminex micro-bead system and compared it to a similar assay previously developed by our lab on the Real-Time PCR platform using a series of 420 blood spots from affected, carrier, and normal individuals. Both chemistries displayed high sensitivity and specificity in this sample series, while the Real-Time platform processed 96 samples in 1.5 hours at a per sample cost of approximately $15 and the Luminex system took twice as long for the same number at a cost of $10. While both assays demonstrated similar effectiveness, the Luminex system was more cost effective compared to Real-Time PCR even with a longer protocol. The Luminex system also has greater expansion capabilities to incorporate the identification of small mutations seen in the 5% of affected who are compound heterozygotes or the addition of other disorders. We have shown that molecular technology exists for the effective and timely identification of newborns with Spinal Muscular Atrophy to hasten their enrollment in clinical trials and drug delivery.

Specific microRNA deregulation in follicular thyroid cancer & clinical implications. *F. Weber, R. E. Teresi, C. Eng*
Cleveland Clinic Genomic Medicine Inst, Cleveland, OH.

Follicular thyroid carcinoma (FTC) poses a diagnostic challenge due to its morphological and molecular similarities to the frequently occurring benign follicular adenoma (FA). In a pre-operative setting both are indistinguishable from each other and surgery is recommended. Micro-RNA's (miRNAs) are a new class of small, non-coding RNAs that may not only lend novel clues to FTC genesis but also help to identify novel diagnostic marker and molecular targets. For the latter process, a deregulated miRNA can orchestrate the aberrant expression of several hundred target genes. We performed a global miRNA and gene expression analysis in a total of 18 follicular thyroid carcinoma (FTC) and 12 benign follicular neoplasia (FA) using 2 high-density array platforms (custom miR-Chip and HG-U133A GeneChip) according to established protocols. Results were validated in independent sample sets by quantitative RT-PCR. In vitro experiments were performed to further characterize the functional effect of miRNA deregulation in thyroid cancer. 2 human miRNAs (miR-197, miR-346) were significantly overexpressed (1.6-2.0-fold, P0.005) in FTC than in FA. Potential miRNA target genes were cross-referenced with our data obtained from GeneChip experiments. A selected set of target genes was further validated, both in vivo and in vitro. Overexpression of miR-197 or miR-346 in HEK293T cells not only induced proliferation (~1.5-fold, p=0.003 and p=0.012) but also caused a ~2-fold transcriptional repression of their respective target genes. Silencing of endogenous miR-197 or miR-346 expression inhibited proliferation in thyroid cancer cell lines. In summary, we identified 2 miRNAs that are specifically overexpressed in FTC. Their deregulation directly affects the downstream transcriptome and cancer phenotype. These specific FTC-miR and downstream transcriptome profiles may be used as an accurate molecular diagnostic to differentiate FTC from FA preoperatively. In addition, interference with the deregulated miRNA expression in FTC will have a cascading effect on downstream target genes and could potentially reverse the malignant phenotype.

Rare case of vertical transmission of transposition of the great arteries. *C. Rigelsky, C. Eng* Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH.

Current estimates suggest that transposition of the great arteries (TGA) has a low recurrence risk or is sporadic. Rare cases have been attributed to X-linked or autosomal genes. The majority of reports estimating recurrence risk for TGA investigate congenital heart defects (CHD) in siblings or other relatives of children born with TGA. These studies provide recurrence risks of between 2 and 10%. We report a father and son with TGA. The father, JB, is a 29 year old with a single functioning hypoplastic right ventricle, large VSD and TGA. JB has had numerous surgeries but remains cyanotic and has severe pulmonary stenosis. JBs condition has remained fairly stable but will probably require a heart transplant. His son, PB, was diagnosed prenatally. Deletion analysis for 22q11 was performed and was negative. After birth, he was found to have TGA with a small muscular VSD. An arterial switch procedure was performed and PB is doing well. Review by a medical geneticist revealed no dysmorphic features and his development has been normal. In an attempt to more accurately define recurrence risk for this family, a karyotype and microarray analysis were performed and both were normal. This case represents a rare occurrence of vertical transmission of TGA, and also provides a very difficult situation for genetic counseling. The current literature on this topic is potentially inadequate at estimating the risk of recurrence in this family. As more individuals with TGA and other complex CHD live into adult years, it is imperative for further studies to focus on their genetic etiology. It is likely that the number of cases of vertical transmission for complex heart defects will increase. This case highlights a growing area of need for further clinical and translational research as this area will likely become an increasing challenge for genetic counseling.

Satellite DNA Methylation Patterns by Hairpin Genomic Sequencing. *C. Shao, M. Ehrlich* Human Genetics, Tulane University School of Medicine, New Orleans, LA.

Both increased levels of DNA methylation in some parts of the genome and decreased levels in others are generally associated with human cancer. Most DNA methylation analyses do not address the issue of hemimethylation at CpG dyads because of technical difficulties. In addition, only genomic sequencing after DNA cloning reveals methylation patterns on individual DNA molecules. To better understand DNA methylation, including hemimethylation, in normal human tissues and cancers, we have used the new hairpin genomic sequencing method of C. Laird *et al*., which involves cleaving DNA with a restriction endonuclease, covalently linking DNA strands, denaturation, bisulfite treatment, PCR, cloning, and sequencing. We adapted this method to study a 0.2-kb subregion of satellite 2 from chromosome 1 after cleavage of DNA with *Bsm*I. First, we analyzed DNA from normal cerebellum, lung, and heart. We found symmetrical methylation and hemimethylation in 84 and 6.5% of CpG sites, respectively, in 56 DNA clones. The hemimethylation, which was seen in 50% of the clones, is not artifactual because its frequency was consistently higher than the frequency of bisulfite-resistant non-CpG Cs (overall, 2.1%). Most of the hemimethylated sites were dispersed in the examined region, and four clones had hemimethylated CpG dyads with opposite directionality. Although there was variety in the methylation patterns from clone to clone, 3 out of 13 CpG positions were symmetrically methylated in more than 90% of the clones. One CpG site, the least methylated one, was symmetrically methylated in only 41% of the clones. We characterized CpG methylation of satellite 2 DNA in ovarian epithelial tumors of different degrees of malignancy by Southern blotting, but the only suitable restriction site that was available was *Bst*BI. To better understand the nature of tumorigenesis-associated epigenetics, we will next use hairpin genomic sequencing to compare exact patterns of methylation in satellite 2 from ovarian carcinomas, low malignant potential tumors, and cystadenomas to that from somatic control tissues. (Supported in part by Louisiana Cancer Research Consortium).

Further confirmation of the polymorphism in a chromosome-specific interstitial telomere-like sequence (ITS) located at 22q11.2. *J. Yan, O. Samassekou, E. Bouchard, N. Bastien* Dept Pediatrics, Université de Sherbrooke, Sherbrooke, PQ, Canada.

Interstitial telomeric sequences (ITSs), telomere-like repeats at intrachromosomal sites, are common in mammals and consist of tandem repeats of the canonical telomeric repeat, TTAGGG, or a repeat similar to this. We previously revealed that the ITS in human chromosome region 22q11.2 is, in the sequenced genome database, 101 tandem repeats (909 bp) of the sequence TTAGGGAGG. Using the primed in situ labeling (PRINS) technique with primers against the canonical telomeric repeat (TTAGGG), we illuminated telomeric sites for all chromosomes and an ITS locus for chromosome 22 at q11.2. Using the TTAGGGAGG sequence, we designed PRINS primers that more efficiently and specifically illuminate the 22q11.2 ITS locus without illuminating telomeric and other ITS loci. We PCR-amplified DNA from 11 normal individuals using primers designed from sequences flanking the ITS locus. Our results demonstrated that the sizes of all PCR fragments are bigger than the 909 bp published in the genome database. A specific PCR pattern for each individual was also observed. In some individuals, the PCR fragments showed clear allelic differences and relations between the family members. Furthermore, DNA sequencing of some PCR fragments confirmed that the different PCR fragments indeed contain TTAGGGAGG repeats. As seen in many reports, the 22q11.2 region is associated with hot spots for disease-related chromosome breaks for multiple disorders, such as DiGeorge syndrome and chronic myeloid leukemia. We describe our findings that the ITS at 22q11.2 is in the same area of, and proximal to the common rearrangements region of multiple disorders. We suggest that the ITS might regulate DNA repair process in this area to protect the chromosome from more serious damage. The population polymorphic ITS locus at 22q11.2 could become a useful marker for linkage analysis, for forensic applications, and for the detection of genetic instability in tumors.

Analysis of the clinical relevance of intron variants in BRCA1 and BRCA2. *M.P.G. Vreeswijk[1], J.N. Kraan[1], H.v.d. Klift,[1], C.J.van Asperen[1], G.R. Vink[1], C.J. Cornelisse[2], P. Devilee[1,2]* 1) Dept. Human and Clinical Genetics, Center for Human and Clinical Genetics, LUMC, Leiden, Netherlands; 2) Dept. Pathology, LUMC, Leiden, the Netherlands.

Germ-line mutations in BRCA1 and BRCA2 confer a high risk to breast and/or ovarian cancer. Whereas mutations causing frameshifts and premature stop codons are unambiguously defined as pathogenic, an increasing number of variants has been identified which cannot be readily distinguished as either disease-associated mutations or benign polymorphisms. These socalled unclassified variants include variants that are located in the intronic sequences of BRCA1 and BRCA2. The purpose of this study was to identify the effect of six of these variants on RNA splicing in order to differentiate between pathogenic or neutral variants.

For the IVS2-6 T>A variant in BRCA1, sequence analysis of cDNA from fibroblasts derived from a carrier of the variant showed the introduction of four bases from intron 2, leading to an out-of-frame fusion of BRCA1 exon 2 and 3.

A coding polymorphism in exon 16 was used to show monoallelic BRCA1 expression in a carrier of the IVS16+5 G>T variant. This was confirmed with the use of a primer specific for the wildtype transcript. Inhibition of nonsense mediated decay (NMD) revealed an additional fragment and sequence analysis showed the insertion of 65 nucleotides from intron 16.

RNA analysis from a carrier of an intronic variant in BRCA2 (IVS21+5 G>A) revealed the absence of transcript from the variant allele. Analysis after inhibition of NMD showed an additional transcript, containing an insertion of 46 nucleotides from intron 21.

Since these intronic variants (IVS2-6 T>A; IVS16+5 G>T in BRCA1 and IVS21+5 G>A in BRCA2) result in aberrant splicing of the mRNA transcript, they are considered to be clinically significant. Two other variants in BRCA1 (113 G>A; IVS4-15delTTTC) and one variant in BRCA2 (IVS2-7 T>A) did not show any effect on RNA splicing and can therefore be considered to be neutral alterations.

Single Cell Whole Genome Amplification Method. *D. Vassar-Nieto, C. Brown, C. Brueck, E. Mueller* Research & Development, Genomics, Sigma-Aldrich Research Biotech, St. Louis, MO.

Analyzing the genomic material in a single cell has long been desirable but heretofore unachievable due to the miniscule amount of DNA available for analysis. We have used a new and sensitive method for whole genome amplification, GenomePlex Single Cell WGA kit, to perform genomic analysis on a single cell. The process amplifies the DNA from a single cell a million fold, allowing the genetic analysis of the ultimate biological unit and opening the secret to maturation, regeneration, and genetic diseases.

In this poster we show the utility of this method with a variety of single cell samples. We show that DNA generated by this process can be used for analysis in various downstream applications such as comparative genomic hybridization and SNP analysis. Additionally we demonstrate the detection limitations of this method by comparing our results to those from unamplified genomic DNA. Finally, we utilize this method to examine the genetic variance between individual cells in an originally clonal culture of the lymphoma cell line U937.

.

Detection of Philadelphia chromosome (Ph) in a patient with no evidence of leukemia: Further evidence of a changing paradigm? *G. Velagaleti, J. Northup, K. Suleman, N. Panova, D. Hudnall* Dept Pathology, Univ Texas Medical Branch, Galveston, TX.

The consistency with which the Ph chromosome is seen in CML lead to two valid assumptions: (1) all bona fide CML patients have a BCR-ABL fusion gene in their malignant cells; (2) finding of a BCR-ABL fusion gene in hematopoietic cells from an individual is a sign of impending/overt CML. Here, we report evidence that mere presence of Ph chromosome and/or BCR-ABL fusion gene, even at high proportion hitherto unreported, does not result in malignant disease. A 33-year old, Caucasian with diagnosis of Hodgkin lymphoma (HL) was evaluated for bone marrow involvement. Bone marrow biopsy showed no evidence of malignancy. However, chromosome analysis showed the characteristic Ph chromosome in 70% of the marrow cell metaphases. FISH studies with dual fusion BCR-ABL probe showed 68% of the interphase nuclei with one fusion signal (1R/1G/1F). Metaphase FISH analysis showed that the fusion signal on der(9) is not present, thus indicating a concomitant deletion. Since, Ph chromosome is not associated with HL, unstimulated blood lymphocytes were karyotyped which showed 38% of the cells with Ph chromosome. FISH studies on frozen lymph node tissue from initial biopsy and the peripheral blood also showed only one fusion signal similar to the bone marrow in 17% and 31% of the cells, respectively. RT-PCR analysis with nested primers showed the typical p210 transcript in the peripheral blood. Since the initial diagnosis in 10/05, his white count has ranged from low to high, but with no morphologic evidence of CML. The occasional increase in his white count is attributed to treatment with GCSF to alleviate leucopenia resulting from chemotherapy for the HL. The patient showed favorable response to chemotherapy and is currently shows no evidence of HL. Low-level BCR-ABL fusion gene expression is seen in normal individuals. However,this is the first report of an individual without CML with a sustained high percentage of hematopoietic cells with BCR-ABL fusion gene. Our results suggest that additional oncogenic events are essential for the development of CML.

Ameloblastin (AMBN) is Associated with Low Caries Experience. *K. Deeley, E.K. Rose, C.A. Brandon, J.M. Resick, S. Wendell, M.L. Marazita, A.R. Vieira* Oral Biology and Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA.

Twin studies and animal models have provided compelling evidence for the existence of a genetic component in caries susceptibility. However caries is a disease greatly influenced by environmental factors such as oral hygiene, diet and fluoride exposure. Controlling for these factors in humans is extremely difficult. One approach is to study populations with similar cultural habits and socio-economic status (i.e. with similar dietary habits, hygiene habits, access to the dentist, and fluoride exposure). For the present study, we used 217 DNA samples collected from individuals and their family members that sought medical treatment for orofacial clefts and other illnesses during the 2006 Children of the Americas medical mission in Tiquisate, Guatemala. All individuals received an oral exam and DMFT scores were obtained. Unrelated individuals with very low caries experience (DMFT scores 2) were selected as controls (N=40), while unrelated individuals with very high caries experience (DMFT 9) were selected as cases (N=40). TaqMan chemistry was used to genotype SNP markers in selected candidate genes that influence enamel formation. Genes influencing enamel development could influence both bacterial adherence and/or the resistance of enamel to acid pH. Six markers were typed in five candidate genes: AMBN (Ameloblastin; hCV496502), AMELX (Amelogenin; hCV2190967), ENAM (Enamelin; rs3796704), TUFT1 (Tuftelin-1; rs3790506 and rs2337360), and TFIP11 (tuftelin interacting protein 11; rs134136). Individuals with very low caries experience presented the less common AMBN hCV496502 T allele more often than individuals with very high caries experience ($p=0.04$). Our results suggest that variation in AMBN may be a protective factor against caries susceptibility. It appears that the approach of comparing individuals with extremely distinct caries experiences is valuable for decreasing the potential influence that different environmental factors may impose to genetic studies of caries. This research is supported by NIH Grants R01-DE016148, R21-DE016930, P50-DE016215, and R01-DE014899.

Modifier genes substantially influence variability in severity of CF lung disease, independent of CFTR genotype and variation in body mass index. *L.L. Vanscoy[2], S. Blackman[2], J.M. Collaco[2], A. Bowers[1], K. Naughton[1], G.R. Cutting[1]* 1) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Department of Pediatrics, Johns Hopkins School of Medicine, Baltimore, MD.

To estimate the contribution of genetic factors other than CFTR genotype to variation in CF lung disease severity, we compared the degree of intra-pair similarity in longitudinal measures of FEV1 in MZ twins to DZ twins and siblings before and after adjusting for nutritional status. To minimize variation due to environmental factors, we analyzed pulmonary function tests (PFTs) obtained while subjects were living with an affected twin or sibling. FEV1 was converted into percent predicted values (FEV1%pred) and CF-specific percentiles for FEV1 (FEV1CF%). FEV1%pred at 20 years (BayesFEV1%pred) was predicted using mixed modeling and Bayes estimation (Schlucter, et al) and average FEV1CF% (AvgFEV1CF%) was calculated using the best quarterly FEV1 measurement from all available PFT data. Nutritional status was calculated using the average of all available body mass index (BMI) z-scores (AvgBMIZ) for each study subject. Intra-pair similarity was determined using correlation coefficients. 47 MZ twin pairs, 10 DZ twin pairs, and 231 sibling pairs with CF were analyzed. CFTR genotype distribution was 51.4% F508/F508, 39.3% F508/other, and 9.2% other/other. All pairs of twins and siblings had identical CFTR genotypes. BayesFEV1%pred and AvgFEV1CF% showed a high degree of correlation for MZ twins (0.82-0.91; $p<0.0001$) and moderate similarity for DZ twins and siblings (0.50-0.64; $p<0.001$). After adjusting for AvgBMIZ, intra-pair correlations for BayesFEV1%pred and for AvgFEV1CF% among MZ twins were unchanged (0.80-0.93; $p<0.0001$), but were decreased for DZ twins and siblings (0.39-0.58; $p<0.05$). Estimates of heritability ranged from 0.54 to 0.64 and increased to 0.70 to 0.82 after adjusting for nutritional status. Controlling for non-genetic variation by studying twins and siblings living together at home enables detection of substantial influence of modifier genes upon variation in CF lung function that is independent of variation in CFTR genotype and body mass index.

Follow-up linkage mapping and family-based association analyses of SNPs in *NTRK2* in the candidate region at 9q22 in the NIMH Alzheimers Disease Genetics Initiative cohort. *R.T. Perry[1], H. Wiener[1], L.E. Harrell[2], D. Blacker[3], R.E. Tanzi[4], L. Bertram[4], S.S. Bassett[5], R.C.P. Go[1]* 1) Dept Epidemiol and Internat Health, UAB, Birmingham, AL; 2) Dept Neurology, UAB, Birmingham, AL; 3) Dept Psychiatry, MGH, Boston, MA; 4) Genetics and Aging Unit, Harvard Medical School, Boston, MA; 5) Dept Psychiatry, JHU, Baltimore, MD.

Purpose: Other than the *APOE* peak at 19q13, the 9q22 region was identified in our original genomic scan as the candidate region with the highest multipoint lod score (MLS) in the subset of late onset Alzheimers Disease (AD) families (MLS = 2.9 at 101 cM) from the NIMH Genetics Initiative sample. We genotyped an additional 12 microsatellites in this region and multipoint analysis showed an increase in the peak MLS from 2.9 to 3.8 at 95 cM near marker D9S1815 with further narrowing of the region from 21.5 cM to 6.6 cM (92.2-98.8 cM). SNPs in the Ubiquilin1 gene (*UBQLN1*), located at 83.3 cM, have been reported to be significantly associated to AD and that some of the linkage signal may have been due to *UBQLN1* (Bertram et al, 2005). We performed additional analyses conditioned on *UBQLN1* genotype and reject the hypothesis that *UBQLN1* could account for all the linkage signal at 9q22. Therefore, additional AD succeptibility genes are likely to be located here. One possible candidate gene is the neurotropic tyrosine kinase receptor 2 (*NTRK2*) gene, located at 84.4 cM. It codes for the receptor for brain-derived neurotrophic factor (BDNF) and is involved with the regulation of both short-term synaptic functions and long-term potentiation of brain synapses. We genotyped 14 SNPs (13 tagSNPs) located in 8 of the 20 haploblocks covering the gene to test for association to AD. **Methods**: We used capillary electrophoresis, TaqMan assay, and family-based association testing (FBAT) to analyze these 14 SNPs in *NTRK2* in the NIMH AD sibling dataset (n=481 families). **Results**: A 3 SNP haplotype located in a functional area of *NTRK2* was significantly associated with AD (p=0.005). **Conclusion**: Follow-up linkage data and preliminary FBAT analyses of SNPs in *NTRK2* supports the presence of more than one AD succeptibility gene located in the 9q22 candidate region.

Combined phenotype of Wolf-Hirschhorn and Beckwith-Wiedemann Syndromes in a female with der(4)t(4;11)(pter;pter). *A. Sathienkijkanchai[1], N.H. Robin[1], S. Prucka[1], J. Sanford Biggerstaff[4], J. Komorowski[3], R. Andersson[3], C. Bruder[1,2], A. Piotrowski[1,2], T. Diaz de Stahl[2], J.P. Dumanski[1,2], A.J. Carroll[1], F.M. Mikhail[1]* 1) Dept. of Genetics, Univ. of Alabama at Birmingham, AL; 2) Dept. of Genetics and Pathology, Uppsala Univ., Sweden; 3) Linnaeus Centre for Bioinformatics, Uppsala Univ., Sweden; 4) Dept. of Lab. Medicine, Sacred Heart Medical Center, WA.

We report an 8-month-old female with a novel unbalanced chromosomal rearrangement, consisting of a terminal deletion of 4p and a paternal duplication of terminal 11p. Each of these is associated with the well known clinical phenotypes of Wolf-Hirschhorn syndrome (WHS) and Beckwith-Wiedemann syndrome (BWS), respectively. She presented for clinical evaluation of dysmorphic features, developmental delay, atrial septal defect, and left hydronephrosis. There was no family history of miscarriages or birth defects. A 500 band karyotype was normal, but subtelomeric analysis revealed a der(4)t(4;11)(pter;pter). Using the *WHSC1* FISH probe (4p16.3), the der(4) showed no hybridization signal, indicating deletion of the WHS critical region. Furthermore, an *IGF2* FISH probe (11p15.5) showed two signals on the chromosome 11 homologues and a third on the short arm of der(4), indicating duplication of at least BWS critical region imprinted domain (ID) 1. Parental karyotype revealed that her father carried a cryptic balanced t(4;11)(pter;pter). The patients final karyotype was: 46,XX.ish der(4)t(4;11)(pter-,*WHSC1*-,pter+,*IGF2*+)pat. A 32K BAC array CGH chip demonstrated that WHS critical regions 1 and 2 were deleted, and that BWS IDs 1 and 2 were duplicated on der(4). Our patient manifests findings of both WHS (a growth retardation syndrome) and BWS (an overgrowth syndrome). Features of WHS included poor weight gain, broad forehead, hypertelorism, and micrognathia, whereas features of BWS included facial hemihyperplasia, earlobe creases, and renal anomalies. However, many clinical features of both WHS and BWS were absent, possibly due to the opposing phenotypes of these two disorders. To our knowledge, this is the first report of a child with this combined phenotype of WHS and BWS.

Chromatin DNaseI Sensitivity of the Facioscapulohumeral Muscular Dystrophy-Linked D4Z4 Repeat Array and an Adjacent Sequence. *K. Tsumagari[1], S. Hauschka[2], M. Ehrlich[1]* 1) Human Genetics, Tulane Medical School, New Orleans, LA; 2) Biochemistry, Univ. of Washington, Seattle, WS.

Facioscapulohumeral muscular dystrophy (FSHD) is a unique dominant disorder involving shortening of an array of tandem 3.3-kb repeats called D4Z4. This size-polymorphic array (1-100 repeat units) is present at both 4q35 and 10q26, but only a short 4q35 array (with 1-10 repeat units) is linked to FSHD. It has been proposed that array lengths in the normal range for 4q35 (11-100 repeat units) are heterochromatic while shorter arrays are not. We used in vivo assays for chromatin DNaseI sensitivity to study the chromatin structure of D4Z4 and its adjacent, non-repeated sequence, p13E-11. For fetal myoblasts, control fibroblasts, and FSHD or control lymphoblasts, we found conditions for DNaseI treatment of nuclei or lysolecithin-permeabilized cells that give differential DNaseI digestion of DNA standards. The standards were constitutively expressed genes, *HMBS* and *B2M*; genes unexpressed in the examined cell populations, *CST5* and *GHRHR*; and satellite 2, the constitutive heterochromatin standard. D4Z4, p13E-11, and the DNA standards give fragments of 1-to-3 kb after exhaustive digestion in vitro by *Sty*I. Degradation of these sequences by partial DNaseI digestion in vivo was quantitated by the phosphorimager-determined decrease in intensity of the corresponding *Sty*I fragment in a single rehybridized Southern blot for each sample. Initial results indicate that normal-length D4Z4 has a DNaseI sensitivity intermediate to that of constitutive heterochromatin and unexpressed genes. In contrast, for four of five tested cell cultures, including myoblasts, p13E-11, which is only 0.1 kb from the beginning of the D4Z4 array, was more sensitive to DNaseI than unexpressed genes. The fifth culture, one of the two FSHD lymphoblast cultures, had similar sensitivities to DNaseI for p13E-11 and unexpressed genes. Therefore, the p13E-11 sequence seems to have a much looser chromatin structure than the array itself, which may be important in the proposed looping between D4Z4 arrays at 4q35 and the currently unknown FSHD gene in cis. (Supported in part by NIH grant R01 NS048859).

A PEX7 Hypomorphic Mouse Model For Plasmalogen Deficiency Affecting the Lens and Skeleton. *R. Zhang[1], L. Chen[1], S. Scheper[1], R. Chaudhury[1], S. Steinberg[2], A. Moser[2], N. Braverman[1]* 1) McKusick-Nathans Institute of Genetic Medicine; 2) Kennedy Krieger Institute, Johns Hopkins Med Ctr, Baltimore, MD.

RCDP1 is a peroxisome biogenesis disorder clinically described by rhizomelia, punctate calcifications in epiphyseal cartilage, congenital cataracts and profound growth and developmental delay. It is caused by defects in PEX7, which encodes the receptor for a subset of peroxisomal matrix enzymes. The pathophysiology involves deficient plasmalogen (i.e. ether phospholipid) synthesis, although the underlying mechanisms are unknown. A few patients have milder phenotypes, residual plasmalogens in tissues and less severe defects in PEX7 that include alleles manifesting reduced PEX7 transcript. Considering the early lethality in RCDP1, we sought to recapitulate a milder phenotype and engineered a hypomorphic allele to reduce PEX7 transcript by introducing an intronic neomycin cassette. The PEX7-neo homozygotes are born in expected ratios, are fertile and have a normal life span. However, they are 70-80% as large as their littermates and 30% have visible cataracts by 3 months of age. PEX7 transcript levels are 1-5% of wild type in several tissues. RBC, brain and heart plasmalogen levels are 30-40% of their heterozygote littermates as measured by gas-liquid chromatography. Immunoblots of fibroblast lysates show reduced amounts of unprocessed thiolase and absence of the plasmalogen biosynthetic enzyme, AGPS, consistent with a defect in the import of PEX7 ligands. Whole mount skeletal staining at P1 indicates a proportionately smaller skeleton with delay in ossification centers; x-rays of adult mice also show a skeleton smaller than their heterozygote littermates. Routine histology of the eye is normal except for the lens, showing posterior proliferation of epithelial cells and enlarged, pale lens cells in the cortex or throughout the lens. Thus, the skeleton and lens are sensitive markers for plasmalogen deficiency and these mice are now being investigated to determine how these lipid compounds function in these tissues. Furthermore, the progression of cataracts in regards to lens phospholipid deficiency is of interest as a potential factor in common age-related cataract formation.

RMRP Analysis in Patients with Variable Clinical Presentations of Cartilage Hair Hypoplasia (CHH). *S. Vidal-Cardenas[1], B. Loeys[2], V. McKusick[1], C. Francomano[3], N. Braverman[1]* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Medical Ctr, Baltimore, MD; 2) Ctr Medical Genetics, Ghent Univ Hosp, Belgium; 3) Harvey Institute of Human Genetics, Greater Baltimore Med Ctr, Baltimore, MD.

CHH is an autosomal recessive, panethnic, pleiotropic disorder characterized by short-limbed dwarfism, metaphyseal dysplasia, sparse hair, anemia, immune deficiency and predisposition to malignancy. CHH is caused by defects in the RMRP gene, which encodes the untranslated RNA component of the mitochondrial ribonucleoprotein (MRP) complex, involved in cleavage of RNA in mitochondrial DNA synthesis and nucleolar cleaving of pre-rRNA. Mutations in RMRP impair ribosome assembly and alter cell cycle regulation, leading to decreased cell growth. A founder mutation, 70 A>G, underlies CHH in the Finnish and Amish. Worldwide, a remarkable 60+ unique mutations and 15+ polymorphisms have been reported in the 400 bp stretch of RMRP genomic sequence, a remarkably high frequency of polymorphic residues compared with the genome average. We identified RMRP mutations in 5 North American probands with various presentations of CHH. We amplified RMRP genomic DNA, directly sequenced the products and cloned these to show their chromosomal arrangements. 3 had classic phenotypes and were (1) homozygous for the founder mutation, (2) a compound heterozygote for 70A>G and 195C>T, a previously reported mutation, and (3) a compound for a novel indel, 28_33delCTACACinsAGGATACAGGGAGGA and 195C>T. Twin brothers with 70A>G and 4C>T had isolated skeletal involvement. Finally, an adolescent with minimal metaphyseal changes had novel mutations in cis, 91G>C and 101C>T, located in a conserved region of RMRP, and 242 A>G on the other allele. ASO analysis of 100 RMRP genes from unrelated control individuals did not identify the novel mutations reported here. 70G occurred on the founder haplotype A, 195T occurred on haplotypes A and B consistent with recurrence, and all other mutations were on haplotype B. Review of our patients and those in the literature suggest that modifying factors play a critical role in the clinical expression of CHH.

The Chemokine (C-C-motif) receptor 3 (CCR3) Gene is Linked and Associated with Age at Menarche in Caucasian Females. *F. YANG[1,3*], D.H. XIONG[2,3*], Y. GUO[4], H. SHEN[2], P. XIAO[2,3], F. ZHANG[3,4], H.W. DENG[1,2,4], * The first two authors contribute equally to this work.* 1) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P R China; 2) Department of Orthopedic Surgery, School of Medicine, University of Missouri-Kansas City, 2411 Holmes Street, Kansas City, MO 64108, USA; 3) Osteoporosis Research Center and Department of Biomedical Sciences, Creighton University, Omaha, NE 68131, USA; 4) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an 710049, P R China.

Chemokine (C-C motif) receptor 3 (CCR3), playing an important role in endometrium related metabolic pathways, may influence the onset of menarche. To test linkage and/or association between CCR3 polymorphisms with the variation of age at menarche (AAM) in Caucasian females, we recruited a sample of 1048 females from 354 Caucasian nuclear families and genotyped 16 SNPs spanning the entire CCR3 gene. LD (linkage disequilibrium) and haplotype blocks were inferred. Both single markers and haplotypes were tested for linkage and/or association with AAM using QTDT (quantitative transmission disequilibrium test). We also tested the association between CCR3 polymorphisms and AAM in a selected random sample of daughters using ANOVA (analysis of variance). In block 2, significant within-family association of SNP9 (p=0.04) with AAM were detected. We also detected total associations of SNP7 (p=0.04), SNP9 (p=0.009) and SNP10 (p=0.03). SNP14 was linked to AAM (p=0.02). In addition, there was evidence of linkage and total association with AAM for the AGA (p=0.03 and p=0.04, respectively) haplotype reconstructed by SNP7, SNP9 and SNP13. ANOVA confirmed the results of association analyses by QTDT (p=0.008, 0.0008, 0.005, 0.02, 0.001 for SNP7, 9, 10, 13 and haplotype AGA, respectively). Our results reported for the first time that CCR3 may have certain effect on AAM variation in Caucasian women. However, further studies are necessary to substantiate our conclusions.

HDC Gene Polymorphisms Are Associated with Age at Natural Menopause in Caucasian Women. *F. ZHANG[1, 3*], D.H. XIONG[2, 3*], W. WANG[1], H. SHEN[3], P. XIAO[3], F. YANG[2, 3], H.W. DENG[1, 2, 4], * The first two authors contribute equally to this work* 1) The Key Laboratory of Biomedical Information Engineering of Ministry of Education, and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an 710049, P.R.China;; 2) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, P.R.China; 3) Osteoporosis Research Center, Creighton University Medical Center, Omaha, NE 68131, USA; 4) Department of Orthopedic Surgery, School of Medicine, University of Missouri-Kansas City, 2411 Holmes Street, Kansas City, MO 64108, USA.

Menopause status is one important anthropological variable influencing the overall health of women, especially those in advanced ages. Extensive researches carried out in human have demonstrated that age at natural menopause (AANM) was under strong genetic control. However, few candidate genes underlying AANM have ever been identified so far. Histidine decarboxylase gene (HDC) encodes histidine decarboxylase, which may physiologically influence menopause status of women. In this study, we aim to investigate whether HDC gene polymorphisms are associated with AANM in Caucasian women. Data were collected from 265 postmenopausal women in 131 nuclear families. All these subjects were genotyped with 14 single-nucleotide polymorphisms (SNP) spanning from Promoter to 3 UTR in the HDC gene. 11 SNPs and the related haplotype blocks of the HDC gene were tested for association with AANM variation by the program QTDT (Quantitative Transmission Disequilibrium Test). Significant within-family associations with AANM for SNP rs854163 and SNP rs854158 were observed (P values = 0.0018 and 0.0197, respectively). Consistently, we also detected a significant within-family association between block 2 defined by SNP rs854163 and SNP rs860526 and AANM in the haplotype analyses (P value = 0.0397). We found that the HDC gene polymorphisms were significantly associated with AANM in Caucasian women. Further molecular genetics studies are required to confirm our results and find the exact causal alleles influencing AANM variation within HDC gene.

Association between Low-density Lipoprotein Receptor-Related Protein 5 (LRP5) Gene and Bone Mineral Density in Caucasian and Chinese Populations. *D.H. XIONG[1], S.F. LEI[3], L. WANG[2], W. WANG[2], H. SHEN[1], H.W. DENG[1,2,3]* 1) Department of Orthopedic Surgery, School of Medicine, University of Missouri-Kansas City, 2411 Holmes Street, Kansas City, MO 64108, USA; 2) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, Xi'an Jiaotong University, Xi'an 710049, P R China; 3) Laboratory of Molecular and Statistical Genetics, Hunan Normal University, Changsha, Hunan 410081, P R China.

Low-density lipoprotein receptor-related protein 5 (LRP5) has been established as a high bone mass gene. However, it is still controversial that whether LRP5 is associated with normal BMD variation. This study is to explore the association of BMD phenotypes at three clinically important skeletal sites - spine, hip and ultradistal radius (UD) - with LRP5 in two independent samples of Caucasians and Chinese background, respectively. The Caucasian sample is made up of 1873 subjects from 405 nuclear families while the Chinese sample consists of 350 unrelated men. High density SNPs across the whole LRP5 gene were genotyped and analyzed in both samples. Linkage disequilibrium analyses showed that the haplotype structures of the LRP5 between Caucasians and Chinese were in excellent agreement. Association testes showed that polymorphisms in the block5 spanning intron7 to intron19 of LRP5 were significantly associated with spine BMD in both samples (the most significant empirical global P values = 0.005 and 0.007, respectively). Furthermore, in Caucasians, a new spine BMD associated SNP- rs7105218 in the 3-UTR of LRP5 was detected (P value = 0.01) and the LRP5 block1 polymorphisms representing the 5-promoter region were significant for hip BMD (P values = 0.03). In Chinese, we found that the polymorphisms in blocks 4 and 5 were significant for hip BMD (P values = 0.022 and 0.008). An independent intron7 polymorphism - rs4930573 was significantly associated with UD BMD (P value = 0.002) in Chinese, too. Our work suggests the presence of both shared and population-specific genetic causal variants within the LRP5 gene that influence the normal BMD variation in various human populations.

SUSCEPTIBILITY GENES FOR CHILDHOOD AND ADULT ASTHMA. *Y. Suzuki[1], Y. Mashimo[1], H. Inoue[1], K. Hatori[1], A. Hata[1], T. Hirota[2], F. Kamada[3], Y. Matsubara[3], M. Tamari[2]* 1) Department of Public Health, Chiba University Graduate School of Medicine, Chiba, Japan; 2) SNP Research Center, The Institute of Physical and Chemical Research (RIKEN), Yokohama, Japan; 3) Department of Medical Genetics, Tohoku University School of Medicine, Sendai , Japan.

Ober et al. reported that 25 genes (IL4, IL13, CD14, ADRB2, HLA-DRB1, HLA-DQB1, TNF, FCER1B, IL4RA, ADAM33, GSTM1, IL10, CTLA4, SPINK5, LTC4S, LTA, GRPA, NOD1, CC16, GSTP1, STAT6, NOS1, CCL5, TBXA2R, TGFB1) showed positive association with either atopy or asthma in 6 or more papers (Gene Immun 7: 95-100 (2006)). We investigated significance of these most promising candidate genes for asthma in our Japanese case-control samples.

SNPs in the above mentioned genes except HLA-DRB1 and HLA-DQB1 were genotyped in the 524 controls, 339 childhood asthma patients, and 508 adult asthma patients who were recruited in Osaka City area, Japan. In the IL4, IL4RA, CTLA4, CCL5, and TBXA2R, association of 2-SNP haplotype was investigated. In the rest of the genes, association of single SNP was investigated. *P* values for chi-square test less than 0.05 were considered significant in the single-SNP association tests with dominant or recessive model. In haplotype frequency comparisons, permutation *P* values less than 0.05 were considered significant. Odds ratios for the disease were calculated using logistic regression formulae.

Significant association with childhood asthma was found in IL4RA(I50V), ADRB2(R16G), ADAM33(13236T/C), GSTP1(I105V). That with the adult asthma was in IL4RA(I50V), IL4(-590C/T:+33C/T haplotype), ADAM33(12433T/C), TNF(-1037C/T), TBXA2R(795T/C:924T/C haplotype). Odds ratios for the childhood asthma were in the order ADAM33IL4RAADRB2GSTP1; those for the adult asthma were IL4ADAM33TNFTBXA2RIL4RA.

Out of 23 promising candidate genes, 7 genes were significantly associated with asthma. ADAM33 and IL4RA seemed common susceptibility genes for childhood and adult asthma in the Japanese population.

The Genetic Structure of Human Populations in Africa. *F.A. Reed[1], A. Froment[2], M.W. Smith[3], S.M. Williams[4], S.A. Omar[5], M.J. Kotze[6], G.S. Pretorius[6], M. Ibrahim[7], O. Doumbo[8], M. Thera[8], C. Wambebe[9], S.E. Dobrin[10], J.L. Weber[10], S.A. Tishkoff[1]* 1) Dept. Biology, Univ. of Maryland, College Park, MD; 2) UR 092,IRD,Orléans, France; 3) Lab of Genomic Diversity, SAIC-Frederick, NCI-Frederick, Frederick, MD; 4) Cen. for Hum. Genet. Res., Vanderbilt Univ., Nashville, TN; 5) KEMRI, Nairobi, Kenya; 6) Div. Human Genet., Univ. of Stellenbosch, Tygerberg, South Africa; 7) Dept. Mol. Biol., Univ. of Khartoum, Khartoum, Sudan; 8) Malaria Research and Training Center, Univ. Bamako, Bamako, Mali; 9) Int. Biomed. Res., Abuja, Nigeria; 10) Marshfield Clinic, Marshfield, WI.

Africa contains the greatest levels of human genetic variation and is the source of the worldwide range expansion of all modern humans. Knowledge of the genetic population boundaries within Africa has important implications for the design and implementation of genetic epidemiologic studies of Africans and African Americans, and for reconstructing modern human origins. A dataset consisting of ~3.7 million genotypes has been generated from the Marshfield panel of 773 microsatellites and 392 in-del polymorphic genetic markers. These markers were genotyped in ~3,200 individuals from >100 diverse ethnic populations across Africa as well as in 118 African Americans and in the CEPH Human Genome Diversity Panel, consisting of 1048 individuals from 51 globally diverse populations. Preliminary analysis of population structure using the program STRUCTURE[1] indicates considerably more substructure amongst global populations (estimate for the number of genetic clusters, K, is 12) and amongst African populations (K = 9) than had previously been recognized[2]. Population clusters are correlated with self-described ethnicity and shared cultural and/or linguistic properties (e.g. Pygmies, Khoisan-speakers, Bantu-speakers, etc). African Americans have predominantly West African Bantu (~80%) and European (~17%) ancestry, although individual admixture levels vary considerably. These results justify the need to include a broad range of geographically and ethnically diverse African populations in studies of human genetic variation. [1]Pritchard JK, et al. Genetics 155:945-59 (2000) [2]Rosenberg NA, et al. Science 298:2381-5 (2002).

Dissecting the role of the *IL1* Gene Cluster in Ankylosing Spondylitis. *A-M. Sims[1,2], J.J. Pointon[1], A.E. Timms[1], B.P. Wordsworth[1], M.A. Brown[1,2], The International Genetics of Ankylosing Spondylitis Consortium* 1) Botnar Research Centre, University of Oxford, Oxford, UK; 2) Centre for Immunology and Cancer Research, University of Queensland, Brisbane, Australia.

Background: The *IL1* gene cluster is known to be associated and linked with ankylosing spondylitis (AS). We sought to refine the association by further LD mapping in a British Caucasian (BC) population, and then by planned meta-analysis, to determine the contribution of this cluster to AS susceptibility in different populations. **Methods**: The *IL1RN-VNTR* and 64 SNPs in the *IL1* gene cluster were genotyped in 330 parent-case trios and 240 extended families of BC descent. Case-control analyses were undertaken using 1 affected individual per family (540) and AFBAC controls (1059). Within-family analyses were performed using conditional extended TDT to identify markers independently associated with AS. The meta-analysis was case-control in design. Nine markers in the *IL1* gene cluster previously associated with AS were studied in a total of 1900 cases and 1571 ethnically matched controls, including BCs, North American Caucasians, Hungarians, Taiwanese and Chinese. Genotype-known controls were provided to each centre for blind genotyping to confirm genotyping accuracy. Analysis was performed using the Mantel-Haenszel ^{2} test. **Results**: The BC case-control and within-family analyses each showed 6 markers individually associated with AS ($p<0.05$) spanning the cluster, but with the major region of disease susceptibility being in *IL1A* ($p<0.05$ at rs17561). Meta-analyses show significant association ($p<0.05$) in *IL1A* (rs2856836, OR=1.23; rs17561, OR= 0.84; rs1894399, OR=0.82), and in *IL1B* (rs16944, OR=1.16). Marginal association was seen with *IL1F10* (rs3811058, OR=1.2). No other association was seen in the combined dataset, although association was observed in at least one dataset for every marker. **Conclusions**: In the BC dataset the primary association of the *IL1* gene cluster with AS lies within *IL1A*. This observation was confirmed by the meta-analysis. *IL1A/B*, which lie in a single haplotype block in the p-telomeric end of the *IL1* gene cluster, are strongly associated with AS in genetically remote populations.

A truncating *DFNA5* mutation shows that only a very specific gain-of-function mutation leads to DFNA5-associated hearing loss. *L. Van Laer[1], N. Myer[2], F. Alasti[1,3], Y. Riazalhosseini[4], M. Malekpour[4], A. Vandevelde[1], M. Moghannibashi[4], K. Kahrizi[4], H. Najmabadi[4], G. Van Camp[1], R.J.H. Smith[2]* 1) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Molecular Otolaryngology Research Laboratories, University of Iowa, Iowa City, Iowa, USA; 3) National Research Center for Genetic Engineering and Biotechnology, Tehran, Iran; 4) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran.

Mutations in *DFNA5* lead to an autosomal dominant type of nonsyndromic, sensorineural hearing loss starting at the high frequencies (Van Laer et al., 1998, Nat. Genet. 20, 194-197). Only three *DFNA5* mutations have been described hitherto: a complex deletion/insertion deleting 5 G-triplets in intron 7, a deletion of 3 nucleotides in the polypyrimidine tract of intron 7 and a nucleotide substitution in the splice-acceptor site of intron 7. Although different at the genomic DNA level, all lead to exon 8 skipping at the mRNA level. Here we describe a fourth *DFNA5* mutation: consisting of the insertion of a C at nucleotide position 640 (AF073308.1:c.640insC, AAC69324.1:p. Thr215HisfsX8). Unlike the previously described mutations, this frameshift mutation truncates the protein in exon 5 of the gene. Although the mutation was found in an extended Iranian family with hereditary hearing loss, it does not co-segregate with the hearing loss, and does not cause any obvious hearing loss. This remarkable fact provides further proof for the hypothesis that DFNA5-associated hearing loss is caused by a very specific gain-of-function mutation, involving skipping of exon 8, and not by haplo-insufficiency as initially thought. This hypothesis was previously supported by experimental evidence showing that mutant DFNA5 leads to cell death when transfected into yeast and into mammalian cells (Van Laer et al., 2004, J. Med. Genet. 41, 401-406).

***KIT, PDGFRA, VEGFR2* and *EGFR* gene amplifications in primary and recurrent astrocytic brain tumors.** *M. Puputti[1], H. Sihto[1], O. Tynninen[2], T. Blom[3], H. Mäenpää[1], J. Isola[4], A. Paetau[2], N. Nupponen[3], H. Joensuu[1]* 1) Department of Oncology, Helsinki University Central Hospital, Finland; 2) Department of Pathology, Helsinki University Central Hospital (HUSLAB) and University of Helsinki, Finland; 3) Molecular Cancer Biology Program, University of Helsinki, Biomedicum Helsinki, Finland; 4) Institute of Medical Technology, University of Tampere, Finland. MP and HS equally contributed to the work.

Histological biopsies taken from 87 primary brain tumors and their recurrent tumors were analyzed for the presence of *KIT*, *PDGFRA*, *VEGFR2* and *EGFR* gene amplifications using either chromogenic *in situ* hybridization (CISH) or fluorescence *in situ* hybridization (FISH). *KIT*, *PDGFRA* and *VEGFR2* receptor tyrosine kinase genes are located adjacent to each other on chromosome 4q12, whereas *EGFR* is located on chromosome 7p12. CISH analyses were performed from a representative tumor tissue microarray. The primary tumors consisted of oligodendroglioma grade II-III (n=20), oligoastrocytoma grade II-III (n=11), astrocytoma (n=38) and anaplastic astrocytoma (N=18). The histological diagnoses of the corresponding recurrent tumors were oligodendroglioma grade II-III (n=17), oligoastrocytoma grade II-III (n=16), astrocytoma (n=17), anaplastic astrocytoma (n=21) and glioblastoma (n=16). *KIT*, *PDGFRA*, *VEGFR2* and *EGFR* gene amplification were detected in 8 (10%), 6 (8%), 10 (12%) and 3 (4%) of the primary neoplasms, respectively. In the recurrent tumors the same genes were amplified in 19 (27%), 13 (18%), 10 (14%) and 6 (8%) of the cases, respectively. *KIT* amplifications were associated with *PDGFRA* and *VEGFR2* amplifications both in primary and secondary gliomas, and with *VEGFR2* amplifications in recurrent gliomas. Aneuploid (3 to 5) *KIT*, *PDGFRA*, *VEGFR2* and *EGFR* gene copy numbers were commonly present in both primary gliomas and in their recurrent tumors. Strong KIT, EGFR and VEGFR2 expression were infrequently found in immunohistochemistry of the tumor tissue. The results suggest that *KIT* and *PDGFRA* amplifications may have a role in the genesis of some human gliomas.

Mt-DNA deletions in muscle biopsies: interpretation and analysis of responsible genes. *M. Tesarova, T. Honzik, J. Buzkova, H. Hansikova, J. Zeman* Dept. of Paediatrics, Faculty of Medicine, Charles University, Prague 2, Czech Republic.

Within last two years, screening for large-scale deletions of mitochondrial DNA (mtDNA) was performed in muscle biopsies of more than 180 patients with myopathy or encephalomyopathy. The results were compared with histological investigations and analyses of the amount and activity of OXPHOS system. Based on these results, candidate genes were analyzed in selected patients. Two methods were used for the detection of deleted mtDNA molecules (-mtDNA): Southern blot and amplification of whole mtDNA molecule using two pairs of primers (LX-PCR). Using LX-PCR method, the presence of -mtDNA was identified in 88 samples of muscle biopsy; age of the patients was 6 - 73 years. Only in 10 samples, D-mtDNA was identified by Southern blot. These patients fulfil the diagnostic criteria of Kearns-Sayre syndrome. In remaining 78 samples, the -mtDNA (single or multiple) was identified only by LX-PCR. Immunohistochemistry revealed other than mitochondrial type of myopathy in 22 patients. In 13 samples of muscle biopsy, no histological changes were present. Based on the phenotype, enzyme and protein analyses of OXPHOS complexes combined with the results of histochemical investigations, the mitochondrial aetiology of the disease is supposed in 43 patients. The candidate genes (*POLG1*, *ANT1*, *TP* or *C10orf2*) were analysed in 19 patients so far. A homozygous mutation G145R in *TP* gene was found in one patient. A heterozygous mutation Y831C in *POLG1* gene was found in two unrelated patients (A,B) and in 5 out of 9 siblings of the patient A. No other pathogenic mutation was found in exons or adjacent intronic regions. The siblings are without clinical symptoms so far. The Y831C mutation wasnt found in 216 control alleles. A dominant mode of inheritance of Y831C mutation in *POLG1* gene has been already proposed in a family with neuropathy. Due to high sensitivity of the LX-PCR used for detection of -mtDNA, interpretation of obtained results and further molecular genetic analysis should be done with respect to biochemical, histological and clinical data. Supported by GAUK 41/2004/C and IGA NR8065-3.

Localisation of a Fifth Gene involved in Autosomal Dominant Hypercholesterolemia. *M. Varret, M. Abifadel, A. Marques, J. Bonneau, M. Devillers, D. Erlich, A. Munnich, J-P. Rabès, C. Boileau* INSERM U781, Hopital Necker-Enfants Malades, Paris, France.

Autosomal Dominant Hypercholesterolemia (ADH), a major risk factor for atherosclerosis, was initially associated with mutations in two genes : LDLR (encoding low-density lipoprotein receptor) or APOB (encoding apolipoprotein B). Our team has pioneered the claim that the disease is far more heterogeneous. We have shown that defects in at least 2 other genes (HCHOLA3 and HCHOLA4) are implicated in the disease. We identified HCHOLA3 as PCSK9 (proprotein convertase subtilisin/kexin type 9) and located the HCHOLA4 gene at 16q22.1 in a 5.31 cM interval. Through the ADH French Research Network, we collected genetic material from a large french pedigree HC126). In this multiplex familly, 26 samples from 16 affected and 10 unaffected members were obtained. Linkage and sequencing analyses in familly HC126 excluded the involvement of the LDLR, APOB and PCSK9 genes. Furthermore, the study of 6 microsatellite markers spanning the HCHOLA4 interval clearly excluded linkage to this locus. These results demonstrate the existence of a HCHOLA5 gene. To evaluate the power of the HC126 family for linkage, 500 simulations were carried out using the SLINK software in which genotypes were simulated using parameters compatible with ADH. The average lod score was 2.08 and the maximum lod score was 3.96 indicating that the statistically-significant threshold of 3 could be reached in this single family. Genomewide scan is underway in collaboration with the French National Genotyping Center. Identification of the HCHOLA5 gene could reveal a new aspect of cholesterol metabolism and may lead to the development of new potent drugs.*LDLR*.

First Trimester Invasive Trophoblast Antigen (ITA) as a Down Syndrome Marker: Prospective Study with Fresh Serum. *P. Wyatt[1], C. Meier[2], L. Neveux[3], G. Palomaki[3]* 1) York Central, Toronto,Canada; 2) St.Michael's, Toronto; 3) Women & Infants, Providence, RI, USA.

Aim: Examine the screening performance of first trimester measurements of ITA, alone or in combination with other markers.
Methods: 12,610 women provided first trimester sera for routine Down syndrome screening. Most were part of an integrated Down syndrome test (both 1st and 2nd trimester sera). All sera were tested for pregnancy associated plasma protein-A (PAPP-A). ITA testing was performed on the fresh samples, but results were not used clinically. Results are reported in weight- and race-corrected multiples of the median (MoM). 30 affected pregnancies/births were identified.
Results: 10,606 women had both ITA and PAPP-A measured; 26 were affected with Down syndrome. At a 5% false positive rate (FPR), 8 cases (31%) were detected using either ITA or PAPP-A results alone. Median levels in affected cases varied by gestation (regressed medians of 2.01, 2.22, 2.47 for ITA at 11 12, and 13 weeks, and 0.23, 0.41, 0.75, for PAPP-A). Logarithmic standard deviations for ITA and PAPP-A in the unaffected were 0.2961 and 0.2526; and 0.2562 and 0.2905 in affected pregnancies. Correlations between markers were 0.1955 and -0.3463, for unaffected and affected pregnancies, respectively. At 12 weeks gestation, modeling indicates that maternal age with PAPP-A and ITA, detects 67% of cases at a 5% FPR; nuchal translucency (NT) measurements increases detection to 84%.
Conclusions: ITA and PAPP-A measurements in fresh samples closely match results from an earlier prospective study of 54 cases(Palomaki et al., Clin Chem 2005;51:1499-04)which found ITA levels in affected cases nearly as high at 11 weeks as 13 weeks. Combinations of maternal age, NT, PAPP-A and ITA also had similar detection when ITA was replaced with free- (FPR of 5%). This is true at each week from 11 through 13. Based on these two datasets, ITA is a suitable replacement for free- in first trimester screening, when combined with PAPP-A and NT.
.

Chromosomal Abnormalities in Ependymal Tumors. *Th. Palm[1], C. Godfraind[2], M. Vikkula[1]* 1) Lab Human Molecular Genetics, Christian de Duve Institute & UCL, Brussels, Belgium; 2) Lab Neuropathology, Cliniques universitaires St-Luc & UCL, Brussels, Belgium.

Ependymal tumors are derived from ependymal cells covering cerebral ventricles and the central canal of the spinal cord. Their overall incidence is 0.28 cases per 100,000 individuals per year in the United States with a mean age at diagnosis of 35 years. Their clinico-pathological presentation varies in between patients. In cytogenetic studies, up to 66% of the ependymal tumors present a normal karyotype. The most frequent aberrations are losses of chromosome 22, 6q and 9p; gains are frequently observed on 1q and on chromosome 7. Additional molecular markers are needed to define prognostic and/or clinical subgroups. In the current study, we used Affymetrix GeneChip 50K Arrays to establish high-resolution profile in a group of 35 ependymal tumors. It included two WHO grade I tumors, 13 WHO grade II tumors, 15 WHO grade III tumors and 5 tumors of unknown WHO grade. For the genomic profiles, only anomalies larger than 10Mb were included. Such chromosomal aberrations were observed in 27/35 tumors (~77%). All grade II tumors exhibited anomalies. In addition, they were more numerous in grade II than in grade III tumors (6.8/case vs. 3.8/case). The most frequent aberrations were monosomy 22 (13/35 cases = 37%), deletion or amplification of 9p (34%), deletion of 6q (31%), amplification of chromosome 7 (25%), and amplification of chromosome 12 (22%). Our results using the Affymetrix SNP-Chips platform are in concordance with previously published data established by microsatellite and cytogenetic studies. The resolution of the arrays allows us to focus on finer genetic alterations. Furthermore, expression studies will be integrated into these results in order to identify molecular markers for diagnostic/prognostic outcomes. (catherine.godfraind@anpg.ucl.ac.be).

High frequency of SDHB mutations in a series of head and neck paraganglioma from Belgium. *A. Persu[1], V. Grégoire[2], P. Garin[3], H. Reychler[4], G. Chantrain[5], G. Mortier[6], J.-F. De Plaen[1], M. Hamoir[7], M. Vikkula[8]* 1) Nephrology Dept, Cliniques universitaires St Luc & UCL, Brussels, Belgium; 2) Radiotherapy Dept, Cliniques universitaires St Luc & UCL, Brussels, Belgium; 3) Otolaryngology Dept, Cliniques universitaires de Mont-Godinne & UCL, Yvoir, Belgium; 4) Oral and Maxillofacial Surgery, Cliniques universitaires St Luc & UCL, Brussels, Belgium; 5) Centre Hospitalier Universitaire Saint-Pierre & ULB, Brussels, Belgium; 6) Center for Medical Genetics, Gent University Hospital, Gent, Belgium; 7) Otolaryngology Dept, Cliniques universitaires St Luc & UCL, Brussels, Belgium; 8) Lab of Human Molecular Genetics, Christian de Duve Institute & UCL, Brussels, Belgium.

Mutations of SDH genes encoding subunits of complex II of the mitochondrial respiratory chain are involved in the pathogenesis of paraganglioma (PG) and pheochromocytoma. While SDHD is more frequently involved in the pathogenesis of head and neck PG, SDHB mutations are mainly associated with malignant and/or extra-adrenal pheochromocytoma. To look for the nature and frequency of SDH mutations as well as for possible genotype-phenotype correlations in head and neck PG from Belgium, genetic screening included 30 patients without familial history of PG and 6 families including 18 subjects with known PG were done. Three frameshift mutations leading to premature stop codon, 2 splice site mutations and one substitution were found in 7 different patients including 5 familial cases and 2 apparently sporadic cases. Four of the mutations were not described previously. Furthermore, 2 different SDHB mutations (substitutions) were found in 4 unrelated patients with apparently sporadic PG. One of them, found in 3 of the 4 subjects, had been already described in a family with malignant pheochromocytoma. Surprisingly, in this Belgian series, SDHB mutations were three times as frequent as SDHD mutations (23 vs. 7%) in sporadic head and neck PG without evidence of dissemination, mainly due to a single mutation previously associated with familial metastatic pheochromocytoma (alexandre.persu@nefr.ucl.ac.be).

Common genetic variants of the ion channel transient receptor potential membrane melastatin 6 and 7 (TRPM6 and TRPM7), magnesium intake, and risk of type 2 diabetes in women. *Y. Song[1], Y.H. Hsu[2], J.E. Manson[1,3], J.E. Buring[1,3,4], S. Liu[1,2]* 1) Div. of Preventive Medicine, Brigham & Women's Hospital, Boston, MA; 2) Dept. of Epidemiology, UCLA School of Public Health, Los Angeles, CA; 3) Dept. of Epidemiology, Harvard School of Public Health, Boston, MA; 4) Dept. of Ambulatory Care and Prevention, Harvard Medical School, Boston, MA.

Ion channel transient receptor potential membrane melastatin 6 and 7 (TRPM6 and TRPM7) play a central role in magnesium homeostasis critical for maintaining glucose and insulin metabolism. We prospectively investigated whether single nucleotide polymorphisms (SNPs) in TRPM6 and TRPM7 genes contribute to the risk of type 2 diabetes. We genotyped 21 haplotype tagging SNPs in TRPM6 and 4 common SNPs in TRPM7 in a nested case-control study of 359 cases and 359 controls in the Womens Health Study and examined their associations with type 2 diabetes. After adjustment for matching factors (age, race, and fasting status), BMI, physical activity, alcohol, smoking, and family history of diabetes, our allele-specific analyses showed no significant association between any single variant and diabetes risk. Although no overall association by haplotype-based analysis was observed, there was a suggestion of a significant interaction between magnesium intake and the haplotype of TRPM6 based on two nonsynomous SNPs (Ile1393Val in exon 29 [rs3750425] and Lys1584Glu in exon 30 [rs2274924]) on diabetes risk. The haplotype 1393Val-1584Glu was significantly associated with increased risk of diabetes (OR, 2.75, 95% CI, 1.04-7.31) only among women with low magnesium intake (in the lowest 25th percentile, 288 mg/day). A similar association was also observed in our sliding-window 2-SNP haplotype analysis after adjustment for multiple comparisons. In conclusion, our results suggest that the two common non-synonymous TRPM6 coding region variants, Ile1393Val and Lys1584Glu polymorphisms, may influence risk of type 2 diabetes in women with low magnesium intake. Our data support the hypothesis that the role of TRPM 6 in the regulation of intestinal magnesium absorption may be critical when passive magnesium transport is slowed by inadequate magnesium intake.

Bicuspid aortic valve and other cardiovascular malformations are genetically heterogeneous. *V. Ramachandran[1], L.J. Martin[2,3], L.H. Cripe[1,3], R.B. Hinton[1,3], M. Tabangin[2], K. Shooner[1], D.W. Benson[1,3]* 1) Department of Cardiology, MLC 7042, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Center for Epidemiology and Statistics, Cincinnati Childrens Hospital Medical Center, Cincinnati, OH; 3) The University of Cincinnati School of Medicine, Cincinnati, OH.

Valvular heart disease remains a common and important problem. Among all forms of valvular heart disease, aortic valve disease is most common and aortic valve replacement is the second most common cardiac surgery in United States. In individuals of all ages aortic valve disease is linked to a common congenital valve malformation bicuspid aortic valve (BAV) with a prevalence of 1-2%. Heritability studies indicate that BAV determination is almost entirely genetic. The aim of the current study was to identify genes causing BAV and other cardiovascular malformations (CVMs) by linkage analysis. Thirty-eight families with BAV and other CVMs including dilated aortic root, coarctation of aorta, ventricular septal defect and hypoplastic left heart syndrome were enrolled in the study. Definitive diagnosis was made by standardized complete 2D and Doppler Transthoracic Echocardiograms. Genome-wide scan was performed using the microsatellite marker panels, ABI Prism Linkage Mapping Set. Phenotypic and genotypic data from 324 individuals belonging to 38 families were used for the genetic analysis. Both parametric and non-parametric linkage analysis was performed with the softwares GENEHUNTER and SOLAR respectively using 2% and 5% prevalence. The highest LOD score, 3.8, occurred on chromosome 18q between markers D18S68 and D18S1161. Other genetic locations 5q (between D5S644 and D5S2027) and 13q (between D13S1265 and 13qter) across the genome exhibited a LOD score of 2.7 suggestive of linkage (LOD greater than 2.0). In this genome-wide scan we demonstrate, for the first time, that BAV and other CVMs are genetically heterogeneous exhibiting linkage to 18q, 5q and 13q. Based on the biology of valve development, candidate genes may be valvulogenesis building block genes such as extracellular matrix proteins, signaling molecules and transcription factors.

Analysis of candidate genes for nonsyndromic cleft lip and/or palate in Brazilian trios with both a parent and offspring affected. *A.L. Silva[1,2,4], L.A. Ribeiro[2], M.E. Cooper[3], M.L. Marazita[3], D. Moretti-Ferreira[1], J.C. Murray[4]* 1) Universidade Estadual Paulista, UNESP, Botucatu, SP, Brazil; 2) Hospital de Reabilitação de Anomalias Craniofaciais, USP, Bauru, SP, Brazil; 3) Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA, USA; 4) Pediatrics, University of Iowa, Iowa City, IA.

Cleft lip and/or palate (CL/P) is a major congenital anomaly with a birth prevalence from 1 in 500 to 1 in 2500 births, depending on geographic, ethnic, and socioeconomic factors. Approximately 2/3 of cases do not show any others anomalies and are classified as nonsyndromic (NS). Studies have suggested a handful of genes and/or loci in humans, as well as environmental disrupters appear to play a role in the genesis of such cases. In the present study we analyzed a total of 29 single nucleotide polymorphisms (SNPs) in 7 candidates the genes: IRF6 (7), TGFA (4), MSX1 (2), FGFR1 (4), FOXE1 (3), BMP4 (2) and TGFB3 (7) in 120 Brazilian trios with both a parent and offspring affected with NS-CL/P. We also performed direct sequencing of the MSX1 gene. TDT analysis for the SNPs was performed in the total group and also in subgroups dependent on the parent affection status. We found significant results for the candidate genes IRF6 (p-value=0.02), TGFA (p-value=0.02), MSX1 (p-value=0.006) and TGFB3 (p-value=0.006). All the genes analyzed in this study are strong candidate genes for nonsyndromic cleft lip and/or palate as previous studies had shown their expression in craniofacial tissues during the development and mutations in some of them are know to cause syndromic forms of oral clefts. This study suggests that cases with two generation family history may arise secondary to the interactive effects of currently recognized candidate genes and may have implications for genetic counseling in these high risk families.

Test Interaction between Two Unlinked Loci Using Composite Linkage Disequilibrium. *X. Wu*[1], *L. Jin*[1], *M. Xiong*[1,2] 1) Fudan University, Shanghai, China; 2) University of Texs Health Science Center at Houston.

Alternative methods to the traditional logistic model and Fishers formulation for testing interactions are to test interaction by measure of linkage disequilibrium (LD). The various measures of LD are based on haplotypes. The haplotype-based methods for detection of interaction have tow limitations. First, when Hardy-Weinberger equilibrium does not hold, it is difficult to estimate haplotypes. Second, the estimation of haplotype frequencies by statistical methods often has errors. It is recently noted that the errors of estimation of haplotype frequencies have big impact on the haplotype-based tests. To overcome these limitations in this report we propose to use composite measure of LD to test interaction between two unlinked loci which allow using genotypes. We develop a general theory for studying composite measure of LD in the disease population under two-locus disease models and explore using composite LD measure between two unlinked loci in the disease population as a function of the measure of interaction between two unlinked loci. We investigate that how interaction between two loci create LD in the disease population and derive the mathematical formulation of new definition of interaction between two loci based the composite LD measure, which motives us to present a composite measure of LD-based statistic to detect interaction between two unlinked loci. The null distribution and the type 1 error rates of the composite measure of LD-based statistic for testing interaction between two unlinked loci are validated using simulation studies. We compare the power of the developed test statistic with the traditional logistic models. Finally, we apply the developed statistic to three real data sets. Preliminary results show that the newly developed statistics have much smaller P-values than that of the traditional logistic models.

Disease Balanced Chromosomal Rearrangements and their relevance in genetic counselling. *A. Sánchez-Díaz[1], C. Morales-Peydro[1,2], E. Margarit[1], I. Madrigal[1], M. Milà[1], A. Soler[1]* 1) Servei Bioquímica i Genètica , Hospital Clínic, Barcelona, Spain; 2) Fundació Clínic, Hospital Clínic, Barcelona, Spain.

Introduction: Balanced Chromosomal Rearrangements (BCR) are the most frequent chromosomal abnormality and imply segmental chromosomal exchange without loss or gain of genetic material, and, essentially, are not associated to clinical features, especially those that are inherited. BCRs de novo are associated to abnormal phenotype in 6% of cases, due to gene truncation at the breakpoints, to positional effect, to uniparental disomy of imprinted chromosomes, or cryptic duplications and deletions. In the present work, we report the genetic study and the phenotypic implications of BCR in our patients. Material and methods: Forty-six BRCs cases diagnosed in our laboratory during the past 5 years were collected and re-analysed. High-resolution cytogenetic analysis was carried out in all cases. In 35 cases, parents were also karyotyped. Some cases were complemented using Fluorescence in Situ Hibridation (FISH) or Multiplex Ligation-Dependent Probe Amplification (MLPA) techniques. A physical examination and a detailed clinical history were done in all cases. Results: Nine out of the 46 cases were de novo and seven of them presented phenotypic affectation; 26 cases were inherited and in one of them the rearrangement co-segregated with the pathology. Eleven cases were of unknown origin. Two cases were complex BCRs involving 3 chromosomes, one of them de novo that was associated to phenotypic abnormalities. Conclusion: this study, according to others previously reported, discloses the high frequency of BCRs associated to abnormal phenotype, mainly when they are de novo. In these cases, the application of complementary molecular techniques is required to obtain an accurate characterization of the rearrangements, in order to establish a genotype-phenotype correlation. Moreover, this allows providing familial genetic counselling, the unique tool of prevention for genetic diseases.

Experiences of genetic counseling in eight families with Vietnamese wives in Taiwan. *H.P. Pan[1,4], S.J. Lin[2,4], M.C. Huang[1,3]* 1) Department of Nursing, National Cheng Kung University Hospital, Tainan, Taiwan; 2) Department of Pediatrics, National Cheng Kung University, Tainan, Taiwan; 3) Department of Nursing, National Cheng Kung University,Tainan,Taiwan; 4) Center of medical Genetic, National Cheng Kung University Hospital, Tainan, Taiwan.

According to report from Taiwan Ministry of Interior in 2005, one out of five newly married couples in Taiwan is international marriage. Among Southeast Asian brides, seventy percent are from Vietnam. For the family with a Vietnam wife, the purpose of marriage is to have a son to carry on the family name. Raising children is the major task in her life. Since couples in an international marriage usually have little time to know each other before wedding and have language obstacles and culture gaps, it will become a much more serious problem when they have to face a genetic disease. In order to improve the effectiveness of counseling, we investigated the genetic counseling process of eight families with Vietnamese spouse during 2004 to 2005 in Southern Taiwan. The process recordings of counseling were taken and analyzed to explore the psychosocial responses in these families. The result is divided into four parts: (1) the reasons for referral (2) the interaction and power structure among family members (3) the responses of family members during counseling (4) the impact of a genetic disease on the Vietnamese spouses. Our results show that reproductive planning in these families is decided by Taiwanese husbands and mothers-in-law. Due to language barrier and social isolation, Vietnamese wives husband and mother-in-law used to dominate the conversation. Genetic counselors could barely know whether Vietnamese wives understand the content of counseling. The result also found the key factors for effective genetic counseling (1) helping these international spouses express themselves well, (2) keeping good communication between their families and medical staff, (3) facilitate their adaptation to the environments in Taiwan.

Hypogonadotrophic hypogonadism associated with a subtelomeric deletion of 9p chromosome in a girl. *L. Telvi*[1], *C. Bouvattier*[2], *M. Minz*[1], *P. Bougneres*[2] 1) Cytogenetics Laboratory, Hospital St Vincent de Paul, Paris,; 2) Endocrinology Department, Hospital St Vincent de Paul, Paris, France.

We report a girl with a subterminal deletion of the short arm of chromosome 9, detected after classical R banding and high resolution banding and confirmed by in situ fluorescence hybridization techniques (FISH) in all analyzed metaphases. The patient showed a short stature (-4 SD), motor and mental retardation with dysmorphic features. Actually, the patient is 20 years-old, and presented a hypogonadotrophic hypogonadism. It was reported that the male patients with 9p deletion is associated with failure of normal testis development. However, there are no report of endocrinological anomalies associated with 9p deletion in female patients. In this report, we analyse the relationship between the endocrinological anomaly as a hypogonadotrophic hypogonadism associated with 9p deletion in female patients. We describe the phenotype of the patient and compare this case to the other female cases reported in the litterature with a subtelomeric deletion of 9p chromosome.

Association study aimed at identifying genes influencing the penetrance of DYT1 Dystonia. *G. Senthil[1], R. Saunders-Pullman[2], D. Raymond[2], S.B. Bressman[2], N. Risch[3], L.J. Ozelius[1]* 1) Department of Molecular Genetics, AECOM, Bronx, NY,United States; 2) Department of Neurology, Beth Israel Medical Center, New York, NY,United States; 3) Center for Human Genetics, University of California at San Francisco, San Francisco, CA, United States.

Dystonia is a neurological movement disorder characterized by sustained muscle contractions and abnormal postures. The DYT 1 locus on human chromosome 9q34 is responsible for the most severe form of hereditary dystonia-early onset, generalized torsin dystonia. This disorder is inherited as an autosomal dominant trait with reduced penetrance of only 30-40%. A single mutation, a 3-bp (GAG) deletion causing the loss of a glutamic acid residue from the encoded protein torsinA, accounts for about 50% of non-Jewish individual and over 90% of Ashkenazi Jewish individuals with this form of dystonia. In an effort to understand the reduced penetrance associated with the disease, we examined genetic variants within the DYT1 gene (3 SNPs) and its interacting partners, TOR1B (located adjacent to DYT1, 2 SNPs) and LAP1B (located on chromosome 1q25, 3 SNPs). The polymorphisms in these candidate genes were assessed in affected, non-manifesting DYT1-GAG deletion carriers and controls, to determine whether any were associated with penetrance. In addition, haplotypes were generated across these genes and also examined for association. Haplotypes across the DYT1 and TOR1B region of chromosome 9 are more frequent in non-manifesting carriers than affecteds suggesting a protective role contributing to the reduced penetrance.

Somatic Mosaicism for an *HRAS* mutation causes Costello Syndrome. *K. Sol-Church[1], D.L. Stabley[1], L. Nicholson[2], J.D. Hoffman[3], K.W. Gripp[2]* 1) Dept Biomedical Research, Alfred I duPont Hospital for Children, Wilmington, DE; 2) Division of Medical Genetics, Alfred I duPont Hospital for Children, Wilmington, DE; 3) Department of Pediatrics, Division of Genetics, Tufts-New England Medical Center, Boston, MA.

De novo heterozygous *HRAS* point mutations have been reported in more than 81 patients with Costello syndrome (CS), but genotype/phenotype correlation remains incomplete because the majority of patients share a common mutation, G12S, seen in 65/81 (80%). Diagnostic testing for *HRAS* mutations is now available and the identification of a mutation in a patient with consistent clinical findings confirms a diagnosis of CS. It is unclear at this time if the absence of an *HRAS* mutation precludes a clinical diagnosis of CS. One area of uncertainty remains in the differential diagnosis to cardio-facio-cutaneous syndrome (CFC).

We report here on a female with findings suggestive of CS in whom mutation analysis performed with standard techniques on white blood cell derived DNA did not show an *HRAS* mutation. However, analysis of DNA derived from three independently collected buccal swabs showed a sequence change qualitatively consistent with the G12S mutation. Allelic quantitation, performed using pyrosequencing, revealed the presence of the mutation in ~25-30% of the sampled buccal cells. Further analysis of the blood sample using restriction endonuclease analysis confirmed the presence of the G12S mutation.

In this patient, standard technology failed to identify the disease causing mutation on DNA derived from a blood sample, highlighting the potential pitfalls in the interpretation of negative mutation studies.

This is the first reported CS patient mosaic for the common *HRAS* mutation, likely due to a somatic mutation occurring early in fetal development.

FFIGdb - A Fast, Flexible, Integrated Genotype Database for storing very large genotype and phenotype data sets. *W. Rayner, E. Zeggini, M.I. McCarthy, and the International Type 2 Diabetes 1q Consortium* University of Oxford, Oxford, Oxfordshire, United Kingdom.

Many current genetic studies are generating increasingly massive data sets, both in terms of phenotypic and genotypic information. Efficient exploitation of these data requires dedicated data management systems with the capacity to store and manipulate these very large data sets.

FFIGdb is a high-throughput data management system initially developed for the International Type 2 Diabetes 1q Consortium. The system is capable of storing both phenotype and genotype information and is currently based on an Oracle database utilising a Perl client interface. The system is widely portable as the database schema utilises standard SQL and is therefore usable, with minor keyword changes, on any other relational database system that supports stored procedures.

Unlike most previous systems using Access or MySQL the system has been designed from the outset to utilise Enterprise level software to deal with multibillion point data sets: for example, on a low end server consisting of dual Xeon processors with a 1.4Tb RAID, it is possible to load in excess of 400 million genotypes/hour. Exports are similarly fast: data, and user-defined subsets of the data, can be exported in a wide variety of formats, including Stata and Helixtree, at a speed of 100 million genotypes/hour.

For flexibility, the database utilises an Entity-Attribute-Value (EAV) data model for storing phenotype, sample and marker data. The EAV model allows for user-defined data sets to be easily loaded thereby giving the system great flexibility and allowing it to be extended to any project. The system also incorporates many features for data management such as genotype and phenotype Quality Control (QC), duplicate sample- and marker-checking and audit trails.

To date, the system is handling multibillion point genome wide association data sets with ease. Development continues to ensure the speed, storage capability and flexibility all keep pace with ever-increasing data sizes.

Differential Gene Expression in Pediatric Embrionary Advanced Rhabdomyosarcomas. *O. Perez-Gonzalez[1], A. Hidalgo-Miranda[1], I. Silva-Zolezzi[1], R.M. Rivera-Luna[2], G. Jimenez-Sanchez[1]* 1) National Institute of Genomic Medicine, Mexico; 2) National Institute of Pediatrics, Mexico.

Rabdomyosarcoma (RMS) is the most frequent soft tissue malignant tumors and accounts for ~6% of all neoplasias in chilhood. The overall survival rate has significantly improved with the current therapy. The allocation of the neoadyuvant antineoplasic treatment is based on the Intergroup Rhabdomyosarcoma Study (IRS) classification system. However, therapeutic response is still inconsistent even in patients under similar classification. Thus, a classification system for a more individualized allocation of the antineoplasic treatment would result in significant benefit to patients with this disease. To explore the existence of a differential gene expression in patients with identical histopathological diagnosis and different responses to neoadjuvant antineoplastic treatment, we analyzed total RNA of nine RMS from pediatric patients from 9 to 12 years old with advanced stages using Affymetrix U133 Plus 2.0 gene expression arrays. Histopatological samples were obtained before administration of neoadyuvant treatment based on the IRS staging system, after which all patients were re-evaluated to classify response rate into good, intermediate or poor, using the same system. We obtained a probe-calling rate of 35-54% and are performing a supervised cluster analysis to find gene expression profiles associated to specific response rates. Results will be confirmed by independent expression analysis methods and the number of samples is continuously increasing. We are currently performing hierarchical clustering analysis using MacOS_Mev_3_1, version 10.2. Differential gene expression profiles in RMS are being analyzed as a mean to provide a more accurate system to allocate neoadyuvant antineoplasic treatment in patients with this disease. In addition, this will allow considering new therapies for those patients with expression profiles consistent with poor response rates.

A Novel X-Linked Locus for Metacarpal Synostosis. *A. Praggastis, Z. Yang, Y. Zhao, J. Baird, E. Pearson, Z. Tong, K. Zhang* Ophthalmology, University of Utah.

Purpose: The failure of the 4th and 5th metacarpal bones to differentiate into separate appendages is a condition known as Metacarpal synostosis. Depending on the severity, this condition can have significant effects on an individuals ability to perform everyday functions. Metacarpal synostosis is genetically heterogeneous and may present as an autosomal dominant, or X-linked recessive trait. We investigated a large Utah pedigree spanning 4 generations with 9 affected individuals. Methods: Clinical examination and testing were performed in all participants. Peripheral blood was taken from 8 members, including 3 affected males and 4 carriers. Genotyping using STR and SNP markers on the X chromosome for metacarpal synostosis was performed. Linkage and LOD scores were computed using Llinkage 5.1 Results: Hand x-ray radiography revealed fusion of the 4th and 5th metacarpal bones in affected individuals. Within this family, there were no females affected and no instances of male-to-male transmission, indicating X-linked recessive transmission. Linkage analysis mapped the disease gene to Xp11.22-Xq21.32 with maximal LOD score of .9053, at theta = 0, with DXS986. Haplotype analysis localized the disease gene in a 18 CM interval between DXS993 and DXS990. Conclusions: We mapped a disease gene for metacarpal synostosis in a Utah family to Xp11.22-Xq21.32. Further mapping and identification of the disease gene for metacarpal synostosis will increase our understanding of the condition and provide us with a more general knowledge of the mechanisms for hand development.

RASA1: an important gene for Parkes Weber syndrome. *N. Revencu[1, 2], L.M. Boon[1, 3], O. Enjolras[4], P.E. Burrows[5], M.R. Cordisco[6], E. Baselga[7], H.J. Paltiel[5], I. Quere[8], A. Delerue[9], C. Delerue[9], J.M. Caballos Quintal[10], R. Vanwijck[3], J.B. Mulliken[5], M. Vikkula[1]* 1) Lab Human Molecular Genetics, Christian de Duve Institute & UCL, Brussels, Belgium; 2) Centre for Human Genetics, Cliniques universitaires St-Luc, Brussels, Belgium; 3) Centre for Vascular Anomalies, Division of Plastic Surgery, Cliniques universitaires St-Luc, Brussels, Belgium; 4) Hôpital Lariboisière,Paris, France; 5) Children's Hospital, Boston, MA, USA; 6) Hospital Nacional de Pediatria, Buenos Aires, Argentina; 7) Hospital de la Sant Pau, Barcelona, Spain; 8) Centre Hospitalier Universitaire, Montpellier, France; 9) Lille, France; 10) Laboratorio de Genetica, Yucatan, Mexico.

Parkes Weber Syndrome (PWS; OMIM 608355) is characterized by a large cutaneous vascular stain in association with soft tissue and skeletal hypertrophy in an extremity, with underlying multiple arteriovenous micro-fistulas. Even if rather different, PWS has often been taken, in the literature, for two other conditions associated with limb hypertrophy: Klippel Trenaunay syndrome and capillary malformation with non-progressive congenital hypertrophy. Previously, we showed that an individual harbouring a germline mutation in the RASA1 gene, had PWS. In addition, this individual had multiple capillary malformations (CMs), which were transmitted as a dominant trait across his family. Therefore, we wanted to test if RASA1 is the causative gene of PWS in general. We screened 21 individuals with PWS for RASA1 mutations by DHPLC followed by sequencing and we identified mutations in 12 individuals (57%). Of these, 10 were familial and 2 were sporadic cases. These individuals and other 4 belonged to a phenotypically homogenous group in which PWS was associated with CMs. The remaining 5 individuals, in whom no RASA1 mutation was identified, constituted a phenotypically distinct group with less overgrowth in the affected limb and without CM lesions. In conclusion, RASA1 is an important gene for PWS with specific clinical characteristics. (vikkula@bchm.ucl.ac.be) (http://www.icp.ucl.ac.be/vikkula).

Evolution of interaction in disease-related, zinc-finger proteins: Stabilization to regulation in WT1, ZIC, and GLI proteins. *G.J. Wyckoff[1], A.K. Solidar[1], A. Bergen[1], J.H. Laity[2]* 1) Div Molec Biol & Biochemistry, Univ Missouri, Kansas City, Kansas City, MO; 2) Div Cell Biol. & Biophysics, Univ Missouri, Kansas City, Kansas City, MO.

Cys_2His_2 zinc finger domains found in transcription factor proteins have been described as beads connected by flexible consensus peptide strings, which become ordered upon binding DNA targets. The highly specific interactions involving conserved zinc finger residue positions and nucleic acid bases underlie canonical zinc finger biology. A novel evolutionary approach is used which identifies over 150 genes within this newly-identified two-finger subclass within the larger Cys_2His_2 superfamily. These genes, including the disease-related proteins GLI, ZIC, and WT1; involved in human brain disoriders and cancer, have functions dependent upon close interactions between N-terminal zinc finger domains mediated by invariant tryptophan residues in each finger. Our data suggest that the evolution of these two-finger motifs proceeded due to selection driving finger stability, eventually leading to interaction between fingers. This produced diverse biological functions including regulatory roles mediated by finger interaction. To assess whether positive, Darwinian selection has acted to drive the functional diversity in the two-finger class, we culled a large number of proteins from human and several other species. While two-finger proteins are relatively well-conserved across homologous proteins, Ka/Ks comparisons across types of domains was often higher than one-- a hallmark of adaptive selection (p-value < 0.0001 via T-test). This finding has implications for understanding disease causal mutation in proteins involved with developmental disorders and cancer mediated by zinc finger function.

The Jackson Laboratory Repository: New mouse models of human disease. *S. Rockwood, D. Bergstrom, B. Chang, L.R. Donahue, K.R. Johnson, C.M. Lutz, M. Sasner, M.T. Davisson, The Repository Team* The Jackson Laboratory, Bar Harbor ME.

The mouse continues in its role as one of the most persistent and utilitarian model organisms, evidenced by the ever increasing number and variety of models generated. To ensure ready access of these mice to the scientific community The Jackson Laboratory Repository serves as a centralized facility for the purpose of developing, rederiving, cryopreserving and distributing mouse models to the international biomedical research community. Approximately 200-300 new strains are added annually to the hundreds of unique mouse strains that comprise the largest collection of characterized mouse strains available. Models newly imported and/or developed for distribution have applications in studies focusing on Spinal Muscular Atrophy (SMA), Cystic Fibrosis and Alzheimers disease. Larger sets of mice originating from Deltagen (NIH-sponsored) and the Consortium for Functional Glycomics have been added to the Repository in the last year. Mutant mice useful in neurological (Grin 1 glutamate receptor KO, and a Tg (Gfap-Tk) 7.1Mvs/J transgenic) and immunological (Ccr7 and Cxcr3 chemokine receptor KOs) studies are also newly available. Supplementing these strains are a wide variety of cre-expressing strains (constitutive or inducible), a growing number of targeted mutants harboring loxP-flanked genes and tetracycline regulated transactivator-expressing mice. Two consomic and 6 Recombinant Inbred strain panels are maintained for complex trait analysis. An on-line resource (www.jax.org) allows researchers to retrieve information related to strains in the Repository. Donating a strain to the Repository fulfills the requirements for sharing of mice required by NIHs policy for the sharing of research reagents. Researchers wishing to have strains considered for inclusion in the Repository may use the submission form available at: http://www.jax.org/grc/index.html The Jackson Laboratory Repository is supported by the NCRR (RR09781, RR11083, RR16049), NIA, The Howard Hughes Medical Institute, The Ellison Medical Foundation and donations from several private charitable foundations.

X chromosome inactivation patterns in females with Prader-Willi syndrome. *M.F. Theodoro[1], Z. Talebizadeh[1], D.J. Driscoll[2], M.G. Butler[1]* 1) Children's Mercy Hospital and University of Missouri-Kansas City, Kansas City, MO; 2) University of Florida, Gainesville, FL.

Prader-Willi syndrome (PWS) is characterized by infantile hypotonia, feeding difficulties, hypogonadism, small hands and feet, mental deficiency, behavioral problems, and obesity in early childhood. This genomic imprinting disorder is caused by loss of paternally expressed genes from the 15q11-q13 region due to a paternally derived deletion of the region or maternal disomy 15 (UPD). Maternal disomy 15 is thought to occur by maternal meiosis I nondisjunction associated with advanced maternal age and after fertilization with a normal sperm leads to trisomy 15, a lethal condition unless trisomy rescue occurs in early pregnancy with loss of the paternal chromosome 15. If trisomy 15 rescue occurs in the early stages of pregnancy, an unequal X chromosome inactivation pattern could result in the embryo. In healthy females, X chromosome inactivation follows a Gaussian or bell-shaped distribution with highly skewed patterns being uncommon events. To further characterize the maternal disomy 15 process in PWS and how it occurred, the status of X chromosome inactivation was calculated to determine whether nonrandom skewing of X inactivation was present which would indicate its origin from a small pool of early embryonic cells. We studied X chromosome inactivation in peripheral blood DNA from 110 Caucasian females (25 with PWS-UPD, 35 with PWS-deletion, and 50 healthy, unrelated controls without PWS) with similar means, medians, and ranges of ages using the X-linked polymorphic androgen receptor (AR) gene assay. No correlation was detected with X chromosome inactivation and age for any subject group. However, a significantly increased level ($p=0.024$) of extreme X inactivation skewness (>90%) was detected in our PWS-UPD group (6 of 25 subjects, 24%) compared to controls (2 of 50 subjects, 4%). This observation would further support that trisomy 15 occurs at conception with poor growth of cells and trisomy rescue in early pregnancy. In addition, extreme X inactivation skewness may lead to expression of X-linked recessive disorders in PWS females with UPD and extreme X chromosome skewness.

Butyrate mediates decrease of histone acetylation centred on transcription start sites and downregulation of associated genes. *C. Wadelius[1], A. Rada-Iglesias[1], A. Ameur[2], S. Enroth[2], C. Koch[3], G. Clelland[3], P. Respuela-Alonso[1], S. Wolcox[3], O. Dovey[3], P. Ellis[3], C. Langford[3], I. Dunham[3], J. Komorowski[2]* 1) Department of Genetics and Pathology, Uppsala University, Sweden; 2) Linnaeus Centre for Bioinformatics, Uppsala, Sweden; 3) Wellcome Trust Sanger Institute, Cambridge, UK.

Butyrate is a histone deacetylase inhibitor (HDACi) with anti-neoplastic properties, which theoretically reactivates epigenetically silenced genes by increasing global histone acetylation. It is structurally similar to valproic acid and phenylbutyrate that are approved for treatment of epilepsy and cancer. However, recent studies indicate that more genes are down-regulated than up-regulated by this drug. We treated hepatocarcinoma HepG2 cells with butyrate and characterized the levels of acetylation at DNA-bound histones H3 and H4 by ChIP-chip, using arrays covering 1% of the genome as defined in the ENCODE project. Western blot showed a marked increase of histone acetylation after treatment. However, ChIP-chip showed that many genomic regions close to transcription start sites were deacetylated after butyrate exposure. Only a few regions showed and increase in histone acetylation. ChIP and locus specific PCR showed that both butyrate and trichostatin A treatment resulted in histone deacetylation at selected regions, while nucleosome loss or changes in histone H3 lysine 4 trimethylation (H3K4me3) did not occur in such locations. Histone deacetylation was observed when colon adenocarcinoma HT-29 cells were treated with butyrate. Genes with deacetylated promoters were downregulated by butyrate, and this was mediated at the transcriptional level by affecting RNA polymerase II (Pol2) initiation/elongation. Immunofluorescence showed that the global increase in acetylated histones was preferentially localized to the nuclear periphery, indicating that it might not be associated to euchromatin. Our results are significant for the evaluation of HDACi as anti-tumourogenic drugs, suggesting that previous models of action might need to be revised, and provides an explanation for the frequently observed repression of many genes during HDACi treatment.

Development of verified quality control materials from the Coriell Cell Repositories fulfills needs of genetic testing community. *T. Sellers*[1], *D. L. Coppock*[1], *L. Kalman*[2] 1) Coriell Institute for Medical Research, Camden, NJ; 2) Centers for Disease Control and Prevention, Atlanta, GA.

Background: The expansion of molecular genetic testing in clinical and public health practice has increased the need for appropriate, verified quality control (QC) materials. However, for many tests the necessary QC materials are not publicly available. **Methods:** The Coriell Cell Repositories (Coriell) routinely conducts surveys at the American and European Societies of Human Genetics meetings to gauge interest in samples with characterized mutations. Individuals citing interest in these samples were asked to indicate desired diseases. Based on the input from these surveys and other sources, Coriell, in collaboration with the CDC's Genetic Testing Quality Control Materials Program (GTQC) and the genetic testing community, is developing verified QC materials based on cell lines from Coriells NIGMS Human Genetic Cell Repository. Cell lines containing clinically important alleles for Huntington disease (HD), Fragile X syndrome (FX) and 9 disorders common in the Ashkenazi Jewish (AJ) population were chosen for QC material development based on input from the genetic testing community. DNA prepared from each cell line was sent to multiple volunteer laboratories that verified the mutation using a variety of testing methods, including DNA sequence analysis. **Results:** Surveys were administered to 633 individuals at 7 meetings from 2001 to 2005. Of the 378 respondents (59.7%) who indicated interest in samples with characterized mutations, FX (45.1%) and cystic fibrosis (36.8%) were most commonly suggested. HD (20.9%) and the AJ disorders were also commonly requested. To date, GTQC, Coriell, and the genetic testing community have verified the alleles in 57 cell lines from 11 disorders and additional verifications are being planned. These materials are publicly available through Coriells NIGMS Repository. **Conclusions:** The development of verified QC materials by this collaborative effort will fulfill needs expressed by the genetics community and will help improve both the quality and accuracy of genetic testing.

Genetic analysis for ordinal traits. *H. Zhang, Y. Ye, X. Wang* Dept Epidemiology/Public Hlth, Yale Univ Sch Medicine, New Haven, CT.

For complex diseases, especially mental health conditions including nicotine dependence and substance use, the outcome variables are often recorded in an ordinal rather than quantitative scale. The naturally recorded ordinal traits are commonly analyzed either as quantitative traits or being dichotomized. We demonstrate that these commonly used approaches to dealing with ordinal traits are inadequate and result in loss of power. We propose a new framework and powerful statistical tests to conduct linkage and association analyses for any complex traits that include ordinal traits. Through simulation studies, we compare the type I error and power of our new methods with existing tests. The empirical result suggests that our methods produce reasonable type I errors and have power far exceeding (sometimes doubling) those of existing tests. We applied our proposed methods to identify genes for complex diseases. For example, using a data set on alcohol dependence, we found that six single nucleotide polymorphisms (SNPs) are significantly associated with alcohol dependence after adjusting for gender and age, and three of them were identified for the first time, underscoring the powerful of our new methods.

Townes-Brocks Syndrome and Renal Disease. *W. Reardon[1], R. Birkenhaeger[2], L. Casserly[3], J. Kohlhase[4]* 1) National Centre for Medical Ge, Our Lady's Hospital for Sick Children, Dublin, Ireland; 2) Dept of Otorhinolaryngology, University Clinics Freiburg, Freiburg, Germany; 3) Regional Hospital, Doordoyle, Limerick, Ireland; 4) Institute of Human Genetics and Anthropology, University of Freiburg, Freiburg, Germany.

Having presented at age 43 with unexplained chronic renal failure, an unrecognised case of Townes-Brocks syndrome was subsequently successfully treated by renal transplantation. First seen in the genetics clinic at age 49, the diagnosis was established clinically and a novel heterozygous mutation, resulting in a premature stop codon (Q507X), identified in the SALL1 gene, the locus for Townes-Brocks syndrome. Some clinical features in the patient, in particular myopia and hypothyroidism, were atypical of Townes-Brocks syndrome, leading us to exclude possible alternative pathologies by radiological and molecular approaches. Renal agenesis is established in mouse models of Sall1 deficiency but affected animals die in the neonatal period. Our observation of renal failure in this adult patient with Townes-Brocks syndrome led us to review the experience of renal malformation and physiological renal disease in this syndrome, establishing that both structural and functional abnormalities of the kidney are associated with SALL1 mutation. We suggest that longitudinal screening for renal disease may be justified in all patients with Townes-Brocks syndrome.

27-hydroxy-7-dehydrocholesterol is an endogenous teratogen in Smith-Lemli-Opitz syndrome that decreases cholesterol levels in patients and increases phenotypic severity in mice. *F.D. Porter[1], N. Javitt[2], M.F. Starost[4], M. Lyman[1], E. Leitersdorf[3], C.A. Wassif[1]* 1) HDB, NICHD, NIH Bethesda, MD; 2) NYU, New York, NY; 3) Hadassah Hebrew Univ Med Center, Jerusalem; 4) DVR, OD, NIH Bethesda, MD.

Smith-Lemli-Opitz syndrome (SLOS) is a malformation, mental retardation syndrome with a variable phenotype. SLOS results from a deficiency of 7-dehydrocholesterol reductase (DHCR7) activity. DHCR7 catalyzes the reduction of 7-dehydrocholesterol (7DHC) to cholesterol. 27-hydroxycholesterol (27-OH-C) which is synthesized from cholesterol by CYP27, may play a role in cholesterol homeostasis. In SLOS an atypical oxysterol, 27-hydroxy-7-dehydrocholesterol (27-7DHC) is present. We thus investigated whether 27-7DHC contributes to the pathology of SLOS. A negative correlation ($r2=0.79$, $p<0.001$) between plasma 27-7DHC and cholesterol levels was found in SLOS patients. No correlation was found between cholesterol and 27-OH-C or 7DHC. Previous work showed that hedgehog signaling is impaired by low cholesterol levels. We thus hypothesized that increased 27-7DHC levels would have detrimental effects during development due to suppression of cholesterol levels. To test this hypothesis we produced SLOS mice (*Dhcr7-/-*) expressing a *CYP27* transgene. *CYP27Tg* mice have elevated *CYP27* expression and 27-C levels, but normal cholesterol levels. *Dhcr7-/-* mice are growth retarded, have a low incidence of cleft palate (9%), and die during the first day of life. *Dhcr7-/-:CYP27Tg* embryos are stillborn and have multiple malformations. These include marked growth retardation, micrognathia, cleft palate (77%), lingual and dental hypoplasia, ankyloglossia, umbilical hernia, cardiac defects, cloacae, curled tails, and limb defects. Autopod defects (polydactyly, syndactyly and oligodactyly) were observed in 77%. Brain defects include abnormalities of the corpus callosum and cortical plate. The *Dhcr7-/-:CYP27Tg* model more closely resembles severe SLOS. As hypothesized, sterol levels were decreased 2-fold in liver and 20-fold in brain tissue in *Dhcr7-/-:CYP27Tg* compared to *Dhcr7-/-* embryos. Recognition of the role of 27-7DHC in SLOS may explain some of the phenotypic variability and may lead to development of novel therapies.

Pancreatic islet cell tumor in a germline CDH1 mutation carrier. *S.M. Weissman[1], W.S. Rubinstein[1,2]* 1) Ctr Medical Genetics, Evanston NW Healthcare, Evanston, IL; 2) Northwestern University Feinberg School of Medicine.

Hereditary diffuse gastric cancer (HDGC), a highly penetrant, autosomal dominant hereditary cancer syndrome caused by mutations in the CDH1 (E-Cadherin) gene, accounts for about 1-3% of all gastric cancers. Female germline CDH1 carriers face an 83% lifetime risk of diffuse gastric cancer (DGC) and a 39% lifetime risk of breast cancer with a predilection towards a lobular histology. Male carriers face a 67% lifetime risk of DGC. Some reports suggest that signet ring colon carcinoma is a feature of HDGC. We report for the first time an individual with a CDH1 germline mutation who developed a pancreatic islet cell tumor. The proband was a 66-year-old Caucasian female referred for a history of bilateral breast cancer (infiltrating lobular at age 58; contralateral infiltrating ductal at age 66) and a family history of breast cancer in her mother (age 77) and ovarian cancer in her maternal grandmother. Expansion of the family history revealed a history of gastric cancer in her sister (age 31) and father (age 50) and breast cancer in her paternal grandmother (age 75) and only paternal aunt (age 66). The proband was tested for BRCA1 and BRCA2 and found to have a previously unreported BRCA2 variant of uncertain significance (E2175Q). Four months after receiving her gene test results while being treated for breast cancer, she was diagnosed with stage IV DGC. During her total gastrectomy, significant adenopathy was noted in the tail of the pancreas and a subtotal distal pancreatectomy was performed. Final pathology revealed a well differentiated, pancreatic islet cell tumor metastatic to 7 of 9 peripancreatic lymph nodes. CDH1 genetic testing performed on research protocol revealed a germline CDH1 mutation (2195G>A) which was confirmed in a clinical laboratory. Further testing in the family revealed her sister with gastric cancer to have been an obligate carrier. This case may be an example of delayed recognition of component tumors of lower penetrance in HDGC. IHC staining of the probands pancreatic islet cell tumor for e-cadherin will be provided as evidence regarding whether the germline CDH1 mutation played an etiologic role in the development of this tumor.

Physical Mapping of 7q22 Deletions and Identification of a New Candidate Gene in Uterine Leiomyoma. *T. Ptacek[1], C. Song[2], C.L. Walker[3], S.M. Sell[2]* 1) Dept Biol, Univ Alabama at Birmingham, Birmingham, AL; 2) Division of Nutritional Genomics, Department of Nutrition Sciences, Univ Alabama at Birmingham, Birmingham, AL; 3) Department of Carcinogenesis, University of Texas and MD Anderson Cancer Center, Smithville, TX.

Uterine leiomyoma (UL) is a common, benign smooth muscle tumor of the uterus that can cause serious health problems. Recently, we reported a 7q22 microdeletion interval containing two known genes: origin recognition complex subunit 5-like (*ORC5L*) (previously studied in UL) and lipoma HMGIC fusion partner-like 3 (*LHFPL3*) (unstudied in UL). *ORC5L* codes for a subunit of the ORC. It has been proposed that hemizygosity of *ORC5L* contributes to tumorigenesis by disrupting ORC regulation. *LHFPL3* is a member of the tetraspanin superfamily of transmembrane proteins; tetraspanins have roles in proliferation, motility, differentiation and extracellular matrix formation, and have been implicated in other cancers. Although our laboratory is the first to study *LHFPL3* in UL, *LHFPL3* may have been missed previously because it was not annotated until recently. For this study we examined *LHFPL3* expression in human and Eker rat UL, and performed bioinformatics analyses of previously described 7q22 deletions from six reports. We present data for two patterns of *LHFPL3* expression in UL (reduced and elevated expression). Our expression data are consistent with reports of multiple expression patterns, at the mRNA and/or protein levels, for other genes in UL. We present data for four distinct deletion intervals at 7q22. Previous studies used the smallest region of overlap (SRO) method to define two 7q22 deletion intervals, and relied on genetic marker order as opposed to the physical placement of the markers. This is the first non-SRO comparison of single sample UL 7q22 deletions using complete human genome sequence information. Our findings support a role for *LHFPL3* in UL, do not rule out a role for *ORC5L*, and suggest the presence of at least four distinct deletion intervals in UL with 7q22 deletions. Future studies will examine the expression of *LHFPL3* in UL using a larger sample size, with tumors typed for UL chromosomal aberrations.

Genetic variation in the paraoxonase 3 (PON3) gene is associated with serum PON activity. *D.K. Sanghera[1], S. Manzi[2], P. Shaw[2], A. Kao[2], F. Bontempo[3], C. Kammerer[1], M.I. Kamboh[1]* 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Division of Rheumatology and Clinical Immunology, Lupus Center of Excellence, University of Pittsburgh, Pittsburgh, PA; 3) 3Department of Medicine, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA.

Low serum PON activity determined by paraoxon substrate is associated with coronary heart disease and diabetes. Recently we have reported that low PON activity is also associated with SLE risk. The known genetic factors that influence PON activity are two SNPs in the PON1 gene, including Q192R and L55M. PON3 is linked to PON1 but, to our knowledge, the role of genetic variation in the PON3 gene in relation to PON activity has not been evaluated. In this investigation, we have examined the role of genetic variation in the PON3 gene in relation to PON activity and SLE risk in a biracial sample comprising 377 SLE patients (336 White, 41 Black) and 482 controls (442 White, 40 Black). We genotyped 6 PON3 tagging single nucleotide polymorphisms (tagSNPs) and examined their associations with PON activity, SLE risk, antiphopholipid autoantibodies (APA), lupus nephritis, carotid vascular disease and lipid profile. With the exception of the PON activity, no other significant associations were found with PON3 SNPs. Multiple regression analysis including all 6 PON3 tagSNPs and PON1/Q192R and L55M SNPs revealed significant associations with 4 SNPs: PON3/rs 740264 ($p<0.0001$), PON3/rs1053275 ($p=0.014$), PON 1/L55M ($p< 0.000$) and PON1/Q192R ($p< 0.000$). These four SNPs explained 3%, 2%, 8% and 19% of the variation in PON activity, respectively. In summary, our new data indicate that genetic variation in the PON3 gene influences serum PON activity independently of the known effect of PON1 genetic variation. The role of combined genetic variation at these linked loci may provide a better picture of the overall genetic control of PON.

Trends in the mortality of black children with sickle cell disease, United States, 1983-2002. *E.A. Yanni, R.S. Olney, S.D. Grosse, Q. Yang, J. Xing* NCBDDD, Centers for Disease Control and Prevention, Atlanta, GA.

BACKGROUND: Sickle cell disease (SCD) is one of the most common disorders identified by newborn screening in the United States. This study aimed to describe national trends in SCD mortality among black children from 1983 through 2002.

METHODS: We used U.S. death certificate data (1983-2002) to calculate the number of SCD-related deaths among black children aged 0-14 years and U.S. census data on the number of black children in each year to calculate SCD mortality rates in three age groups (0-3, 4-9, 10-14 years). We divided the study period into five intervals (1983-1987, 1988-1992, 1993-1996, 1997-2000, and 2001-2002) to analyze the possible effects of public health interventions on SCD mortality trends. We excluded deaths among children with SCD presumably caused by perinatal conditions, congenital anomalies in the early age group, autoimmune diseases, and different types of traumas.

RESULTS: The SCD mortality rate among black children decreased by 77% from 1983 through 2002 for 0- to 3-year-olds and by 51% for 4- to 9-year-olds. Statistically significant changes in mortality rates were also found for these age groups over specific, key time intervals. The SCD mortality rate decreased by 44% for 0- to 3-year-olds and by 34% for 4- to 9-year-olds for the period 1997-2000 versus 1983-1987 and by 36% for 0- to 3-year-olds for the period 1992-1996 versus 1983-1987. From 1997-2000 and 2001-2002, larger decreases in SCD mortality were observed at both 0-3 and 4-9 years of age. No significant changes in mortality rates for 10- to 14-year-olds were observed.

CONCLUSIONS: There was a significant decline in the mortality rates of black children with SCD younger than 10 years of age during the period of nationwide expansion of newborn screening for hemoglobinopathies. The substantial further decline in SCD mortality in recent years among younger children coincides with the approval of the 7-valent pneumococcal conjugate vaccine for infants in 2000. The 10- to 14-year age group might require different health care interventions to reduce SCD-related mortality.

Did phenylketonuria (PKU) arise after the Out-of-Africa migration? *C.R. Scriver[1], P. Hardelid[2], M. Cortina-Borja[2], A. Munro[3], H. Jones[4], Y. Foo[3], M. Cleary[3], M. Champion[4], C. Dezateux[2]* 1) Montreal Child Hosp Res Inst, McGill Univ, Montreal, PQ, Canada; 2) UCL Institute of Child Health, London, U.K; 3) Great Ormond Street Hospital, London, U.K; 4) Evelina Children's Hospital, London, U.K.

Prevalence rates of PKU in White Europeans and Chinese are similar (~ 1/10,000). While rare *PAH* mutation profiles are different, *PAH*-locus polymorphic haplotypes describe an "Out-of-Africa" human migration ~ 100,000 years ago (http://www.pahdb.mcgill.ca). There are no primary data on PKU prevalence for populations in Africa. Because anecdotal data known to us suggest that prevalence rates for PKU are low in populations of African descent, we studied prevalence rates in the multiethnic population of London (UK), where PKU screening and follow up are free and universal. We collected ethnic group data for all children screened for and diagnosed with PKU in the North and South East Thames areas (1994-2004 inclusive) as part of an audit of screening services. The denominator population was estimated by applying 2001 Census estimates of the ethnic group distribution of children aged <1yr to the number of live births in these areas, since direct estimates of births by ethnic group are not available. We obtained score-test-based confidence intervals for prevalence rates using Wilson's method. To date, complete data are available for North Thames. Among 121 children with PKU, 96 (79%) were of White British, White Irish or other White background; 23 (19%) were of Asian or other ethnic background and two were of unknown ethnic origin. No Black Caribbean, Black African or Other Black children with PKU were identified. The estimated proportions of White and Black births were 70 % and 9% respectively yielding birth prevalence rates for PKU in White children of 1.19/10,000 (95% CI 0.97-1.45/10,000), and 0/10,000 (0-0.39/10,000) in Black children. The findings support our hypothesis that the PKU phenotype is rare in African populations and arose after the Out-of-Africa migration of H. sapiens. Acknowledgements: Pia Hardelid is funded by the Medical Research Council (UK) and Department of Health.

Identification of Kalirin gene as a novel coronary artery disease gene through peak-wide association mapping on chromosome 3q13-21. *L. Wang[1], E.R. Hauser[1], S.H. Shah[1,2], C. Haynes[1], M. Harris[1], J. Rombaut[1], D. Crosslin[1], S. Nelson[1], A.B. Hale[1], S.G. Gregory[1], W.E. Kraus[2], M. Pericak-Vance[1], P.J. Goldschmidt-Clermont[2,3], J.M. Vance[1], GENECARD. Investigators[1,4,5,6]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Dept of Med and Division of Cardiology, Duke Univ Medical Ctr, Durham, NC; 3) Miller School of Med, Univ of Miami, Miami, FL; 4) Vanderbilt Univ, Nashville, TN; 5) Univ of Wales College of Med, Cardiff, UK; 6) Univ of Sheffield, Sheffield, UK.

A susceptibility locus for coronary artery disease (CAD) has been mapped to chromosome 3q13-21 in a linkage study. Previously, we reported that one gene (LSAMP) underneath the linkage peak marker was associated with severe CAD. Herein, we completed a peak-wide association mapping using two independent Caucasian case-control datasets (CATHGEN, initial and validation) to see if additional loci were contributing to this region. Single nucleotide polymorphisms (SNPs) evenly spaced at 100 Kb intervals were screened in the initial dataset (N=372). Promising SNPs ($p<0.1$) were then examined in the validation dataset (N=383). Significant findings ($p<0.05$) were evaluated in additional datasets, including a family-based dataset (N=2954), an African-American case-control set (N=220), and a population-based Caucasian control set (N=255). The association between SNP and atherosclerosis was examined in 140 human aortas. Peak-wide survey found 3 SNPs in Kalirin gene to be associated with early-onset CAD (age-at-onset<55) in both CATHGEN datasets ($p<0.05$). Further genotyping in the gene found that rs9289231 was associated with early-onset CAD in all datasets ($p<0.05$). In the joint analysis of all Caucasian early-onset CAD cases (N=461) and controls (N=619), rs9289231 was highly significant ($p=0.0001$) with an odds ratio estimate of 2.2. In addition, the risk allele of this SNP was associated with atherosclerosis burden ($p=0.03$). Kalirin gene was associated with CAD in multiple independent datasets (N>4000). Kalirin is a protein with many functions, including the inhibition of inducible nitric oxide-synthase. Our data suggest that Kalirin is a novel candidate gene for CAD susceptibility.

Decreased expression of *Abcg5/Abcg8* is associated with increased tissue incorporation of dietary plant sterols and stanols in diabetic BB rats. *K.A. Scoggan[1,2], H. Gruber[1], L.J. Plouffe[1], J.M. Lefebvre[1,3], H. Rocheleau[1], B. Wang[1], J. Bertinato[1], M.R. L'Abbé[1], W.N.M. Ratnayake[1]* 1) Nutrition Research Division, Health Canada, Ottawa, ON, Canada; 2) Department of Biochemistry, Microbiology and Immunology, University of Ottawa, Ottawa, ON, Canada; 3) Department of Biochemistry, Carleton University, Ottawa, ON, Canada.

Type 1 diabetes is associated with low synthesis and high absorption of cholesterol which also characterizes the rare autosomal recessive disorder, sitosterolemia. Mutations in either ABCG5 or ABCG8 cause sitosterolemia and result in increased retention of dietary plant sterols. The objectives of this study were to determine if insulin-treated diabetic BB rats (BBdt), a model for type 1 diabetes, incorporated elevated levels of dietary plant sterols and stanols (PSS) in tissues and blood and to determine if sterol incorporation was associated with alterations in *Abcg5* and *Abcg8* transporters. BBdt and non-diabetic control (BBc) rats were fed a control diet or diets supplemented with plant sterols or stanols (5 mg/g diet) for four weeks. Tissue levels of PSS were measured by gas chromatography. Expression of *Abcg5/8* in liver and intestine was assessed by Western blot and/or RT-qPCR. The coding region of *Abcg5* and *Abcg8* genes were also investigated for mutations. BBdt rats showed increased accumulation of PSS, especially plant sterols, in the aorta, red blood cells, and liver compared to control rats when fed diets supplemented with plant sterols or stanols, respectively. Liver and intestinal *Abcg5/8* mRNA expression was lower in BBdt versus BBc rats fed the control diet. *Abcg8* protein was also decreased in liver of BBdt rats. Several SNPs were identified in *Abcg5* and *Abcg8* genes, however, none of these sequence variations resulted in amino acid changes. In conclusion, lower steady-state levels of *Abcg5/8* in BBdt rats may account for the increased accumulation of plant sterols in tissues of these rats. The lower levels of *Abcg5/8* in BBdt rats were not due to mutations in the coding region of either *Abcg5* or *Abcg8* genes. These results warrant studies to investigate the cause of increased incorporation of PSS in diabetic individuals.

Profiling Breast Cancer Cell Lines with High-density Oligonucleotide Array CGH. *S. Yu[1], M. Jorda[2], C. Gomez[2], Y.S. Fan[1]* 1) Dr. John T. Macdonald Foundation Center for Medical Genetics Leonard Miller School of Medicine, Miami FL University of Miami Medicine, Miami , FL; 2) Department of Pathology, University of Miami Miller School of Medicine, Miami, FL.

Genome-wide screening for DNA copy number changes in breast cancer cells will facilitate the identification of tumor suppressor genes and oncogenes. In this study, we have analyzed 4 epithelial breast cancer cell lines by microarray based comparative genomic hybridization (Array CGH) using 60-mer oligo microarrays (Agilent) containing 44 k probes for the whole human genome with a resolution of 35 ~75 kb. We have identified novel DNA segment alterations in addition to those occurring in previously reported regions. In brief, we found 80 gains of DNA segments ranging from 20 kb to 245 Mb in size (40 Mb in average) and 90 losses of DNA segments ranging from 35 kb to 138 Mb (25 Mb in average). 17 DNA segments showed multiple DNA copy amplifications. Very interestingly, we noted an over 30-fold amplifications of a DNA segment that contains only the cadherin genes, CDH1 and CDH3, in one cell line although E-cadherin has been considered as a tumor suppressor. There were 41 homologous DNA losses with a size ranging from 11kb to 55 Mb (average 26 Mb). Among them, common homologous DNA losses in at least two cell lines were observed on chromosomes 2p23.2(1.5Mb),3q28(7Mb), 8q21.13pter(58Mb), 17q11.1(2.9Mb), 17q12.1(200Kb), 17q2.32(4.5Mb), Xp11.21(3.8Mb). Complex alterations with multiple levels of changes occurred frequently on chromosome arms 3q, 8q, 17p, 17q, 22q and Xq. Novel DNA alterations identified by the array CGH at this time are being verified by fluorescence in situ hybridization (FISH) and Real-Time PCR. Further, FISH and real-time PCR will be performed on pure tumor cells isolated from breast cancer specimens by laser captured microdissection. Differential presentation of genomic alterations in breast cancer cells with different grades may also provide useful information for guiding treatment and predicting outcome of the patients.

HEM Dysplasia and Mouse Ichthyosis are not due to Sterol 14-Reductase Deficiency. *C.A. Wassif[1], K.E. Brownson[1], W.K. Wilson[2], M.F. Starost[3], F.D. Porter[1]* 1) Heritable Disorders Branch, NICHD, NIH, Bethesda, MD; 2) Rice University, Houston, TX; 3) DVR, OD, Bethesda, MD.

Mutations of the lamin B receptor (LBR) have been shown to cause HEM dysplasia in humans and Ichthyosis in mice. LBR has both a lamin B binding and a sterol 14-reductase domain. Although only a minor sterol abnormality has been observed, it has been proposed that LBR is the primary sterol 14-reductase, and that impaired sterol 14-reduction underlies HEM dysplasia. However, *DHCR14* also encodes a sterol 14-reductase. To test the hypothesis that LBR and DHCR14 are redundant sterol 14-reductases, we obtained Ichthyosis mice (Lbr-/-) and disrupted *Dhcr14*. *Dhcr14-/-* mice are phenotypically normal. No sterol abnormalities were found in either *Lbr-/-* or *Dhcr14-/-* tissues at 1 and 21 days of age. We then bred these mice to obtain compound mutant mice. *Lbr-/-:Dhcr14-/-* and *Lbr-/-:Dhcr14+/-* die *in utero*. *Lbr+/-:Dhcr14-/-* mice appear normal at birth, but by 10 days of age they are growth retarded and neurologically abnormal (ataxia and tremors). Pathological evaluation demonstrated vacuolation of and swelling of the myelin sheaths in the spinal cord consistent with a demyelinating process. This was not observed in either *Lbr-/-* or *Dhcr14-/-* mice. In contrast to *Lbr-/-* mice, *Lbr+/-:Dhcr14-/-* mice had normal skin and did not have Pelger-Huët anomaly. Peripheral tissue sterols were normal in all three mutant mice. However, significantly elevated levels (50% of total sterols) of cholesta-8,14-dien-3-ol and cholesta-8,14,24-trien-3-ol were found in brain tissue from 10 day-old *Lbr+/-:Dhcr14-/-* mice. Sterols were identified by GC/MS and NMR. These sterols were undetectable in *Lbr-/-* brain and only present at trace levels in *Dhcr14-/-* brain. Analysis of LBR and DHCR14 in human control and HEM dysplasia fibroblasts supports the redundant nature of these two proteins with respect to sterol 14-reduction. Our data supports the idea that HEM dysplasia and Ichthyosis are due to impaired lamin B receptor function rather than impaired sterol 14-reduction. Impaired sterol 14-reduction gives rise to a novel murine phenotype for which a corresponding human disorder has yet to be identified.

Developing genetic competency in undergraduate nursing students through the context of disease and the constructivist framework. *L. Tribble* Education Div, Greenwood Genetic Ctr, Greenwood, SC.

Background: The largest group of healthcare providers is registered nurses whose work allows a unique and holistic view of patients, often caring for patients throughout the life span. Nurses need to understand basic genetic concepts including the role of genes in common diseases, to identify individuals at risk through the collection of detailed family histories, to provide information about genetic testing and informed consent, and to know when and how to suggest referrals for genetic services.

Objective: To assess student opinion regarding constructivist methods of teaching in a semester-long course in human genetics for undergraduate nurses.

Methods: The study design was a single group, pretest-posttest of 35 3rd year nursing students in a semester course in human genetics. Students completed a 51 item objective assessment tool at the beginning and end of the course. Instruction utilized 3 constructivist approaches including case studies, family history analyses, and "shrink wrapped" lectures in addition to traditional lecture.

Results: Group analysis of pre-course and post-course objective assessments indicated statistically significant improvement in content knowledge. A post-course subjective assessment of teaching approaches showed preference to all 3 constructivist styles over traditional lecture and student presentations. Participants indicated confidence in their ability to obtain current genetic information and educational resources as well as an enhanced view of the role of genetics in common, complex diseases.

Conclusion: Based on the results of student preferences, it is suggested that curriculum design for nurses' training programs incorporate characteristics of constructivism, using a variety of teaching approaches. The curriculum should emphasize relevancy and application of material to nurses' work. Future studies should be conducted to determine if and how this instruction is utilized in actual clinical practice.

.

Long-term improvement of bone disease and quality of life scores following treatment with Cerezyme in patients with skeletal manifestations of Type I Gaucher disease: Results of a 48-month single-arm, open label, clinical trial. *K.B. Sims[1], J. Barranger[2], P. Kaplan[3], H. Mankin[1], S. Packman[4], G.M. Pastores[5], B. Rosenbloom[6], D. Rosenthal[1], J. Angell[7], M.A. Fitzpatrick[7], N. Weinreb[8]* 1) Mass General Hosp, MA; 2) Univ of Pittsburgh, PA; 3) Children's Hosp of Philadelphia, PA; 4) Univ of California, San Francisco, CA; 5) NYU School Med, NY; 6) Tower Hematology/Oncology, CA; 7) Genzyme Corp, MA; 8) Univ Res Foundation, FL.

Objective: To evaluate the long-term effects of Cerezyme (CZ) on the skeletal and biochemical manifestations of Type I Gaucher disease (GD) and patients health-related quality of life (QOL). **Methods:** 33 CZ-naïve patients (age 12-70y) with skeletal manifestations of GD, and not treated with bisphosphonates, received CZ 60U/kg every 2 weeks for up to 48 months. Assessments included changes in bone mineral density (BMD) using dual energy x-ray absorptiometry (DEXA); incidence of bone pain (BP), bone crises (BC), and skeletal events; bone remodeling biomarker levels; and QOL (SF-36). **Results:** The mean change in BMD from baseline in lumbar spine and femoral neck DEXA Z-scores at 36 mos were +0.40 and +0.19, respectively ($p<0.05$). The incidence of BP decreased from 72% at baseline to 36% at 36 mos. No further episodes of BC were noted in 85% of patients with a history of BC. Bone formation biomarkers (osteocalcin and bone alkaline phosphatase) showed an increase from baseline by 6 mos and remained elevated through 48 mos ($p<0.05$). Osteoclast activity and bone resorption biomarkers (D-PYD and N-telopeptide crosslinks) decreased from baseline. New incidents of medullary infarction, avascular necrosis, lytic lesions and fractures were few and limited to the first 24 mos of CZ. QOL mean physical and mental component summary SF-36 scores increased by 24 mos ($p<0.01$) and achieved normal scores by 48 months compared with the reference population. **Conclusions:** CZ over 48 months resulted in meaningful improvements in the skeletal manifestations of GD that were associated with favorable changes in biomarker profile. These observations may account, in part, for the improvements in QOL.

The homogeneous mutant collagen in Brtl/Mov compound mice is associated with a milder osteogenesis imperfecta phenotype than occurs in heterozygous Brtl/+ mice, despite increased matrix insufficiency due to the mov13 null allele. *T.E. Uveges[1], J.A. Megnack[2], E.L.H. Daley[2], S.A. Goldstein[2], J.C. Marini[1]* 1) BEMB, NICHD/NIH, Bethesda, MD; 2) Ortho Res Labs, U. Mich, Ann Arbor MI.

The Brtl mouse (Brtl/+), a model for dominant-negative type IV osteogenesis imperfecta (OI), has a glycine substitution (G349C) in one col1a1 allele and a heterogeneous population of collagen forms, with 0, 1 or 2 mutant 1(I) chains. Surprisingly, mice homozygous (Brtl/Brtl) for this dominant mutation have a milder phenotype, with growth, BMD, and femoral geometry and mechanical properties intermediate between wt and Brtl/+. Brtl/Brtl synthesize homogeneous collagen with only mutant 1(I) chains (Forlino, 2005 EJHG 13(S1):61-65:C12), suggesting that heterogeneity of type I collagen may be an essential factor in OI severity. We generated mice with homogeneous mutant collagen by an alternative route; we crossed Brtl/+ with Mov13/+ mice, which have a null col1a1 allele. Analysis of the offspring indicate that Brtl/Mov mice also have a milder phenotype than Brtl/+ mice. Brtl/Mov, like Brtl/Brtl, has normal perinatal survival vs 30% lethality in Brtl/+. On skeletal staining, Brtl/Mov and Mov/+ do not have the in utero rib fractures of Brtl/+. Growth curves of Brtl/Mov and Mov/+ are intermediate between wt and Brtl/+. At 2 months of age, Brtl/Mov and Mov/+ dermal collagen fibril diameters were significantly smaller than Brtl/+ or wt fibrils. Brtl/Mov femurs have normal BMD and the same geometric adaptations found in Mov/+ (increased cross-sectional area and cortical thickness) rather than the improved material properties found in Brtl/Brtl. Brtl/Mov femurs also have improved mechanical properties (energy to failure and brittleness) compared to Brtl/+. Since Brtl/Mov femoral geometry and mechanics resemble Mov/+, we cannot rule out the possibility that the type I collagen insufficiency associated with the mov13 allele is disorganizing the matrix in a way that masks the weakening effect of the structurally abnormal collagen. However, the data on Brtl/Mov and Brtl/Brtl are most consistent with the interpretation that a homogeneous population of mutant collagen is associated with a milder OI phenotype.

Concurrent but apparently unrelated structural rearrangements of the band p13 of both chromosome 16 homologues in a case of renal angiomyolipoma. *S. Wei[1], C. Abbud-Mendez[2], M.W. Lee[2], A. Adeyinka[1]* 1) Dept Medical Genetics, Henry Ford Health System, Detroit, MI; 2) Dept of Pathology, Henry Ford Health System, Detroit, MI.

Angiomyolipoma is a benign neoplasm arising from the mesenchymal tissues of the kidney and exhibiting a collection of blood vessels, smooth muscle, and mature adipose tissue. It is the most common mesenchymal tumor of the kidney and accounts for 0.7-2% of all kidney tumors. About 80% of renal angiomyolipoma are sporadic and are not associated with Tuberous Sclerosis Complex (TSC), whereas 20% are associated with tuberous sclerosis. TSC-associated angiomyolipomas are often multiple and bilateral, but histologically indistinguishable from sporadic renal angiomyolipoma. Clonal chromosome aberrations have been reported in 7 cases of sporadic renal angiomyolipoma including trisomy 7 as a sole abnormality in 3 tumors, trisomy 8 as a sole abnormality in one case, monosomy 8 with deletions in 11q23 and Xq26 in one tumor, a t(7;12) in one tumor and a complex rearrangement involving chromosomes 12 and 21 in one tumor. Loss of heterozygosity (LOH) in the chromosomal region for the TSC2 gene (16p13) has been documented in up to 60% of TSC-associated angiomyolipomas, whereas only few cases of sporadic angiomyolipoma have had LOH of 16p13. We report the cytogenetic findings in a renal angiomyolipoma from a 47-year-old woman without clinical history of tuberous sclerosis. Metaphase cells from primary cultures of the renal mass were 46,XX,der(7)t(7;16)(q11.2;p13.3),der(16)t(7;16)(q11.2;p13.3)t(16;17)(q13;q22),inv(16)(p13q22),add(17)(q11.2). Both chromosome 16 homologues had structural rearrangement of band p13 the chromosomal location of the TSC2 tumor suppressor gene. Since two events are required to inactivate both copies of a tumor suppressor gene, the present findings suggest that concurrent structural changes involving both chromosomal bands 16p13 may be a mechanism of tumorigenesis in sporadic renal angiomyolipoma.

Gross Rearrangement in the MID1 gene in a patient with familial Opitz/GBBB syndrome: Implications for Molecular Diagnosis of Opitz/GBBB Syndrome. *A.B. Santani[1], E. Frackelton[1], C. Mulcahy[1], E. Zackai[2,4], D.M. McDonald-McGinn[2], T. Shaikh[2,4], D. Driscoll[3], C.A. Stolle[1]* 1) Dept of Path & Lab Med; 2) Div of Hum Genet, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Dept of Ob & Gyn; 4) Dept of Pediatrics, UPenn School of Med, Philadelphia, PA.

Opitz G/BBB syndrome (OS), is a multiple congenital anomaly disorder that primarily affects midline structures. Clinical findings may include hypertelorism, cleft lip and palate, tracheo-esophageal clefts, heart defects, hypospadias, and developmental delay. Mutations in the MID1 gene have been identified in about 15-45% of males with the X-linked form of OS. This low mutation detection rate may reflect genetic heterogeneity, presence of intron/promoter mutations, or inability of current methodologies (SSCP, DHPLC, sequencing) to detect gross rearrangements. Three previous reports have identified genomic rearrangements of MID1 in patients with OS. Using Southern Blot analysis we identified a novel deletion encompassing the last two exons of the MID1 gene in a patient with familial OS. Characterization of the junction fragments by primer walking and long range PCR, confirmed the presence of a 13.8-kb deletion in the proband. Until recently, no rapid and reliable method was available to detect gross rearrangements. Assays such as Southern blot and FISH have obvious limitations. We have developed a real-time quantitative PCR assay for rapid identification of rearrangements in the MID1 gene. RQ-PCR primer/probe sets were designed for exons 8 and 9 that were deleted in the proband. The copy number of each exon was accurately determined for ten normal males and females demonstrating the high sensitivity and specificity of this assay. Analysis of the probands mother by RQ PCR confirmed her status as a carrier for the same deletion. Our results, along with previous studies, underline the importance of screening for major genomic rearrangements in the MID1 gene. The RQ-PCR assay is a simple, sensitive technique for rapid detection of exon dosage and we suggest that mutation screening in MID1 should include quantitative gene analysis in addition to DHPLC.

Attitudes Toward Genetic Testing and African Ancestry: How is Genetic Research Valued? *E.R. Santos[1], C. Glover[2], C. Bonilla[1], W. Hernandez[1], S.E. Hooker[1], P. Payne[2], R.A. Kittles[1], C. Royal[2]* 1) Ohio State University, Columbus, OH; 2) Howard University, Washington, DC.

Previous research has shown that African Americans distrust research; genetic research in particular. Yet genetic medicine has the potential to do more than just predict. It may ultimately be used at a personalized level to prevent and treat disease. There is a need to better understand the perceptions and attitudes toward genetic research that focuses beyond rare disorders. Insight into the knowledge, attitude, and behavior of African Americans is needed to better tailor prevention and treatment for individuals with high risk for cancer. Triangulation of quantitative and qualitative data helps elucidate associations between the knowledge, attitudes, and behaviors of two comparable populations. A volunteer sample of 415 adult participants was surveyed using Likert scale and open-ended questions that assessed knowledge, attitude, and behavior towards genetic testing. Triangulation of concepts combined quantitative (contingency tests) and qualitative data (content analyses) to investigate reported perceptions with behavior relevant to genetic testing. African Americans (n=415) from four communities from Oklahoma City, OK; Cincinnati, OH; Harlem, NY; and Washington, DC were surveyed. Baseline demographics of the four communities were comparable. Quantitative analysis revealed a strong association between different levels of knowledge regarding DNA testing and education (P0.005). Content analysis of the free-response survey questions showed recurring themes of prevention and family as important in seeking genetic testing. In comparison, a deterrent to seeking genetic testing was commonly stated to be the suspicion of abuse of information. Insight and understanding of knowledge, attitudes, and behaviors toward genetic research could possibly help maximize the impact of biomedical advances on communities most affected by health disparities. Proper utilization of genetic research could lead to more than diagnoses but also improving the odds through prevention and possible treatment; thereby fine tuning clinical treatment.

Gender-Related Clinical Features in a Large Cohort of Cowden Syndrome (CS) and Bannayan-Riley-Ruvalcaba Syndrome (BRRS) Patients with *PTEN* Mutations. *R. Pilarski[1], J. Stephens[2], H. Hampel[1], XP. Zhou[1], C. Eng[3]* 1) Human Cancer Genetics Program, and; 2) Center for Biostatistics, Ohio State University, Columbus, OH; 3) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH.

CS is a multisystem disease involving hamartomatous tissue overgrowth and increased risks for thyroid, breast and uterine cancer. Benign breast, thyroid, uterine and skin lesions are also common. BRRS is an allelic disorder characterized by macrocephaly, intestinal polyps, lipomas and pigmented penis macules. 80-85% of patients with CS and 60-65% of patients with BRRS have germline mutations in *PTEN*. Because of the rarity of these disorders, prior data on the frequencies of component clinical features have been based on small numbers of patients. METHODS: 2205 patients with at least one major and two minor or three minor CS/BRRS diagnostic criteria were accepted for research *PTEN* analysis. Clinical features present at the time of molecular testing were ascertained through the referring clinician using a checklist. When available, medical records were also reviewed. Age of onset was obtained for all cancer diagnoses. RESULTS: 206 patients (107 female, 99 male) were found to have probable deleterious mutations in *PTEN*. Age at molecular diagnosis was significantly earlier (23.8 vs 34.3 yo; $p<0.001$) for male vs. female patients. The expected clinical features of CS/BRRS were seen at increased frequency over the general population. Macrocephaly was almost twice as common as previously estimated (80% vs. ~40%). Aside from gender-specific features, female mutation carriers had more hemangiomas ($p=0.037$), thyroid cancers ($p=0.004$) and thyroid goiters ($p=0.003$) in contrast to MR/DD ($p=0.012$) favoring males. Borderline differences were seen for skin papules ($p=0.052$) and trichilemommas ($p=0.066$). DISCUSSION: This is the largest cohort of *PTEN* mutation-positive patients on whom clinical features have been reported. Significant differences were noted between genders in the frequency of several clinical features. In addition, macrocephaly and hemangiomas/AVMs were reported more commonly than expected from the literature. Projected lifetime risks for the component cancers will be presented.

Association of a functional SNP in the Interferon Regulatory Factor 5 (IRF5) Gene with Childhood-onset Systemic Lupus Erythematosus in Mexican Population. *R. Velazquez[1, 2], V. Baca[3], F. Espinosa-Rosales[4], M. Morales-Marin[1], G. Jimenez-Sanchez[1], L. Orozco[1]* 1) Laboratory of Research, National Institute of Genomic Medicine, Mexico City, Mexico; 2) PhD Biomedical Sciences-UNAM; 3) Department of Pediatric Rheumatology, CMN-Siglo XXI, IMSS. Mexico City, Mexico; 4) Department of Immunology, INP,SS. Mexico City, Mexico.

Introduction: Recently several studies have identified a functional single nucleotide polymorphism (SNP) rs2004640 C/T in the Interferon Regulatory Factor 5 (IRF5) gene as a susceptibility allele in Systemic Lupus Erythematosus (SLE) and Rheumatoid Arthritis. These findings and the observation that several autoimmune diseases tend to cluster in the same families suggest that different autoimmune diseases may share common susceptibility genes. The rs2004640 T allele creates a 5' donor splice site in an alternative exon 1 of IRF5, allowing expression of several unique IRF5 isoforms. Objetive: To asses the possible association between the rs2004640 SNP in the IRF5 gene and SLE in Mexican population. Methods. We performed a case control association study in 250 pediatric patients with SLE and 282 unrelated healthy Mexican controls. Genotyping of the rs2004640 SNP was carried out by the 5'exonuclease assay (TaqMan). Association with the SNP was analyzed by Chi square test. Results: The T allele frequency of the rs2004640 SNP was more frequent in SLE patients than in controls (63% vs 46%, P=1.33 x 10-7; OR=1.93, 95%CI= 1.5-2.5). We found a single copy of the rs2004640 T allele in 43% of cases, which conferred modest risk (OR=1.97, P=0.003), whereas the 41% of cases homozygous for the T allele were at a greater risk for SLE (OR= 3.31, P= 6.87 x 10-7). A family-based association was carried out in 130 families to rule out the possibility of stratification, (P=0.02). Conclusion: Our results confirm the association of IRF5 rs2004640 SNP with SLE and suggest that IRF5 gene could play an important role in childhood onset SLE susceptibility in Mexican population.

Albinism and Developmental Delay in an African patient: Emphasizing the need to test for 15q11-q13 deletion. *R. Saadeh, MD[1], E. C. Lisi, MS[1], D. Riegert-Johnson, MD[2], D.A. Batista, PhD[3,4], I. McIntosh, PhD[1,5], J.E. Hoover-Fong, MD[1]* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Dept. of Gastroenterology, Mayo Clinic, Rochester, MN; 3) Dept. of Pathology, Johns Hopkins University, Baltimore, MD; 4) Cytogenetics Laboratory, Kennedy Krieger Institute, Baltimore, MD; 5) Dept. of Molecular and Cell Biology, American University of the Caribbean, St. Maarten.

Oculocutaneous albinism type 2 (OCA2) is the most common form of albinism worldwide and particularly common in Africans and African-Americans. OCA2 is an autosomal recessive disorder characterized by decreased pigmentation of the skin, hair, retina and iris with nystagmus, foveal hypoplasia, decreased visual acuity and optic nerve misrouting. Mutations in the P gene, located within the Angelman syndrome (AS) and Prader-Willi syndrome (PWS) critical region at 15q11-q13, cause OCA2. Patients with albinism should not have features found in AS (severe speech impairment, seizures, gait/movement disorder and happy demeanor) or PWS (psychomotor retardation, infantile hypotonicity, hyperphagia, obesity, hypogonadism and short stature). We report a 17-month old African female with cutaneous and ophthalmologic features of OCA2, as well as microcephaly, absent speech and tremulous somatic movement. Suspected co-morbid OCA2 and AS were confirmed by a cytogenetically visible deletion on chromosome 15q and absence of fluorescence in situ hybridization of the SNRPN probe for AS/PWS at 15q11.2. Molecular analysis revealed she inherited the common African 2.7-kb deletion in exon 7 of the P gene from her father and acquired a large de novo deletion of the AS critical region, including the P gene, from her mother. Query of 30,000+ patient pedigrees in the Johns Hopkins Genetic Clinic database revealed 49 albino patients, 8 with phenotypic features suggestive of AS or PWS. Further evaluation of these patients is underway to evaluate for these co-morbid conditions. Therefore, phenotypic features of AS or PWS in a patient with albinism should prompt investigation for these disorders.

An Analysis Pipeline for Large SNP Genotype Scans. *S. Stefanov, J. Lautenberger, M. Dean, B. Gold* LGD, NCI-Frederick, Frederick, MD.

Single nucleotide polymorphism (SNP) genotyping arrays are gaining in popularity. We developed an efficient pipeline for analysis of genotyping scan results. PC-Linux or Macintosh computers are advantageous because they avoid high performance hardware and most proprietary statistical software costs. Therefore, we developed an analytic platform in which extensive General Public License (GNU) software was coupled with Perl scripting. This permits efficient assembly of genotype calls and confidence scores from genotype data. We analyzed Affymetrix microarrays using both Dynamic Modeling (DM) and Bayesian Robust Linear Modeling using Mahalanobis Distance (BRLMM) algorithms. Calls are assembled into a single Prettybase file because it provides as an economic representation of SNP typing data that lends itself to analytic transportability. SAS software converts the prettybase files into SAS data sets and performs further analyses. For each marker and population, summary statistics including measures of Hardy-Weinberg equilibrium, Fis, allele and genotype frequencies are computed. We then calculate population differentiation statistics including informativeness for assignment (In), Kullback-Leibler divergence, entropy, Fst, and Ds. Pairwise linkage disequilbrium statistics D, D and R2 are elaborated using the command line version of HaploView. We have also used an R-program, provided by C. Carlson, to detect selection signatures via the Tajima's D statistic. The path of our pipeline consists of a contingency table analysis that calculates the likelihood of genetic association by comparing marker allele and genotype frequencies in affected versus unaffected individuals. Significant associations may indicate the proximity of a disease gene to the marker. Chi-square tests permit computation of a P-value for a genotype test, an allele test, and an Armitage linear trend test. In addition, we perform exact tests and compute odds ratios for both trend and allele statistics. Subsequent Perl scripts permit loading the SAS output into the Generic Genome Browser (gbrowse) for comprehensive visualization.

Polymorphisms in the PDCD1 are associated with childhood-onset Systemic Lupus Erythematosus in Mexican population. *Y. Saldaña[1], V. Baca[2], R. Velazquez[1,3], F. Espinosa-Rosales[4], M. Morales-Marin[1], S. Jimenez-Morales[1], G. Jimenez-Sanchez[1], L. Orozco[1]* 1) Laboratory Research, National Institute of Genomic Medicine, Mexico City, Mexico; 2) Department of Pediatric Rheumatology, CMN-Siglo XXI, IMSS, Mexico City, Mexico; 3) PhD Biomedical Sciences Program, UNAM; 4) Department of Immunology, INP, SS. Mexico City, Mexico.

Systemic Lupus Erythematosus (SLE) is a complex autoimmune disorder that predominantly affects women during their childbearing age. It is estimated that 15-17% of all SLE patients present in children younger than age 16. Initial manifestations of childhood-onset SLE are diverse and often more severe than in adults. Susceptibility to SLE has been attributed to complex interaction between genetics and environmental factors. Moreover, it has been suggested that genetics may play a greater role in children than adult onset SLE. An intronic polymorphism (PD1.3A) on the programmed cell death gene (PDCD1) has been associated with SLE susceptibility in several large case-control studies on adult patients. We hypothesized that the associated allele PD1.3A may also play a role in childhood onset SLE in Mexican patients. We performed a case-control association study in 261 unrelated childhood-onset SLE Mexican patients and 355 healthy individuals as control. We genotyped PD-1.3G/A polymorphism and three more single nucleotide polymorphisms (SNPs) within the PDCD1 gene (PD-1.1 G/A, PD-1.5C/T and PD-1.6A/G). Genotyping was carried out by 5'nuclease assay (TaqMan). The frequency of PD-1.3A allele was more frequent in SLE patients when compared with healthy controls (5.2% vs 2%, P=0.003; OR= 2.71; 95% CI = 1.35-5.50). Nevertheless, the frequencies of the PD1.1 G/A, PD1.5C/T and PD1.6A/G alleles were similar between the childhood-onset SLE patients and controls (30% vs 33%, 63% vs 64% and 54% vs 56% respectively). On the other hand in the haplotype analysis we observed that one haplotype characterized by the presence of PD1.3A allele, showed association with SLE susceptibility. Our results shown that PD1.3A is also a risk allele in childhood-onset SLE in Mexican population.

1p36 interstitial deletion and CVS mosaicism for add(1)(p36.1) in a child with asymmetry and multiple anomalies. *J. Wagstaff[1], L. Shaffer[2,3], D. Boles[4], A. Baughman[1], F. Grass[1]* 1) Clinical Genetics Program, Carolinas Medical Ctr, Charlotte, NC; 2) Health Research and Education Center, Washington State University Spokane; 3) Signature Genomic Laboratories, Spokane, WA; 4) Cytogenetics Laboratory, Presbyterian Hospital, Charlotte, NC.

Cytogenetic analysis of CVS direct preparation from a 32-year-old woman with history of a previous fetus with trisomy 21 revealed 8 cells with a structural abnormality involving additional material translocated onto 1p36 and 1 cell with normal female karyotype. Cultured chorionic villi and amniocytes each showed 20 cells with apparently normal female karyotype, 46,XX. The child was born at term with birthweight at the 5th percentile, length less than 3rd percentile, and head circumference at the 5th percentile. Her left ear was smaller than her right ear, and she had hypoplasia of the right fourth and fifth fingers and limb asymmetry with right upper extremity shorter than left and left lower extremity shorter than right. She was diagnosed with coarctation of the aorta at one week of age. Lymphocyte chromosome analysis showed a possible deletion of 1p36 in all cells. FISH with a subtelomeric probe from 1p36 detected no deletion; however FISH with a 1p36 probe containing D1S1347 and D1S1310 showed heterozygous deletion in all cells. Microarray CGH of lymphoblastoid cell line DNA confirmed a heterozygous interstitial deletion extending from 2.75 Mb to 9.25 Mb in 1p36. FISH analysis of 1p36 in lymphocytes from both parents gave normal results. The cytogenetic and molecular analysis of this patient suggests that she is mosaic for 2 cell lines: one cell line contains a 6.5 Mb interstitial deletion of 1p36; the other cell line contains translocation of unidentified chromosome material onto 1p36. We hypothesize that this mosaicism arose from a 1p36 break in an unreplicated chromosome, either in a gamete or in the zygote, followed by chromosome replication, then by repair of the break by different mechanisms on the two sister chromatids: on one sister chromatid by interstitial deletion, and on the other sister chromatid by translocation.

Mutations in the Novel Mitochondrial Protein REEP1 Cause Hereditary Spastic Paraplegia Type 31. *G. Wang[1], K. Viet[1], M. Nance[2], P. Gaskell[1], A. Ashley-Koch[1], M. Pericak-Vance[1], S. Züchner[1, 3]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Park Nicollet Clinic, Minneapolis, MN; 3) Department of Psychiatry and Behavioral Science, Duke University Medical Center, Durham, NC.

Hereditary spastic paraplegia (HSP) comprises a group of clinically and genetically heterogeneous diseases that affect the upper motor neurons and their axonal projections. HSP is characterized by progressive lower limb spasticity and paresis of varying severity. So far, 11 genes have been identified for autosomal dominant HSP with most of them being a rare cause. In two multigenerational families we have found a novel HSP locus on chromosome 2p12. The combined two-point LOD score was 4.7 at marker D2S2951. By direct sequencing of candidate genes in the chromosomal area we isolated two deletions in the gene receptor expression enhancing protein 1 (REEP1). We screened index patients from 92 unselected HSP families and found out a total of six unique mutations which includes one missense mutation, a splice site mutation, and two small deletions leading to frame shifts and alternative stop codons. Two other changes occurred in a conserved predicted micro RNA target sites in the 3`-UTR of REEP1. We did not detect these mutations in 360 ethnicity matched controls. Using a REEP1 specific antibody we showed in different cell lines that the endogenous REEP1 protein targeted mitochondria. We conclude that the novel mitochondrial protein REEP1 accounts for about 6.5% of all HSP.

Evidence for paternal allele-specific chromatin extension and looping of the *SNRPN* to *UBE3A* locus in mature neurons by fluorescence in situ hybridization. *K.N. Thatcher, R.O. Vallero, J.M. LaSalle* Dept Med Micro & Immuno, Univ California, Davis, Davis, CA.

The imprinted region 15q11-13 contains a cluster of imprinted genes whose complex developmental and tissue specific expression is regulated by small imprinting control regions (ICR) within the cluster. Several neurodevelopmental disorders are associated with deletions, mutations or aberrant gene expression in this region including Angelman syndrome, Prader-Willi syndrome, autism, and Rett syndrome. It has been proposed that chromatin looping in this region may allow the paternal ICR to bi-directionally regulate gene expression over several Mb. *SNRPN* is a paternally expressed gene within the cluster whose gene products are involved in splicing and are highly expressed in brain. The brain-specific *SNRPN* transcription unit also includes multiple small nucleolar RNAs and the antisense to *UBE3A*. *UBE3A* is oppositely oriented to *SNRPN* and is paternally silenced in neurons, presumably by the *UBE3A* antisense. Utilizing DNA FISH we have found visual evidence for allele-specific chromatin extension and looping of the locus from *SNRPN* to *UBE3A* in human post-mortem brain. In mature neurons, the paternal allele was highly extended and looped into the euchromatin while the maternal allele was observed as a single spot found primarily in the heterochromatin. A similar pattern was found using a probe to the *Snrpn* locus in mouse brain samples of multiple ages. The paternal allele-specific chromatin extension increased with brain age and neuronal maturity (~0.5m at P1d to ~4m at P70d), while the maternal allele remained small and compact (~0.5m at all ages). High concentrations of RNAse A used pre- or post-hybridization did not affect the size of the chromatin structures, demonstrating that the extended signal was due to DNA not RNA. Extended paternal chromatin loops were specific to neurons as they were not found in glial cells, thymus, kidney, liver or spleen. These results suggest dynamic changes in chromatin conformation of the paternal *SNRPN* to *UBE3A* locus during neuronal maturation that may serve to regulate neuronal specific expression and imprinting in this region.

Tissue Specific Expression Of Type X Collagen In Hypertrophic Chondrocytes Is Specified By A 150 BP *Col10a1* Distal Promoter Element. *Q. Zheng[1], B. Keller[1], G. Zhou[1], D. Napierala[1], Y. Chen[2], A. Parker[3], B. Lee[1, 2]* 1) Molec & Human Genetics, Baylor College Med, Houston, TX; 2) Howard Hughes Med Inst. Houston, TX; 3) Respiratory and Inflammation Res. Area, Astrazeneca, Cheshire U.K.

Type X collagen gene (*Col10a1*) is a specific molecular marker of hypertrophic chondrocytes, a stage of late endochondral ossification during cartilage development. Multiple cis-elements and trans-acting factors have been shown to be involved in the regulation of type X collagen expression and therefore contribute to chondrocyte maturation. We have recently generated a series of transgenic mouse lines harboring various *Col10a1* promoter/intronic fragment (**Tg-10kb**) or distal *Col10a1* promoter elements (**Tg-6kb** and **Tg-4.6kb**) each driving a *LacZ* reporter. High-level tissue-specific reporter expression was observed in these transgenic lines. These data together with previous observations suggest that the *Col10a1* distal promoter element (-4.6 to -3.9 kb) harbors a critical tissue-specific enhancer that mediates its high-level expression in hypertrophic cartilage *in vivo*. (**Tg-4kb**, Zheng et al., 2003; Gebhard et al., 2004). To further localize the tissue-specific enhancer element within this region, three additional reporter constructs have been generated for similar transgenic studies. These constructs contain different *Col10a1* distal promoter fragments upstream of the *Col10a1* basal promoter each driving a *LacZ* gene (**Tg-2x700**, **Tg-4x300** and **Tg-4x150**). All three transgenic lines showed high-level tissue-specific reporter expression. This demonstrated that the 150 bp (-4.3 to -4.15 kb) *Col10a1* promoter element is sufficient to direct its high-level tissue-specific expression *in vivo*. Lastly, we have also generated a transgenic reporter construct in which Cre-expressing cassette is placed under the control of the 4x300 bp element and the *Col10a1* basal promoter. The tissue specificity of transgenic founders is being tested upon breeding onto the RosA26R genetic background. These potential hypertrophic chondrocyte-specific Cre-expressing transgenic lines and the **Tg-4x150** reporter lines enable us to study genes of interest that involve molecular pathogenesis of skeletal disorders and/or osteoarthritis.

Efficient multipoint analysis of association studies. *B. Servin, P. Scheet, M. Stephens* Statistics, University of Washington, Seattle, WA.

We present a new statistical method for analysing genetic association studies. The method improves on standard approaches in two ways. First, it exploits the availability of dense genotype data in a "panel" of unrelated individuals (eg the HapMap) to effectively increase the number of markers typed in the phenotyped individuals, and hence to increase both the power to detect association in a given region, and the ability to accurately identify the most plausible functional variants within a region. Second, instead of using a p value to measure the strength of the evidence for association between each SNP and the phenotype, we instead use a Bayesian measure of the strength of the evidence, a Bayes Factor (BF). Our presentation will include a description and illustration of some of the advantages of BFs over p values, including i) BFs naturally weight different SNPs according to how informative they are (eg their minor allele frequency), effectively reducing the burden of multiple testing; and ii) BFs provide a natural and efficient way to combine information over multiple SNPs in a region. For those who prefer p values to Bayesian approaches, we will also describe how the BFs for multiple individual SNPs can be turned into p values for assessing the overall strength of the evidence for association between the phenotype and the group of SNPs, and illustrate how this approach has increased power compared with the natural alternative of performing multiple single-SNP tests and correcting for multiple comparisons. We argue that single-SNP BFs, rather than single-SNP p values, should therefore become the standard choice for initially assessing associations in genomewide association studies.

Development of TaqMan snoRNA Assays for Endogenous Controls. *L. Wong, D. Ridzon, Y. Liang, P. Sali, C. Barbacioru, R. Samaha, E. Spier, D. Ginzinger, K. Livak, K. Guegler, C. Chen* Arrays and SDS R&D, Applied Biosystems, Foster City, CA.

Quantitation of microRNA (miRNA) genes has become a critical step in determining the function and identifying the biomarkers related to cell differentiation and disease states. A total of 236 TaqMan miRNA assays were used to profile the level of miRNA expression in 40 normal human tissues and 59 NCI-60 cell lines. Two types of endogenous controls were examined for normalizing the expression data. House-keeping genes including -actin, GAPDH, 18S rRNA, and 2M were first examined: of the four genes, 18S rRNA showed the least variation. Non-coding genes including snoRNAs and tRNAs were then considered as a new class of endogenous controls for normalizing miRNA expression data. Genes were selected based on the size, abundance, and ubiquitous nature of the small RNAs; and assays were designed using similar chemistry as the TaqMan miRNA assay. Eight tRNA and fifteen snoRNA candidates, ranging from 45 to 200 nucleotides, were evaluated. Expression of these small RNAs showed that they were relatively abundant and constant across all 40 human tissues or 59 NCI-60 cell lines. In particular, snoRNAs showed similar expression pattern to 18s rRNA as well as the least variable miRNA controls, indicating that snoRNAs are better controls for normalizing TaqMan miRNA expression data. A total of ten snoRNA assays including RNU24, RNU66, RNU19, RNU38B, RNU49, Z30, RNU6B, RNU48, RNU44, and RNU43 have been successfully released worldwide. Further, fourteen of the same snoRNA genes used in the TaqMan miRNA assays were subjected to conventional TaqMan assay design. Conventional TaqMan assays were then performed and data compared to the TaqMan miRNA assays. Similar to the TaqMan miRNA assays, the expression levels for these assays were constant across 38 normal human tissues. In addition, similar expression patterns for these snoRNAs were observed from both conventional TaqMan and TaqMan miRNA-like designs, suggesting that the small non-coding genes may also be better endogenous controls than the typical coding genes for normalizing conventional TaqMan assay expression data.

Penetrance of craniofacial anomalies in mouse models of Smith-Magenis syndrome is modified *in trans* by genomic sequence surrounding *Rai1*. *J. Yan*[1], *W. Bi*[1], *J.R. Lupski*[1, 2, 3] 1) Dept Molecular & Human Gen; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 3) Texas Childrens hospital, Houston, TX.

A characteristic craniofacial phenotype is presented in many genetic syndromes, which can enable an initial diagnostic impression to an experienced clinical geneticist and dysmorphologist. Craniofacial abnormality is one of the major clinical manifestations of the Smith-Magenis syndrome (SMS) and distinct enough to enable a clinical diagnosis. We constructed several SMS mouse models with chromosome engineered deletions of the mouse genomic region that maintains conserved synteny to the human SMS interval. The models include *Df(11)17* (a 2 Mb deletion) and *Df(11)17-1* (a 590 kb deletion), as well as *Rai1* targeted disruption. Analyses of these mutations in a mixed N2 genetic background revealed that the penetrance of the craniofacial phenotype is reduced with decreased deletion size. We have generated an additional deletion strain, *Df(11)17-4*, which contains a 1 Mb deletion. Remarkably, the penetrance of its craniofacial anomalies in an N2 background was between those of *Df(11)17* and *Df(11)17-1*. We further analyzed the deletion mutations and *Rai1*-/+ allele in a pure C57BL/6 background to examine isogenic littermates and to control for nonlinked modifier loci. The penetrance of the craniofacial anomalies was markedly increased for all the strains in comparison to the N2 background. Mice with *Df(11)17* and *Df(11)17-1* deletions had a similar penetrance for the craniofacial abnormalities, whereas that of *Rai1*-/+ mice was significantly reduced. Our results suggest that a *trans* regulator(s), that resides within the 590 kb genomic interval surrounding *Rai1*, is the major modifying genetic element(s) affecting the craniofacial penetrance. Moreover, we confirmed the influence of genetic background and different deletion sizes on the phenotype. The complicated control of the penetrance for one phenotype in SMS mouse models provides tools to elucidate molecular mechanisms for penetrance and clearly shows that null alleles caused by deletion can have different phenotypic consequences than null alleles due to gene inactivation.

Impact of haplotype frequency estimation and use of molecularly phased haplotypes in linkage analysis of a candidate gene region with linkage disequilibrium. *W. Sieh[1], C.-E. Yu[2], T.D. Bird[1,3], G.D. Schellenberg[2,3], E.M. Wijsman[1,4]* 1) Medical Genetics, University of Washington, Seattle, WA; 2) Gerontology and Geriatric Medicine, University of Washington, Seattle, WA; 3) Neurology, University of Washington, Seattle, WA; 4) Biostatistics, University of Washington, Seattle, WA.

Most current linkage analysis programs assume linkage equilibrium (LE) between markers. Violation of this assumption by the use of densely spaced SNPs in investigations of candidate genes can lead to inflated evidence for linkage. Linkage disequilibrium (LD) between SNPs can be accommodated by using multi-SNP haplotype frequencies, if known, rather than the component SNP allele frequencies. Phased haplotypes in candidate genes can provide gold standard haplotype frequency estimates, and are also of inherent interest as markers in linkage analysis.

We evaluate the impact of using haplotype frequencies estimated by molecular phase determination, maximum likelihood estimation, or by assuming LE in LOD score analysis. We also compare the effects of using directly observed haplotypes rather than unphased SNP markers for linkage analysis of a cluster of five SNPs in a candidate region for Alzheimers disease (AD) on chromosome 19p. Strong LD (r^2 = 0.88-0.95) was observed between two SNP pairs, while moderate LD (r^2 = 0.29-0.67) was found among the other SNP pairs. We show that ignoring LD between markers can lead to substantial (79%) inflation of the LOD score (from the referent value of 1.05 to 1.88), but that the method of haplotype estimation makes little difference provided that LD is allowed. Use of phased haplotypes produces a modest (8%) increase in the LOD score over unphased SNPs, under the same set of haplotype frequencies. Gains from using phase information may be important in studies where the costs of family recruitment and phenotyping greatly exceed the costs of marker phase resolution. Thus, molecular haplotyping may be a cost-effective approach in studies of AD, where the cost for recruiting and phenotyping each affected person is more than ten-fold higher than for a genome scan.

Strong genetic evidence for DYX1C1 as a susceptibility factor for dyslexia. *M. Zucchelli[1], F. Dahdouh[2], H. Anthoni[1], M. Peyrard-Janvid[1], I. Tapia Paez[1], J. Schumacher[2], G. Schulte-Körne[4], J. Kere[1,3], M.M. Nöthen[5]* 1) Department of Biosciences and Nutrition at Novum and Clinical Research Center, Karolinska Institute, Stockholm, Sweden; 2) Institute of Human Genetics, University of Bonn, Bonn, Germany; 3) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 4) Department of Child and Adolescent Psychiatry and Psychotherapy, University of Marburg, Marburg, Germany; 5) Dept of Genomics, Life & Brain Center, University of Bonn, Germany.

The DYX1C1 gene on chromosome 15 was the first candidate gene associated to Developmental Dyslexia based on cloning of a translocation breakpoint cosegregating with dyslexia and association of SNPs in a Finnish cohort of unrelated patients (Taipale et al. 2003). Until present, five groups have published replication studies on DYX1C1. One study that found significant association, though to a different haplotype, was considered positive replication, whereas four were interpreted as negative. However some of them reported nominally significant p-values to the same haplotype as the one in the positive replication. Thus, the role of DYX1C1 as a common susceptibility gene for dyslexia remains unsettled. To address this question, we resequenced the gene and found two new SNPs. Adding these and two more polymorphic sites from the database to the SNPs reported earlier, a refined haplotype structure was disclosed, splitting the most common haplotype into two. We show that the new most common haplotype is associated to dyslexia in a population of German descent (p-value = 0.008) and a similar trend is present in a small sample of Finnish descent (p-value = 0.27). A meta-analysis of our data and all the previous studies shows a global haplotype association p-value of 0.003. Finally, one the new SNPs that tags the haplotype division is found to regulate transcription factor binding, suggesting a mechanism for DYX1C1 susceptibility effect.

Study of the untranslated region of CFTR (ABCC7) by 5'-RACE in the human tissue. *X. Pepermans[1], V. Janssens[1], A. Bosmans[1], N. Bletard[2], C. Sempoux[2], Ch. Verellen-Dumoulin[1], P. Lebecque[3], K. Dahan[1]* 1) Center for Human Genetics, Cliniques Universitaires Saint-Luc, Bruxelles, Belgium; 2) Pathology, Cliniques Universitaires Saint-Luc, Bruxelles, Belgium; 3) Pediatric, Cliniques Universitaires Saint-Luc, Bruxelles, Belgium.

CFTR chloride channels are encoded by the gene mutated in patients with cystic fibrosis (CF), a recessive condition affecting all exocrine epithelia. Our goal was to validate in human tissues a recent publication showing strong evidence for additional CFTR exons 1 in cardiac rabbit (Davies et al., J Biol. Chem. 279, 2004:15877-15887). Indeed, they have identified two non-coding mRNA (AY256886 and AY256887) and one new coding mRNA (AY256888). We then examined the 5 untranslated region of CFTR mRNA in human pancreas, human colon and human liver selected to their high CFTR Transcriptional activity. Rapid amplification of 5cDNA and PCR (5RACE-PCR) revealed no novel form of exon 1 in a variety of human tissues suggesting that if alternative promoters of CFTR exist, they have no efficient transcriptional activity. Interestingly, we have observed the appearance of two RNA molecules from the colonic biopsy, one normal (r.-) and one containing an insertion of an 74bp intronic sequence between exon 2 and exon 3 (r.296_297ins74pb), responsible for a new reading frame ending in a stop codon at position +4 (p.Arg55ArgfsX59). This additional exon 2b never reported so far caused at the genomic level by a T-to-C transition within intron 2 (c.296+685T>C). The causal effect of this splice defect need to be evaluted in a control and affected population.

Increased efficiency of case-control association analysis by using allele-sharing and covariate information. *S. Schmidt, M. Schmidt, X. Qin, E.R. Martin, E.R. Hauser* Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC.

It has been reported previously that the efficiency of a case-control association analysis, which relies on linkage disequilibrium (LD) between marker and disease susceptibility alleles, can be improved by using linkage information to select cases for follow-up genotyping. Specifically, a linked best design that includes only cases from multiplex families with non-negative NPL scores was shown to provide power similar to a design including all family probands at a fraction of the genotyping cost (Fingerlin et al. 2004). The previous study did not examine the effect of disease-associated covariates, which may include environmental risk factors or measured endophenotypes, and may partially account for the genetic heterogeneity of many complex human diseases. Here, we examine the efficiency of several case and control selection strategies under three plausible covariate models: a QTL underlying a a trait that is a measured risk factor for the disease, a multiplicative gene-environment interaction (GxE) model and a heterogeneity model in which covariate distributions differ between linked and unlinked families. Results of our simulation study show that the linked best design provides very similar power as an analysis of all familial cases (all) under all three covariate models, even though linked best does not use covariate information. Under the QTL and heterogeneity models, an analysis of cases identified by the ordered subset analysis (OSA) can be substantially more powerful than either the linked best or all design. The extent of the power difference depends on the covariate model, the proportion of linked families in the dataset (), the susceptibility allele frequency and the strength of LD. For example, for a recessive QTL model with p=0.35, r^2=0.1, =0.5, the linked best and all designs both have power of 65%, compared to 87% for OSA, and for a recessive heterogeneity model with =0.2, the respective numbers are 41% vs. 84%.

Chronic renal insufficiency among South Indians with Type 2 diabetes mellitus: Role of oxidative stress pathway genes. *B. K. Thelma[1], ArunK. Tiwari[1], Pushplata. Prasad[1], K. M. Prasanna Kumar[2], A. C. Ammini[3], Arvind. Gupta[4], Rajeev. Gupta[5]* 1) Dept.Genetics,Univ.Delhi South Campus,New Delhi; 2) Dept.Endocrinology & Metabolism,MSR Medical College,Bangalore; 3) Dept.Endocrinology,Dept.Nephrology, AIIMS,New Delhi; 4) Jaipur Diabetes & Research Centre, Jaipur; 5) Monilek Hospital and Research Centre, Jaipur,India.

Chronic Renal Insufficiency(CRI), a microvascular complication, developing in ~20% patients with type2 diabetes mellitus(DM) is a leading cause of end stage renal disease worldwide. Genesis of CRI involves myriad of factors, hyperglycaemia and ethnicity being major ones along with variable genetic susceptibility. Hyperglycaemia induced oxidative stress plays a central role in the development of diabetic complications. Using CRI as a phenotype, we investigated the contribution of 26 SNPs from 13 commonly investigated genes, involved in maintenance of cellular redox balance, among patients with type2 DM with CRI (n=106)and without(n=148). CRI patients were those with duration of diabetes was 2yrs, serum creatinine 3mg/dl,UAER200mg/l and presence of diabetic retinopathy. PCR-RFLP based genotyping of the SNPs and test of allelic/genotypic association was carried out. Polymorphisms tested in SOD1, SOD3, VEGF, CYBA, PON1, PON2, GSTM1 & T1 genes were not associated with CRI. The wt genotype of SOD2 Ala9Val was found to be in excess in the CRI group [OR 1.92,95%;CI(1.15-3.21);p=0.01 for Ala/Ala]. Similar association and excess of the wt genotype was observed for UCP1 -112T>G [OR 2.07 (1.18-3.62); p=0.009 for TT]; UCP1Ala64Thr [OR 2.58,(1.31-5.07); p=0.005 for Ala/Ala]; eNOSGlu298Asp [OR 2.10,(1.19-3.69); p=0.009 for Glu/Glu] & GSTPI Ile105Val [OR 2.41,(1.42-4.06);p=0.0008 for Ile/Ile] SNPs. Unlike the other markers mentioned above, in UCP2 -866G>A SNP, the wt allele (p=0.03)& genotype GG was protective [OR 0.56,(0.34-0.93);p=0.02 for GG]. The notable observation in this study was the excess of wt allele in CRI patients for several associated markers. Thus, we may conclude that oxidative stress genes are an important predictor of development of complications and carriers of wt allele are probably more likely to survive the comorbid complications.

Comparative analysis of Copy Number Variation polymorphisms between Mexican Mestizos and European population. *L. Uribe-Figueroa, A. Hidalgo-Miranda, I. Silva-Zolezzi, J. Estrada-Gil, M. Arrieta, A. Contreras, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Copy number variation (CNV) has been recently identified as a major source of human genomic diversity. These polymorphisms have been identified in several chromosomal regions. However, there is limited information about potential differences in CNV within and between populations. To identify CNV in the Mexican Mestizo population and compare them with European population, we used the Affymetrix 100K SNP Mapping Array and the DChip software to infer CNV in 104 samples from Mexican Mestizos. We compared our results with those obtained from the 60 parental samples of the CEU population analyzed in the International HapMap Project that were generated by the same technological platform. Results from each population were loaded into DChip and fluorescence intensity was normalized using the Invariant Set method. Signal values from each microarray set were calculated using the Perfect Match/Mismatch (PM/MM) Difference Model. To analyze CNV in the Mexican population, we performed a 1% trimmed analysis using a 3 SNP median smoothed window. For comparative analysis between populations, we calculated copy number in the Mexicans and compared it with 60 European samples used as a normal diploid control. Trimmed analysis in the Mexican samples showed several regions with 1 copy in 20% of the cases, while regions with 5 copies were detected in 15% of the samples. *In silico* comparative analysis with the European sample set showed a higher number of CNV sites, both gains and losses, present in more than 50% of the Mexican population. Our results suggest that the Mexican Mestizo population is, in general, homogeneous for CNV. However, they show important differences when compared with this European set of samples. CNVs have been reported in association with different pathologies. Thus, characterization of these variants in different populations will contribute to better understand their molecular contribution to human disease.

Cosegregation of the ND4 G11696A mutation with the LHON-associated ND4 G11778A mutation in a four generation Chinese family--Lebers hereditary optic neuropathy in a Chinese family. *J. Qu[1], X. Zhou[1], Y. Tong[1], L. Yang[1], F. Zhao[1], C. Lu[1], F. Lu[1], M.X. Guan[2]* 1) Dept Ophthalmology/Optometry, Wenzhou Medical Col, Wenzhou, Zhejiang, China; 2) Division of Human Genetics, Cincinnati Childrens Hospital Medical Center, Cincinnati, Ohio 45229, USA.

Lebers hereditary optic neuropathy (LHON) is a maternally inherited disorder leading to the rapid, painless, bilateral loss of central vision. Recently, a systematic and extended mutational screening of mtDNA has been initiated in the large clinical population of Ophthalmology Clinic at the Wenzhou Medical College, China We report here the characterization of a four-generation Han Chinese family with LHON. This Chinese family exhibited a variable severity and age-at-onset of visual impairment. Notably, the average-age-at-onset of vision impairment changed from 26 years (generation III) to 14 years (generation IV), with the average of 18 years in this family. In addition, 30% and 50% of matrilineal relatives in generation III and IV of this family developed visual loss with a variability of severity, ranging from blindness to normal vision. Sequence analysis of the complete mitochondrial DNA in this pedigree revealed the presence of the homoplasmic ND4 G11778A mutation and 33 other variants, belonging to the Asian haplogroup D4. Of other variants, the homoplasmic G11696A mutation in the ND4 gene is of special interest as it was implicated to be associated with LHON in a large Dutch family and five Chinese pedigrees with extremely penetrance of visual loss. In fact, the G11696A mutation caused the substitution of an isoleucine for valine at amino acid position 312, located in predicted transmembrane region of ND4. These imply that the G11696A mutation may act in synergy with the primary LHON-associated G11778A mutation in this Chinese pedigree.

Energy Balance Analysis of Metabolic Networks. *Q. Zhou[1], L. Jin[1], M. Xiong[1,2]* 1) Genetics, Fudan University, Shanghai; 2) Human Genetics Center, University of Texas Health Science Center at Houston.

Abstract The purpose of metabolism is to produce metabolites and proteins, which in turn to generate the energy required by the cell and materials to construct the cells and tissues. The organisms have evolved and developed control structures to ensure optimal growth in response to environmental changes and maximizing their chance for survival. Although kinetic model provides detailed results, it is difficult to use them for modeling real metabolic networks because of limited availability of kinetic parameters for most metabolic networks. However, for many organisms the structural information of metabolic networks is available. Therefore, many researchers focus on flux balance analysis (FBA) approach. FBA studies how the metabolic networks operate at steady state and determine distribution of metabolic flux under optimal growth. Although FBA has been successfully applied to optimization of the metabolic networks, its limitation is that FBA does not consider energy balance whether including energy balance equation constraints has big impact on the optimization of the metabolic networks has not been systematically investigated. In this report, we performed optimization of metabolic networks in E. Coli under both flux and energy balance to investigate the impact of the energy balance on the behavior of metabolic networks. However, our preliminary results showed the impact of posing energy balance constraints on the optimization of metabolic networks is limited.

Acute megakaryoblastic leukemia in an infant with t(1;22)(p13;q13) and complex secondary chromosomal aberrations including hyperdiploidy. *D. Wei[1], K.H. Ramesh[1], D.T. Walsh[1], C. Johnson[1], V.R. Pulijaal[1], H. Ratech[1], E.A. Kolb[2], L.A. Cannizzaro[1]* 1) Dept Pathology, Montefiore Medical Ctr. Bronx, NY 10467; 2) Dept Pediatrics, Albert Einstein Col Med. Children's Hospital at Montefiore Bronx, NY 10467.

Acute megakaryoblastic leukemia (AMKL) is an uncommon acute leukemia. It is classified as acute myeloid leukemia-M7 (AML-M7) in the FAB system, and as AMKL in the WHO system. AMKL occurs at all ages. The t(1;22)(p13;q13), characteristic of AMKL, is restricted to infants and children. It has been reported as the sole chromosomal aberration (CA) in about 60% of AMKL cases below 6 months of age and above the age of 6 months, the t(1;22) is often associated with complex secondary CA including hyperdiploidy. In both cases, the prognosis appears to be poor. We report a 2 years old infant with a history of anemia, thrombocytopenia and peripheral blasts. Bone marrow (BM) biopsy showed normocellular marrow, diffusely replaced by blasts and essentially no normal hematopoiesis except for a few scattered megakaryocytes. Immunohistochemical stains revealed blasts that expressed CD117+, CD15-, CD34-, CD68-, bcl-2- (protein). Flow cytometry revealed CD7+, CD13+, CD33+, CD34-, CD38+, CD64+, CD117+, MPO-, CD56-, TdT-, HLA-DR-, and 5% CD61+. The differential diagnoses included acute promyelocytic leukemia, acute monoblastic leukemia and AMKL. Cytogenetic analysis of BM showed a 57,XY,+Y,+1,der(1)t(1;22)(p13;q13)x2,+2,+add(4)(q31),+6,der(7)t(1;7)(p36;q36),+8, +9,+10,+13,+19,+21,-22,+der(22)t(1;22)(p13;q13)t(1;?)(p36;?)[17]/46,XY[3] karyotype. The t(1;22) was questionable by G-banding, as the der(22) had evolved with additional unidentifiable changes. FISH analyses however, confirmed the der(1) and the der(22) chromosomes to be products of the t(1;22). The final cytogenetic results were strongly in favor of AMKL in this infant. The diagnosis of AMKL, particularly in infants and children is difficult to establish in spite of all the hematological parameters pointing to acute leukemia. Therefore, chromosome analyses and FISH tests are highly significant in the final diagnosis of AMKL.

De Novo 4q Partial Duplication with Congenital Cataract, Hypothyroidism and no Urogenital or Preaxial Limb Defects. *A. Singer[1], A. Polishchuk[2], A. Aviram[3], C. Vinkler[4]* 1) Clinical Genetics, Barzilai Medical Center, Ashkelon, Israel; 2) Cytogenetics,Barzilai Medical Center, Ashkelon, Israel; 3) Cytogenetics, Shiba Medical Center, Tel-Hashomer,Israel; 4) Clinical Genetics, Wolfson Medical Center, Holon, Israel.

De novo partial duplication of 4q, has been described in less than 20 patients so far. In an attempt to further delineate the clinical findings we present a patient with some characteristics which were not previously described. The patient is a three and a half years old girl, born at term to healthy unrelated parents. Right after her birth she was found to have a complicated heart defect (Tetralogy of Fallot). She also has a cataract in one eye and hypothyroidism. She has growth and psychomotor retardation. Head circumference is in the 2nd percentile. Brain MRI demonstrated delayed myelination and enlarged ventricles. On examination she has, a prominent metopic suture, low hairline, hypertelorism, epicantal folds, short philtrum, carp mouth, retromicrognathia, small cupped ears, and rockerbottom feet. Cytogenetic and CGH analysis demonstrated an abnormal karyotype 46XX,dup(4),(q26;q34) Urogenital anomalies were previously associated with the 4q25q31 duplication. However our patient does not have urogenital malformation. Thumb anomalies were previously assigned, by karyotype/phenotype relationship, to duplication site encompassing the 4q27q28 location. Our patient does not have a preaxial anomaly . It is hence suggested that both preaxial limb anomaly and urogenital malformations be assigned to a location proximal to q26. While congenital cataract has not been described in association with duplication of 4q, hypothyroidism is a frequent endocrine problem in neonates and could be accidental.

Tuning Relief for Genome-Wide Association Analysis of Epistasis. *B.C. White, J.H. Moore* Computational Genetics Laboratory, Department of Genetics, Dartmouth Medical School, Lebanon, NH.

Detecting epistasis in the absence of marginal effects is both a statistical and a computational challenge. This is particularly true in genome-wide association studies where it is not computationally feasible to exhaustively evaluate all combinations of SNPs. One strategy to address this problem is to statistically select or filter a subset of SNPs that can then be exhaustively evaluated for interactions. Our goal was to develop a powerful and efficient algorithm for filtering SNPs that have a high likelihood of interacting. To accomplish this goal, we selected the Relief algorithm (Kira and Rendell 1992) as a starting point. Relief determines the quality of a SNP by repeatedly sampling subjects and considering the relevance of the SNP for the nearest subject of the same and different class. We modified this algorithm by introducing a tuning parameter that iteratively removes noisy SNPs. This new Tuned Relief (TuRF) algorithm was evaluated using simulated epistatic interactions of varying heritability (0.01, 0.025, 0.05, 0.1, 0.2, 0.3, 0.4) and minor allele frequency (0.2, 0.4) that were embedded in genome-wide datasets (100 replicates each) with varying numbers of SNPs (1000, 10000, 100000) and varying sample sizes (200, 400, 800, 1600, 3200, 6400). We found that the TuRF algorithm significantly outperformed both ReliefF and a myopic chi-square test of independence for selecting epistatic SNPs from among thousands of candidates. There are three important advantages of the TuRF algorithm. First, TuRF is able to assign a single measure of relevance to each SNP in a dataset without ignoring the context of the other measured variations. Second, the TuRF algorithm is computationally efficient and can be applied to a single genome-wide dataset with 100000 or more SNPs in a matter of minutes. Finally, we have made TuRF available in an open-source software package for anyone to use. This study demonstrates that it is possible to filter epistatic SNPs from a genome-wide association study. (Funded by NIH R01s LM009012 and AI59694, PI-Moore).

Hearing loss in biotinidase deficiency: Preliminary results indicate genotype-phenotype correlation. *B. Wolf[1], H.S. Sivri Kalkanoglu[2], G.A. Genc[3], L. Sennaroglu[4], H.I. Aydin[2], A. Dursun[2], A. Tokatli[2], T. Coskun[2]* 1) Dept. Medical Genetics, Henry Ford Hospital, Detroit, MI; 2) Hacettepe University, Dept. of Pediatrics, Nutrition and Metabolism Unit, Ankara, Turkey; 3) Hacettepe University, Dept. ENT, Audiology Unit, Ankara, Turkey; 4) Hacetteppe University, Dept. ENT, Ankara, Turkey.

Biotinidase deficiency (BD) is an autosomal recessively inherited disorder that is due to an inability to recycle the vitamin biotin. If not treated with biotin, the clinical features of BD usually include cutaneous and neurological symptoms, including hearing loss. Newborn screening for BD is not conducted in Turkey. We studied 18 Turkish children with profound BD (less than 10 % of mean normal serum activity); 9 symptomatic children (homozygous with null mutations), 6 symptomatic children (homozygous with missense mutations), and 3 asymptomatic children who were diagnosed and treated immediately after birth because an older sibling was affected (homozygous with null mutations). Audiologic, impedancemetric, auditory brainstem response and otoacoustic emissions measurements were performed on all patients. Hearing loss of varying degree occurred in all symptomatic children with null mutations, whereas all symptomatic children with missense mutations had normal hearing. The three children with null mutations who were treated since birth did not develop hearing loss. These preliminary results indicate that symptomatic children with null mutations are likely at risk of developing hearing loss, whereas those with missense mutations may not develop hearing loss even if they are not diagnosed or treated for a prolonged period of time. In addition, once hearing loss occurs, it appears to be irreversible in spite of biotin treatment, although treatment may prevent progression of the hearing loss. Biotin treatment immediately after birth appears to prevent hearing loss in children with null mutations. Our study further supports that BD should be considered in all children with sensorineural hearing loss and all newborns should be screened for this readily treatable disease.

Gene expression profiling of archival specimens distinguishes *BRCA1*-mutated from sporadic breast cancers.

W.S. Rubinstein[1], X. Ge[1], K.L. Kaul[1], H.T. Lynch[1,2] 1) Evanston Northwestern Healthcare, Evanston, IL; 2) Creighton University School of Medicine, Omaha, NE.

Purpose To refine gene expression profiling (GEP) of *BRCA1* germline-mutated (*BRCA1+*) breast cancers and to adapt GEP for analysis of paraffin-embedded formalin-fixed (FFPE) specimens. Methods We performed genome-wide GEP on 7 *BRCA1+* and 15 mutation negative fresh-frozen breast tumors using Affymetrix HG-U133 Plus 2.0 arrays. We used these data, along with published GEP data on 25 *BRCA1+* tumors and *BRCA1* interacting genes, to create a 128-gene custom Illumina DASL array with 3 probes per transcript. 64 of 68 FFPE samples qualified for analysis (94% had ≥50% probe detection): 35 *BRCA1+* of which 8 were estrogen receptor (ER) positive, 28 sporadic, and 1 *BRCA2+*. Sporadic tumors were *BRCA* mutation negative; age-, pathology-, receptor-, and grade-matched; or both. Student *t*-test was applied to a 41-sample training dataset to select *BRCA1+* associated genes. Since ER status markedly affects global gene expression, genes more strongly associated with ER were discarded. Hierarchical clustering and k-nearest neighbor (kNN) were used for unsupervised and supervised classification, respectively. Results We selected 18 genes that distinguish *BRCA1+* from sporadic breast tumors and 25 genes associated with ER status. Among 18 independent test samples, kNN predicted *BRCA1* status with 91% sensitivity and 83% specificity. Accurate *BRCA1+* classification was accomplished for archival tumors as old as 39 years. Conclusions We show for the first time that GEP of FFPE specimens can reliably distinguish *BRCA1+* from sporadic breast tumors, independently of ER status. False positives may be due to an imprecise classifier, *BRCA1* promoter methylation, or undiscerned mutations, possibilities which require exploration. Discriminating genes may lend insight into *BRCA1* biological functions. GEP may be useful for prescreening breast cancers given the high false negative rate of family history; analyzing archival specimens from deceased relatives; as a functional assay to define *BRCA* variants as benign or deleterious in combination with established methods; and as an adjunct for genetic counseling and testing.

Weekly enzyme replacement therapy may slow decline in renal function in a subset of Fabry patients after long-term biweekly dosing. *R. Schiffmann, H. Askari, M. Timmons, C. Robinson, M. Ries* DMNB/NINDS, National Institutes of Health, Bethesda, MD.

Agalsidase alfa (Replagal, Shire Human Genetic Therapies, Inc.) infused at a dose of 0.2 mg/kg every other week (EOW) is approved in 35 countries for the treatment of Fabry disease. This dosing regimen maximally reduces plasma Gb_3 and stabilizes renal function in most patients with mild-to-moderate chronic kidney disease. This study was performed to determine if adult male patients who demonstrate a continuing decline in renal function despite two or more years of conventionally dosed agalsidase alfa therapy show an improved clinical response with weekly administration of the same 0.2 mg/kg dose. Eleven of 41 (27%) adult male Fabry patients who participated in long-term clinical trials and who had demonstrated a continuing decline in estimated glomerular filtration rate (MDRD, eGFR) of ? 5 mL/min/1.73m^2 per year during long-term treatment with agalsidase alfa at 0.2 mg/kg, EOW, were enrolled in this open-label prospective study. Patients were switched to weekly infusion of 0.2 mg/kg and followed for an additional 24 months. The primary outcome measure was the slope (linear regression) of the change in eGFR over 24 to 54 months before compared to the slope over 24 months after switching dosing regimens. Mean baseline eGFR was 81.6 8.1 mL/min/1.73m^2 (mean SEM) and mean rate of change in eGFR was -7.9 0.9 mL/min/1.73m^2 per year with EOW dosing. During the 24-month follow-up after increasing the dosing frequency from EOW to weekly, the mean rate of change in eGFR had slowed to -3.2 2.0 mL/min/1.73m^2 per year (P=0.01). After switching to weekly dosing, the slope of the change in eGFR became positive or less negative in all but 3 patients. A multiple regression model confirmed the weekly infusion regimen as the strongest explanatory variable for the change in eGFR (P=0.009) with a weaker contribution from the use of ACE-I/ARB medication (P=0.03). These preliminary results suggest that weekly infusions of agalsidase alfa may be considered for patients whose kidney function continues to decline with EOW dosing and warrants further study. *Not approved in the US.

Homozygosity Mapping of Autosomal Recessive Disease Gene in Patient of a Consanguineous Family by High Density Oligonucleotide Arrays. *J.Y. Wu[1,2], H.H. Wang[1], C.F. Chang[1,3], F.J. Tsai[2], Y.T. Chen[1,4]* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Department of Medical Research, China Medical University Hospital, Taichung, Taiwan; 3) Molecular Medicine Program, Institute of Microbiology and Immunology, National Yang Ming University, Taipei, Taiwan; 4) Department of Pediatrics, Duke University Medical Center, Durham, NC 27710, USA.

Acromesomelic dysplasia, type Maroteaux (AMDM [MIM 602875]), is one form of skeletal dysplasia that involves shortenings of the limbs (Maroteaux et al. 1971). This skeletal dysplasia is identified of autosomal recessive inheritance and therefore mostly found in consanguineous families. In fact, 17 of the 21 families of different ethnic backgrounds are consanguineous in the mapping of NPR2 as the gene responsible for causing AMDM (Bartels et al. 2004). We have identified a small nucleus Han Chinese family with one patient diagnosed of ADMD whose parents are cousins. While linkage analysis and positional candidate approach were successfully adopted to zoom in the interval to 9p12-q12 (Kant et al. 1998) and subsequently concluding on the mutations of NPR2 as the cause of AMDM, and high density single nucledotide polymorphism (SNP) genotyping assays have been utilized as the substitute of genomewide linkage analysis of complex disease with their higher information content (Middleton et al. 2004, John et al. 2004), there has not yet an instance of using such approach in mapping the homozygosity region and thereafter the disease gene of autosomal recessive disease in a small consanguineous family. We report here the use of high density SNP genotyping array for filtering the homozygosity regions from the whole genome and then locating the mutation that leads to AMDM in a family with only one affected member in a total of six members.

Association between a matrix metalloproteinase 3 promoter polymorphism and functional severity in a Japanese rheumatoid arthritis cohort. *S. Tsukahara, K. Ikari, E. Inoue, S. Momohara, T. Tomatsu, M. Hara, H. Yamanaka, N. Kamatani* Institute of Rheumatology, Tokyo Women's Medical University, Japan.

Rheumatoid arthritis (RA) is a systemic, chronic disease that causes progressive joint destruction, thereby leads to impaired functioning and a poor quality of life. Matrix metalloproteinase 3 (MMP-3) plays a pivotal role in joint destruction seen in RA. A biallelic polymorphism on promoter region, one allele has a run of six adenosines (6A) and the other has five (5A), was found to influence the production of MMP-3. A recent prospective study indicated that this promoter polymorphism is associated with the progression of radiographic joint destruction in European patients with early RA. The aim of the present study was to determine whether this MMP-3 promoter polymorphism is associated with long-term functional impairment in Japanese RA patients.

The study was approved by the Tokyo Women's Medical University Genome Ethics Committee. It was a part of a Japanese RA cohort project that included over 4000 Japanese RA patients (IORRA: Institute of Rheumatology RA cohort). DNA samples were available from 1284 patients, of whom, 1128 were randomly selected for this study. Genotyping of the 5A/6A polymorphism (rs3025058) was performed using TaqMan SNP genotyping assay (Applied Biosystems). The Health Assessment Questionnaire (HAQ) was used to assess functional severity of the patients. A cross-sectional analysis using the HAQ data in the cohort study in April 2003 was performed on 1077 patients (patients with missing data for HAQ were excluded). Differences in HAQ score among genotypes of 5A/6A polymorphism were analyzed by regression analysis, which was implemented in the R software package. Significant differences were found among MMP-3 genotypes for HAQ ($p = 0.01$; mean HAQ were 0.95, 0.75 and 0.66, respectively for genotype 5A/5A, 5A/6A and 6A/6A). We conclude that MMP-3 gene is associated with the functional severity of RA in a Japanese population.

A novel ORF15 frameshift mutation of RPGR in a Chinese family with Dominant X-linked retinitis pigmentosa.

J.Q. Sheng[1,2], Z. H. Tang[1], W. Chang[1], Q.B. Ding[3], P. Liu[1], T. Ke[1], F. G. Jiang[1], X. Ren[1], J.Y. Liu[1], Q.K. Wang[1,4], M. Liu[1] 1) Center for Human Genome Research and College of Life Science and Technology of Huazhong University of Science and Technology, Wuhan, Hubei, China; 2) Xiaogan University, Xiaogan, Hubei,China; 3) People Hospital of Tiantai, Tiantai, Zhejiang, China; 4) The Cleveland Clinic Foundation, Cleveland, OH.

Retinitis pigmentosa (RP) denotes a group of hereditary retinal dystrophies, characterized by the early onset of night blindness followed by a progressive loss of the visual field. This paper aim is to found the genetic basic for a Chinese family with X-linked dominant retinitis pigmentosa. Peripheral blood was taken from all the members of the retinitis pigentosa family. Linkage analysis was performed using a panel of microsatellite markers flanking candidate genetic loci for known retinitis pigentosa genes, and linkage analysis results excluded all autosomal dominant retinitis pigentosa (ADRP) loci as causative of the dominannt RP family, but show positive link with markers DXS993 and DXS1068, where RPGR is located. For mutation analysis, direct sequence of whole coding region of RPGR with DNA from the proband revealed a hemizygous 1166A deletion of ORF15 in affected male, this deletion results in a frameshift leading to altered amino acid structure and early termination of RPGR. The 1166delA mutation co-segregated with all affected individuals, but didnt present in normal members in the family, the clinical feather of the mutant carriers show high intrafamilic variability in the family.

Testicular expressed genes are missing in familial X-linked Kallman syndrome due to Two large different deletions around the KAL1 gene. *R. Parvari[1], N. Loewenthal[2], A. Peretz[2], E. Hershkovitz[2]* 1) Dept Genetics& Virology, Ben Gurion Univ, Beer Sheva, Israel; 2) Pediatric Endocrinology & Metabolic Unit, Soroka Medical University Center, Beer Sheva 84101, Israel.

X-linked Kallman syndrome is caused mainly by point mutations in the KAL1 gene. Large deletions of more then 1Mb are rare events in the human population and commonly result in contiguous gene syndromes. We report on two large deletions on Xp22.3 causing isolated Kallman syndrome in two pairs of cousins, sons of two sisters. The deletions were identified by the failure to PCR amplify the Kallamn genes exons using patients DNA. The definition of the deletions' borders was done by STS analysis. The definition of the genes in the deletions and the elucidation of significant sequences at the deletion borders was done by in-silico analysis. The identification of two different, apparently independent deletions larger then 1 Mb, in two pairs of first degree cousins with Kallman syndrome (KS) of two sisters was unexpected. One of the events causing the deletion appears to have been mediated by an L1 transposition, the other by non homologous end joining. The deleted sequences encompass the KAL1 gene and four known additional genes exclusively expressed in testis. Although our patients presented clinically as an isolated Kallman syndrome, the findings of contiguous gene deletions which involves the deletion of testis specific genes would be probably of clinical relevance. The absence of these genes may impair future fertility despite replacement therapy. The demonstration of an additional mechanism creating deletions in the Kallman region may hint that deletions in Kallman patients involving testicular expressed genes are more frequent then previously recognized.

Familial colorectal neoplasia is not associated with the *TGFBR1*6A* allele. *G.L. Wiesner[1,2,5], W. Morgan[1], J. Willis[3,5], S. Lewis[1], S.D. Markowitz[2,5], R. Elston[4,5], D. Daley[4,6]* 1) Depts of Genetics; 2) Medicine; 3) Pathology; 4) Epidemiology; 5) and Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH; 6) University of British Columbia, Vancouver, BC, Canada.

Case-control studies have reported an association between TGFBR1*6A, a common variant in the type 1 transforming growth factor beta receptor, and risk for human colorectal cancer. TGFBR1 co-localizes to 9q22.2-31.2, which was first identified by the Colon Neoplasia Sibling Study as a region containing a putative susceptibility locus for colorectal neoplasia (PNAS 100:12961, 2003). In order to determine whether the *6A allele is responsible for the observed linkage at 9q22.2-31.2, 53 kindreds having two or more siblings affected with colon cancer or advanced colon adenomas were genotyped for the presence of the *6A or *9A allele. The percentage of affected individuals with one or more *6A alleles in kindreds linked to the region was less than the percentage of affected individuals in unlinked kindreds (11% and 25%, respectively). Further, the distribution of the *6A allele did not differ between affected or unaffected siblings. The TGFBR1 genotypes were then analyzed along with the17 polymorphic markers first used in the linkage analysis of this region. Rather than increasing the evidence for linkage at 9q22.2-31.2 as expected, including the TGFBR1 genotypes into the analysis decreased the significance (P= 0.0005 to P= 0.001) for linkage. Additionally, no significant impact on the linkage evidence was found when the number of *6A alleles was added as a covariate in the regression analysis. These data indicate that in our population the *6A allele is not the causative susceptibility allele, nor is it in significant linkage disequilibrium with a causative allele close by. There remains an unidentified susceptibility locus for colorectal neoplasia at 9q22.2-31.2.

Empirical observations on detection of linkage disequilibria by testing homozygosity of haplotypes. *X. Sheng, S. Guha, R. Chakraborty* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

Excess homozygosity (EH) of haplotypes has been advocated as a measure of linkage disequilibrium (LD) in the literature. In particular, EH has been claimed to have advantages to detect LD for highly polymorphic multiallelic markers, since it avoids haplotype determination from multilocus genotype data and provides a single statistic to measure LD. In spite of the fact that under the assumption of Hardy-Weinberg equilibrium, expected EH is algebraically related with LD, and dependence of EH on recombination distance of loci has been worked out, empirical data on the ability of detect significant LD by using EH for loci of varying recombination distance is not yet available. In this study, we used genome wide data on 784 microsatellite loci from 36 worldwide populations to examine the power of detecting significant LD by using EH. Six geographic grouping (Africa, Asia, Europe, Middle-East, America, and Oceania) of populations resulted in the following observation: (i) EH exhibits significant LD more often than the level of significance of the test procedure only for America and Middle-East when the loci are less than 10cM recombination distance apart (power in the range of 0.09 to 0.16); (ii) the power of detecting LD by permutation tests of EH is in general low, particularly for populations of higher heterozygosity; and (iii) for small populations, albeit for lower heterozygosity, power appears to be somewhat larger. We conclude that these observations are caused by the discrete sampling distribution of EH, particular when the homozygosity in at least one locus is not large, and sample size is small. For example, when at least one locus has a homozygosity of 0.1, measuring EH from genotype data on 100 individuals can give rise to only 11 distinct values of EH, resulting in low power and a non-monotonic decrease in power with increasing recombination distance. These statistical properties of EH apparently outweigh the advantages of using EH for studying background LD levels for microsatellite loci. (Research supported by the NIH grant GM 41399 to RC).

DNA repair gene polymorphisms and G2 chromosomal radiosensitivity. *C.S. Wilding[1], G.B. Curwen[1], E.J. Tawn[1], X. Sheng[2], J.F. Winther[3], J.D. Boice Jr.[4,5], R. Chakraborty[2]* 1) Genetics Department, Westlakes Research Institute, Moor Row, Cumbria, United Kingdom; 2) Center for Genome Information, University of Cincinnati College of Medicine, Cincinnati, OH 45267, USA; 3) Institute of Cancer Epidemiology, Danish Cancer Society, DK-2100, Copenhagen, Denmark; 4) International Epidemiology Institute, Rockville, MD 20850, USA; 5) School of Medicine, Vanderbilt University, Nashville, TN 37232, USA.

Prior research suggests major gene susceptibility for G_2 chromosomal radiosensitivity and association of enhanced chromosomal radiosensitivity with cancer predisposition. Based on this, we have undertaken a preliminary investigation of the association of polymorphisms in DNA repair genes with G_2 chromosomal radiosensitivity. Sixteen candidate polymorphisms (13 SNPs and 3 microsatellites) were examined at nine genes of four DNA repair pathways in 83 subjects, comprising 23 survivors of childhood and adolescent cancer, their 23 partners and 37 offspring. Genotypes at the Asp148Glu SNP site on the APEX gene of the BER pathway appeared to be significantly associated with cancer in survivors ($p = 0.001$, significant even after multiple test adjustment), due to the enhanced frequency of the APEX Asp148 allele in survivors in comparison to that in their partners. Analysis of variance (ANOVA) of G_2 radiosensitivity in the pooled sample, as well as family-based association test (FBAT) of the family-wise data, showed sporadic suggestions of association of G_2 radiosensitivity with polymorphisms at two sites (the Thr241Met SNP site on the XRCC3 gene of the HRR pathway for ANOVA, and the Ser326Cys SNP site on the hOGG1 gene of the BER pathway for FBAT analysis), neither of which remained significant after multiple test adjustment. These, together with near non-significance of the haplotype level association analyses, suggest that polymorphisms at one or more DNA repair pathway genes may be associated with G_2 radiosensitivity governing cancer predisposition. (Research supported by US Public Health Service grants CA104666, GM41399 from the US National Institutes of Health and a grant from Westlakes Research Institute).

Evaluation of the Third Wave InPlex CFTR Microfluidics Card Assay: Limitations and Controls. *H. Rennert, A. Khazanova, J. Sipley* Department of Pathology and Laboratory Medicine, NewYork Presbyterian Hospital-Weill Medical College of Cornell University, New York, NY.

The InPlex CFTR Microfluidic Card Assay (Third Wave, Madison, WI) is a new method for the detection of 46 Cystic Fibrosis (CF) mutations and polymorphisms; including the 25 American College of Medical Genetics (ACMG) recommended mutations, using single-tube multiplex Invader reactions. This assay uses target amplification of template DNA, followed by multiplex Invader reactions in a microfluidics card. Samples are scored as either WT, heterozygous (HET), homozygous mutant (MUT) or equivocal (EQ). We have analyzed a total of 76 controls that included 44 Coriell, 12 College of American Pathologists proficiency testing samples and 20 DNA samples from a reference laboratory. In addition, we have evaluated the tests performance using commercial single-tube controls obtained from AcroMetrix (28 mutations) and Molecular Controls (44 mutations). Of the 76 DNA samples tested, 73 samples generated the expected results while 3 samples yielded equivocal results. Of the three, two were deltaI507 samples that were called equivocal (EQ) for deltaF508, and one was a G551D/R553X that was called homozygous (MUT) for both mutations. All negative controls were called as expected. Both controls were able to accurately call as MUT the majority, but not all, mutations contained within these controls, generating a complex genotype composed of MUT, heterozygous (HET), EQ and low signals. The HET or EQ calls were predominantly seen for mutations adjacent to one another, such as G551D, G542X, S549N and S549R, and are likely a result of hybridization interference of allele-specific probes. These results demonstrate that certain mutations and genotypes are more likely than others to yield imprecise calls, and therefore test results for these mutations should be interpreted with caution. The use of commercial controls for this assay requires further optimization.

Sample size estimation under fixed statistical power and FDR (false discovery rate) control in microarray experiments using a nonparametric test. *J.G. ZHANG[1], J.F. LIU[1], H.W. DENG[1,2,3]* 1) Basic Medical Science, University of Missouri/Kansas, Kansas City, MO; 2) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan, P. R. China; 3) The Key Laboratory of Biomedical Information Engineering of Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, P.R.China.

Motivation: One main task for DNA microarray analyses is to detect differentially expressed genes between different tissues or cell samples, such as healthy vs diseased. Microarrys data usually do not follow normal distributions, even after some data preprocessing and transformation. Nonparametric tests (e.g. Wilcoxon rank sum test) were recommended for analyses of microarray data. However, statistical power estimation for non-parametric tests, which is significant for planning experiments, is not available. In this paper, we develop a sample size estimation algorithm for Wilcoxon rank sum test under fixed FDR (false discovery rate)-controlling levels and pre-determined detecting statistical power. We elucidate how the experimental factors affect sample size estimation, FDR control and detecting power. Results: We investigate the situations when expressions of various genes are independent or correlated with each other at the same levels. We assume expression of each gene follows a normal-uniform mixture distribution. The sample sizes needed for two-sample Wilcoxon rank sum tests are computed by our newly developed algorithm. The computed results agree very well with the Monte Carlo simulation results. Factors such as sample allocation proportion for comparing groups, effect size of differentially expressed genes and noise levels (as reflected by the proportion of the uniform distribution in the mixed distribution of gene expression), can influence the sample size calculation under fixed FDR levels and detecting statistical power. We observe that correlation structures among gene expressions may increase variance of computed statistical power and FDR levels compared with the independent gene expression model.

Segregation of mtDNA in the female germline. *T. Wai, E.A. Shoubridge* Human Genetics, Montreal Neurological Institute-McGill University, Montreal, Quebec, Canada.

Mitochondrial DNA (mtDNA) is a high copy, maternally inherited genome coding for polypeptides essential for oxidative phosphorylation (OXPHOS). Typically, a cell contains one mtDNA genotype, homoplasmy, but in some circumstances two genotypes can coexist, heteroplasmy. Studies in animals and human pathogenic mtDNA mutations have demonstrated that there is a genetic bottleneck during oogenesis that can affect the segregation of mtDNA sequence variants. This genetic bottleneck is believed to occur during the development of primordial germ cells (PGC) to primary oocytes because of the amplification of an estimated 10 copies of mtDNA found in PGCs to the 105 copies that are found in oocytes. We hypothesize that modulating mtDNA copy number and OXPHOS function during oogenesis can affect mtDNA segregation, and ultimately the size and shape of the genetic bottleneck. We are testing this hypothesis in a mouse model heteroplasmic for two mtDNA sequence variants (NZB and BALB) using the Cre-lox recombination system to knock out genes essential to maintain mtDNA copy number (TFAM) or OXPHOS function (COX10), at early or late stages of oogenesis. mtDNA heteroplasmy levels and copy number are assessed in single cells throughout oogenesis to investigate the impact of copy number and OXPHOS on this genetic bottleneck. Oocytes from Heteroplasmic TFAM+/- mice demonstrate increased an increased heteroplasmic variance when compared to oocytes from TFAM+/+ littermates, yet the distribution of heteroplasmy in COX10+/- oocytes does not differ significantly from wild type littermates. Since previous studies have demonstrated that mtDNA copy number correlates directly with TFAM levels, this suggests that a reduction in mtDNA copy number, but not diminished OXPHOS, can constrict the size of the bottleneck.

Confirmation of PREDICTED and generation of novel sequences for the calcitonin (CALCR) and vitamin D3 (VDR) receptors in *Bos taurus*. *M.J. Paolella, K.M. Bilides, M.L. Fitzmaurice, C.E. Horbal, S.M. Lombardi, K.E. Mannion, V.L. Martucci, R.A. Nunez, J.E. Pachesa, B.K. Reidy* Science, Sacred Heart Academy, Hamden, CT.

As the recipients of a grant to engage in a 3-year study of osteoporosis, and the interest in the implications of the calcitonin (CALCR) and the vitamin D3 (VDR) receptors, another group of students chose to continue to focus on these genes for the second year. After having confirmed a portion of the PREDICTED *Bos taurus* sequence for CALCR and COLIA1 last year (gb: DQ114140 and DQ114141), but without conclusive results for VDR, and the sustained research on CALCR as a major influence of bone mineral density, the genes offered an opportunity to further the students knowledge on the relationship of these two genes. GenBank sequences of these genes from related organisms, specifically *Homo sapiens* and *Rattus norvegicus*, were aligned and the areas of greatest similarity were BLASTed against unidentified genomic *Bos taurus* contigs. Results guided primer design to amplify the significant areas of homology using multiple bovine templates including L1 Dominette 01449 (courtesy of USDA). Successful PCR products were purified, quantitated and sequenced in the schools ABI Prism 310 Genetic Analyzer with the same primers used in PCR. Forward and Reverse sequencing results were aligned with each other, BLASTed, and compared to CALCR and VDR genes in related organisms. Student results confirmed a portion of the PREDICTED *Bos taurus* VDR sequence variants and revealed partial coding regions. Student results for the bovine CALCR sequence, reflective of the *Sus scrofa* and *Homo sapiens* CALCR genes, determined the 3UTR for *Bos taurus*. Sequencing results are posted in GenBank: DQ519355, DQ 519356, and in later June, 2006: DQ659276 and DQ659277.

New molecular findings in Turkish cystinosis patients. *B. Tinloy[1], R. Topaloglu[2], T. Coskun[2], M. Gunay-Aygun[1], Y. Anikster[3], A. Jeong[1], A. Bakkaloglu[2], N. Besbas[2], S. Kalkanoglu[2], W.A. Gahl[1], R. Kleta[1]* 1) SHBG, MGB, NHGRI, NIH, Bethesda, MD, USA; 2) Hacettepe University Faculty of Medicine, Ankara, Turkey; 3) Sheba Medical Center, Tel Hashomer, Israel.

CTNS, located on chromosome 17p13, codes for cystinosin, a protein that facilitates obligatory lysosomal cystine egress. Without proper functioning of cystinosin, patients manifest nephropathic cystinosis, developing renal Fanconi syndrome in infancy and glomerular kidney failure within the first 10 years of life. Many cystinosis patients of European descent have a common 57 kb deletion (allele frequency 50-60%). Consequently, molecular analyses involve an initial multiplex PCR, checking for the presence or absence of this founder deletion, and subsequent sequencing of the 9 coding exons of CTNS. Early and accurate diagnosis is critical because treatment with cysteamine can prevent many disease complications. Here we report our molecular findings in 12 Turkish cystinosis patients. Six of the patients reached end-stage renal failure at ages ranging from 6.5 to 15 years, necessitating renal replacement therapy. None of the 12 nephropathic cystinosis patients carried the 57 kb deletion. Instead, one patient had a new homozygous 10 kb deletion of exons 4 to 9 of CTNS. One patient was homozygous for a known 4 bp deletion in exon 3, i.e., c.357del GACT. Two patients were homozygous for new missense mutations in exons 7 and 9, i.e., c.451G>A (R151G) and c.518A>G (Y173C), respectively. The most common mutation in our Turkish patients was a new exonic splice site mutation in exon 9, i.e., c.681G>A (E227E). Of 24 alleles studied, 7 carried this mutation, which is expected to disrupt proper splicing. Two patients were compound heterozygous for one of the above-mentioned mutations and a known missense mutation in exon 12, i.e., c.1015G>A (G339R). In two patients, we could not find any disease-causing mutations and in two others, we could find only one disease-causing mutation. In summary, cystinosis patients of Turkish ancestry show CTNS mutations different from those of Western European patients. These findings are pertinent to molecular-based screening of cystinosis.

MCMC provides practical linkage analysis on general pedigrees with many STRs or dense SNPs. *E. Wijsman*[1,2], *J. Rothstein*[2], *E. Thompson*[3] 1) Dept Medical Genetics; 2) Dept. Biostatistics; 3) Dept. Statistics; Univ Washington, Seattle, WA.

Linkage analysis needs to adapt to full-chromosome multipoint linkage analysis with either SNPs or STRs. While exact computational tools are available for use with small pedigrees, equivalent exact computation for large pedigrees remains intractable. Markov chain Monte Carlo (MCMC) based methods currently provide the only computationally practical option. No systematic comparison of performance of MCMC-based programs is available, nor have these programs been systematically evaluated for use with dense SNPs. We used simulated data to evaluate performance of two MCMC-based linkage analysis programs: lm_markers (LMM) from the MORGAN package and SimWalk2 (SW). Pedigrees consisted of 14, 52, or 98 individuals in 3-6 generations with up to 4 generations of missing data in the largest pedigree. 100 replicates of markers and trait data were simulated on a 100-cM chromosome, with up to 10 STRs and up to 200 SNPs used simultaneously for computation of multipoint LOD scores. Exact computation was available for comparison in most situations, and comparison with a perfectly informative marker or inter-program comparison otherwise. Both programs were fast and accurate with STRs. For example, computation on the 52-member pedigree (PED 52) for 3 markers required 2-2.5 min. with LMM, SW, or Vitesse; the median discrepancy, d, relative to exact LOD scores was 10%;, and even for 10 markers, computation times for the MCMC programs increased to only 5.7 and 14 CPU min., respectively. In contrast, for large numbers of dense SNPs only LMM was able to provide accurate results in computationally practical time. For PED52 and an analysis of 67 dense SNPs, LMM required only ~11 CPU min/pedigree with a median d=19%, compared to ~11 CPU hrs/pedigree for SimWalk2 yielding a median d=62%. Similar results were obtained for the smallest pedigree, with LMM requiring 2 min to achieve a median d=10% of the truth, while SW required 66 min to achieve a median d=20% of the truth. Thus the MORGAN package provides a computationally practical option for accurate linkage analyses in genome scans with both large numbers of SNPs and large pedigrees. Supported by NIH GM46255.

A novel mutation in the RAB27A gene causing Griscelli Syndrome. *M. Tuchman[1], R. Kleta[1], M. Gunay-Aygun[1], M. Huizing[1], W. Westbroek[1], A. Helip-Wooley[1], J.M. Hertz[2], W.A. Gahl[1]* 1) SHBG, MGB, NHGRI, NIH, Bethesda, MD, USA; 2) Department of Clinical Genetics, Aarhus University Hospital, Denmark.

Griscelli syndrome (GS) is an autosomal recessive disorder characterized by a pigment abnormality, silvery gray hair (caused by uneven distribution of pigment in the hair shaft), and an immune regulation defect. Three genes (RAB27A, Myosin 5A, and melanophilin) are associated with different types of GS. These genes function in melanosome movement into the periphery of melanocytes. RAB27A, located on chromosome 15q21, encodes a small GTPase that also plays a crucial role in granule release by T cells of the immune system. Therefore, mutations in RAB27A make patients more susceptible to viruses and other infectious agents. GS patients exposed to viral infections can develop an acute syndrome characterized by fever, hepatosplenomegaly, leucopenia, and neurological problems. We describe a novel mutation in the RAB27A gene of a six-year old Afghani male who is a product of a consanguineous marriage. The mutation, in exon 2, codon 43, changes a glycine (GGC) to a serine (AGC). Glycine 43 is conserved among various species RAB27A genes and also among other Rab genes. It is located within the switch I domain that is thought to play a role in binding of regulators to the RAB27A peptide. This discovery confirms the diagnosis of the patient and confirms the functional importance of this specific region of the gene. Although GS is rare, identification of the genes associated with this disease has provided some understanding of fundamental aspects of cell function, such as vesicle trafficking and immune modulation. Additional investigations involving mutation detection of other GS patients can provide insights into the molecular regulation of intracellular vesicle trafficking and may allow the design of targeted therapies in the future.

Redefining a locus for autosomal dominant Fanconi syndrome with kidney failure. *H. Stanescu[1], R. Unwin[2], T.J. Heikkila[2], C. Willoughby[2], C.M. Laing[2], M. Kashgarian[3], K. O'Brien[1], N. Siegel[3], W.A. Gahl[1], S. Povey[2], R. Kleta[1]* 1) SHBG, MGB, NHGRI, NIH, Bethesda, MD, USA; 2) UCL, London, UK; 3) Yale Medical School, New Haven, CT, USA.

Renal Fanconi syndromes are defined by the presence of glucosuria, generalized amino aciduria, phosphaturia, small molecular weight proteinuria and proximal tubular acidosis. Clinical consequences can be severe, involving growth disorders, rickets, and electrolyte imbalances. Cystinosis is the most common identifiable reason for renal proximal tubular failure in childhood. In this lysosomal storage disease, enhanced apoptosis of renal tubular cells has been proposed as the mechanism. For other types of renal Fanconi syndrome, the responsible cellular mechanisms are currently unknown. Familial occurrences of renal Fanconi syndrome appear to be rare. However, we have studied three families in the UK and the US with an autosomal dominant pattern of renal Fanconi syndrome and subsequent glomerular failure, including the original family described by Dent and Harris in 1951. Whole genome mapping with 2000 highly polymorphic markers revealed that all three families are compatible with a linked locus on chromosome 15q with a total lod score above 4. This locus of approximately 17 Mb contains 169 genes (NCBI build 36.1) and was described earlier using a different US family. Our data confirm this locus. Cloning the gene for this form of autosomal dominant renal Fanconi syndrome with subsequent kidney failure will give invaluable insights into renal proximal tubular functions. We are attempting to recruit more patients and to establish active collaborations.

The use of genetic testing by pediatric otolaryngologists. *S. Prucka[1], R.D. Duncan[2], B.J. Wiatrak[2], R. Smith[4], N.H. Robin[1, 3]* 1) Genetics, University of Alabama at Birmingham (UAB), Birmingham, AL; 2) Surgery, UAB, Birmingham, AL; 3) Pediatrics, UAB, Birmingham, AL; 4) Internal Medicine, Otolaryngology, and Pediatrics, University of Iowa, Iowa City IA.

Clinical genetic testing for *GJB2* was introduced in the late 1990s and has become an important tool in evaluating children with sensorineural hearing impairment (SNHI). Prior to the introduction of genetic testing clinicians ordered an extensive battery of tests, which often had a low yield, to evaluate the underlying etiology of a childs SNHI.

To assess the use of genetic testing by pediatric otolaryngologists in evaluating a child with SNHI, a questionnaire was developed and made available to pediatric otolaryngologists through the American Society of Pediatric Otolaryngology (ASPO) website (www.aspo.us). In total 63 ASPO members completed the questionnaire, but not all respondents answered every question of this survey. We found that the majority (42/61; 69%) use genetic testing of *GJB2* as an initial test in their work-up. However, while 30/42 (71%) stated that they provide genetic counseling to their patients we also found that 17/38 (45%) answered questions regarding recurrence risks incorrectly, or stated that they did not know the correct response. In addition, the majority of individuals (36/61; 59%) indicated using other tests, such as ECG, inner-ear CT, MRI, audiometry on family members, congenital infection screening, and/or thyroid function testing, as part of the initial evaluation either before or in conjunction with genetic testing. **CONCLUSIONS**: This questionnaire has demonstrated that many otolaryngologists do not understand the full implications of genetic testing. In addition, while many pediatric otolaryngologists use DNA-based testing in their initial work-up of a child with SNHI over half still use other tests that are both expensive and unnecessary for the initial evaluation. Although genetic testing is playing a larger role in clinic practice, these results demonstrate that knowledge is still lacking in this physician population. *This work was supported by NIH NIDCD R03 DC006217-01 (to NHR).*

Synergistic effect of two connexin-26 mutations results in profound hearing loss and inner ear malformation. *B. Tinkle[1], A. Bedard[1], J. Greinwald[2]* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Departments of Otolaryngology and Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Mutations in connexin-26 (GJB2) are the most common genetic cause of non-syndromic deafness. Most mutations in GJB2 are recessive but few are autosomal dominant. We report a compound heterozygote with both a recessive and a novel dominant mutation in GJB2 with profound sensorineural hearing loss and inner ear malformations. The proband was identified shortly after birth with profound hearing loss. His father, paternal uncle, and paternal grandfather had juvenile-onset hearing loss consistent with an autosomal dominant, non-syndromic pattern. The child underwent audiologic, radiographic, and molecular studies. Audiometry revealed profound sensorineural hearing loss (SNHL). Temporal bone CT scans showed abnormally partitioned cochlea and enlarged vestibular aqueducts (EVA). Molecular studies involved sequencing of GJB2 and SLC26A4 (Pendrin) as well as connexin-30 (GJB6) deletion analysis. Both SLC26A4 and GJB6 studies were normal. Sequencing of GJB2 demonstrated the common 35delG mutation as well as a novel 604T>C (C202R) missense mutation. Morle et al. (2000) reported a similar missense mutation (C202F) as a cause of autosomal dominant hearing loss of juvenile-onset similar to the paternal family history. Parental studies were attempted but only the mother was available. She carried the 35delG mutation suggesting that the father contributed the C202R mutation to the proband which was also consistent with the fathers phenotype and familial inheritance pattern. Although EVA is seen in association with idiopathic juvenile-onset hearing loss as well as Pendred and other syndromes, in a study of 500 individuals with hearing loss, Yaeger et al (2006) found no individual with EVA who also had a GJB2 mutation. However, in our patient, it is most likely that the synergistic effect of the 35delG (null) mutation and the dominant C202R in GJB2 were the cause of the inner ear malformation and SNHL.

Comparison of two admixed populations for MALD: 2,000 years versus 200 years. *S. Xu[1], W. Huang[2, 3], Y. Wang[2], H. Wang[2], J. Qian[1], L. Jin[1, 2, 4]* 1) Institute of Genetics, Fudan University, Shanghai, China; 2) Chinese Human Genome Center at Shanghai, Shanghai, China; 3) Rui Jin Hospital, Shanghai, China; 4) CAS-MPG Partner Institute of Computational Biology, Shanghai, China.

Mapping by admixture linkage disequilibrium (MALD) has been shown to be a potentially powerful approach to mapping genetic variants that are involved in human disease. The strategy of MALD has good prospect to performing in many admixed populations with similar histories to African-American. However, challenges are remained for older admixed populations. In this study, using more than 21,000 SNPs spanning over almost entire chromosome 21, we investigated the genetic structures of Uyghurs in China (UIG) and African-American (AfA). Our results showed both UIG and AfA are typical admixed populations, the overall admixture proportions were estimated as UIG with 52.1% European ancestry and 47.9% Asian ancestry, AfA with 19.8% European ancestry and 80.2% African ancestry. Under the assumption of a hybrid isolation (HI) model, the admixture event of UIG was estimated to have taken place about 92-98 generations or 1840-1960 years ago assuming 20 years per generation, while the admixture event of AfA was estimated to have taken place 6-8 generations ago, or 120-160 years ago. Comparing with AfA, we found it is not easy to screen ancestry informative markers (AIMs) with either enough number or enough information for inferring ancestral origins of chromosomal segments in Uyghurs. More powerful methods would be needed for admixture mapping in older admixed populations.

Genome -wide Association Studies Incorporating Searching Genetic Interaction Networks. *G. Pen*[1], *L. Jin*[1,3], *M. Xiong*[1,2] 1) Genetics, Fudan University, Shanghai, China; 2) Human Genetics Center, University of Texas Health Science Center at Houston; 3) CAS-MPG Partner Institute for Computational Biology.

Underlying genetic mechanism of complex diseases involves many genes that influence disease susceptibility primarily through genetic interaction networks and interactions with environments. Incorporating gene-gene interactions and gene interactions networks into genome-wide association studies are an essential and challenging problem in the genetic studies of complex diseases. An exhaustive evaluation of the all possible interactions between SNPs is impossible even if we use a large supercomputer. Therefore, it is urgent to develop efficient and powerful statistical methods and computational algorithms for searching combinations of SNPs, associated with disease and construction of genetic interaction networks, which will largely determine whether genome-wide association will success or not. To date, mathematical formulation of identification of subsets of SNPs or genes and construction of genetic interaction networks has not been well developed. In this report, we propose to formulate them as a combinatorial optimization or a feature selection problem, i.e., given a set of candidate SNPs or genes, selects the best sets in an optimization or classification task. In practice, we need to define: (1) an object function, (2) search algorithm and (3) validation procedure. We develop a novel statistic that can test association of networks with the diseases as the object function. Although genetic algorithms (Gas) that are randomized, evolutionary and population-based algorithms have been the most commonly used search algorithms. capturing the relationships among the variables of the problem (SNPs) is an essential issue for the success of Gas. To overcome the problems of GAs, we develop Estimation of Bayesian Network Algorithm (EBNA) that combines evolutionary computation and probabilistic graphical models as a search engine to discover high-order genetic interactions and genetic interaction networks associated with the disease. The proposed methods for Genome -wide association studies incorporating searching genetic interaction networks are applied to two real data sets. The results show that the proposed methods may open a new avenue for network based approach to genome-wide association studies.

Clinical features and molecular analysis of eight LHON Chinese families carrying the ND6 T14484C mutation. *X. Zhou[1], J. Qu[1,2], Y. Sun[3], F. Zhao[2], L. Yang[1], Y. Tong[1,4], Q. Wei[3], R. Li[5,6], Y. Qian[5,6], F. Lu[1], M.X. Guan[5,6]* 1) School of Ophth and Opto, Wenzhou Medical College, Wenzhou, Zhejiang, China; 2) Zhejiang Provincial Key Laboratory of Medical Genetics, School of Life Sciences, Wenzhou Medical College, Wenzhou, Zhejiang 325003, China; 3) Department of Ophthalmology, Dongfang Hospital, Beijing University of Chinese Medicine and Pharmacology, Beijing 100078, China; 4) The First Affiliated Hospital, Fujian Medical University, Fuzhou, Fujian 350005, China; 5) Division of Human Genetics, Cincinnati Childrens Hospital Medical Center, Cincinnati, Ohio 45229, USA; 6) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, Ohio 45229, USA.

With the aim of investigating the molecular basis of development of Lebers hereditary optic neuropathy (LHON), a systematic and extended mutational screening of mtDNA has been initiated in the large clinical population of Ophthalmology Clinic at the Wenzhou Medical College, China. In the current study, we report the clinical, genetic and molecular characterization of eight Chinese families with LHON. Clinical and genetic evaluations revealed the variable severity and age-of-onset in visual impairment in these families. Penetrances of visual impairment in these Chinese families ranged from 20% to 55%. Furthermore, the average age-at-onset in those Chinese families ranged from 11 to 22 years old. In addition, the ratios between affected male and female matrilineal relatives in these Chinese families ranged from 1.5 to 5, respectively. Sequence analysis of the complete mitochondrial genomes in these pedigrees showed the distinct sets of mtDNA polymorphism, in addition to the identical T14484C mutation associated with LHON in these families. The fact that mtDNA of those pedigrees belonged to different haplogroups C, D, F, and M suggested that the T14484C mutation occurred sporadically and multiplied through evolution of the mtDNA in China. Furthermore, nuclear modifier gene(s) or environmental factor(s) or mitochondrial haplotype(s) seem to account for the penetrance and expressivity of LHON in these Chinese families carrying the T14484C mutation.

Phenylalanine blood levels and clinical outcomes in phenylketonuria: A systematic review and meta-analysis. *S.E. Waisbren[1], H. Leibowitz[1], K. Fahrbach[2], K. Noel[2], A. Dorenbaum[3], H. Levy[1]* 1) Children's Hospital, Boston, Boston, MA; 2) United BioSource Corporation Medford, MA; 3) BioMarin Pharmaceutical, Inc., Novato, CA, USA.

Blood phenylalanine (Phe) levels provide a practical and reliable method to diagnose and manage phenylketonuria (PKU) patients. To examine the question of whether blood Phe levels can be used as a predictive biomarker of clinical outcomes for the development of new PKU treatments, we conducted a systematic literature review and meta-analysis of all published trials from January 1980 through February 2004 that included Phe levels, neurological outcomes, and dietary compliance in PKU patients and we assessed the global relationship between blood Phe and IQ. Within-study correlations between blood Phe and IQ were extracted from 43 studies. Correlations derived from meta-analyses between IQ and blood Phe were significant during critical periods ranging from 0 to 12 years of age ($r = -.35$, $n = 459$); each 100 mol/L increase in blood Phe during the critical period predicted an average 1.3 to 3.1 point decrease in IQ over a range of blood Phe from 423 to 750 mol/L. Similar correlations were found between IQ and lifetime blood Phe levels ($r = -.34$, $n = 436$); each 100 mol/L increase in lifetime blood Phe predicted an average 1.8 to 3.8 point decrease in IQ over a range of blood Phe from 394 to 666 mol/L. Within-study correlations between IQ and concurrent blood Phe levels were also significant ($r = -.31$, $n = 666$). Each 100 mol/L increase in concurrent blood Phe predicted an average 0.5 to 1.6 point decrease in IQ, over a blood Phe range from 390 to 1863 mol/L. Compliance with the PKU diet was reported in 24 studies involving 928 PKU subjects. A high level of non-compliance was seen even in children ages 0-6 yrs. This percentage increased significantly as children got older. These results confirm previous studies reporting a significant correlation between concurrent and long-term blood Phe levels and IQ in PKU patients and highlight the need for development of new PKU therapies.

First report: Phenotypic and Molecular analysis in an extensive Colombian Pedigree with Fabry disease. *P. Paez[1], A. Lopez[1], S. Ospina[1], N. Gelvez[1], C. Duran[1], J.C. Prieto[1,2]* 1) Dept Cundinamarca, Inst de Genetica Humana, Bogota, Colombia; 2) Dept Genetica, Hospital la Victoria, Bogota, Colombia.

Fabry disease is an X-linked inborn error of glycosphingolipid metabolism resulting from mutations in the. alpha-galactosidase A (alpha-Gal A). Classically affectad males present acroparesthesias, hypohidrosis, angiokeratomas, corneal opacities, and abdominal pain, renal failure and cerebrovascular and cardiovascular complications. Fabry female carriers can be asymptomatic or clinically affected. We evaluated a Colombian family with classic criteria for Fabry disease. Phenotype analysis: 5 affected males and 2 obligate carriers from this family were analized, all affected and obligate carriers were studied with alpha Gal A levels, laboratory studies, echocardiogram, EKG and specialized valoration by neuropsicology and ophthalmology. Molecular analysis: Genomic DNA was isolated from affected males and obligate carriers females and the entire -Gal A coding region and flanking sequences were amplified by PCR and analysed by automated sequencing. STR loci (DXS101 and DXS7424) were analised determined in 50-X chromosome haplotypes from unrelated individuals and the frequencies of observed alleles. % heterozygosity and PIC were determined. One family with Fabry disease patients was referred by carrier detection for segregation analysis of highly polymorphic STR loci. The proband and other affected males were identified to be hemizygotes of GLA mutation. A C-to-T transition of g11002 in codon 342 of exon 7 (CGA to TGA), substituting a arginine codon by a termination signal (R342X), and deletion of 87 residues. Mothers of the affected males were heterozygotes carrying the same mutation as their sons. Haplotype analyses with polymorphic markers used for this purpose was informative for DXS7424 y DXS10; analyses indicate that all affected males and obligate carriers from this family have the allele that transmits the disease. The frequencies of all observed alleles, % heterozygosity and PIC were estimated and compared in several ethnic groups. Results derived from this study area useful for carrier detection and genetic counseling in Fabry disease.

Atypical Presentation of a Patient with Pityriasis Rubra Pilaris. *J.C. Prieto[1,3], P.M. Hurtado[1], A. Motta[2]* 1) Inst de Genetica Humana, Univ Javeriana, Bogota Cundinamar, Colombia; 2) Departamento Dermatologia, Hospital Simon Bolivar, Bogota, Colombia; 3) Departamento de Genetica, Hospital la Victoria, Bogota, Colombia.

Introduction. Pityriasis rubra pilaris is a very rare papulosquamosus disease which has chronic course and still unclear etiology. Already, we know that this dermatosis occurs as often in male as in female, can be present in each age and has genethics background. Diagnostic and especially therapy of those skin diseases is very difficult and can make a lot of problems not only dermatologist. Case report. A 12 year-old female was referred for genetic evaluation because of a history of reddish-orange patches on the skin, severe flaking, uncomfortable itching, and thickening of the skin on the feet and hands, since she was 2 year-old. This paper presents the case of a 12-year-old woman with diagnosed and histological confirmed Pityriasis rubra pilaris, and also hypotiroidism documented two months ago. This patient also presents short stature. Discusion. Pityriasis rubra pilaris is a papulosquamous disorder of unknown cause that is characterized by follicular hyperkeratosis, perifollicular erythema and that may progress to generalized erythroderma, and palmoplantar hyperkeratosis. Lesions are characteristically orange or yellow, with approximately 1-cm islands of sparing. Five types of pityriasis rubra pilaris have been described, which differ with respect to age, clinical features, course, and prognosis. The five types include the classic adult and juvenile types (I and III), the atypical adult and juvenile types (II and V), and the circumscribed juvenile type (IV). We didnt find in the literature, reports of Pytiriasis rubra pilaris in association with short stature and hypotiroidism.

Application of array-CGH method to the study on the genetic effects of atomic bomb radiation. -Copy number variants detected in the pilot study-. *N. Takahashi[1], K. Sasaki[1], M. Kodaira[1], Y. Satoh[1], Y. Kodama[1], H. Omine[1], Y. Shimoichi[1], K. Sugita[2], H. Katayama[2], N. Tsuyama[3]* 1) Dept Genetics, Radiation Effects Res Fdn, Hiroshima, Japan; 2) Dept Info Tech, Radiation Effects Res Fdn, Hiroshima, Japan; 3) Dept Anal Mol Med Dev, Hiroshima Univ Grad Sch Biomed Sci, Hiroshima, Japan.

[Purpose] We have studied the effects of atomic-bomb radiation on human germline cells at the genome level. To conduct this study at the genomewide level, we have introduced DNA micro-array based comparative genomic hybridization (array CGH) method. The pilot study using arrays having about 2,240 target Bac-clones revealed that, using the experimental conditions established by us, deletion-type and amplification-type variants with the size of 50 kb or more could be reliably detected. Before launching a large-scale study using the array-CGH, the feasibility of this technique was validated in a pilot study. We will summarize the results in the pilot study. [Experiment] We used an array with about 2,240 Bac-clones. These target clones were distributed in entire human autosomes at an interval of about 1.2 Mb. We examined genomic DNA obtained from 40 offspring of A-bomb survivors and 40 controls. [Results and Discussion] In the pilot study, a total of 253 copy numbers variants (CNVs) were detected. Among them, 14 were rare CNVs, each of which was detected in only one person in this population. Out of these 14, eight CNVs were amplifications and six were deletions. The unit sizes of rare CNVs were in the range of 50 kb to 500 kb (means were 73 kb in deletion type and 161 kb in amplification type). Furthermore, family studies showed that all of these CNVs were inherited from one of the parents. The remaining 239, which were common CNVs observed in two or more persons, were identified on 16 kinds of targets. Of those CNVs, 165 were amplifications and 74 were deletions. This mean number of CNVs (253/80 or 3/person) was considerably smaller than that reported previously by others (about 10/person) on individuals from different geographic backgrounds.

Inferring TGF-B pathway using time series data. *X. Yang[1], P. Yan[1], X. Sun[1], L. Jin[1, 3], M. Xiong[2], X. Zhou[2], D. Lu[1]*
1) State Key Laboratory of Genetic Engineering, School of Life Sciences, Fudan University, Shanghai, China; 2) University of Texas - Houston, TX, USA; 3) CAS-MPG Partner Institute for Computational Biology, Shanghai, China.

The TGF-b signal acts like a powerful molecular traffic light, which regulates growth and proliferation of cells, blocking the growth of many different cell types. Despite its importance in many biological processes such as inflammation, tissue repair and bone formation, its complete structure and computational models have not been well developed. Particularly, its dynamics to respond the external stimuli have not systematically investigated. To study dynamical behavior of TGF-b pathway, we performed three experiments to measure the expression levels of total 48 genes at 11 time points. We use state-space equations to represent dynamics of TGF-b pathway, extended kalman filter (EKF) to estimate both the states and parameters in the state space model (SSM) and EM algorithm to estimate system noise covariance Q and measurement noise covariance R of SSM. To improve the accuracy in estimation of state, we assume that the full set of observations is available, and use a full set of observation to predict the state at the current time. The concrete structure of TGF-b pathway is constructed and the accuracy of prediction is very high. The developed SSM of the TGF-b pathway can be used to study how TGF-b pathway responds the external stimuli and to aid the development of the treatment.

Haplotype inference error in association studies: A two-locus model. *Y. Wang*[1], *M. Xiong*[1, 2], *L. Jin*[1, 3] 1) State Key Laboratory of Genetic Engineering, School of Life Sciences, Fudan University, Shanghai, China; 2) University of Texas - Houston, TX, USA; 3) CAS-MPG Partner Institute for Computational Biology, Shanghai, China.

Haplotypes analyses have become increasingly common in association studies. Since experimental determination of haplotype is expensive, computational approaches were developed to extract haplotype information from genotyping data. However, haplotype inference error (HIE) is an intrinsic problem in all these computational approaches. It is worth systematically investigating how the error of haplotype frequency estimation affects the results of association studies by both theoretical analysis and intensive simulation studies over large parameter spaces. In this study, we derive the general formula to calculate the mean and variance of the HIE and the several statistics in association studies as well. We then use a two-locus model to demonstrate the magnitude of HIE and its effects on association study and the measure of linkage disequilibrium by both theoretical analysis and large-scale simulations. We show that the chi-square is usually about 10%-50% inflated depends on the frequency of four haplotypes. So an adjustment is suggested to be operated on the original chi-square statistic to avoid false positive.

Single nucleotide polymorphisms in *TNFSF15* confer susceptibility to Crohns disease. *K. Yamazaki[1], D. McGovern[2,3], J. Ragoussis[2], M. Paolucci[2], H. Butler[2], D. Jewell[2,3], L. Cardon[2], M. Takazoe[4], S. Saito[5], A. Iida[5], A. Takahashi[6], T. Tsunoda[6], M. Lathrop[7], Y. Nakamura[5], A. Hata[1]* 1) Laboratory for Gastrointestinal Diseases, SNP Research Center, RIKEN, Yokohama, Japan; 2) The Wellcome Trust Centre for Human Genetics,Oxford, UK; 3) Gastroenterology Unit, University of Oxford, Oxford, UK; 4) Department of Medicine, Division of Gastroenterology, Social Insurance Chuo General Hospital, Tokyo, Japan; 5) Laboratory for Genotyping, SNP Research Center, RIKEN, Yokohama, Japan; 6) Laboratory for Medical Informatics, SNP Research Center, RIKEN, Yokohama, Japan; 7) Centre National de Genotypage, Evry Cedex, France.

The inflammatory bowel diseases (IBD), Crohns disease (CD) and ulcerative colitis, are chronic inflammatory disorders of the digestive tract. The pathogenesis of IBD is complicated, and it is widely accepted that immunologic, environmental and genetic components contribute to its etiology. Our previous studies indicated that there may be ethnic differences in genetic susceptibility to CD that are not explained by the minor demographic and phenotypic differences between the populations. In order to identify genetic susceptibility factors in CD, we performed a genome-wide association study in Japanese patients and controls using nearly 80,000 gene-based single nucleotide polymorphism (SNP) markers, and investigated the haplotype structure of the candidate locus in Japanese and European patients. We identified highly significant associations ($p = 1.71 \times 10^{-14}$ with odds ratio of 2.17) of SNPs and haplotypes within the *TNFSF15* (the gene encoding tumor necrosis factor superfamily, member 15) genes in Japanese CD patients. The association was confirmed in the study of two European IBD cohorts. Interestingly, a core *TNFSF15* haplotype showing association with increased risk to the disease was common in the two ethnic groups. Our results suggest that the genetic variations in the *TNFSF15* gene contribute to the susceptibility to IBD in the Japanese and European populations.

Molecular diagnosis for fragile X syndrome in Korea. *S.J. Park, J.A. Yang, S.Y. Jeong, H.J. Kim* Dept Medical Genetics, Ajou Univ School of Medicine, Suwon, Korea.

Fragile X syndrome (FXS) is the commonest cause of inherited mental retardation in males. Several population-based studies in Caucasians of mostly northern European descent have established that the prevalence is probably between one in 6,000 to one in 4,000 males in the general population and one in 8000 females. The FXS is the prototype of triplet repeat disorders, caused by the expansion of a CGG repeat in the 5'UTR of the *FMR1* gene which is located in the Xq27.3 region of the long arm of the X chromosome, eventually causing promoter methylation and transcriptional silencing of the gene. A full mutation is found in patients with mental retardation and corresponds to large expansions of the repeat (>200 repeats). Premutations are moderate expansions (5-200 repeats) and are found in normal transmitting males and in the majority of clinically normal carrier females. About 15% of patients show a mosaic pattern consisting of both full mutations and premutations. We screened for FXS in 96 unrelated individuals (male 80 and female 16) with mental retardation of unknown cause. We have used PCR and Southern blotting (nonradioactive) for determination of a CGG repeat size and methylation-specific PCR (MS-PCR) for detection of the methylated allele in male. We found five male patients (6.3%, 5 in 80 male examined) with full mutation and the CGG repeat size range was 300-500. Among them, three patients revealed to have a mosaic full mutation and normal size alleles. We also found one premutation carrier male with the approximately 100 CGG repeats. These results indicate that a high incidence of FXS is found in Korean males with inherited mental retardation, compare to other ethnic groups, providing an insight into the prevention of FXS by genetic counseling and prenatal diagnosis.

S100A8, as a candidate of NF-kappa B pathway, participates in the genesis of laryngeal squamous cell carcinoma. *K.L. Sun[1], W.N. Fu[1], D.F. Huang[1], Y. Guo[1], C. Shang[1], Z.M. Xu[2], X.H. Sun[2]* 1) Medical Genetics, China Medical University, Shenyang, Liaoning, China; 2) The 463 Hospital of PLA, Shenyang, China.

S100A8, as a candidate of NF-kappa B pathway, participates in the genesis of laryngeal squamous cell carcinoma Kailai Sun1, Dai-Fa Huang1, Wei-Neng Fu1, Yan Guo1, Chao Shang1, Zhen-Ming XU2, Xing-He Sun2 1. Department of Medical Genetics, China Medical University, Shenyang, 110001, P.R. China; 2. The 463 Hospital of PLA, Shenyang, 110042, P.R. China To explore the function and molecular mechanism of S100A8 in laryngeal squamous cell carcinoma. Semi-quantitative RT-PCR, immuno- histochemistry analysis and Western blotting were used to investigate the association of S100A8 with LSCC. RNA interference was applied to evaluate the function of S100A8 in NF-B pathway. The co-immunoprecipitation combined with peptide mass fingerprinting based on matrix-assisted laser adsorption/ionization time-of-flight mass spectrometry were used to reveal the interacted proteins to S100A8. Both mRNA and protein levels of S100A8 increasing in LSCC demonstrated that S100A8 was involved in the genesis of LSCC. Increased apoptotic cells and decreased trans-membrane cells after RNAi S100A8 in Hep-2 cells were observed. No changes of P65, RELB, IKK and IKKmRNA levels were found in Hep-2 cells after RNAi S100A8, but S100A8 mRNA was down-regulated in Hep-2 cells after RNAi P65. Some proteins interacted with S100A8 were found. They were MHC class I HLA-B,similar to T-box 1 isform C, sarcolemmal associated protein 1 and hypothertical protein L0C80154. The abnormalities of S100A8 are common events in LSCC. S100A8 has the abilities of inhibiting apoptosis and promoting metastasis. S100A8 might be a new member of NF-B pathway and probably lie in the downstream of P65. Key words: laryngeal squamous cell carcinoma (LSCC); RNA interference (RNAi); S100A8; NF-B pathway.

Systemic assessment of MMP2 gene and the risk for endometriosis and adenomyosis. *R.S. Wu[1], H.Y. Hsieh[2], M.T. Wu[3], M.C. Huang[4], E.M. Tsai[5], S.H. Juo[1]* 1) Graduate Institute of Medical Genetics,Kaohsiung Medical University,Taiwan; 2) Graduate Institute of Behavior Sciences,Kaohsiung Medical University,Taiwan; 3) Departments of Occupational Medicine and Family Medicine, China Medical University & Hospital,Taiwan; 4) Department of Nutrition,Kaohsiung Medical University Hospital,Taiwan; 5) Department of Obstetrics and Gynecology, Kaohsiung Medical University Hospital,Taiwan.

Background: To test if the MMP2 gene are associated with the risk of endometriosis and adenomyosis. **Methods**: We performed case-control studies, where the cases had at least one of the two diseases and controls were disease free women. We selected a functional promoter single nucleotide polymorphism (SNP1) along with 16 tagging SNPs (SNPs2-17). 107 patients had pure endometriosis, 102 had pure adenomyosis, 20 had both diseases. Two types of controls were used: 203 hospital-based and 183 community-based controls. Logistic regression model was used to assess the genotypic effect. **Results**: Genotype distributions were in Hardy-Weinberg equilibrium for both cases and controls. We found significant association at SNPs16 and 17 for both endometriosis and adenomyosis.The risk genotype CC at SNP16 had an OR of 2.41(P=0.014) and AC at SNP17 had an OR of 2.05(P=0.0027) when comparing endometriosis with hospital-based control. The results by comparing endometriosis with community controls were similar to those in the hospital controls, but somewhat less significant. Using the hospital controls, the OR slightly increased for severe endometriosis at SNP16 (OR=2.58;P=0.012)and SNP17 (OR=2.12;P=0.003). SNPs16 and 17 were also associated with adenomyosis, although the results were not as significant as endometriosis. The risk genotype CC at SNP16 had an OR of 2.23(P=0.037) and AC at SNP17 had an OR of 1.91(P=0.011). Similarly, the results were more significant when hospital-based subjects were used as controls than community controls. **Conclusions**: The present study found significant association between endometriosis and adenomyosis. The association was more significant endometriosis than adenomyosis. The association slightly increased between the SNPs and severe endometriosis.

The R192 allele of the PON1 gene is associated with reduced serum arylesterase activity in autistic patients and in their first-degree relatives. *A.M. Persico[1,2], L. Gaita[1,2]* 1) Lab. of Molecular Psychiatry & Neurogenetics , University "Campus Bio-Medico", Rome, Italy; 2) I.R.C.C.S. Fondazione S. Lucia, Rome, Italy.

The PON1 gene is located in ch 7q21.3 and encodes paraoxonase, the serum enzyme responsible for organophosphate inactivation. This enzyme also exerts an arylesterase activity, which is strictly correlated with PON1 gene expression and directly reflects the amounts of enzyme present in the serum. We have recently described a significant case-control and family-based association between the R192 allele of the PON1 gene and autism in Caucasian-American, but not in the Italian families. In conjunction with our prior results, this finding points towards possible contributions of prenatal organophosphate exposure to autism pathogenesis in the U.S.A., and not in Italy. To explore whether the R192 allele associated with autism also affects PON1 gene expression in families with autistic probands, we have measured serum arylesterase activity and genotyped at the Q192R polymorphism in 183 autistic patients and first-degree relatives belonging to 39 simplex and multiplex Caucasian-American families recruited by the AGRE consortium. Overall, the presence of one or two copies of the R192 allele is strongly associated with significantly lower serum arylesterase activity both in autistics and in their first-degree relatives (two-way ANOVA $F=7.7$, 2 df, $p<0.001$). Furthermore, autistic patients display a trend towards reduced arylesterase activity compared to first-degree relatives, regardless of Q192R genotype ($F=2.47$, 3 df, $p=0.06$). We are now in the process of replicating previous results showing no effect of the Q192R genotype on arylesterase activity among normal controls. These findings indicate that in autistic patients, and to a lesser extent in their first-degree relatives, the R192 allele is associated with decreased PON1 gene expression, which may enhance the risk to undergo altered neuronal migration in the event of prenatal exposure to organophosphate insecticides. Supported by Cure Autism Now, Telethon-Italy (GPP02019), the Fondation Jerome Lejeune and the National Alliance for Autism Research.

Mitochondrial DNA depletion is a major cause of multiple respiratory chain defects. *E. Sarzi[1], A. Bourdon[1], D. Chretien[1], M. Zahrate[1], J. Corcos[1], A. Slama[2], V. Cormier-Daire[1], P. de Lonlay[1], A. Munnich[1], A. Rotig[1]* 1) INSERM U781, Necker Hosp, Paris, France; 2) Laboratoire de Biochimie 1, Hôpital Bicêtre, Le Kremlin-Bicêtre.

Mitochondrial DNA depletion syndrome (MDS) is a clinically and genetically heterogeneous condition characterized by reduction in mtDNA copy number responsible for multiple oxidative phosphorylation (OXPHOS) enzyme deficiency. In order to determine the actual incidence of mtDNA depletion in multiple respiratory chain deficiency, we have carried out the real-time PCR quantification of mtDNA in liver or muscle tissue of 100 of 270 children with unexplained multiple OXPHOS deficiency. Half of the patients presented a reduction in mtDNA copy number below 50% of control values in liver and/or muscle (50/100). Most patients (16%) presented a neonatal form with severe liver involvement, a second group was represented by Alpers syndrome (4%) and 20% of the patients presented encephalomyopathy. DGUOK or POLG mutations could be identified in 22% of patients with liver disease, POLG mutations were consistently found in all but one patient with Alpers syndrome. Two patients carried a homozygous TK2 or MPV17 mutation respectively. Our findings show that mtDNA depletion is a very frequent cause of multiple respiratory chain deficiency with a incidence of at least 18% of children with unexplained OXPHOS deficiency.

CLINICAL AND MORPHOLOGICAL CHARACTERIZATION OF THE MACROCEPHALIC ENDOPHENOTYPE IN AUTISM. *R. Sacco[1,2], R. Militerni[3], C. Bravaccio[3], A. Frolli[3], M. Elia[4], S. Trillo[5], P. Curatolo[6], B. Manzi[6], C. Lenti[7], M. Saccani[7], A.M. Persico[1,2]* 1) Lab. of Mol. Psychiatry & Neurogenetics, Univ. Campus Bio-Medico, Rome, Italy; 2) IRCCS "Fondazione S. Lucia", Rome, Italy; 3) Child Neuropsychiatry, II Univ. of Naples, Italy; 4) Neurology Serv., IRCCS "Oasi Maria S.S.", Troina (EN), Italy; 5) Assoc. Macrocephaly (i.e., cranial circumference > 97th percentile) represents one of the most consistent endophenotypes described in autism research, present in approximately 20% of patients. Since this subgroup may share at least some pathogenetic mechanisms, we defined its clinical and physical characteristics in a sample of 200 autistic patients. Macrocephaly, present in 56 (28.0%) of our patients, is not an isolated morphological feature, but is instead part of a broader macrosomy phenotype, characterized by strong correlations between cranial circumference (CC), weight (W) and height (H) (Spearman rho: CC-W=0.45, CC-H=0.49, H-W=0.62, all $p<0.001$). Clinically, macrocephalic patients appear more severely impaired (for example, VABS Scores: Communication, $p<0.001$; Daily Living Skills $p<0.01$; Socialization $p<0.01$; Motor Skills $p<0.05$), with levels of impairment matched only by patients with cranial circumferences < 25th percentile. Interestingly, they also display enhanced frequencies of hyperkinesia ($p<0.05$), motor stereotypies ($p<0.05$), history of food allergies in first-degree relatives ($p<0.05$) and possibly of allergies in the patient ($p=0.065$). Instead, the development of verbal language, when present, occurs significantly earlier ($p<0.05$) in macrocephalic children compared to other patients. Our study conclusively proves that macrocephalic autistic children are in reality macrosomic, it outlines their spectrum of severe clinical symptoms, and points towards pathogenetic links with immune dysfunction and altered control of cell cycle progression as possibly playing a more prominent role in this subgroup of patients. Supported by Telethon-Italy (GPP02019), the National Alliance for Autism Research, Cure Autism Now, and the Fondation Jerome Lejeune.

Association between an endoglin gene polymorphism and systemic sclerosis related pulmonary arterial hypertension. *J. Wipff[1,2], A. Kahan[2], E. Hachulla[3], J. Cabane[4], O. Meyer[5], L. Mouthon[6], L. Guillevin[6], C. Boileau[1], Y. Allanore[1,2]* 1) INSERM U 781, Necker Hospital, Paris, France; 2) Rheumatology A, Cochin hospital, Paris, France; 3) Internal Medecine department, Claude Huriez Hospital, Lille, France; 4) Internal Medicine Department, Saint-Antoine hospital, Paris, France; 5) Bichat Hospital, Rheumatology department, Paris, France; 6) Internal medecine Department, Cochin hospital, Paris, France.

Background Systemic sclerosis (SSc) is a connective tissue disorder characterized by early generalised microangiopathy with endothelial activation and apoptosis. Endoglin gene (ENG) encodes an accessory receptor for the TGFbeta superfamilly crucial for maintaining vascular integrity. ENG mutations are responsible of one of the two major types of Hereditary Haemorrhagic Telangiectasia. An intron 7 insertion polymorphism of ENG has been reported to be associated with intracranial saccular aneurysms. Objective. To investigate the association between the polymorphism in ENG intron 7 and SSc in a multicentric French Caucasian population. Methods. The insertion polymorphism was investigated in 280 SSc patients: mean age was 5713 years, 29/280 had associated pulmonary arterial hypertension (PAH) diagnosed by catheterism. The control group consisted in 140 patients with osteoarthritis. Allelic and genotypic frequencies were compared between cases and controls using a ² test. Results. The polymorphism was in Hardy Weinberg equilibrium. The frequency of the polymorphism did not differ between SSc patients and controls (19.3% versus 23.9%, NS). However, there was a significant lower frequency of 6bINS allele in SSc patients with associated PAH compared to controls (10.3% versus 23.9%, p=0.01) and a trend in comparison to SSc patients without PAH (10.3% versus 20.3%, p=0.05). Genotype carrying 6bINS allele was also less frequent in SSc patients with PAH than in controls (20.7% vs 42.9%, P = 0.02). Conclusion. The frequency of ENG intron 7 insertion polymorphism differs between SSc patients with or without PAH which suggests the implication of ENG in this devastating vascular complication of SSc. The sequencing of ENG among SSc patients is ongoing.

Mitochondrial DNA Lineages in the Yukaghir, Chukchi and Siberian Eskimos, and Resettlement of Arctic Siberia after the Last Glacial Maximum (LGM). *N.V. Volodko[1], R.I. Sukernik[1], E.B. Starikovskaya[1], M.A. Lvova[1], D.C. Wallace[2]* 1) Institute of Cytology and Genetics, Siberian Branch, Russian Academy of Sciences, 10, Lavrent'ev Ave, Novosibirsk, Russian Federation, 630090; 2) Center for Molecular and Mitochondrial Medicine and Genetics, University of California, Irvine, 2014, Hewitt Hall, Irvine, CA 92697-3940.

In this study, we filled important gaps in the previously unidentified internal sequence variation within haplogroups A, C and D prevailing in the former western Beringia through extended survey of mtDNA diversity in the Yukaghir, Chukchi, and Siberian Eskimos. By integrating 71 entire A, C, and D mtDNAs selected from ~350 individuals with those previously revealed in other Siberian populations, we were able to identify novel A, C, and D lineages. Unlike the Chukchi and Siberian Eskimos of Chukotka, who harbored the Beringian specific A2a, A2b and D2, distinguished by the mutations 3330 and 16292, 11365 and 16265, and 11215, respectively, the core of the genetic makeup of adjoining Yukaghir tribes in the west consisted of a unique combination of C and D mtDNA lineages that apparently were continental Siberian. A phylogeny of the entire D revealed a wide range of distinct lineages (D1-D13) identifiable by characteristic mutations. Of these, the Yukaghir D3-D9 were a subset of the Siberian/Asian haplogroup D variation, and their coalescence ages ranged from 8,000 to 43,000, in consistence with the range of their distribution in Siberia/Asia. The ages of Paleosiberian C2 and C3 (~18,000 years), when compared to that of Native American C1 (~23,000) and entire C (~28,000), have major implications for the origin of the Yukaghir. On the other hand, the estimated ages of the Chukchi-Eskimo subset of the Beringian A2a and A2b (~5,000), and D2 (~10,000) define the time frame for the fission-fusion events in the Chukotka and adjacent Alaska. Overall, our data suggest that the direct ancestors of the Yukaghir were primarily drawn from the southern belt of Siberia after ~13,000 years ago when environment conditions changed permitting re-colonization of the Siberian arctic and subarctic after the LGM.

Prognostic evaluation of trisomy 13 syndrome: Review of 23 cases. *K. Sameshima[1], H. Yoshihashi[1], Y. Igarashi[1], Y. Itani[2], M. Yamanaka[3], K. Kurosawa[1]* 1) Division of medical genetics, Kanagawa Children's Medical Center; 2) Division of Neonatology, Kanagawa Childrens Medical Center; 3) Division of Obstetrics and Gynecology, Kanagawa Childrens Medical Center, Yokohama, Japan.

Trisomy 13, known as Patau syndrome, is the third most common autosomal trisomy, and occurs at a frequency of 1 of 5,000 births. Triosmy 13 is associated with multiple severe structural abnormalities, and represents high infant mortality rate. From January 1995 to December 2005, all 23 cases of trisomy 13 diagnosed at our hospital were reviewed, including 15 cases prenatally diagnosed. Data are presented on pregnancy, delivery, medical complications, growth, cause of death, cytogenetics, and recurrence risk. We also examined median survival time or median age at death and factors associated with longer survival. Median survival time was 18 days. 96% of infants died within the first year. Major anomalies detected by means of ultrasound(US) included holoprosencephaly(9[39%]) or other central nervous system anomalies(16[69%]), cleft lips and palates(15[65%]) and cardiac (18[78%]) defects. The presence of holoprosencephaly is associated with significant shorter lifespan, but the presence of a congenital heart defect is not. Although the ascertainment of cases is based toward survivors, the data provide information useful in counseling families of newborn infants, and valuable insights into the natural history of trisomy 13. When prenatal or postnatal decisions need to be made regarding the care of fetus or child, it is important that the full spectrum of the natural history of these conditions be presented to the parents to enable them to make the best possible decisions for their family.

Could the expression of Jagged1 gene mutations play a role in modulating a CADASIL-like phenotype? *C. Ungaro, T. Sprovieri, FL. Conforti, A. Patitucci, A. Magariello, AL. Gabriele, M. Muglia, R. Mazzei* ISN-CNR, Mangone , Cosenza, Italy.

The aim of this study was to investigate the possible role of Jagged1 gene mutations in modulating clinical features in patients with CADASIL-like phenotype resulted negative for Notch3 gene mutations. Sixty-five CADASIL-like patients without Notch3 gene mutations were investigated for 5 out 26 exons of the Jagged1 gene. Amplicons were analyzed by DHPLC and direct sequencing. The sequence of exons 3,4 and 23 revealed the presence of four already described polymorphisms in Jagged1. 1001C/T in exon 4 was found in 3 patients, IVS23+18del(T) in 24 patients, IVS4-15T/C in 11 patients, IVS3-43C/T in one patient; in four patients we found both the polymorphism 1001C/T and IVS4-15T/C. CADASIL is an autosomal dominant disorder caused by mutations in Notch3 gene, encoding a transmembrane protein involved in cellular signalling and cell differentiation. Notch receptor signalling is a conserved fundamental mechanism modulating several processes through interaction with ligands of the Delta/Serrate family, like that Jagged1. Mutations in the human Jagged1 gene cause Alagille syndrome (AGS). In some patients (16%), the literature documents multiple case reports of intracranial vessel abnormalities and other vascular anomalies in AGS (1). Intracranial bleeding, which ranges from massive fatal events to asymptomatic cerebral infarcts, is a recognized complication and cause of mortality in AGS. Further evidence of the role of Jagged1 and Notch in vascular development is provided by the phenotype of targeted Notch pathway mutants. In fact, mice homozygous for mutation in Jagged1 die of haemorrhage during early embryogenesis because of defects in angiogenic vascular remodelling in the yolk sac and embryo (1). As mutations in the gene for Notch3 receptor cause adult onset CADASIL which is associated with intracranial bleeding, the mechanism of the vasculopathy in CADASIL may be similar to that seen in AGS (2). Conclusion: The present study demonstrates that the Jagged1 gene does not play a role in patients with a CADASIL-like phenotype.

Gossypol-induced abnormal chromosome pairing during meiotic prophase of male mice (Mus musculus).

xiao.hua dai[1], mu.gen liu[1], qing.k wang[1,2], Jing.yu liu[1] 1) Huazhong Univ Sci & Tech, Human Genome Research Ctr, Wuhan, Hubei , China; 2) Department of Molecular Cardiology, Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, Ohio, USA.

Gossypol, a reported male antifertility compound isolated from the seed, roots, and stem of the cotton plant (Gossypium sp.), was assayed for its effects on synaptonemal complexes(SCs) damage in male mice. The mice were taken orally daily gossypol acetic acid (XIAN NORTH PHARMACEUTICAL COMPANY LTD) (suspension in 1 % methylcellulose with an oral administration dose of 30 mg /kg body weight) for 4 and 10 weeks. Other treated groups were administered daily dose of 60 mg /kg body weight for 4 weeks. Whole-mount SC spreads were prepared by surface spreading-silvers staining transmission electron microscope (TEM) technique. The structure and pairing of chromosomes and SCs from control male mice (untreated by gossypol) and experiment mice (treated by gossypol) were observed by light microscope (LM) and TEM. SC aberrations in spermatocyte of treated male mice could be induced by gossypol. SC abnormalities were classified as various forms of breakage and synapsis errors. It included various forms as follows: breakage of the SC; lateral element break; asynapsis; non-homologous synapsis; XY-mispairing; XY separation; synapsis irregularity. The chromosomes abnormalities in MI stage were showed as follows: univalents of autosomes; isochromatid break of autosomes; multivalent; univalent of XY. More serious damage could be observed as the increased dosage or prolonged treated time of gossypol, but no special aberration forms were produced in high dosage gossypol. It is concluded that we can evaluate the genetic risk induced by gossypol in males by SC analysis. The relationship between the behavior of SC and the mechanism of infertility was discussed.

Mutation screening of the *ATRX* gene in Japanese familial mental retardation. *T. Wada[1], S. Saitoh[2], Y. Fukushima[1]*
1) Dept Medical Genetics, Shinshu Univ Sch Medicine, Matsumoto, Japan; 2) Dept Pediatrics, Hokkaido Graduate Univ Sch Medicine, Sapporo, Japan.

Mental retardation (MR) is relatively common and about 2-3 % of population has MR (IQ <70). It is important to know the pathogenesis of MR to develop well-grounded medical treatment. Up to now, more than 60 genes, including more than 20 genes for non-syndromic X-linked MR (XLMR), have been identified to be involved in MR, and the European XLMR Consortium has made great contribution to this accomplishment. The Japanese Mental Retardation Consortium was started in 2003, and more than 50 MR families have been registered. We have participated in the Consortium and conducted our study on the MR families. X-linked -thalassemia/mental retardation syndrome (ATR-X, OMIM #301040) is a syndromic form of XLMR, and it is caused by a mutation in the *ATRX* gene. An *ATRX* gene mutation is involved not only in other syndromic XLMRs but also in non-specific XLMR in males. Recently we reported that the *ATRX* gene mutation caused MR in females by escaping a skewed X chromosome inactivation (Wada T et al. Am J Med Genet, 2005). In this study, we performed mutational analysis of the *ATRX* gene in 33 mentally retarded probands of the MR families by a new method we have established, using mismatch-specific endonuclease (Surveyor^{TM}) (Wada T et al. Am J Med Genet, 2006, in press), in order to evaluate the frequency of *ATRX* mutations in familial MR cases in Japan.We have not found any mutations in these families so far. Although it is expected that an *ATRX* mutation may not be such a frequent cause of MR as *FMR1*, *MECP2* or *ARX* mutations, our data should provide further information of the molecular genetic etiology of familial MR in Japan. Our study would also be important to establish the genotype-phenotype correlations of the *ATRX* gene mutations and to understand the function of ATRX protein.

The novel L1649Q mutation in the *SCN1A* epilepsy gene is associated with familial hemiplegic migraine: genetic and functional studies. *K.R.J. Vanmolkot[1], M. Pusch[2], B. de Vries[1], A.H. Stam[3], E. Babini[2], T. Freilinger[4], M.A. Welch[5], N. Ramadan[5], R.R. Frants[1], M.D. Ferrari[3], M. Dichgans[4], A.M.J.M. van den Maagdenberg[1, 3]* 1) 1Department of Human Genetics, Leiden University Medical Centre, Leiden, The Netherlands; 2) Istituto di Biofisica, Genova, Italy; 3) Department of Neurology, Leiden University Medical Centre, Leiden, The Netherlands; 4) Department of Neurology, Klinikum Grohadern, Ludwig-Maximilians-Universität, München, Germany; 5) Department of Neurology, Rosalind Franklin University of Medicine and Science, The Chicago Medical School, Chicago, IL.

Familial hemiplegic migraine (FHM) is an autosomal dominant severe subtype of migraine with aura characterized by hemiparesis during the attacks. Mutations in the calcium channel gene *CACNA1A* (FHM1) and the Na,K-ATPase gene *ATP1A2* (FHM2), have led to the conclusion that abnormalities in ion fluxes play an important role in the pathophysiology of FHM. This was further strengthened by the recent discovery of the Q1489K mutation in the sodium channel gene *SCN1A* (FHM3) located at chromosome 2q24. Interestingly, mutations in *SCN1A* have also been associated with severe myoclonic epilepsy of infancy (SMEI) or generalized epilepsy with febrile seizures (GEFS+). Here we performed mutation scanning in 10 FHM families without mutations in the *CACNA1A* and *ATP1A2* genes. We identified a novel missense mutation, L1649Q, in a North American family with pure FHM without associated ataxia or epilepsy. Investigation of the biophysical consequences of the mutation by patch-clamp experiments in transiently transfected human tsA201 cells, using the closely related SCN5A cDNA, revealed a slower inactivation and a two-fold faster recovery from fast inactivation. Our findings confirm the role of neuronal Nav1.1 sodium channels in FHM, strengthen a common channelopathy mechanism of FHM and further support a possible link between epilepsy and migraine.

Synergistic association of neuronal UCP genes with schizophrenia. *K. Yasuno[1], S. Ando[2], S. Misumi[1], S. Makino[2], T. Muratake[3], N. Kaneko[3], H. Amagane[3], T. Someya[3], H. Inoko[1], H. Suga[4], K. Kanemoto[4], I. Inoue[1], G. Tamiya[2]* 1) Dept Mol Life Sci, Tokai Univ Sch Med, Kanagawa, Japan; 2) Div Hum Mol Genet, Dept Neurol, Tokushima Univ Sch Med, Tokushima, Japan; 3) Dept Psych, Niigata Univ Grad Sch Med and Dent Sci, Niigata, Japan; 4) Dept Neuropsych, Aichi Med Univ, Aichi, Japan.

Accumulating evidence suggest an involvement of mitochondrial dysfunction in schizophrenia (SZ). Three mitochondrial uncoupling proteins (UCPs), UCP2, UCP4 and UCP5 are present in selected neurons and their activities allow controlled proton leak back into the mitochondrial matrix, thereby reducing the membrane potential. These neuronal UCPs may regulate calcium homeostasis and productions of ATP and reactive oxygen species. Since dysregulations of these mechanisms have been implied in SZ, functional mutatinos in neuronal UCP genes may affect the risk of SZ. To explore this possibility, we conducted a case-control association study using a Japanese sample of 335 cases and 501 controls. We determined 7 tag SNPs (3 in UCP2, 3 in UCP4 and 1 in UCP5) from genotyped 16 SNPs following Carlson et al (Am J Hum Genet 74:106-120, 2004) and tested them for association with SZ. Four tag SNPs were significantly associated with SZ even after correcting for multiple comparisons: A55V (P=0.004) and rs649446 (P=0.007) in UCP2, and rs10807344 (P=0.003) and rs2270450 (P=0.004) in UCP4. We further explored the possibility of gene-gene interactions using the multifactor dimensionality reduction and the logistic regression. We observed a significant (P<0.05) synergistic interaction between UCP2 (A55V) and UCP4 (rs10807344). The highest OR was obtained for homozygotes of risk alleles at both loci while the lowest for individuals homozygous of risk alleles at UCP2 and having 1 or 2 non-risk alleles at UCP4. Individuals in the former class have 7.6-fold risk compared with the latter. These results suggest that dysfunctions of neuronal UCPs are likely to be involved in the genetic etiology of SZ accompanied with the interaction between them. Our findings thus offer new avenues for a better understanding of the roles of mitochondria in SZ.

Analysis of epigenetic abnormalities in an autistic population. *M. Rosales, I. Cuscó, B. Gener, M. Del Campo, L.A. Pérez Jurado* Genetics Unit, Experimental & Health Sciences, Universitat Pompeu Fabra, Barcelona, Spain.

The Austistic Spectrum Disorders (ASD) comprise a group of neurodevelopmental diseases characterized by impairments in social interaction, communication problems and restricted range of interests. There is strong evidence for a neurobiological and genetic etiology of ASDs, but no major genes have been found, concordance in MZ twins is less than 100% and the phenotypic expression of the disorder varies widely. Therefore, a mixed genetic/epigenetic component to the disease has been proposed, supported in part by its association with several imprinted regions. *Methods*: To search for epigenetic alterations in our autistic population consisting of 88 children and 97 adults (all meeting DSM-IV criteria), we have first screened for chromosomal rearrangements by karyotyping, Q-PCR and a-CGH; and fragile-X, and then performed a battery of assays: 1) assessment of methylation patterns at SNRNP imprinted domain by QAMA; 2) genotyping of MTHFR alleles; 3) X-inactivation patterns in female patients and patients' mothers; 4) assessment of mono-biallelic expression at 44 putatively imprinted genes by RTPCR from lymphocyte RNA (69 cases / 7 controls) using 61 SNPs in 3 multiplex Sequenom assays. *Results*: QAMA confirmed the maternal 15q11-q13 duplication found in 4 patients and identified a patient with an epigenetic mutation at the same region in a mosaic pattern (verified by Southern Blot). MTHFR allele distribution and X-inactivation patterns did not differ significantly between patients and controls. Out of the 51 informative SNPs analysed in the 38 genes detectable by RTPCR, average heterozygosity was 30%. Eighteen genes showed consistent biallelic expression in all cases while 7 genes were always monoallelic, reflecting their imprinted status. Variable expression, either mono or biallelic, was found in several patients but not in controls for 13 genes, which are therefore candidates for epigenetic defects in our ASD sample. *In conclusion*, our preliminary data suggest that epigenetic abnormalities and alterations in the patterns of allelic expression of imprinted genes might be pathogenically related with ASD in a proportion of cases.

Parkin mutations in patients with early onset parkinsonism. *F.E. Rocca, F. Annesi, P. Tarantino, I.C. Cirò Candiano, S. Carrideo, D. Civitelli, G. Provenzano, E.V. De Marco, G. Annesi* Inst. of Neurological Sciences, National Research Council, Mangone, Cosenza, Italy.

Parkin gene mutations are reported to be a major cause of early-onset parkinsonism (age-at-onset 45 years) in families with autosomal recessive inheritance and in isolated early-onset Parkinsons disease (IEOPD). The mutations in the parkin gene are extremely varied and include many different point mutations and exonic rearrangements. The Parkin protein is an ubiquitin E3 ligase that functions to prepare substrates for protein degradation mediated through the ubiquitin-proteasome system. To evaluate the frequency of parkin mutations in patients with IEOPD, we studied 57 patients from Southern Italy. Our patients were selected according to the following criteria: parkinsonism; no family history of PD and age at onset 45 years. All patients were screened for mutations in the parkin gene by a combination of gene dosage and sequencing of entire coding region Among the 57 patients, 10 (17,5%) had mutations in the parkin gene. Five carried single heterozygous mutations (Thr55Ile, Asp18Asn, Lys32Thr, Leu261Leu, Arg42Pro); one was a compound heterozygous (Leu174Leu and Arg402Cys); four carried homozygous mutations (202-203delAG, ex2-3del, ex3 del). Six of these were previously described and four were novel nucleotide changes. Genomic rearrangements were excluded by absolute quantification in real time PCR. The frequency of IEOPD patients carrying a single heterozygous parkin mutation in this study is similar to that reported by other authors. Most of the variants found in our patients are localized in two important parkin regions: the N-terminal ubiquitin-like that might mediate protein-protein interactions, which have an impact on the stability of parkin; the C-terminal cassette of two Ring finger domains (R1-R2) that are responsible for ubiquitination of target protein. Our patients with IEOPD may suffer from haploinsufficiency, due to a loss of one parkin allele wich reduces normal expression and subsequent enzymatic activity, thus representing a risk factor for the disease. Functional studies are required to clarify the role of single heterozygous parkin mutations in IEOPD.

HNPP due to a novel frameshift mutation of the PMP22 gene. *A. Patitucci[1], M. Muglia[1], R. Rizzi[2], C. Ungaro[1], FL. Conforti[1], AL. Gabriele[1], A. Magariello[1], R. Mazzei[1], L. Motti[2], R. Saladini[2], T. Sprovieri[1], N. Marcello[2], A. Quattrone[1,3]* 1) ISN-CNR, Mangone , Cosenza, Italy; 2) Department of Neurology, Arcispedale S. Maria Nuova, Reggio Emilia, Italy; 3) Institute of Neurology, University "Magna Graecia", Catanzaro, Italy.

Hereditary neuropathy with liability to pressure palsies (HNPP) is an autosomal dominant inherited disorder characterized by recurrent sensory or motor dysfunction, often precipitated by minor trauma. Electrophysiological studies demonstrate an underlying generalized neuropathy with moderate slowing of conduction velocities, predominant over entrapment sites and prolonged distal latencies. Characteristic pathological changes are sausages-like myelin thickening, commonly referred to as tomacula. In 85% of HNPP cases the genetic defect is a 1.5 Mb deletion on chromosome 17p11.2, encompassing the gene for the peripheral myelin protein (PMP22). Point mutations in the PMP22 gene are responsible for rare HNPP phenotype. Up to now, 11 point mutations of PMP22 have been associated with HNPP. We investigated a 17 years old girl who was referred at our clinic because she noted a four months history of severe hypesthesia at the 4th and 5th fingers of the left hand, that persisted for about two months, and then spontaneously regressed. Electrodiagnostic test revealed a sensory motor demyelinating neuropathy showing a conduction block in the left ulnar nerve at the elbow. Screening of the entire coding sequence of the PMP22 gene by DHPLC analysis showed a modified pattern for exon 2. Direct sequencing of exon 2 revealed a heterozygous deletion of one tymidine at position 11. The deletion was also confirmed by cloning of fragment containing exon 2. The mutation was also detected in the fathers patient, but it was not found in 100 normal chromosomes. The novel mutation here reported c.11delT creates a shift on the reading frame starting at codon 4 and lead to the introduction of a premature stop at codon 6. The c.11delT would lead to a truncated protein that is rapidly degraded resulting in reduced dosage of PMP22, comparable to the 1.5Mb deletion.

Analysis of Genes Affecting Susceptibility to Systemic Lupus Erythematosus. *T. Tahira[1], T. Horiuchi[2], D. Sakaguchi[1], M. Yamai[1], H. Miyagawa[2], H. Tsukamoto[2], K. Hayashi[1]* 1) Res Ctr Genetic Info, Med Inst Bioreg, Kyushu Univ. Fukuoka, Japan; 2) Med. and Biosys. Science, Kyushu Univ. Grad. School of Med. Sciences, Fukuoka, Japan.

A genetic predisposition has been implicated in the occurrence of systemic lupus erythematosus (SLE). To identify SLE-susceptibility genes in Japanese population, we carried out case-control association studies for candidate genes using PLACE-SSCP analysis of pooled DNA. In this method, allele peaks are separated by capillary electrophoresis in non-denaturing conditions and precisely quantified. Candidate genes selected were genes involved in the lymphoid activation and apoptosis, those responsible for SLE-like symptoms in mice and those previously reported to be associated with SLE in the case-control studies. A total of 700 SNPs in 130 genes were subjected to allele frequency quantification by PLACE-SSCP analysis. The SNP that showed largest estimated allele frequency differences between cases and controls was rs752637 in interferon regulatory factor 5 (IRF5) gene. The association of this SNP with SLE was confirmed by sequencing 692 control and 506 SLE patients (p=0.00018). We also analyzed rs2004640 in IRF5, because T allele of this SNP that create exon 1B donor site was reported as a risk allele for SLE in European (Sigurdsson et al. 2005; Graham, et al. 2006). Although allele frequency of this SNP in Japanese controls (28%) differed from European controls (44-56%), rs2004640 T allele showed strong association with SLE in Japanese descent (p=0.000018). During this sequence analysis, we found a new SNP 6 bp downstream of rs2004640 that was rare (1.1%) in Caucasian but common (19%)in Japanese. The SNP showed weak association with SLE (P=0.068) in Japanese. Another SNP in IRF5 gene (rs2280714), which was reported to associate with increased mRNA expression, showed weak association with SLE (P=0.027), consistent with the finding that this SNP do not confer risk by itself (Graham et al. 2006). In this study, we show for the first time that a haplotype of IRF5 is associated with increased risk of SLE in Asian samples. These results support the involvement of IRF5 in the pathogenesis of SLE.

LD Tag SNPs Selection for candidate gene association studies using HapMap and gene resequencing data. *Z. Xu*[1], *N.L. Kaplan*[2], *J.A. Taylor*[1,3] 1) Epidemiology Branch, NIEHS, RPT, NC; 2) Biostatistics Branch, NIEHS, RPT, NC; 3) Laboratory of Molecular Carcinogenesis, NIEHS, RPT, NC.

The recently completed HapMap provides linkage disequilibrium (LD) information on a sample of 3.7 million SNPs that can be used for whole genome association studies. HapMap data can also be used for LD tag SNP selection in candidate genes, although its performance has yet to evaluated against gene resequencing data where there is near-complete SNP ascertainment. The Environmental Genome Project (EGP) is the largest gene resequencing effort to date with over 500 genes resequenced in 90 or more individuals, although individual ethnic information is only available for the 127 genes included in EGP Panel 2. For EGP Panel 2 genes we used HapMap data to select LD tag SNPs and evaluated gene tagging proportions against EGP resequencing data. Median gene tagging proportions (the proportion of common SNPs correlated with at least one tag SNP) were 48%, 78% and 72% for African, Asian, and European groups respectively. These low gene tagging proportions may be problematic for some candidate gene studies. We show that median gene tagging proportions can be improved to 80%, 90%, and 87% by adding a parsimonious set of tag SNPs selected from EGP ethnic-specific multi-SNP LD bins. This strategy cannot be implemented for the genes in EGP Panel 1, because individual ethnic information is missing. We demonstrate that ethnic-mixed data can still be used to improve HapMap gene tagging proportions, although not as efficiently as with ethnic-specific data. Despite that HapMap targeted non-synonymous SNPs, we estimate, using EGP data, that HapMap SNPs only tag ~26% of total non-synonymous SNPs. Finally, we investigated the possibility of developing a single panel of tag SNP that can be applied across multiple populations rather than using separate ethnic-specific tag SNP panels. We generalized the greedy algorithm proposed by Carlson et al. (2004) to pick multi-population tag SNPs from HapMap data. We also evaluate the utility of supplementing these SNPs with multi-population tag SNPs selected from ethnic-specific and ethnic-mixed EGP data.

Interactions between BBS proteins provide functional support for oligogenic inheritance in Bardet-Biedl syndrome. *A.J. Ross, J. Hill, P.L. Beales* Molecular Medicine Unit, Inst Child Health, London, United Kingdom.

Bardet-Biedl syndrome (BBS) is a pleiotropic disorder primarily characterized by retinal degeneration, obesity, polydactyly, kidney dysfunction, genitourinary tract malformations and cognitive impairment. Eleven causative genes (*BBS1-11*) have been identified to date and the underlying cellular pathogenesis is associated with basal body/ciliary dysfunction. Although it is usually transmitted as a recessive trait, some families display a complex inheritance pattern whereby mutations at different loci interact genetically to cause and/or modify the phenotype. BBS2 is one of the least well-studied of the BBS proteins. Its amino acid sequence provides few clues to function, with the exception of a region of shared homology with BBS1 and BBS7, and a predicted coiled-coil domain suggestive of protein-protein interactions. To identify binding partners for BBS2, we performed a yeast two-hybrid screen of an adult kidney cDNA library. We identified several candidate interactors including two other known BBS proteins, which were verified by co-immunoprecipitation studies. Furthermore, we show that some missense mutations within BBS2 ameliorate these BBS-BBS interactions. These data provide the first evidence of interactions between BBS proteins and provide a possible functional explanation underlying oligogenic inheritance.

Autosomal Dominant Early Onset Pagets Disease of the Bone and Progressive Proximal Myopathy Maps to Chromosome 16q22.3-q24.1 in a family. *G. Watts[1], E.C. Fulchiero[1], S. Ramdeen[1], S.G. Mehta[1], C. Zhao[2], V.E. Kimonis[1]* 1) Division of Genetics and Metabolism, Childrens Hospital, Harvard Medical School, 300 Longwood Avenue, Fegan 10, Boston, MA 02115; 2) Center for Medical Genetics, Molecular Genetics Laboratory, 1000 North Oak Avenue, Marshfield, WI, USA.

We previously reported this family with autosomal dominant Pagets disease of the bone and limb girdle muscular dystrophy (LGMD) and excluded the IBMPFD (inclusion body myopathy, PDB and frontotemporal dementia) locus on 9p and the loci for PDB and LGMD (Waggoner *et al*. 2001). The six affected individuals have progressive proximal muscle weakness at a mean age of 41 years. EMGs and muscle biopsies in several individuals showed non-specific myopathic changes that were negative for amyloid staining. Within affected muscle fibers numerous ringbinden, marked central nucleation and rare rimless vacuoles were observed. The myopathy either preceded or followed Pagets disease of the bone, which presented mainly in the long bones and eventually progressed to the spine, scapulae and other bones with a mean age of onset being 42 years. Radiographs reveal coarse trabeculation and patchy sclerosis. We identified linkage to chromosome 16q22.3-q24.1 utilizing a genome-wide scan, with a maximal LOD score of 2.25 for markers D16S515 and D16S3091. Haplotype analysis narrowed the disease locus to a 14.8Mb region flanked by markers GATA81D12M and D16S520. This new region is known to contain a quantitative trait locus (QTL) for bone mineral density (BMD), a highly heritable trait and a key osteoporotic fracture risk factor. Ralston *et al*. (2005) identified 8 QTL for regulation of BMD by a genome wide scan involving 3691 individuals from 715 families. Families had reduced BMD values at the lumbar spine or femoral neck in probands. One QTL with a LOD score of greater than 2.2 mapped to 16q23-q24 and was flanked by markers D16S3091 and D16S520. Identification of the gene for this unique disorder will facilitate our understanding of the complex interaction between bone and muscle pathogenesis and help develop treatment strategies for this and other related debilitating disorders.

Variations in adiponectin receptor genes and susceptibility to type 2 diabetes in US women: A tagging-SNP haplotype analysis. *L. Qi*[1], *A. Doria*[2], *D. Hunter*[1], *F. Hu*[1] 1) Department of Nutrition, Harvard School of Public Health, Boston, MA; 2) Joslin Diabetes Center, Department of Medicine, Harvard Medical School, Boston, MA.

Adiponectin has been associated with improved insulin sensitivity and a lower risk of type 2 diabetes. Recent studies indicate that the metabolic effects of adiponectin are mediated by adiponectin receptor 1 (gene symbol ADIPOR1) and adiponectin receptor 2 (gene symbol ADIPOR2). We conducted a prospective, nested case-control study of 714 incident cases of type 2 diabetes and 1,120 matching control subjects from the Nurses' Health Study. Six polymorphisms in ADIPOR1 and sixteen polymorphisms in ADIPOR2 genes were determined. A 3 UTR polymorphism, rs1139646 (C>G), showed significant association with greater diabetes risk (OR=1.26, 95%CI 1.03-1.53). Adjustment for age, BMI, and other diabetes risk factors improved the associations (OR=1.36, 95%CI 1.10-1.70). When haplotypes possessing the six ADIPOR1 polymorphisms were analyzed, we found that haplotype 112222 (1 codes the common allele and 2 codes the minor allele) was associated with 39% increased risk of type 2 diabetes compared with the most common haplotype 221111 (OR=1.39, and 95%CI 1.03-1.87; P=0.027). Polymorphism rs1139646 was associated with higher plasma levels of interleukin 6 (adjusted means: CC, 2.09; CG, 2.54; and GG, 2.37 ng/mL). There were no significant associations between ADIPOR2 polymorphisms, individually or in haplotypes, and the risk of type 2 diabetes. In conclusion, our data indicate a significant association between ADIPOR1 rs1139646 and diabetes risk but do not support an effect of ADIPOR2 variability on the disease.

An Apoptosis Gene Differentiates Childhood Absence Epilepsy from Juvenile Absence Epilepsy. *L.J. Strug[1], M. Durner[1], E. Cayanis[3], F. Zhang[1], D. Politis[1], I. Klotz[1], E. Dicker[1], D.A. Greenberg[1,2,3], Our collaborators, critical to this study. Space limitations make it impossible to name them here.* 1) Dept Biostatistics, Columbia University, New York, NY; 2) Psychiatry, Columbia University, New York, NY; 3) Genome Center, Columbia University, New York, NY.

Absence seizures in Juvenile Absence Epilepsy (JAE) and Childhood Absence Epilepsy (CAE) appear similar. Differentiating these two syndromes are the age of onset, and the frequency of the absence seizures. In linkage genome scans for the juvenile absence phenotype, we found evidence for linkage on chromosome 5p. There are at least two candidate genes in this region: Succinate dehydrogenase complex subunit A (SDHA) and Programmed cell death 6 (PDCD6). We examined this region for association with JAE and CAE, genotyping single nucleotide polymorphisms in and around SDHA and PDCD6. We used case-control and family-based association methods to determine the degree of association. We found that CAE is strongly associated with all SNPs tested in the PDCD6 gene (maximum chi-squared = 21.22, $p<0.0001$ at rs4957014). JAE, in contrast, was not significantly associated with PDCD6 or any SNPs in the region studied. These results were confirmed in the family-based association analysis. The odds of having CAE if one carries at least one copy of the associated allele at the rs4957014 locus is 3.2 times the odds for an individual without a copy of the allele at this locus (95%CI: 1.91 - 5.37). Our results suggest that not only does PDCD6 play a role in CAE susceptibility, but that different genes contribute to susceptibility in CAE and JAE; no association was seen in the JAE group. This implies that CAE and JAE cannot necessarily be treated as having the same genetic basis. Although there may be susceptibility genes common to the two (or more) syndromes, treating them as one genetic entity could mask the existence of genes for only one of the syndromes. It is especially interesting that this is at least the second apoptosis gene that appears to be related to a form of IGE.

Interstitial chromosome 3q deletion in a newborn with hydrocephalus and hypoplastic kidney. *S. Ramanathan[1], R. Woldenberg[2], S. Gupta[3], P. Koduru[3], L. Mehta[1]* 1) Div. of Medical Genetics, Schneider Children's Hospital at North Shore, Manhasset, NY; 2) Dept. of Radiology; 3) Dept. of Laboratories, North Shore University Hospital, Manhasset, NY.

We report on a female infant with facial dysmorphisms, hydrocephalus and a hypoplastic right kidney. She was delivered to a 35 year-old G4P1021. Prenatal history was significant for high MSAFP. Prenatal ultrasound showed polyhydramnios, suspicion of agenesis of corpus callosum, and small right kidney in the fetus. Fetal MRI showed mild to moderate hydrocephalus but was inconclusive for other abnormalities. Birth weight was 3030 gm. Head circumference was 34.6 cm (~75%). Facial features were mildly dysmorphic with frontal bossing, sharply depressed nasal bridge, prominent nasal tip, short philtrum and downturned mouth. Right ear lobule was large. There were bilateral single to bridged palmar creases. The 2nd and 4th toes were deviated with mild 2-3 digit syndactyly. There were no heart defects. Postnatal MRI showed large 4th ventricle communicating with a prominent retrocerebellar CSF space, suggestive of a Dandy Walker malformation (DWM) variant with compensated hydrocephalus. On ultrasound, kidneys measured 2.3 cm (right), and 4.7 cm (left). Peripheral blood chromosome analysis showed 46,XX,del(3)(q24q25). Deletions of this region on chromosome 3q have been previously reported in the literature to be associated with facial dysmorphisms, central nervous system malformations, congenital heart defects and mental retardation. Our patient shows several of the described findings. To our knowledge, this is the first case of deletion 3q24-q25 presenting with renal hypoplasia. Grinberg et al. have recently identified deletions of two linked Zinc finger genes, *ZIC1* and *ZIC4* in 7 individuals with DWM and interstitial deletions of the 3q24-q25 region. The finding of DWM variant in our patient with a similar deletion further supports the conclusion that heterozygous deletion of the *ZIC1* and *ZIC4* genes causes DWM. DWM is a heterogeneous disorder with variable expression. Patients such as ours can contribute to identifying the proportion of DWM associated with mutations/ deletions of *ZIC1* and *ZIC4*.

Genetic Testing for Hearing Impairment in African Americans. *D.M. Pekarek[1], S.K. Prucka[1], R.J.H. Smith[3], N.H. Robin[1, 2]* 1) Dept Genetics; 2) and Pediatrics, UAB, Birmingham, AL; 3) Depts Internal Medicine, Otolaryngology, and Pediatrics, University of Iowa, IA.

BACKGROUND: Mutations in GJB2 and GJB6 at the DFNB1 locus are the most common cause of genetic hearing impairment (HI) in persons of Northern European extraction and account for approximately 30% of simplex and 50% of mulitplex cases of congenital severe-to-profound non-syndromic deafness. However, DFNB1-related HI is infrequent in the African American (AA) population. Previous studies have demonstrated that AA are cautious about participating in medical research in general, further complicating efforts to determine the overall prevalence of DFNB1 mutations in AA. STUDY: We asked parents of deaf/hard of hearing (D/HOH) AA children to complete a questionnaire regarding their interest in genetic research and testing for HI and offered free testing. RESULTS: 34 families completed questionnaires, including 3 multiplex sibships, although not all questions were answered. Of the 34 families, 7 declined testing. Including siblings, a total of 31 persons had genetic testing. Of the group that underwent testing (T), the majority (15/27) were married; in the questionnaire only group (QO), the majority were single (4/7). In both groups, the majority had some post high school education and the majority had an income less than $15,000/yr. The majority in both groups strongly agreed or agreed that genetic research for deafness would benefit their childrens healthcare (7/7 in QO and 16/21 in T). Both groups strongly disagreed or disagreed that genetic research was discriminatory (5/6 in QO and 18/22 in T). Both groups strongly disagreed or disagreed that they mistrusted the researchers (6/7 in QO and 20/25 in T). Of those tested, one individual was found to have a GJB2 mutation, one subject had one abnormal allele, and one subject had a -6T->A, which is of unknown significance. CONCLUSIONS: Our results show that the prevailing attitude towards genetic testing for deafness among African-Americans is positive and most believe it to be non-discriminatory. Furthermore, as in previous studies, we found that mutations at DFNB1 are not a common cause of HI among AA.

An unusual structural rearrangement involving chromosome 2 in a patient with dysmorphic features, developmental delay and Pierre-Robin sequence. *V. Tonk[1], M. Sehrawat[2], M. Drummond-Borg[3], M. Ito[4], L. Lockhart[5], G. Velagaleti[5]* 1) Dept Pediatrics, Texas Tech Univ, Lubbock, TX; 2) PGIMS, Rohtak, India; 3) Texas Dept Health, Austin, TX; 4) Ctr Hum Genet, Boston Univ, Boston, MA; 5) Dept Pediatrics, Univ of Texas Med Branch, Galveston, TX.

The Pierre-Robin sequence (PRS) is a clinical entity characterized by cleft palate and micrognathia that results in glossoptosis. The overall incidence of PRS is 1/8500-14,000 births. Genetics appear to play a major role in the etiology of PRS. Studies have shown several chromosomal regions causally implicated in PRS including chromosome 2q24.1-q33.3. No candidate genes have been identified in this region, although GAD67 at chromosome 2q31 was considered as a potential candidate gene. We report here a case of a de novo unusual structural rearrangement involving the chromosome 2q22-q34 region. A 3-year old, Hispanic male was referred because of PRS, developmental delay and additional dysmorphic features. His prenatal and birth history was unremarkable. He was noted to have acrocyanosis and PRS. On physical examination, his height, weight and OFC were at 5th, 50th and 97th percentile, respectively. He had a large head with broad forehead and frontal bossing. Palpebral fissures were large and eyes were deep set. Nose was broad and up-turned. He had significant developmental delay. Chromosome analysis showed a structurally rearranged chromosome. Based on the G-banding analysis, the rearrangement appeared to be complex, similar to a recombinant chromosome. The karyotype was interpreted as 46,XY,der(2)del(2)(q31q32.2)dup(2)(q33.1q34)inv(2)(q22q24.3). Parental karyotypes were normal. To better characterize the rearrangement, FISH studies with BAC clones localized to q31.2, q31.3, q33.1 and q33.3 regions were carried out. BAC-FISH results confirmed the presence of inversion. Because of the ambiguity with banding analysis, additional studies with Affymetrix 250k SNP chip are being carried out. Results from the array analysis might help us narrow the region and identify potential candidate genes involved in PRS.

A new locus for autosomal recessive spastic paraplegia, mental retardation and brainstem dysraphia (SPG32) on chromosome 14q12-q21. *G. Stevanin[1,2], C. Paternotte[3], P. Coutinho[4,5], S. Klebe[1], J.L. Loureiro[4,5], V.T. Cruz[4], A. Durr[1,2], J.F. Prudhomme[6], J. Weissenbach[3], A. Brice[1,2], J. Hazan[3,7]* 1) IFR Neurosciences, INSERM U679-NEB, Paris, France; 2) APHP, Salpetriere Hospital, Dept of Genetics, Paris, France; 3) Genoscope, CNS, Evry, France; 4) Dept of Neurology, Sao Sebastiao Hospital, Santa Maria da Feira, Portugal; 5) UNIGENE, University of Porto, Portugal; 6) Genethon, Evry, France; 7) MRC centre for Developmental Neurobiology, King's College London, Guy's Hospital Campus, London, UK.

Hereditary spastic paraplegias (HSP) are a genetically heterogeneous group of neurodegenerative disorders characterized by progressive spasticity of the lower limbs. In the present study, we carried out a genome-wide linkage analysis on a consanguineous Portuguese family affected by an autosomal recessive complex form of HSP combining mild intellectual impairment, brainstem dysraphia and a clinically asymptomatic cerebellar atrophy. The disease has an early onset but a very benign course. We have mapped the disease locus, SPG32, to chromosome 14q12-q21 within a 30-cM interval, flanked by markers D14S264 and D14S58, which partially overlaps the initial SPG3A locus but excludes the atlastin gene.

Interacting proteins of Autoimmune Regulator (AIRE). *M.C. Rosatelli[1], D. Corda[1], E. Fiorillo[1], A. Cao[2], A. Meloni[2]* 1) Dipartimento di Scienze Biomediche e Biotecnologie, University of Cagliari, Cagliari, Italy; 2) Istituto di Neurogenetica e Neurofarmacologia, Consiglio Nazionale delle Ricerche, Cagliari.

The Autoimmune Polyendocrine Syndrome Type 1 (APECED; OMIM 240300) is a rare autosomal recessive disease that is more frequent in some isolated populations. It is characterised by three major clinical symptoms: hypoparathyroidism, Addisons disease, and chronic mucocutaneous candidasis. The disease is caused by mutations of the Autoimmune Regulator gene (AIRE). The AIRE protein has several functional domains such as, two PHD finger, 4 LXXLL motifs, a SAND domain and a HSR domain which are typical of transcription regulators. AIRE is able to activate in vitro transcription and binds with CREB binding protein. The AIRE expression is predominant in the thymic medullary epithelial cells and the monocyte-dendritic cell lines involved in the deletion of autoreactive T cells by negative selection. In this study we carried out functional studies by the two-hybrid technique in yeast cells in order to identify interacting proteins. The AIRE protein fused to a DNA-Binding Domain was used as bait to screen interacting proteins within a cDNA human thymus library. This approach allowed us to establish that 84% of isolated clones contained the cDNA which codified for the AIRE protein, confirming previous data on the homodimerization properties of the AIRE protein. Of the isolated clones, 12% contained the cDNA codifying for the UBC9 protein which represent the E2 enzyme of Sumoylation. Sumoylation is a posttranslational modification which mediates various processes such as nuclear localization, protein-protein interactions and the transcriptional repression and activation. By deletion study, we were able to map the domains of interaction in the N-term portions of both AIRE and UBC9. With the aim to confirm the interaction between AIRE and UBC9 we tested their binding by two-hybrid technique in mammalian cells and co-immunoprecipitation. In order to establish the role of AIRE in the Sumoylation process, we carried out the Sumoylation test in vitro. These experiments gave negative results and allowed us to exclude the involvement of AIRE in this posttranslational modification process.

Intra- and inter-population genotype reconstruction from tagging SNPs. *P. Paschou[1], M.W. Mahoney[2], A. Javed[3], J.R. Kidd[1], A.J. Pakstis[1], S. Gu[1], K.K. Kidd[1], P. Drineas[3]* 1) Department of Genetics, Yale University, New Haven, CT; 2) Department of Mathematics, Yale University, New Haven, CT; 3) Department of Computer Science, RPI, Troy, NY.

The optimal method for tSNP selection, the applicability of a reference LD map to unassayed populations, and the scalability of these methods to genome-wide analysis, remain important research questions. Taking advantage of recent results in computer science, we design novel matrix algorithms that address these issues and evaluate them on data from four genomic regions (248 SNPs typed over a total of 2.7Mb for approximately 2000 individuals from 38 worldwide populations). A separate dataset for the same genomic regions, available from the HapMap database (1336 SNPs for four populations), is also analyzed. We define the tSNPs selection problem as a reconstruction problem and attempt the accurate prediction of untyped SNPs based on a few carefully selected tSNPs. To justify the linear algebraic algorithms that we develop, we quantify the linear structure of the data using the Singular Value Decomposition (SVD) of matrices. We select tSNPs using a heuristic variant of a Monte-Carlo algorithm for approximating the SVD of large matrices. Next, we predict untyped SNPs using the CUR matrix decomposition. Our results show that keeping a small number of tSNPs suffices for 85-95% prediction accuracy for most studied populations. African populations prove to be the most resistant to extrapolation. Testing the portability of tSNPs across populations, we select tSNPs in each of our worldwide samples and measure the reconstruction error of unknown genotypes in the remaining populations. A considerable amount of tSNP transferability is revealed especially within geographic regions but also across them. The algorithms we employ for tSNP selection and unassayed SNP reconstruction do not require haplotype inference, are block-free multimarker tests, and they are, in principle, scalable even to genome-wide analysis. Algorithms from the computer science literature, proven already successful in mining large datasets, can become a powerful tool for mining information in the large volume of available genomic data.

Gene mutation analysis of genetic leukoencephalopathies in China. *X. Wu, Y. Jiang, J. Wang, Y. Wu, H. Wei, J. Xiao, J. Qin, Y. Yang, Y. Zhang* Pediatrics, Peking University First Hospital, No.1, Xi'an Men Street, West district, Beijing 100034, China.

Genetic leukoencephalopathies are a heterogeneous group of diseases with mainly white matter destruction or failed development caused by genetically determined molecular abnormality. Genetic analysis is always an important tool to diagnose these diseases. Therefore, we reported here our preliminary data of gene mutation analysis of genetic leukoencephalopathies, such as arylsulfatase A (ARSA) gene in Metachromatic leukodystrophy (MLD), glial fibrillary acidic protein (GFAP) gene in Alexander disease, MLC1 gene in Megalencephalic leukoencephalopathy with subcortical cysts (MLC), and Eukaryotic translation initiation factor 2B subunit (eIF2B5) in childhood ataxia with central nervous system hypomyelination/ vanishing white matter (CACH/VWM). From four Chinese patients with MLD, five DNA variations of ARSA gene were identified. Two frame shift mutations (177-180insCA and 1337-1338ins C) were novel and the other three were known missense mutation (p.R84W, p.G99V, and p. R288C). All 4 patients had heterozygous compound mutations. From 3 patients with Alexander disease, two different missense GFAP mutations were found in exon 1, which are all heterozygous, de novo mutations. Two patients carried the same arginine mutations (p. R88C), and one had tyrosine mutation (p. Y83H) which has not been reported yet. These results suggested that Exon1 of GFAP may be the hot spot mutated exon for Chinese infantile Alexander disease. That is similar with the results from USA. From 2 patients of MLC, we found 3 mutations, c.218G>A (p.Gly73Glu), c.823G>A (p.Ala275Thr), c.772-1G>C (splice-site mutation). Both two patients had heterozygous compound mutations. All these three mutations have not yet been reported. From 9 CACH/VWM patients (diagnosed on the basis of distinct clinical features and MRI characteristics), we had only finish part work for one subunit gene (eIF2B5) analysis, and found one homozygous missense mutation, c. 1759 A>G in a patient. Other analysis work is undergoing now. All these gene mutations were first reported in Chinese.

Large-scale In Vivo Enhancer Analysis of Extremely Conserved Human Noncoding Sequence. *L.A. Pennacchio[1,2], A. Visel[1], N. Ahituv[1,2], S. Prabhakar[1,2], I. Dubchak[1,2], E.M. Rubin[1,2]* 1) Genomics Division, Lawrence Berkeley Natl Lab, Berkeley, CA; 2) DOE Joint Genome Institute, 2800 Mitchell Drive, Walnut Creek, CA.

A significant challenge exists in identifying and characterizing the complete set of distant acting transcriptional enhancers present in the human genome. In this study, we leveraged extreme evolutionary sequence conservation as a filter to identify putative gene regulatory elements and characterized the in vivo enhancer activity of human-fish conserved and ultraconserved noncoding elements on human chromosome 16. We initially tested 165 of these extremely conserved sequences in a transgenic mouse enhancer assay and observed that 48 percent functioned reproducibly as tissue-specific enhancers of gene expression at embryonic day 11.5. While driving expression in a broad range of anatomical structures in the embryo, the majority of the 79 enhancers drove expression in various regions of the developing nervous system. Studying the set of DNA elements that specifically drove forebrain expression, we identified DNA signatures specifically enriched in these elements and used these parameters to rank all ~3,400 human-fugu conserved noncoding elements in the human genome. The testing of the top predictions in transgenic mice resulted in an enrichment for sequences with forebrain enhancer activity. These data dramatically expand the catalogue of in vivo-characterized human gene enhancers and illustrate the utility of such training sets for a variety of biological applications including decoding the regulatory vocabulary of the human genome.

As a community resource, we have established a database to visualize and query the activity of these enhancer sequences at http://enhancer.lbl.gov.

A Genome-wide Scan for Quantitative Trait Loci Underlying Obesity -Related Variation in 434 Caucasian Families. *L. Zhao[1], Y.J. Liu[2], P. Xiao[1], H. Shen[2], D.H. Xiong[1], Y.Z. Liu[1], R. Recker[1], H.W. Deng[1,2,3,4]* 1) Creighton Univ, Omaha, NE; 2) University of Missouri-Kansas City, Kansas City, MO; 3) Xi'an Jiaotong University, Xi'an, Shan'Xi, China; 4) Hunan Normal University, Changsha, Hunan, China.

Introduction: Obesity is a common complex disease that has strong genetic determination. Materials and Methods: To identify QTLs for regulation of obesity, we performed a large-scale whole genome linkage scan (WGS) involving 4,102 individuals from 434 families. All the subjects were genotyped with 410 microsatellite markers from the Marshfield screening set 14 spaced ~8.9 cM apart across the human genome. Using the variance component method implemented in SOLAR, we performed a linkage analyses in the total sample and in a specific gender. Results: Linkage evidence was found in the regions of 20p11-12 for fat mass (LOD = 3.31) and percentage fat mass (PFM) (LOD = 2.92). We also identified several suggestive linkage signals (threshold LOD=1.9) showing linkage to obesity, such as 5q35, 8q13, 10p12 and 17q11. Of them, 20p11-12 and 5q35 were particular interest because they were linked to obesity in multiple previous linkage studies and associated with multiple obesity candidate genes. Subgroup analysis revealed that the effect of 20p12 and 5q35 on obesity were present in whole sample, and males, but not in females. Conclusions: Together with the findings from other studies, the current study has further delineated the genetic basis of obesity and highlighted the importance of increasing sample size to confirm linkage findings and to identify new linkage regions. Our findings in this study laid a foundation for further replication and fine-mapping studies as well as for positional and functional candidate gene studies on obesity.

Life without sulfatases: a mouse model lacking all sulfatase activities. *C. Settembre[1], I. Annunziata[1], C. Spampanato[1], G. Cobellis[1], E. Nusco[1], M. Sardiello[1], E. Zito[1], M.P. Cosma[1], A. Ballabio[1,2]* 1) Telethon Institute of Genetics and Medicine (TIGEM), Naples, Italy; 2) Medical Genetics, Dpt. of Pediatrics, Federico II Univ., Naples, Italy.

Sulfatases are involved in several biological functions as diverse as degradation of complex molecules, production of steroid hormones and cell signaling. Humans have 17 different sulfatases and 8 diseases due to individual sulfatase deficiencies are known. In patients with Multiple Sulfatase Deficiency (MSD), the activities of all sulfatases are substantially reduced due to a defect in their post-translational modification. Recently, we and others identified the Sulfatase Modifying Factor 1 (SUMF1) gene, which is involved in the post-translational modification of sulfatases and is mutated in patients with MSD (Cosma et al and Dierks et al, Cell 2003). We have now generated a Sumf1 KO mouse model. In Sumf1-/- mice the activities of all sulfatases tested were found completely absent, indicating that sulfatase post-translational modification in mammals absolutely requires SUMF1. The residual sulfatase activities observed in MSD patients are likely due to hypomorphic SUMF1 mutations, as demonstrated by expression of SUMF1 mutant cDNAs in murine Sumf1-/- embryonic fibroblasts. Sumf1-/- mice display congenital growth retardation and frequent mortality within the first 2 months of age, with correlation between growth rate and lifespan. They also show striking skeletal abnormalities resembling those observed in human patients, including a flat facial profile, and a severe kyphosis. Histologically, we observed storage of glycosaminoglycans (GAGs) leading to progressive cell vacuolization and a massive inflammatory response (i.e. macrophage activation) in all examined tissues, particularly in the brain, suggesting an involvement of inflammation in the pathogenesis of disease manifestations. This exceptional mouse model, in which the function of an entire protein family has been completely abolished, offers an unprecedented opportunity to perform functional studies, to dissect disease mechanisms and to test new therapeutic strategies for diseases due to both single and multiple sulfatase deficiency.

High-throughput Screening Genomic Deletions and Duplications in the Chinese DMD Gene by Using Array-based MLPA Approach. *F. Zeng[1], Z.R. Ren[1], S.Z. Huang[2], C.L. Jin[3], M. Mommersteeg[4], M. Smit[4], S.Z. Huang[1], R. Beuningen[4], Y.T. Zeng[1], Y. Wu[4]* 1) Institute of Medical Genetics, Shanghai Jiao Tong University, Shanghai, P.R.China; 2) Institute of Basic Medical Science, the Chinese Academy of Medical Science, Beijing, P.R.China; 3) China Medical University, Shenyang, P.R.China; 4) PamGene International BV, The Netherlands.

Duchenne muscular dystrophy (DMD) is the most common and severe X-linked disease, with an incidence of 1 in 3,500 male births in China. Deletions and duplications are known to cause approximately two-thirds of DMD cases. Due to technical difficulties, screening for such mutations in the entire DMD gene is often not performed. Here, we present a technology that simplifies the quantitative analysis of copy number, enables the rapid analysis of over 100 genetic loci by a single tube reaction. Using a universal array employing address sequence tags immobilized on an aluminum-oxide substrate, along with a single multiplex ligation-PCR amplification for analysis, 96 samples can be analyzed in parallel in less than 1 hour. Using this method, we have screened 79 exons of the DMD gene for 44 control individuals and 237 DMD patients, and detected rearrangements in 76% of these patients, of which 92% showed deletions and 8% duplications. Most deletions observed occurred in the middle of the gene and 26% involved only one exon. The majority of the duplications were simple and contiguous duplications, although we detected two none-contiguous duplications among these patients. Our study demonstrated great potential of such technology for the rapid DNA diagnostics in clinical applications.

GABAergic dysfunction may modify clinical severity of Angelman syndrome. *S. Saitoh, K. Egawa, K. Hosoki, N. Asahina, H. Shiraishi* Dept Pediatrics, Hokkaido Univ Sch Medicine, Sapporo, Japan.

Angelman syndrome (AS) is a neurodevelopmental disorder caused by a defect of the imprinted *UBE3A* gene. Five molecular classes (maternal 15q11-q13 deletion, paternal uniparental disomy of chromosome 15, imprinting defects, *UBE3A* mutations, and unknown etiology) underlie the deficit of *UBE3A*, although AS patients with the deletion (AS-del) show more severe clinical phenotypes than those with other molecular classes (AS-non-del). Three $GABA_A$ receptor subunit genes (*GABRB3*, *GABRA5*, and *GABRG3*), which are not imprinted, are located in the deletion, and hemizygosity of these genes may contribute to more severe phenotypes in AS-del. *Gabrb3* heterozygous knock-out mice have epileptic discharges on EEG, similar to seizures in AS and raising the possibility of GABAergic dysfunction in AS. We therefore conducted a series of studies to evaluate what role the GABAergic system may play in AS. Eleven AS-del patients, three AS-non-del patients including one with an imprinting defect and two with a *UBE3A* mutation, and six epilepsy patients as controls participated in the study. We investigated primary somatosensory responses by measuring somatosensory evoked field in response to median nerve stimulation using magnetoencephalography. The N1m (first component) peak latency was significantly delayed in AS-del, but not in AS-non-del. This delay was partially restored by administration of clonazepam, which activates $GABA_A$ receptor function. Moreover, this unique somatosensory response pattern only in AS-del was reproduced by conventional somatosensory evoked potential, although peak latency delay differed between the two measurements. These findings establish GABAergic dysfunction in AS-del. Surprisingly, $GABA_A$ receptor expression studies in five AS-del and two AS-non-del patients by $[^{11}C]$flumazenil positron emission tomography indicated a higher $[^{11}C]$flumazenil binding potential in AS-del and AS-non-del than that in controls. These findings were inconsistent with previous reports, and we proposed that total $GABA_A$ receptor expression was not declined in AS. In conclusion, functional deficits of the GABAergic system are likely to modulate clinical severity in AS.

Identification of a novel imprinted transcription factor on human chromosome 7q32.3. *L. Parker-Katiraee[1,2], T. Yamada[1], S.N. Abu-Amero[3], G.E. Moore[3], M. Kaneda[4], H. Sasaki[4,5], K. Nakabayashi[1,4], S.W. Scherer[1,2]* 1) Dept. of Genetics & Genomic Biology, Hosp. for Sick Children, Toronto, Canada; 2) Dept. of Medical Genetics, Univ. of Toronto, Canada; 3) Inst. of Child Health, Univ. College London, UK; 4) Div. of Human Genetics, Dept. of Integrated Genetics, Nat. Inst. of Genetics, Research Org. of Info. and Systems; 5) Dept. of Genetics, School of Life Science, Graduate Univ. for Advanced Studies, Mishima, Japan.

Imprinted genes are expressed in a parent-of-origin specific manner. Aberrations in their expression have been associated with various developmental disorders, including Russell-Silver Syndrome (RSS). The imprinted cluster at 7q32.3, which harbours the paternally expressed *MEST*, is considered to be a prime candidate region for RSS. Here we describe the imprinting of *KLF14*, an intronless transcript located at 7q32.3 and a member of the Krüppel-like family of transcription factors. We show that the gene has monoallelic maternal expression in all embryonic and extra-embryonic tissues studied, in both human and mouse. We examine epigenetic modifications in the *KLF14* CpG island by sequencing bisulfite treated DNA from human fibroblast cell lines and murine embryos and find this region to be hypomethylated in both species. In addition, we perform chromatin-immunoprecipitation and find that the murine Klf14 CpG island lacks allele-specific histone modifications. Despite the absence of these defining features, our analysis of *Klf14* in offsprings from *Dnmt3a* conditional knockout mice reveals that the genes expression is dependent upon a maternally methylated region. We suggest that the differentially methylated region associated with *Mest* is a strong candidate as a primary germline control element regulating the expression of *Klf14*. Due to the intronless nature of *Klf14* and its homology to *Klf16*, we suggest that the gene is an ancient retrotransposed copy of *Klf16*. By sequence analysis in numerous mammalian species, we place the timing of this event after the divergence of Marsupialia, yet prior to the divergence of the Xenarthra superclade. Thus, *KLF14* is the first example of a maternally expressed protein-coding retrotransposed gene imprinted in both human and mouse.

Association of 5 region polymorphic markers of the Fibrillin-1 gene with systemic sclerosis and related pulmonary fibrosis in caucasian european patients. *Y. Allanore[1,2], J. Wipff[1,2], M. Giraud[3], H.J. Garchon[3], A. Kahan[2], C. Boileau[1]* 1) INSERM U 781, Necker hospital, Paris, France; 2) Rheumatology A, Cochin hospital, Paris, France; 3) INSERM U 580, Necker Hospital, Paris, France.

Introduction: A growing body of evidence suggests that systemic sclerosis (SSc) is a fibrillin disorder and associations with the fibrillin-1 gene (FBN1) were found in Choctaw and Japanese populations. Patients and Methods: First, we investigated 331 French subjects: 198 SSc and 133 controls with osteoarthritis. We then investigated three Italian cohorts from Florence (89 SSc/79 controls), Brescia (115/50) and Verona (62/24). We studied six FBN1 gene polymorphisms: one SNP in intron C and five microsatellite markers: D15S1028, MTS2, MTS3, D15S123 and D15S143. We used Arlequin, Cocaphase and Phase 2 software for statistical analysis. Results: All markers were in Hardy-Weinberg equilibrium. Two sets of markers were in linkage disequilibrium: one in the 5 (D15S1028, Intron C, MTS2, MTS3) and one in the 3 region (D15S123, D15S143). In the French cohort, the MTS3 146 allele was associated with SSc (p = 0.046), pulmonary fibrosis (p = 0.008) and related restrictive syndrome (p=0.04). We also detected an association between SSc and alleles 173 and 171 of marker D15S1028; respectively in SSc patients and controls, allele 173 was present in 7% versus 2% (p=0.03) and allele 171 in 4% versus 11% (p=0.04). In the Brescia cohort, D15S1028 179 allele was more frequent in SSc patients than in controls (20% vs 6%, p=0.005) and in SSc patients with pulmonary fibrosis (22% vs 6%, p=0.008). In the Verona cohort, we also observed a significant difference between SSc patients with pulmonary fibrosis and controls for the D15S1028 175 allele (17% vs 46%, p=0.03). Conclusion: These data show an association not only between the 5 region of the FBN1 gene and SSc but more importantly with pulmonary fibrosis in Caucasian European patients. These findings confirm the hypothesis of a key role for FBN-1 in the fibrotic process of this devastating disease.

A *Coch* knock-in mouse model for late-onset DFNA9 deafness. *N.G. Robertson[1], T.A. Sivakumaran[1,2], S.A. Hamaker[1], A.B.S. Giersch[1,2], C.C. Morton[1,2]* 1) Depts. OB/GYN & Pathology, Brigham & Women's Hospital; 2) Harvard Medical School, Boston, MA.

COCH, encoding cochlin, is expressed at high levels in the inner ear. Six familial *COCH* missense mutations have been found in the autosomal dominant late-onset deafness and vestibular disorder, DFNA9, showing abnormal eosinophilic deposits in the cochlear and vestibular labyrinths. To create a mouse model for DFNA9, we generated a mouse knock-in by introducing one of the *COCH* mutations (G88E). The targeting construct consists of ~5.6kb of 129/SvJae mouse *Coch* genomic sequence spanning introns 3 to 8. Positive and negative selection were performed through neomycin (*neo*) flanked by *loxP* sites in *Coch* intron 5, and thymidine kinase upstream of the *Coch* sequence, respectively. J1 embryonic stem (ES) cells were transfected with the *Coch* mutant construct and 240 ES cell clones were screened. Integrity of the recombination, *loxP* sites, the mutation, and exons were confirmed by PCR, Southern blots, and sequencing. A homologous recombinant ES cell clone was microinjected into C57BL/6 blastocysts, yielding several chimera that showed germline transmission of mutant *Coch*.

F1 mice heterozygous for the mutant allele were mated with EIIA-*cre* deletor mice for removal of *neo*, which interfered with efficient transcription or splicing of mutant *Coch*. After *neo* excision, RT/PCR of $Coch^{G88E/+}$ showed presence of the mutant *Coch* transcript. Immunohistochemistry on inner ears of $Coch^{G88E/G88E}$ mice showed strong immunostaining for cochlin, indicating the mutant protein is being successfully produced. For expression analysis, total RNA has been obtained from nine pairs of cochlea from each genotype to be used for analysis on Affymetrix expression chips as well as on cochlear-derived cDNA microarrays developed in our laboratory. Continued studies of these mice until advanced ages include auditory brainstem response (ABR) and vestibular testing, histopathology and immunohistochemistry, cochlear cDNA microarray and proteomic analyses. At 11 months of age, auditory and vestibular testing are within normal limits.

Linkage and mutational study in two families with Familial Hemiplegic Migraine. *P. Tarantino[1], E.V. De Marco[1], F. Bono[2], A. Gambardella[2], P. Forabosco[3], S. Carrideo[1], F. Annesi[1], D. Civitelli[1], F.E. Rocca[1], I.C. Cirò Candiano[1], G. Annesi[1]* 1) Inst Neurological Sciences, National Research Council, Mangone, (CS), Italy; 2) Inst of Neurology, University "Magna Graecia", Catanzaro, Italy; 3) Inst of Population Genetics, National Research Council, Alghero (SS),Italy.

Familial Hemiplegic Migraine (FHM) is a rare autosomal dominant subtype of migraine with aura, characterized by the occurrence of hemiplegia or hemiparesis during the attacks. Up to now, mutations in three genes have been shown to be causative for FHM: CACNA1A, ATP1A2, and the newly identified SCN1A, all coding proteins involved in regulating ionic flow through the membranes. The aim of this study was to investigate if these genes were associated to the disease in 2 FHM families from Calabria. FHM was diagnosed according to the criteria of the International Headache Society in 6 individuals (three in each family). DNA was made available from 20 members of the two families: 6 affected individuals, 1 obligate carrier and 13 unaffected individuals. All subjects were genotyped for 9 microsatellite markers to exclude linkage to CACNA1 and ATP1A2 by ABI 3130xl. Linkage analysis was performed by LINKAGE and GENEHUNTER. Sequencing analysis for mutation detection in SCN1A was performed on ABI 3130xl. The LOD score values obtained in the two FHM families allowed us to exclude linkage to CACNA1A and ATP1A2. Concerning the SCN1A gene, no mutations, including the already published one, have been identified in the 16 exons analyzed so far. Mutational screening on the 10 remaining exons is still in progress. To date, several mutations in the CACNA1 and ATP1A2 genes have been identified as causing FHM, but a consistent number of families do not show evidence of linkage to either of them. Very recently a mutation in the SCN1A gene was found in three European FHM families, but other families have been reported not to link to this gene. Our preliminary data led us to exclude both the linkage to CACNA1 and ATP1A2, and the presence of the already published mutation in SCN1A in our families. Further studies are needed to evaluate the role of SCN1A in FHM.

White Americans Beliefs on Genetic Contributions to Perceived Racial Differences in Athleticism: Impact on Prejudice Toward and Negative Stereotyping of Blacks. *E.M. Petty[1], J.P. Sheldon[2], T.E. Jayaratne[1]* 1) Univ Michigan, Ann Arbor, MI; 2) Univ Michigan, Dearborn, MI.

Individuals - in sports to science - have debated whether Blacks possess superior innate athletic abilities. The belief that Blacks are naturally athletic may reflect the large presence of talented Blacks in televised US sports and Blacks domination of Olympic sprinting events. National polls reveal that most Americans, especially Whites, believe that genetics underlies Blacks supposed athletic superiority. Such beliefs can serve as a legitimizing myth, supporting a White social dominance perspective. Historically, the Eugenics movement illustrated how beliefs in heritable racial differences led to stereotyping, prejudice and oppression. Recently, a negative stereotypical view of Whites having the brains and Blacks having the brawn has emerged in publicized discussions of athletics. We hypothesized that White Americans belief in a genetic difference for athleticism between Blacks and Whites would predict prejudice and negative stereotyping. To examine this, 600 self-identified Whites randomly selected from across America were asked about these issues during a telephone survey of genetic beliefs. Demographic information, including variables hypothesized to relate to Whites racial stereotyping and prejudice was obtained. Measures of their (1) belief in a genetic basis for race differences in athleticism, (2) level of racial prejudice, and (3) endorsement of negative racial stereotypes regarding intelligence and work ethic were analyzed. Supporting our hypothesis, Whites belief in a genetic race difference in athleticism, regardless of thier gender, predicted significantly higher levels of prejudice toward and negative stereotyping of Blacks. Thus, Whites praise of Blacks athletic superiority operates as backhanded compliment when it denigrates Blacks intellectual ability and work ethic. This suggests that a public better informed about genetics, race, and racial diversity may lead to more desirable social outcomes. Accurate reports of socially responsible research on, and decreased stereotyped and essentialist media portrayals of, genetics and race are needed.

MicroRNA expression profiling of lung cancer cell lines. *A. Pertsemlidis[1], Irnov[1], L. Du[1], J. Schageman[1], S. Goodson[2], J.M. Thompson[2], S. Hammond[2], L. Girard[3], M. Sato[3], J. Shay[3], A.F. Gazdar[3], J.D. Minna[3]* 1) McDermott Center for Human Growth and Development, UT Southwestern Medical Center, Dallas, TX; 2) Lineberger Comprehensive Cancer Center, School of Medicine, University of North Carolina, Chapel Hill, NC; 3) Hamon Center for Therapeutic Oncology Research, UT Southwestern Medical Center, Dallas, TX.

Using microRNA expression profiling of small cell lung cancer (SCLC) cell lines, non-small cell lung cancer (NSCLC) cell lines and immortalized human bronchial epithelial cells (HBECs), we have identified 35 microRNAs with patterns of expression that distinguish SCLC and NSCLCs, 10 microRNAs that distinguish HBECs from lung cancer cell lines, 3 microRNAs that correlate with drug sensitivity in NSCLC cell lines and 1 microRNA that correlates with progression in genetically manipulated HBECs. We have also found 3 microRNAs, miR-93, miR-98/let-7f and miR-197, which are over-expressed in SCLC cell lines relative to NSCLC cell lines and HBECs. Using a method of predicting gene targets of miRNA regulation developed in our lab, we predicted that all three miRNAs translationally repress FUS1/TUSC2, a lung cancer tumor suppressor gene located on human chromosome 3p21.3. Over-expression of FUS1 has been shown to lead to G1 arrest and growth inhibition of lung cancer cells, and to significant inhibition of tumor growth and progression in mouse models. Using an in vitro assay, we tested the hypothesis that these three microRNAs repress protein expression via interaction with a target site in the 3UTR of the TUSC2 transcript. The results show that miR-93, miR-98, and miR-197 inhibit luciferase expression by targeting the TUSC2 3UTR. miR-93, miR-98/let-7f and miR-197 are therefore negative regulators of FUS1, supporting a model in which aberrant over-expression any of the three miRNAs leads to the loss of FUS1 protein expression in SCLC. This suggests that the three miRNAs may be relevant in the development of lung cancer and may serve as effective diagnostic markers and therapeutic targets.

QTL fine-mapping reveals several discrete loci with small individual effects. *E.M. Smith[1], L. Martin[2], A. Kissebah[1], M. Olivier[1]* 1) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 2) Children's Hospital Medical Center, Cincinnati, OH.

A previously identified quantitative trait locus (QTL) strongly linked to plasma triglyceride (LOD 3.7) and LDL levels (LOD 2.2) in subjects with the metabolic syndrome was selected for further investigation. A total of 1,048 single nucleotide polymorphisms (SNPs) were genotyped in an attempt to narrow the QTL, located on chromosome 7q36.

All non-synonymous SNPs in the region were genotyped in addition to tagSNPs selected based on the linkage disequilibrium (LD) patterns of the CEPH (Centre dEtude du Polymorphisme Humain) population of the HapMap (Phase 1 data). This resulted in a final overall density of one genotyped SNP every 4.6 kb. SNPs were genotyped in 1,560 samples on a custom-designed array using molecular inversion probe technology (Affymetrix).

One hundred of the 1,048 SNPs (9.5%) were determined to have marginal association with nominal p-values less than 0.05, a further nine (0.9%) had nominal p-values below 0.001. Of these 109 SNPs, 98 (89.9%) are located in regions of high LD ranging in size from 1.5 to 388 kb (average 35.8 kb). These can be condensed into six main regions of interest (size range 0.4 - 1.6 Mb) spread throughout the QTL interval, encompassing 14 known and six putative genes.

Individually, the associated SNPs are responsible for less than five percent of the overall linkage. However the number of loci identified indicates that the detected linkage is not caused by a single gene (or genetic locus.) Rather, it is more likely that the initial linkage analysis detected a cluster of loci of small individual effect that combine to create the observed overall effect on the plasma lipid profile.

The Mutation in the Renin Receptor (ATP6A2) Associated with X-linked Mental Retardation-Epilepsy (XMRE) Reduces ERK1/2 Activation by NGF in PC-12 Cells. *C.E. Schwartz, J. Norris, K.J. Franek* J.C. Self Research Institute, Greenwood Genetic Center, Greenwood, SC 29646.

The renin-angiotensin system (RAS) is essential for blood pressure control and water-electrolyte balance. The discovery of a mutation in the renin receptor (ATP6A2) in a family with X-linked mental retardation and epilepsy (XMRE; OMIN #300423) points to a novel role for the renin receptor. The neutral mutation (p.D107D) in the renin receptor (RER) resulted in an in-frame deletion of exon 4 (RERD4), due to an altered exon splice enhancer site (Ramser et al. HMG, 2005). In order to further characterize RERs function and potential role in brain development, we have transfected both wild-type and mutant RER cDNA into rat PC-12 pheochromocytoma cells. The RERwt was particularly localized to the tips of neural projections. However, RERD4 did not appear to accumulate at neurite tips. No other morphological differences between PC-12 cells expressing RERwt and RERD4 were evident. Nerve growth factor (NGF)-stimulated PC-12 cells expressing RERwt exhibited a nearly 100 percent increase in ERK1/2 phosphorylation compared to control cells (empty vector transfected PC-12 cells), whereas their RERD4 counterparts demonstrated approximately 30% lower phosphorylation levels relative to controls. Unstimulated PC-12 cells expressing RERwt and RERD4 were similar to the controls regarding phosphorylation of ERK1/2. Using differentially epitope-tagged RERwt and RERD4, we determined that RERD4 can dimerize with itself (RERD4-RERD4), as well as with wild type (RERD4-RERwt). Together, our data suggest that the RERD4 mutation associated with XMRE results in a form of renin receptor that may impair the ability of neurons to respond to NGF via the ERK1/2 pathway. These findings confirm the important role of the RER in cognitive function.

Combining trend tests for genome-wide association studies:Double trend tests. *K. Song[1], G. Zheng[2], R.C. Elston[3]*
1) GlaxoSmithKline, King of Prussia, PA; 2) National Heart, Lung and Blood Institue, Bethesda, MD; 3) Case Western Reserve University, Cleveland, OH.

To test marker-disease association in a case-control design using 100K-500K single-nucleotide polymorphisms (SNPs), a single marker analysis may be the first step. It provides insight into SNPs causing susceptibility to the disease or into further haplotype analysis. For genome-wide association studies with more than 100K SNPs (hypotheses), the significance level required in single marker analysis (single hypothesis) is less than 5 × 10-7. Such a significance level may not be achieved in a single stage analysis with the usual test statistics. We propose a procedure combining two trend tests, referred to as the double trend test (DTT), which is based on both the Hardy-Weinberg Disequilibrium trend test (HWDTT) and the Cochran-Armitage trend test (CATT), in a two-stage analysis. Our purpose is to screen SNPs in the first stage using the HWDTT and test in the second stage using the CATT a reduced number of SNPs that pass the screening stage. However, the features of our twostage analysis are (1) that the two trend test statistics are independent under the null hypothesis with Hardy-Weinberg equilibrium, so all samples are used in both stages to enhance the power in each stage, and (2) that it allows flexibility to choose the significance levels while ensuring asymptotic control over the overall Type I error rate. We discuss the optimal choice of the significance levels in both stages that ensures the asymptotic power of this two-stage analysis is at least as powerful as that using the CATT in a single-stage analysis. The results are illustrated with application to real data.

Homozygote Twinkle mutation in mitochondrial DNA depletion. *A. Rotig[1], D. Chretien[1], V. Serre[1], A. Slama[2], A. Munnich[1], E. Sarzi[1]* 1) INSERM U781, Hosp Necker, Paris, France; 2) Laboratoire de Biochimie 1, Hôpital Bicêtre, Le Kremlin-Bicêtre, France.

Twinkle is a mitochondrial 5-3 DNA helicase of particular importance for mitochondrial DNA (mtDNA) maintenance. Dominant Twinkle mutations have been reported in progressive external ophthalmoplegia with multiple mtDNA deletions (adPEO) whereas recessive Twinkle mutations are associated with infantile onset spinocerebellar ataxia (IOSCA). Because Twinkle controls mtDNA copy number, the Twinkle gene was regarded as a candidate gene in mtDNA depletion. We selected a series of 10 patients born to consanguineous parents and presenting with a severe mtDNA depletion of yet unknown origin and we studied the segregation of microsatellite markers flanking the Twinkle gene in these patients. Homozygosity of the flanking markers was found for two sibs belonging to the same family. They presented neonatal lactic acidosis, trunk hypotonia, seizures, cytolysis and cholestasis. A combined deficiency of complexes I, III and IV of the mitochondrial respiratory chain and as severe mtDNA depletion were found in their liver (8% of the normal mtDNA content). Homozygous mutation at a conserved position of the protein was found in the two patients (T457I). The similarity of Twinkle with the GP4D helicase of phage T7 prompted us to model the structure of this human helicase using the X-ray coordinates of the homohexameric GP4D protein as a tertiary template. Interestingly, the mutation is located in the interface between two monomers of the hexameric enzyme, and most likely induces a local conformational change. This work reports the first description of a Twinkle mutation in mtDNA depletion in human.

Molecular evolution of the acyl-CoA dehydrogenase (ACAD) family. *Z. Swigonova, J. Vockley* Pediatrics, University of Pittsburgh School of Medicine, Children's Hospital of Pittsburgh, Pittsburgh, PA.

Mammalian ACADs constitute a family of flavoproteins that catalyze the ?,?-dehydrogenation of acyl-CoA thioesters to corresponding trans 2,3-enoyl-CoA products. Eleven members of this family have been described, however, the substrate specificity of two remains undetermined. Combining bioinformatic and phylogenetic approaches we investigated the evolutionary history of the ACADs with particular focus on substrate specificity prediction for the unknown enzymes. The origin of the ACAD family can be traced back more than 2 billion years ago to the origin of the Archaea, Bacteria, and Eukaryota. At least two primordial ACADs were already present at this time, one of which was the ancestor of glutaryl-CoA dehydrogenase. The emergence of the ACAD family is marked by several rounds of gene duplication at or early after the divergence of the three domains. The rise of the archaeal domain was accompanied by gene duplication early after its divergence producing ACADs specific to the archaeal lineage and by consecutive rounds of gene amplifications specific to extant archaeal taxa. This finding corresponds with known differences between the membrane lipids of Archaea and of Bacteria/Eukaryota. Unlike Eukaryota and Bacteria that have ester-linked fatty acids in lipids, Archaea have ether-linked lipids with C20-C40 isoprenoid (branched hydrocarbons) chains. Nevertheless, these long branched isoprenoid hydrocarbon fatty acids are not exclusive to Archaea but are also found to be prominent in basal Metazoa. Bacteria and Eukaryota emerged already equipped with 6-8 ACAD homologs and there were only occasional lineage-specific duplications towards extant taxa. Two additional duplications occurred in parallel before speciation of higher eukaryotes, particularly Coelomata, about 400-600 mya. The most parsimonious scenario suggests that the most ancestral ACAD had branched-chain specificity and that ACADs with straight-chain specificity derived later at the root of Bacteria and Eukaryota. Furthermore, our analysis suggests that the two undetermined ACADs will likely have specificity towards long branched-chain fatty acid substrates, particularly iso C-15 and C-17.

Incomplete medical follow up of birth defects patients in Bogotá Colombia. *I. Zarante, F. Suárez* Inst de Genetics Humana, Pontificia Univ Javeriana, Bogota, Colombia.

Government Birth defects surveillance is absent in Colombia. Latin American Collaborative Study of Congenital Malformations ECLAMC is the only program of epidemiological surveillance. Due to the absence of a structured system of genetics patients follow up, and the lack of medical genetics services, birth defects affected patients have an incomplete or missed diagnosis. Using the ECLAMC methodology during 2 years a total of 272 patients with major birth defects in 4 hospitals of Bogotá were detected. The actual health status of 225 patients (82.7%) is unknown. 10 patients (3.7%) died without a definitive diagnosis. A complete medical follow up and confirmed diagnosis after 6 months of birth defect detection in the new born, was accomplished in 37 patients (13%). During the first evaluation a syndromatic diagnostic was achieved in 24 cases (64.9%) and a new diagnosis was establish in 13 cases (35,1%) during the first visit 6 months later. 21 cases (56.8 %) had low birth weight and height, which remain below Percentile 5 in 18 cases after 6 moths. Most of the diagnosed syndromatic patients remain with low weight and height and there was a statistical difference in relation with the non syndromatic patients (p=0,005). Due to the nature of the disease in the new born, we expected that the clinical following were made at least once by a medical genetics specialists, but it only occurred in 18,9% of the cases (p=0,00001). All of the patients had the clinical indication of a karyotype but just in 8 cases (21.6%) were made. More than half of the patients (51.4%) showed clinical signs of developmental delay but only 5 had a specific therapy or treatment. None of the cases had genetic counseling. The diagnostic concordance between the prenatal diagnostic and the definitive diagnostic was insignificant: =0.053 agreement: 0.51 (95% Confidence Interval: -0.052, 0.157). These results shows the almost complete absence a good quality medical attention to the patients affected with birth defects in these population, and we firmly believe that this reflects the situation of the Colombian health system that ignores the families and patients with genetic diseases.

Telomeric associations in two cases of papillary renal cell carcinoma. *J. Tsai, B. Huang, M. Thangavelu, N. Qin, M. LeMieu, S. Lass* cytogenetics, Genzyme genetics, Corona, CA.

Telomere plays an important role in maintaining chromosome integrity and stability. Telomere association(TAS) is a rare phenomenon and has been reported in varioun solid tumors include renal cell carcinoma. TAS was proposed as one of the mechanisms of oncogenesis in these tumors. We present two cases of telomeric associations in papillary renal cell carcinoma. Multiple clonal numerical and structural rearrangements were observed in both cases, including gain and loss of chromosomes 7, 12, 17, and Y, frequent findings in papillary renal cell carcinoma. In addition, numerous TASs were observed. In the first case, TASs involved chromosomes 2, 4, 8, 12, 14, 15, 16, 17, 21, 22, and X were observed. In the second case, TASs were even more extensive, and involved chromosomes 1, 3, 7, 8, 9, 10, 16, 17, 19, 20, and 21. The majority of the associations were clonal and included chromosomes 16, 17, 19, and 20. A double telomeric association involves chromosomes 16, 19, and 21 was also observed. Overeall, twenty two different telomeric associations were observed in this case. The presence of multiple TASs, in addition to other chromosome abnormalities suggests chromosome instability and may be a sign of tumor progression.

Assessing the effect of missense variants in oligogenic disease. *N.A. Zaghloul, C.C. Leitch, N. Katsanis* Institute of Genetic Medicine, The Johns Hopkins University, Baltimore, MD.

A major challenge in human genetics is the assignment of pathogenicity to alleles. This problem is particularly poignant in oligogenic and complex traits, where the phenotype is the result of the combined effect of numerous, potentially mild alleles across several genes. Bardet-Biedl Syndrome (BBS) represents a useful oligogenic model, where mutations at a second locus can modify the penetrance and/or expressivity of the disorder. Numerous mutations in eleven genes have been identified in BBS patients, including 76 missense variants, some of which do not segregate with the disorder in the traditional Mandelian sense, suggesting that they are either benign polymorphisms or candidate modifiers. To determine the potential pathogenicity of each known missense variant, we capitalized on our recent development of BBS zebrafish models and assessed the ability of mutant bbs message to rescue the morphant phenotypes. Embryos treated with morpholinos alone showed a phenotype consistent with defects in convergence and extension, including shortened body axes, notochord defects, abnormal somites, and reduced brain size. Co-injection with wild type human mRNA rescued these phenotypes, whereas co-injection with mRNA bearing individual missense mutations produced a spectrum of effects. Most variants tested resulted in a partial rescue, suggesting that they are hypomorphic alleles, whereas some variants failed to rescue the phenotype and are therefore likely functional null alleles. Intriguingly, the introduction of some alleles recapitulated the morphant phenotype in the absence of morpholino, suggesting that these alleles might exert a dominant negative effect, including some alleles that have been associated with oligogenic inheritance. Although our approach is limited to the role of the BBS proteins during early development, this model potentially provides a powerful means to rapidly assess the effect of alleles for which genetic and computational data are inconclusive, a situation that is likely to represent an acute problem in oligogenic and complex traits.

Anterior versus posterior teeth hypodontia in families. *E. Severin, C. Albu, D.F. Albu* Dept Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania.

Background: isolated hypodontia is one of the most common congenital anomaly affecting the tooth development of one or both dentitions.As a familial trait, hypodontia is found more commonly among individuals related with hypodontia patients than in the general population identifying it as a genetic disorder. Mutations in Pax9 gene are associated with posterior teeth hypodontia (permanent molars and second premolars). It is known that tooth agenesis does not represent a public health problem, but it may cause masticatory and speech dysfunctions or esthetic problems.**Objectives:** to describe the clinical phenotypes and modes of inheritance of hypodontia in families; to find evidence that mutations in Pax9 gene cause both anterior and posterior teeth agenesis.**Patients and Methods:** the sample consisted of 22 Caucasian patients from 15 families with hypodontia in two or three successive generations. They were evaluated by clinical and radiographic examinations.Blood samples were collected from 15 unrelated patients with hypodontia and 15 healthy control subjects and DNA was isolated and analyzed by PCR. **Results:** all patients and their affected relatives presented hypodontia of permanent teeth as an isolated trait. Three clinical phenotypes of hypodontia were described: missing anterior teeth (9 cases), missing posterior teeth (8 cases) and missing both anterior and posterior teeth (5 cases). Bilateral hypodontia appeared to be more frequent than unilateral absence of teeth. There were differences between right and left sides hypodontia. No significant sexual differences in the frequencies have been found. Hypodontia was inherited as an autosomal dominant condition with variable expression and incomplete penetrance. There were no clear correlations between the pattern of hypodontia and certain mutation of Pax9 gene. **Conclusions:**familial hypodontia is a genetic disorder with clinical variation; individuals within the same family would be expected to have the exact mutant genes and their different phenotypes could demonstrate the gene expression variation; anterior and posterior teeth hypodontia are two inherited conditions caused by different mutations.

A family-based association study of CYP17 and CYP19 gene polymorphisms with obesity phenotypes. *H. YAN*[1], *L.J. ZHAO*[3], *D.H. XIONG*[3], *R.R. RECKER*[3], *H.W. DENG*[1,2,3,4] 1) School of Life Science and Technology, Xi'an Jiaotong University, Xian, Shaanxi, 710049, China; 2) School of Medicine, University of Missouri- Kansas City, Kansas City, Missouri, 64108, USA; 3) Osteoporosis Research Center and Department of Biomedical Sciences, Creighton University, Omaha, Nebraska, 68131, USA; 4) College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, China.

Background: 17-Alpha-Hydroxylase (CYP17) and aromatase (CYP19) are two key biosynthesis enzymes of estrogen which is a critical regulator of adipogenesis and adipocyte development in humans. **Methods:** To investigate the association between CYP17 and CYP19 genes with obesity phenotypes, we performed a family-based association test (FBAT) in a large sample comprising 1,873 subjects from 405 Caucasian nuclear families. 7 single nucleotide polymorphisms (SNPs) in the CYP17 gene and 27 SNPs in the CYP19 gene were genotyped. Obesity phenotypes tested included obesity (OB, defined as BMI exceeds 30 kg/m^2), body mass index (BMI), fat mass, percentage fat mass (PFM), and lean mass, with the latter three measured by dual-energy X-ray absorptiometry (DXA). **Results:** Single markers and haplotypes (CYP17:1 block; CYP19: 5 blocks) were tested for associations. For the CYP17 gene, association was found between SNP1 (rs619824) and BMI (P value = 0.0386), between SNP5 (rs3740397) and both lean mass (P value = 0.0366) and BMI (P value = 0.0161), between SNP6 (rs6163) and both lean mass (P value = 0.0397) and BMI (P value = 0.0183), between haplotype CGCTCCA and both lean mass (P value = 0.0152) and BMI (P value = 0.0131), between haplotype AAAAGAA and both lean mass (P value = 0.0251) and BMI (P value = 0.0500). For the CYP19 gene, SNP 17 (rs2470176), SNP18 (rs730154) and SNP23 (rs1902584) showed association with BMI (P value = 0.0243, 0.0407 and 0.0117 respectively). Association was also observed between haplotype GGCAAAAA of block 4, containing SNP17 and SNP 18, with BMI (P value = 0.0168). **Conclusion:** In summary, our results suggest that both CYP17 and CYP19 genes are associated with obesity phenotypes in our study Caucasian population.

An extended angiotensinogen haplotype is associated with essential hypertension. *W.S. Watkins[1], W. Tolpinrud[1], S. Hunt[2], G.H. Williams[3], J-M. Lalouel[1], L.B. Jorde[1]* 1) Human Genetics, University of Utah, Salt Lake City, UT; 2) Department of Medicine, University of Utah, Salt Lake City, UT; 3) Brigham and Women's Hospital, Boston, MA.

Angiotensinogen (AGT) is the initial precursor of angiotensin II, a potent vasoconstrictor and regulator of blood pressure. Genetic variation at the angiotensinogen locus has been implicated in essential hypertension (EH). To further assess the genetic contribution of AGT variation to the hypertensive phenotype, we genotyped 24 SNPs (m.a.f. > 0.05) that span the promoter and exonic regions of the AGT locus in 372 hypertensive and 129 normotensive European-American subjects. Six SNPs were strongly associated with the hypertensive phenotype ($p < 0.01$). Four haplotype blocks were identified statistically in the 14 kb genomic region, and at least one haplotype in each block showed association with EH ($p < 0.05$). Interestingly, SNPs comprising one of the blocks were not associated with EH when tested individually, suggesting increased power to detect associations using haplotypes rather than individual polymorphisms. Combining the associated haplotypes from the 4 blocks revealed an extended haplotype present in 6% of controls and 11% of EH cases ($p < 0.017$). The extended haplotype was confirmed in one hypertensive individual homozygous for all 24 loci. This haplotype contains 6 promoter variants including the -1074T, -532T, -217A, -6A polymorphisms and the non-synonymous 4072C change (235T). No significant associations were found for African-American cases (59) and controls (21).

We also assessed the ability of HapMap tag SNPs to detect associations with EH. Seventeen SNPs were identified as tagging SNPs for Europeans using the HapMap. Nine of these were represented in our set of 24 SNPs identified from complete resequencing data and typed in our cases and controls. One tagging SNP, rs2004776, located less than 2 kb from -6A, was strongly associated with EH ($p < 0.001$). This result indicates that HapMap haplotype tagging SNPs could have successfully identified an association between AGT SNPs and essential hypertension in this case-control study.

C282Y and H63D Mutations in the HFE Gene, Are Not Rare In Jews of North African Ancestry In Israel. *O. Reish[1], V. Libman[1], G. Goltsman[2], I. Lorber[2], D. Chapman- Shimshoni[1]* 1) Genetics Institute, Assaf Harofeh Medical Center, Zerifin, Israel and The Sackelr School of Medicine, Tel Aviv University, Tel Aviv Isarel; 2) Department C of Internal Medicine, Assaf Harofeh Medical Center.

Hereditary Hemochromatosis (HHC) is one of the leading causes of iron overload due to increased absorption of dietary iron from the GI tract leading to iron accumulation and dysfunction of multiple organs. Only two mutations, C282Y and H63D in the HFE gene cover more than 95% of HHC chromosomes. About 60-90% of the patients are homozygotes for C282Y, while compound heterozygosity for C282Y/ H63D contributes to additional 3% of disease causing chromosomes. Despite being among the most common autosomal recessive diseases in Caucasians from North Europe, the disease has rarely been described in the Jewish population. We describe here an independent segregation of C282Y and H63D mutations in one family of Moroccan ancestry leading to 2 clinically affected patients with C282Y/ C282Y and one young, yet unaffected individual, with C282Y/ H63D genotype. We also screened 191 chromosomes derived from healthy North African Jews for the C282Y mutation and detected 4 mutated chromosomes. Screening for the H63D mutation showed 29 mutated out of 169 screened chromosomes. This preliminary study demonstrates gene frequency of 0.021 for the C282Y and 0.17 for the H63D, that correlate with carrier frequencies of 1/24 and 1/3 respectively. These findings may raise the possibility of under recognition of HHC among Jews of North African ancestry, and should increase the index of suspicion for this disease at least when initial clinical findings are detected.

Clinical and molecular studies of thirteen families with achromatopsia. *W. Wiszniewski, R.A. Lewis, J.R. Lupski*
Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Achromatopsia (ACH) or rod monochromacy is an autosomal recessive and genetically heterogeneous disease. It is characterized by a lack of color discrimination, poor visual acuity, photophobia and pendular nystagmus. Patients show absence of functioning cone photoreceptors in the retina in electroretinographic recordings while rod function is preserved. To date mutations in three genes have been reported including and subunits of the cyclic nucleotide-gated cation channel (CNGA3 and CNGB3 respectively) and cone photoreceptor transducin - GNAT2. The aim of this study was to determine the prevalence of mutations in ACH causing genes in a cohort of thirteen patients with both clinical and electroretinographic evidence for the disease. The patients were screened for mutations in each gene by direct sequencing of all coding exons. Mutations were detected in twelve out of thirteen families finding twenty two mutated alleles. Of the twelve ACH patients with detected mutations, nine had alterations in the CNGB3 gene, three in CNGA3 and none in GNAT2. The most frequent mutation - T383fs in CNGB3 was found in fifteen alleles. The analysis of SNPs within CNGB3 in unrelated patients with T383fs revealed transmission of a common haplotype. The high frequency of this mutation may reflect a founder effect. We identified three novel variants (R223G, G557R and L664F) in CNGBA and one (S435R) in CNGB3. We conclude that defects of these two genes are responsible for the vast majority of cases with complete achromatopsia.

Family Based Association Tests between sclerostin (*SOST*) gene and obesity phenotypes in a large sample. *L. WANG[1], L.J. ZHAO[3], D.H. XIONG[3], R.R. RECKER[3], H.W. DENG[1,2,3,4]* 1) Xi'an Jiaotong University, Xi'an, Shaanxi, 710049, China; 2) School of Medicine, University of Missouri- Kansas City, Kansas City, Missouri, 64108-2792, USA; 3) Osteoporosis Research Center and Department of Biomedical Sciences, Creighton University, Omaha, Nebraska, 68131, USA; 4) College of Life Sciences, Hunan Normal University, Changsha, Hunan 410081, China.

Introduction: Mesenchymal stem cells have the capacity to differentiate into osteoblasts and adipocytes. Such differentiations are triggered by cytokines and/or proteins. The secreted protein product of the *SOST* gene, sclerostin, is one of the regulation proteins.

Methods: To investigate the association between *SOST* polymorphisms with obesity, four SNPs of *SOST* gene were genotyped in 1,873 Caucasian subjects from 405 nuclear families. Five obesity related phenotypes, including obesity (defined as BMI exceed 30kg/m^2), fat mass, body mass index (BMI), lean mass and percentage of fat mass (PFM), were measured by dual-energy X-ray absorptiometry (DEXA). Linkage disequilibrium (LD) block structure of the *SOST* gene was examined by the program Haploview. A family-based association test (FBAT) was performed for the traits of obesity.

Results: Marginal significant association was found between SNP4 (rs1230393) and the three quantitative obesity-related phenotypes (fat mass, BMI and PFM). Haplotype A-G-G-G, with frequency of 0.32, showed significant association with fat mass, BMI and PFM (P = 0.0036, 0.0021, and 0.0036, respectively).

Conclusion: This study provides the first evidence that the genetic variation of *SOST* is associated with phenotypes of obesity.

Second Trimester Invasive Trophoblast Antigen (ITA) as a Down Syndrome Marker: A Prospective Cohort Study Using Fresh Serum Samples. *G. Palomaki[1], L. Neveux[1], C. Meier[2], P. Wyatt[3]* 1) Women & Infants Hospital, Providence, RI; 2) St. Michael's Hospital, Toronto, Canada; 3) York Central Hospital, Toronto, Canada.

Aim: Examine Down syndrome screening performance of second trimester ITA measurements, both alone and in combination with other biochemical markers. **Method:** For 1 year beginning in 11-2003, 20,346 women in Toronto provided a second trimester serum sample for Down syndrome screening (including 60% for an integrated test). Samples were tested for AFP, uE3 and hCG. ITA testing was performed on fresh samples with results converted to weight and race-corrected MoM levels, but not used clinically. 31 Down syndrome pregnancies were identified. **Results:** 18,462 women had ITA and triple markers, including 28 affected with Down syndrome. At a 5% false positive rate (FPR), 9, 8, 12 and 15 of the 28 cases were detected using AFP, uE3, hCG or ITA alone. The median MoM in Down syndrome pregnancies for hCG and ITA were 2.14 and 3.46. The logarithmic SD for hCG and ITA in unaffected pregnancies were 0.2252 and 0.2939 and 0.2678 and 0.3858 in Down syndrome pregnancies. Correlations between hCG and ITA were 0.801 and 0.868. At a fixed cut-off level for a 35 year old woman, the triple test with hCG or ITA detected 24 of 28 cases (86%, 95% CI 67% to 96%) with FPRs of 7.5% and 6.9%. When ITA and hCG were included with AFP and uE3, 23 of 28 (83%) cases were detected, with a 6.5% FPR. **Conclusions:** The observed performance of ITA and hCG in the second trimester (using fresh samples) is consistent with predictions from an earlier study of 45 cases, where sera were stored for 8 years, thawed and measured (Clin Chem 50:1804, 2004). The study predicted that 66% of cases can be detected by either version of the triple test. Using both ITA and hCG in a quadruple test improved detection to 76%. **Observed rates are higher than predicted. The reduced detection associated with including both markers is likely due to the small number of cases.** Based on these two datasets, ITA is a suitable replacement for hCG in second trimester screening, and screening is likely to be improved when both are measured and interpreted together with other second trimester markers.

Disclosing misattributed paternity: A survey of genetic counselors in the United States and Canada. *S.A. Zelenietz[1], C. Harrison[2], C. Trevors[1], C. Shuman[1], D. Chitayat[1, 3], P. McKeever[4]* 1) Genetics, HSC, Toronto, ON, Canada; 2) Department of Bioethics, The Hospital for Sick Children, Toronto, ON; 3) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, ON; 4) Faculty of Nursing, University of Toronto, Toronto, ON.

The inadvertent discovery of misattributed paternity (MP) may lead to conflicts between professional obligations, ethical principles and the interests of the parties involved, thereby making it difficult to determine to whom to disclose this information. Previous studies have shown that genetic counselors (GCs) typically disclose MP to the female partner only; however, these reports have been narrow in scope, drawing conclusions from single case scenarios. The purpose of this study was to explore practice regarding the disclosure of MP, and to determine how GCs made this decision in diverse situations. GCs were surveyed using four case scenarios designed to simulate dilemmas in the disclosure of MP. Of the 273 survey respondents, 204 (75%) completed at least one case scenario. Respondents had been practicing for an average of 6.6 years, had seen an average of 1.6 cases of MP, and most (97.2%) indicated that their employer did not have a documented policy that governed the disclosure of MP. Overall, the results revealed little consensus concerning the disclosure of MP both within and between case scenarios. GCs chose to disclose MP to the female partner, male partner, child, or not to disclose. GCs considered factors including determination of the primary patient, the information included in the signed consent, the provision of accurate genetic counseling, the biological fathers right to know his carrier status, and the medical relevance of MP in medical decision-making. Non-maleficence was the most often cited ethical principle used in decision-making. The lack of consensus found in this study suggests that developing institutional guidelines and/or a professional position statement concerning the disclosure of MP would benefit GCs. Such policies could lead to the development of a decision-making framework which would serve to help guide GC practice.

A Robust Multiple Testing Method of Controlling the False Discovery Rate. *M. Rao, R. Chakraborty* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

Currently multiple testing is almost a routine scenario in most statistical genetic applications. However, in most genomic studies, the individual tests are not necessarily independent, nor the joint distribution of their significance levels (p-values) can be parametrically specified. Data on genome-wide, or candidate gene based association studies, gene expression data on arrays of genes involving multiple networks (or pathways) are examples of such situations, where hundreds, if not thousands of tests, are required to be simultaneously performed, with no assumption on the joint distribution of their p-values. Standard Bonferroni-type of adjustment of multiplicity effect in multiple testing only controls the Family Wise Error Rate (FWER), but the False Discovery Rate (FDR) has gaining acceptance as the prime choice of error rate, which needs to be controlled. A step-up procedure of sequential inference, suggested recently, has an upper bound of FDR, based on the number of tests performed, proportion of true null hypotheses, and the over-all level of significance of the test procedure. In this research, we propose a step-down multiple testing procedure, built sequentially on the basis of the ordered p-values of the individual tests, and show that the upper bound of the FDR of the proposed test procedure is smaller than that of the step-up procedure suggested in the literature. Like the step-up procedure, the newly suggested step-down procedure also does not need any assumption regarding the joint distribution of p-values of the individual tests. Numerical illustrations of the efficiency of reduced FDR (i.e., ratio of upper bounds) are given for some choice of parameters (i.e., number of tests, proportion of true null hypotheses, etc.) that may commonly be encountered in genomic data analyses. (Research supported by US Public Health Service grant GM41399 from the US National Institutes of Health).

Transcriptional Profiling of Nicotine Dependence. *R. Philibert, G.-Y. Ryu, J.-G. Yoon, H. Sandhu, N. Hollenbeck, T. Gunter, A. Barkhurst, A. Madan* Psychiatry, University of Iowa, Iowa City, IA.

Transcriptional profiling has been used to identify gene expression patterns indicative of general medical illnesses such as atherosclerosis. However, whether these methods can identify common psychiatric disorders has not been established. To answer this question with respect to nicotine use, we used genome wide expression profiling (n=15) followed by real-time PCR (RT-PCR) (n=94) to examine gene expression patterns in lymphoblast derived RNA from 94 subjects in the Iowa Adoption Studies. As compared to controls without a history of smoking (n=9), 1163 of 29,0908 known genes were found to be differentially expressed two fold or more with false discovery rate of 5%. Of these, 579 genes were significantly up-regulated and 584 genes were significantly down-regulated. RT-PCR confirmation of three select RNA levels confirmed the validity of the overall profile and revealed highly significant relationships between 1) major depression, 2) nicotine use and 3) cannabis use. We conclude that the use of expression profiling may contribute significant insights into the biology of complex behavioral disorders and serve as a laboratory mechanism to confirm and extend clinical diagnosis of these disorders.

Analyzing and modeling dichotomous traits in large complex pedigrees. *C. Papachristou, C. Ober, M. Abney*
Human Genetics, University of Chicago, Chicago, IL.

Although it is believed that many common complex disorders have a genetic basis, attempts to unravel the transmission mechanism governing such traits have met with limited success. This shortcoming is partly attributed to genetic heterogeneity, trait loci of small contribution, and large contributions from environmental factors. It has been suggested that isolated founder populations, particularly ones with a large, known pedigree, may be advantageous for complex trait mapping. This is not only because of their extensive genealogical information, but also because a small number of founders is expected to reduce the number of alleles that contribute to susceptibility, and the homogeneity in lifestyle and uniformity of environment significantly attenuate many confounding effects. We are proposing a likelihood method for mapping dichotomous traits based on data from complex pedigrees. This method is an extension to that introduced by Abney et al. (2002) for mapping QTLs, which was developed in the context of linear mixed models. A natural extension of their method to accommodate binary traits can be easily found in the framework of the generalized linear mixed models (GLMMs) (McCulloch and Searle 2001). More specifically, our approach is based on a hierarchical model where we first assess the probability of each individual having the trait and then formulate a likelihood assuming conditional independence of individuals. The advantage of our formulation is that it easily incorporates information from pertinent covariates as fixed effects, as well as taking into account the correlation between related individuals that share genetic background through random effects. Due to the high dimensionality of the integration involved in the likelihood, exact computations are infeasible in most cases. Instead, a Monte Carlo expectation maximization (MCEM) algorithm is employed for obtaining the maximum likelihood estimates of the polygenic model parameters. We have developed a software package that efficiently implements our method and we are using it to analyze data from a 13-generation pedigree consisting of 1,653 Hutterites, focusing on the diabetes phenotype.

Defining Subphenotypes for Orofacial Clefts Based on Dental Development. *A. Letra[1,2], R. Menezes[1], J.M. Granjeiro[3], M.E. Cooper[1], M.L. Marazita[1], A.R. Vieira[1]* 1) Oral Biology and Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Biological Sciences, University of São Paulo, Bauru, SP, Brazil; 3) Department of Cellular and Molecular Biology, Fluminense Federal University, Niterói, RJ, Brazil.

Subjects with cleft lip/palate (CL/P) present more dental anomalies (DA) than controls. It may be an indication that DA are an extended phenotype of CL/P. 1,000 individuals, 500 with CL/P and 500 controls were examined to determine presence of DA outside the cleft area such as tooth agenesis (TA), microdontia, supernumerary teeth (ST), tooth impaction, tooth malposition, shape anomaly and transposition. Cleft individuals were divided according to cleft completeness or incompleteness and laterality. Cleft cases presented significantly more DA than controls (OR=8.72; 95%CI: 6.05-12.56). TA was most frequently observed affecting the left side in cases with complete unilateral right clefts (p=0.01). Contrarily, cases with unilateral left clefts presented more TA on the right side (p=0.01). Bilateral TA occurred more commonly in cases with bilateral clefts (p=0.04). TA affecting upper teeth was more common to unilateral right clefts (p=0.02). Left lateral incisors were most frequently absent in cases with unilateral right clefts (p=0.00001). The opposite was true for right lateral incisors, which were most frequently absent in cases of unilateral left clefts (p=0.007). Cases with complete unilateral right clefts presented more microdontia of upper left teeth (p=0.00001). As for ST, most were observed in cases with unilateral left clefts (p=0.002) with no significant differences when comparing side of the ST. Lower canines are more commonly rotated (lingual surface facing buccal) than any other type of teeth in cleft cases (p=0.00001). The consistent presence of DA on the opposite side of unilateral clefts with preferential TA of the lateral incisor could mean an unsuccessful bilateral cleft, and, moreover, the genes that contribute to laterality of the cleft may be different resulting in alternate phenotypes for DA also. Supported by NIH grants R21-DE016718, R01-DE016148, P50-DE016215, and CAPES BEX341305-5, Brazil.

Detecting Disease-Gene Association in the Presence of Misclassification of Control Subjects. *R. Seiver, M. Rao, X. Lei, R. Chakraborty* Ctr Genome Information, University of Cincinnati, Cincinnati, OH.

Population based case-control designs have gained popularity in recent years for disease-gene association studies. Though case-control study designs have been used for a long time in epidemiological research, for several diseases precise methods of control selection is hampered by lack of consent of subjects or invasiveness of tests for determining affection status of subjects. When controls are selected based on less rigid criteria of determining affection status, or for late onset of diseases, some fraction of recorded controls may indeed be affected. In this research, we derive analytical formulae to predict the extent of dilution of the strength of disease-gene association (odds ratio, OR) in the presence of misclassification errors in controls. We obtained the maximum likelihood estimate of OR in the presence of misclassification, and developed algorithms to determine the extent to which power of detecting significant OR is reduced in the presence of misclassification error. Effect of misclassification on diluting the strength of OR appears to be insensitive to the prevalence of allele/genotypes in controls. For example, with 10% misclassification rate in controls, OR reduces from 1.5 to approximately 1.43 for a prevalence rate in the range of 1 to 20 percent in the controls. Of course, with increasing rate of misclassification, OR gets closer to one monotonically, consequently reducing the power of detecting its significance. A user-friendly web-based software is developed for systematic evaluation of reduction of power for any specified fraction of control subjects that are truly affected. (Research supported by US Public Health Service grant GM41399 and a Summer Undergraduate Research Training grant (REU) from the US National Institutes of Health).

Genetic evaluation of the serotonergic system in Chronic Fatigue Syndrome. *A.K. Smith, M.S. Rajeevan* Centers for Disease Control & Prevention, Atlanta, GA.

Chronic Fatigue Syndrome (CFS) is a significant public health problem of unknown etiology. Central nervous system abnormalities, particularly hyperactivity in the serotonergic (5HT) and hypoactivity in the hypothalamic pituitary adrenal axis (HPA) systems, have been implicated in the pathogenesis of CFS. Since alterations in 5HT signaling may result in altered HPA activity, polymorphisms were examined in genes of the serotonergic system to identify putative risk factors for CFS and potential mechanisms for altered serotonin or HPA systems. A total of 79 polymorphisms in 14 genes related to serotonin synthesis (*TPH2*), signaling (*HTR1A, HTR1E, HTR2A, HTR2B, HTR2C, HTR3A, HTR3B, HTR4, HTR5A, HTR6,* and *HTR7*), transport (*SLC6A4*), and catabolism (*MAOA*) were examined in 137 subjects (40 CFS, 55 with insufficient fatigue, and 42 non-fatigued controls) derived from a study in Wichita, Kansas. Subjects participated in a clinical evaluation where exclusionary conditions were identified and assessment of functional impairment, fatigue and symptoms was performed. Three polymorphisms located in the 5HT receptor subtype *HTR2A* (rs6311, rs6313, and rs1923884) were associated with CFS when compared to non-fatigued controls (p=0.0065-0.015). Consistent associations were observed between *HTR2A* variants and quantitative measures of functional impairment (p=0.0031-0.040), fatigue (p=0.0037-0.047) and symptoms (p=0.017-0.022) in all subjects. No haplotype effects or gene-gene interactions were observed. The most compelling association was with rs6311 (-1438 G/A). Functional studies of rs6311 report increased promoter activity with the A allele relative to the G allele. *In silico* analysis of the variants revealed that the rs6311 A allele creates a consensus binding site for Th1/E47, a transcription factor expressed in the brain and implicated in nervous system development. These results suggest enhanced activity of HTR2A in CFS subjects carrying the rs6311 A allele and supports the hypothesis that alterations in the serotonergic or HPA axis systems are involved in the development or progression of chronic fatigue. Future studies will be needed to verify Th1/E47 binding at rs6311 and to replicate these findings in a larger group of subjects.

Large-scale sequence variation detection in diploid samples using Affymetrix arrays. *A.B. Sparks, N. Patil, F. Collin, S. Walsh* Affymetrix, Santa Clara, CA.

Large-scale sequencing projects require increasingly rapid, accurate, and cost-effective methods for variant detection. Affymetrix next-generation GeneChip CustomSeq Resequencing Arrays employ higher density 8m X 8m features, improved sample prep methods, and improved base calling algorithms to enable analysis of up to 300kb of unique DNA sequence on a single chip. To demonstrate the performance of these arrays in detecting SNPs in diploid samples, we designed a chip to query 300kb of contiguous sequence within an ENCODE interval on chromosome 4. A 250kb region was amplified from each of 16 CEPH DNA samples using 25 long range PCR amplicons, and the resulting 16 sets of PCR products were pooled, fragmented, labeled, and hybridized to arrays. The arrays were stained and scanned, and the intensity data from the 16 scans was analyzed using the GSEQ 4.0 base calling software package, set to detect heterozygous as well as homozygous variants. The array-derived base calls were compared to reference capillary sequence/genotyping data obtained from the ENCODE project for the same 250kb interval in the same 16 CEPH samples. The array call rates across the 16 samples ranged from 95% to 98% (average of 96.5%), whereas the capillary sequence coverage ranged from 67% to 81% (average of 74%). Average call rates remained above 90% for probe GC compositions ranging up to 70%. Overall array base call accuracy (as compared to the reference dataset) was found to be 99.95%. The homozygous variant detection rate was 96.9%, and the heterozygous variant detection rate was 89.1%. Approximately 4 in 10,000 non-variant positions were identified as variant in the array-derived base call data. To reduce this false-positive rate, we developed a set of post-GSEQ filters, which together increased the overall accuracy from 99.95% to 99.98% and decreased the rate of false positives from 4 in 10kbp to 1.6 in 10kbp, while only decreasing the overall call rate from 96.5% to 96.0%. To demonstrate the utility of arrays for querying discontinuous sequences, we have designed a kinase exon resequencing chip. Sample prep methods and performance data for this array will be presented.

Identification of genetic epistasis models within large SNP datasets. *D.A. Ross[1], J. Shaw[2], G. Shaw[2], J.H. Moore[3], B. White[3], J. Sninsky[1], M. Frome[2]* 1) Celera Diagnostics, Alameda, CA; 2) Focus Biology, San Jose, CA; 3) Dartmouth College, NH.

Causation in complex disease is manifested as a spectrum of genetic and environmental effects. The genetic effects range from rare events with large effect to common polymorphisms with modest to large effects. Systems biology experiments suggest that proteins/RNA interact as modules to perform tasks; SNPs effecting gene function could have epistatic effects within or between modules that would lead to variation in epidemiological causes of the disorder. Statistical methods are being explored to identify these epistatic interactions. The problem is in three parts. 1. Can the SNPs in a model be extracted from a large dataset with high specificity? In a real dataset there are false positives that do not replicate in additional datasets; it is therefore important that the model SNPs be extracted consistently and the metric used to rank the SNPs be robust. 2. Can the model SNPs be extracted when increasing numbers of noise SNPs are added? This requires a parallel computation algorithm for large numbers of SNPs. Using either a functional genome scan of 30K SNPs or a positional genome scan of 500K SNPs should not impact specificity and occur with acceptable runtimes. 3. Can the original model be regenerated given the cut-off used in part 1? We have used the suite of data mining techniques in FOCUS Biologys FOCUS Discovery SNP analysis software and evaluated the search for two genetic models. The epistatic models investigated included four SNPs. In model A, two of the SNPs have a dominant-dominant interaction (M27)(Li and Reich Human Heredity(2001)) and two SNPs lacking main effects (M170). Model B has two pairs of SNPs interacting as M170. All SNPs are in HWE. Heritability, in the broad sense, was examined at 0.4, 0.2, 0.1 and 0.05 with ten replicates for each model type and level of heritability. Under all levels of heritability, FOCUS Discovery successfully identified the SNPs at high sensitivity and specificity, even with Model B, down to a heritability of 0.05, the 4 SNPs were identified in the top 3%. Evaluation of the models with 300 to 300K noise SNPs will be presented.

Likelihood ratio tests of association for X-linked QTL in family-based designs. *L. Zhang[1,2], R.W. Morris[2,3], R.-H. Chung[1,2], E.R. Martin[2], Y.-J. Li[2]* 1) Bioinformatics, NCSU, Raleigh, NC; 2) Center for Human Genetics, DUMC, Durham, N.C; 3) Anesthesiology, DUMC, Durham, N.C.

Although genetic association methods for detecting quantitative trait loci (QTL) in family-based designs have been well developed for autosomes, comparable methods for X-linked QTL have received little attention. Here we develop a test for genetic association using X-linked markers in nuclear families with multiple offspring and possibly missing parental genotype information. We extend the model of Abecasis et al. (2000) by modifying the scheme for scoring marker genotypes in the sexes, and by incorporating variance components developed by Kent et al (2005). We show that the fixed effect within family remains a direct estimator of additive genetic value conditional on sex. Restricted Maximum Likelihood (REML) and Fisher Scoring method are applied to calculate variances of the random genetic or environmental effects. The means of the fixed effects between and within families are estimated through General Least-Squares Estimation. In addition, we introduce a parameter for dosage compensation, which can be used to model X-inactivation in females. Simulation results show correct type I error rates and that estimates of the genetic effect of marker alleles is unbiased and equal that of QTL alleles when linkage disequilibrium between the marker and QTL is maximum. Power is illustrated for a variety of nuclear family structures and genetic models. The loss of efficiency with missing parental genotypes can be offset by additional sibling genotype information. As an example in real data, we present analysis of monoamine oxidase genes (MAOA and MAOB) on the X chromosome using age of onset of Parkinson disease as a quantitative trait.

Subtelomeric chip: Novel assay for detection of subtelomeric and genome wide aberrations. *G.A. Toruner, D. Streck, J.J. Dermody, M.N. Schwalb* Center for Human and Molecular Genetics, UMDNJ - NJ Medical School Newark, NJ.

Global developmental delay (GDD) and mental retardation (MR) are important child heath issues. According to various estimates, the prevalence of GDD/MR is between 1-10%. During the genetic evaluation of GDD/MR, in addition to history and physical examination, laboratory tests such as karyotyping, subtelomeric FISH, mutation analysis of FMR1 and MECP2 genes are performed. The total yield of these diagnostic tests is only 10%. Microarray comparative genomic hybridization (CGH) has been developed to detect deletions or duplications in very small segments of chromosomes and the use of this technology is expected to increase the diagnostic yield. The major limitation of the current BAC based array technologies employed in some clinical diagnostic labs, however, is the low resolution (~1MB) of the chip and having not enough coverage in the subtelomeric regions. Our aims were to design a novel array-CGH chip with high-density coverage in the subtelomeric regions and to conduct a pilot study in previously clinically tested specimens for the evaluation of the novel array. For this purpose, we used Human Genome CGH Microarray 44B chip (Agilent), which contains 42K test probes and 2K control probes, as the template for the novel design. Using e-array 4.0 (Agilent), one third of the probes were randomly removed from the chip and replaced by 14,000 subtelomeric probes (probes at most 1MB away from telomeres) The average density of the probe coverage is 3 KB in subtelomeric regions and 125 KB genome wide. Currently, eighteen clinical samples were tested (including subtelomeric aberrations and other microdeletion syndromes) and the concordance rate between chip results and conventional lab testing is 100%. The results of the pilot study are highly encouraging and the analysis of additional samples are still undergoing.

A small molecule enhances RNA interference and promotes the biogenesis of microRNAs. *G. Shan[1], J. Zhang[2], K. Szulwach[1], Y. Qin[1], R. Duan[1], H. Ju[1], A. Chan[1], C. He[2], P. Jin[1]* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Chemistry, University of Chicago.

RNA interference (RNAi) is a well-conserved and universal mechanism that uses small noncoding RNAs to silence gene expression post-transcriptionally. The endogenous small RNAs, called microRNAs (miRNAs), are processed from hairpin precursors and could shape diverse cellular pathways. Since small double-stranded RNAs, called small interfering RNAs (siRNAs), could induce sequence-specific mRNA degradation when introduced into cells, RNAi has become attractive for functional genomics and human therapeutics. Although the major components in the RNAi pathway have been identified, however, the regulation of this pathway remains largely unknown. Here we have developed a novel cell-base assay to monitor the activity of RNAi pathway and taken a small-molecule-based approach to dissect the RNAi pathway. Through screening a chemical library with diversified compounds, we have identified a small molecule (RNAi-E) that could enhance siRNA-mediated mRNA degradation as well as miRNA-mediated translational suppression. Furthermore, RNAi-E could promote the biogenesis of endogenous miRNAs. We identified TRBP as the potential protein target of RNAi-E. Application of RNAi-E could enhance the knocking-down efficiency of both siRNA and shRNA as well as reduce the dosage of siRNA duplex at least 5-fold. We also demonstrated that RNAi-E could function in animal models including C. elegans and mice. The identification of RNAi-E not only helps further understand the modulation of the RNAi pathway, but also facilitates the development of siRNAs as therapeutic reagents.

Combined saposin C and D mutations in mice affect processing of prosaposin and lead to a severe neurological phenotype with predominant glucosylceramide and hydroxy ceramide accumulation. *Y. Sun[1], M. Zamzow[1], H. Ran[1], B. Quinn[1], W.P. Witte[2], G.A. Grabowski[1]* 1) The Division and Program in Human Genetics; 2) Division of Pediatric Pathology, Children's Hospital Research Foundation, and University of Cincinnati College of Medicine, Department of Pediatrics, Cincinnati, OH.

Saposins (A, B, C and D) are ~80 amino acid glycosphingolipids activator proteins that derive from their precursor, prosaposin. In both humans and mice, prosaposin/saposin deficiencies lead to severe neurological deficits. Deficiencies of individual saposins have been reported in only a few humans, thus limiting the availability of the patient samples for physiological function analysis. Here, the generation of saposin C and saposin D combined deficiencies (CD-/-) in mice were produced by introducing mutations into critical cysteines of each saposin. The mutations of saposin C and D influenced the processing of prosaposin, and led to increases of prosaposin and decreases of saposin A and B cellular levels. The CD-/- mice developed a severe neurological phenotype and showed ataxia, kyphotic posturing and hind limb paralysis. They had an extended life span (~56 days) relative to prosaposin null mice (~30 days). Loss of Purkinje cells was evident after 6 weeks. The storage cells were in spinal cord, brain and dorsal root ganglion. There were marked accumulations of glucosylceramides and hydroxy ceramides. Only slight increases of lactosylceramide (LacCer) were present in liver suggesting that saposin B compensates for saposin C in LacCer degradation in specific tissues. In addition, the deficiency of saposin C in CD-/- mice resulted in decreases of GCase activity and protein. This CD saposin mutant mouse provides a model to explore the in vivo function of saposin(s) in glycosphingolipid metabolism and lysosomal storage diseases.

Spatiotemporal patterns of Bex1/2 expression in developmental mouse brains. *J.Z. Yang[1], W. Ju[2], H. H. Zhu[1], J. Shen[2], G.Y. Wen[2], C.P. Corbo[2], R. Zhong[1], Y.Z. Zhang[1], J.H. Zou[1], W.T. Brown[2], N. Zhong[1,2].* 1) Peking University Center of Medical Genetics, Beijing, China; 2) New York State Institute for Basic Research.

The Bex (brain expressed X-linked) is a gene family comprised of Bex1-6, named originally with the characteristics of highly expressed in brain and localized at chromosome X. Among Bex1-6, Bex1 and Bex2 share a high homologue in their primary sequences and were characterized to interact with an olfactory marker protein (OMP). However, biological features of Bex1/Bex2 involved in brain development are yet unknown. ThereforeJun, we have undertaken a study to investigate the protein expression and localization of Bex1/Bex2 in the mouse developmental brains. Our results showed a spatiotemporal expression pattern of Bex1/Bex2 at different stages of mouse developmental brains. Bex1/Bex2 were expressed comprehensively in E15 and P0 mouse brain, non-diffusely located in specified encephalic region and nucleus groups. High expression was observed in olfactory system, hypothalamus and limbic system such as hippocampus, cingulum and amygdaloid nucleus. Subcellular localization in human SY5Y neuroblastoma cell line indicates Bex1/Bex2 are cytoplasm protein with a few distributions in the neuronal nuclei, which can be confirmed by electronic immunogold stain. The spatiotemporal expression patterns suggested Bex1/Bex2 might have played some functional roles in the neuron differentiation and brain development.

X-linked and autosomal gene expression in human tissues: Male and female comparisons. *Z. Talebizadeh, S.D. Simon, M.G. Butler* Childrens Mercy Hospital and University of Missouri-Kansas City, Kansas City, MO.

Dosage compensation in mammalian females occurs in early development and results in inactivation of one X chromosome leading to equality of X-linked gene products between male and female. X chromosome genes, in particular, are of interest for their involvement in neurodevelopmental disorders such as mental retardation and autism where unequal gender prevalence exists, but not all X-linked genes are inactivated. *In vitro* assays using somatic cell hybrids or human fibroblasts suggest that 25% of X-linked genes escape inactivation at least to some degree but *in vitro* results may not reflect what happens *in vivo*. Therefore, we analyzed the female/male (F/M) gene fold expression ratio from 11 different tissues of an existing *in vivo* microarray database including 14 males and 10 females for 299 X-linked and 7,795 autosomal genes to determine the percentage of X-linked genes compared with autosomal genes that are overexpressed (or underexpressed) in females. On average 5.1 and 4.9% of genes showed higher expression (F/M gene fold ratio 1.5) in females compared with 7.4 and 7.9% in males, respectively for X-linked and autosomal genes. More variations were seen in gene expression from the cerebrum and adrenal gland compared with other tissues studied. A trend was found for F/M gene fold ratios greater than 1.5 for several X-linked genes indicating overexpression in females among multiple tissues. Only nine (3%) of the 299 X-linked genes showed overexpression in females in at least 3 of the 11 tissues studied. Of the 9 genes, 6 were located on the short arm and 3 on the long arm of the X chromosome. Six (*HDHD1A*, *PNPLA4*, *AP1S2*, *ZFX*, *UTX*, and *RPS4X*) of the 9 genes were previously reported to escape X inactivation. However, in general, no consistent pattern was seen for the expression of X-linked genes between *in vitro* and *in vivo* systems. This study indicates that factors other than the X inactivation process (e.g., sex hormone influence, tissue specificity, monoallelic expression) may impact on expression of X-linked genes resulting in an overall similar gender expression for both X-linked and autosomal genes.

Comprehensive and highly efficient molecular diagnostics of autosomal dominant polycystic kidney disease (ADPKD) by mutation screening. *S. Rossetti[1], M.B. Consugar[1], A.B. Chapman[2], V.E. Torres[1], J.J. Grantham[3], L.M. Guay-Woodford[4], C.M. Myers[5], J.P. Miller[6], P.C. Harris[1] for CRISP Consortium* 1) Nephrology, Mayo Clinic, Rochester, MN; 2) Nephrology, Emory Univ., Atlanta, GA; 3) Kidney Inst., Kansas Univ., Kansas, KA; 4) Nephrology, Univ. of Alabama, Birmingham, AL; 5) NIDDK, Bethesda, MD; 6) Biostatistics, Washington Univ., St. Louis, MO.

ADPKD is a common inherited kidney disease characterized by progressively enlarging kidney cysts leading to kidney failure. ADPKD is genetically heterogeneous, *PKD1* accounting for ~85% and *PKD2* for 15% of cases. Diagnostics of ADPKD is mainly performed by renal imaging techniques, but molecular diagnostics plays a role particularly in young, pre-symptomatic individuals, where the imaging data may be inconclusive. We have screened for *PKD1/2* mutations in a large and very well characterized clinical population (the CRISP population) by DHPLC, direct sequencing, and screening for large deletions. We have developed an algorithm to predict the pathogenicity of missense and atypical splicing changes. This included the chemical difference, evolutionary conservation in a multi-sequence alignment, scoring of potential splice variants, and population data (analysis in pedigrees and normal controls). Using this comprehensive screening approach on the 202 probands, mutations were determined in 181 (90% final detection rate). *PKD1* accounted for 155 mutations (86%), and *PKD2* for 26 (14%). For the *PKD1* dataset, 103 (66%) were truncating mutations (either frameshift-50, nonsense-37, or splice-16), 43 (28%) aminoacid substitutions and 9 (16%) small in-frame deletions. For the *PKD2* dataset, 22 (84%) were truncating, and only 4 (16%) aminoacid substitutions or small in-frame deletions. Most of these mutations were private, but 36 changes (20%) were recurrent in apparently unrelated pedigrees. This study has shown the utility of molecular diagnostics in ADPKD with a high overall detection rate, 2/3 of all mutations being truncating, and employing a careful evaluation of other variants for pathogenicity. Molecular diagnostics of this disorder is likely to become very important as therapies are developed and clear diagnoses are required in young individuals.

KABUKI SYNDROME WITH CENANI-LENZ SYNDACTYLY: CASE REPORT. *A.B.A. Perez, N.L.M. Sobreira, M.C.P. Cernach, D. Brunoni* Centro de Genetica Medica, Unifesp - EPM, Sao Paulo, São Paulo, Brazil.

Cenani-Lenz Syndactyly (CLS) is characterized by phalanges with a disorganized aspect, syndactyly and oligodactyly, metacarpal and carpal fusion, radioulnar synostosis, mesomelic shortening of the upper members, luxation of the radial head and feet with a variety of anomalies. There are no defined craniofacial characteristics. Drohm et al.(1976), Verma et al.(1976) and Seven et al.(2000) described large ears. Temtamy et al.(2003) described a broad forehead, downward slanting palpebral fissures, hypertelorism, small and prominent philtrum, malar hypoplasia and curved upper lip, long palpebral fissures, discrete eversion of the lower lid, and high-arched palate. Elliott (2004) described a boy with non-classical Cenani-Lenz syndactyly, with syndactyly and oligodactyly of the fingers and a phenotype consistent with Kabuki Syndrome. The pattern of inheritance is autosomal recessive. Kabuki Syndrome (KS) has a sporadic occurrence and presents limb alterations such as: persistence of pads, brachydactyly, short medial phalanx of the fifth finger, cutaneous syndactyly of the toes and polydactyly. Wessels et al. (2000) evaluated 300 patients with KS, 71% of which had dental anomalies. These are not common in patients with CLS. We report the case of a 6-year-old female patient, the fifth child of a non-consanguineous and healthy couple. On physical examination, the findings were: downslanting palpebral fissures, eversion of the lower lids, long eyelashes, sparse medially flared eyebrows, depressed nasal root, anteverted nostrils, long philtrum, thin upper lip, persistence of pads, spatulated fingers, clinodactyly of fifth fingers. The patients feet presented bilateral syndactyly of the first and second and of the fourth and fifth toes and hypoplasia of the third toe. The patient presents recurrent infections and normal NPMD. Karyotype: 46,XX. The genes causing CLS and KS are unknown and their elucidation may determine to which extent they are genetically related. Meanwhile, a careful evaluation of the craniofacial characteristics of patients with CLS is necessary, in order to correctly characterize this association.

A likelihood approach to defining homozygous tracts using high-density SNP genotypes. *J.P. Struewing, R.J. Clifford, L.H.M. Pereira, M.A. Pineda, C.E. Fasola, H. Zhang, R.P. Finney, J. Zhang, K.H. Buetow* Lab of Population Genetics, NCI/NIH, Bethesda, MD.

Current high-density genotyping platforms allow one to identify chromosomal regions in which a given individual is homozygous, representing possible autozygous segments inherited identical by descent from a common ancestor. We defined homozygous tracts by extension of the likelihood based method of Broman & Weber (AJHG 1999) originally applied to short tandem repeat polymorphisms. A log likelihood odds (lod) score was calculated at each SNP position, contrasting the likelihood of observing the genotype assuming the surrounding segment is autozygous with the likelihood if it is not autozygous. The method accounts for population-specific allele frequencies as well as for genotyping error and mutation. Since SNPs are not independent, the lod score was adjusted using a log-transformation of a recombination measure (in cM/kbp, from the Oxford HapMapI r16c.1 UCSC tract) at each SNP position. We used Affymetrix 500K SNP chip data (490K autosomal SNPs, mean 1 SNP per 5.8kb) for the 4 HapMap populations, and for 12 unrelated, anonymous Bedouin DNA samples. For every run of two or more consecutive homozygous SNP sites in an individual, the adjusted lod scores were summed and a homozygous tract was defined when the score reached 20. Using this threshold, the median number of tracts per subject ranged from 22-66 in the 5 population groups, with median lengths of 567kb to 893kb and SNP density within tracts of 1 per 5.0kb to 6.0kb. Bedouin subjects had a significantly greater proportion of their genome within homozygous tracts (median 2.5%) compared to the other populations (0.6% to 1.0%). Among HapMap populations, 3 JPT subjects and one CEU subject had significantly greater homozygous tracts (2.9% or higher), while 7 Bedouin subjects had this level of homozygosity. We are developing methods to identify genomic regions that are homozygous more frequently in cases than controls. If performed in isolated populations, particularly those with consanguinity, such methods may be a powerful strategy for mapping susceptibility genes for complex traits, especially autosomal recessive alleles.

Genome-wide linkage scan of blood pressure in the Beaver Dam Eye Study: confirmation of multiple loci and identification of novel loci. *C. Xing[1], B.E.K. Klein[2], R. Klein[2], K.E. Klein[2], S.K. Iyengar[1]* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Department of Ophthalmology and Visual Sciences, University of Wisconsin Medical School, Madison, WI.

Blood pressure, as a specific predictor of cardiovascular disease, may contribute to 50% of the global cardiovascular disease epidemic. By understanding the hypertension predisposing genes we may gain insights into novel pathophysiological mechanisms and potential therapeutic targets. The Beaver Dam Eye Study (BDES) is a population-based cohort study of age-related eye diseases, and therefore, it gives us a particular opportunity to study the genetic effect of blood pressure. In the current study we aim to identify the genetic regions / genes predisposing susceptibility to essential hypertension by genome-wide linkage scans. At the time of census 4,926 subjects between 43 and 86 years of age participated in the baseline examination from 1988 to 1990; 602 pedigrees containing at least two eligible participants were then constructed. We already performed a genome-wide scan for systolic blood pressure (SBP) and diastolic blood pressure (DBP) employing the Haseman-Elson regression approach on 1049 sib pairs with the 10-centiMorgan density microsatellite markers map, and identified 15 regions with linkage signals, including novel evidence at 1q24, 2q35, 4q32, 8p21, 10q26, 13q13, and 16p12 (P 0.01) and replications at 2p25, 3q26, 4p15, 8q24, 15q26, 16q12, 17q25, and 20q11 (P 0.05). Currently the Center for Inherited Disease Research is genome-widely genotyping dense single nucleotide polymorphisms (SNPs). We anticipate that with more accurate inheritance information we can localize the hypertension disposing genes by both linkage and association approaches, the results of which will be presented at the meeting.

Anonychia-Onychodystrophy with Hipoplasia or Absence of Distal Phalanges (Cooks Syndome). Report of the first case in México. *E.J. Ramirez-Lizardo[1,2], N.O. Dávalos-Rodríguez[3], S.E. Totsuka-Sutto[1], E.G. Cardona-Muñoz[4]* 1) Instituto de Genética Humana Dr. Enrique Corona Rivera CUCS, Universidad de Guadalajara,Guadalajara,Jalisco, México, elizardo@cucs.udg.mx; 2) Departamento de Genética, Instituto Jaliscience de Cirugía Reconstructiva, Secretaria de Salud Jalisco; 3) Dpto. Genética, Instituto de Seguridad y Servicios Sociales de los Trabajadores del Estado; 4) Unidad de Investigación Cardiovascular, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco México.

The anonychia is defined as the absence of all or part of one or several nails. Anonychia-onychodystrophy with hipoplasia or absence of distal phalanges (OMIM % 106995) or Cooks syndrome is a rare disorder autosomal dominant described in 11 cases in the literature. It is characterized by onycodystrophy, anonychia, brachydactyly of the fifth finger and digitalization of the thumbs, with absence or hypoplasia of the distal phalanges of the hands and feet. The proposita, 6 month old, was born after a 40-week gestation. She was the result of the first pregnancy of healthy and unrelated parents. The father was 17 and the mother was 18 years of age at the time of birth, the history family reveled similar clinical findings in her father. At physical examination showed normal weight and heigh, flat face with prominent eyes, small nose, depressed nasal bridge, high and narrow palate, low-set ears, short neck. Limbs were normal with normal finger and fingernails in hands, on feet bilateral anonychia on 4th toes and bilateral dystrophic toenails on 3rd and 5th toes. The radiological examination was normal in our case and her father showed hypoplasia of the distal phalanges of the feet. The present case show a family with anonychia-onychodystrophy support on the clinical date of partial anonychia and onychodystrophy in the proposita and hypoplasia of the distal phalanges of the feet in her father, this is a condition with autosomal dominant inheritance by the male-to-male transmission observed in 2 families, one reported by Cooks in 1985 and the other by Nevi in 1995 with seven and four affected individuals respectively. To our knowledge this is the first case in Mexico.

Discontinuities and unsynapsed regions in meiotic chromosomes have a trans effect on meiotic recombination of some chromosomes in normal human males. *F. Sun[1, 2], M. Oliver-Bonet[1, 2], T. Liehr[3], H. Starke[3], E. Ko[2], A. Rademaker[4], R.H. Martin[1, 2]* 1) Medical Genetics, University of Calgary, Calgary, Canada; 2) Genetics, Alberta Children's Hospital, Calgary, Canada; 3) Institute of Human Genetics and Anthropology, Jena, Germany; 4) Preventive Medicine, Northwestern University Medical School, Chicago, USA.

During meiosis, homologous chromosome pairing is essential for subsequent meiotic recombination (crossover). Discontinuous chromosome regions (gaps) or unsynapsed chromosome regions (splits) in the synaptonemal complex (SC) indicate anomalies in chromosome synapsis. Gaps and splits were most frequently observed in the heterochromatic regions of chromosome 9, and we have previously demonstrated that gaps and splits significantly altered the distribution of MLH1 recombination foci on the SC 9. Here, recently-developed immunofluorescence techniques (using antibodies against SC proteins and the crossover-associated MLH1 protein) were combined with fluorescence in situ hybridization (using centromere-specific DNA probes) to examine the effect of gaps/splits on meiotic recombination patterns in chromosomes other than chromosome 9 during the pachytene stage of meiotic prophase from three normal human males. Gaps and splits significantly altered the number of MLH1 foci on some SCs. In 64 analyzed cells with a gapped SC 9, the frequency of MLH1 foci in SCs 5 and 10 and in SC arms 10q, 11p and 16q was decreased compared to 168 cells analyzed in controls. In 24 analyzed cells with splits (unsynapsed regions) in SC 9, there was a significant reduction in MLH1 focus frequency for SC 10q and the whole bivalent. The positioning of MLH1 foci in other SCs in cells with gapped/split SC 9 was not altered. These studies suggest that gaps and splits not only have a cis effect, but can also have a trans effect on meiotic recombination distribution in humans.

Familial high myopia in a Polish population. *M. Rydzanicz[1], A. Frajdenberg[2], M. Podfigurna-Musielak[3], S.M. Leal[4], K. Pecold[2], B.A. Bejjani[5,6], M. Gajecka[1,5]* 1) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland; 2) Department of Ophthalmology, Marcinkowski University of Medical Sciences, Poznan, Poland; 3) Department of Ophthalmology, Leszno Hospital, Leszno, Poland; 4) Baylor College of Medicine, Houston, TX; 5) Washington State University, Spokane, WA; 6) Sacred Heart Medical Center, Spokane, WA.

Myopia is the most common of all ocular conditions. Although high myopia (myopia in excess of - 6.0 diopters [D]) is far rarer than mild/moderate myopia, the importance of high myopia is significant because the development of high myopia involves anterior-posterior enlargement of the eye, abnormal changes in the eye and frequent detachment of the retina. The etiology of myopia is not known. Both genetic and environmental factors seem to play a role. In high myopia, genetic factors appear to play a predominant one. To date, we have examined, collected blood and purified DNA from 199 individuals from 32 unrelated high myopia families in Poland. The preliminary genotyping was conducted in 23 families. Prior to proceeding with the targeting genotyping, linkage to markers for Stickler syndrome types I, II and III, Marfan syndrome and juvenile glaucoma were tested. Next, we examined previously proposed familial high myopia loci as a first step before embarking on a genome-wide screen aimed at mapping and cloning gene(s) responsible for high myopia in these Polish families. Genotyping of high-myopia-associated loci [18p11.31 (MYP2), 12q21-23 (MYP3), 7q36 (MYP4), 17q21-23 (MYP5), 2q37, 4q22-4q27 (MYP11), and 10q21.1 were performed. Additionally we performed genotyping to test the linkage for mild/moderate myopia established in Ashkenazi Jewish families [22q12 (MYP6] and to the *PAX6* gene region reported for dizygotic twins [11p13 (MYP7)]. Linkage to Stickler syndrome, Marfan syndrome and juvenile glaucoma loci were excluded. Genotyping with well-spaced polymorphic markers of high myopia associated loci revealed no evidence of linkage to any of the candidate genes. A genome-wide screen is in progress.

OMOSDYSPLASIA: REPORT OF A CASE IN SIBS AND REVIEW OF THE LITERATURE. *N.L.M. Sobreira, A.B.A. Perez, M.C.P. Cernach, D. Brunoni* Centro de Genética Médica, UNIFESP-EPM, São Paulo, São Paulo, Brazil.

Omodysplasia is a skeletal dysplasia with neonatal manifestation, characterized by severe micromelia with shortening of the humerus and femur, radioulnar diastasis of the elbows and facial characteristics. The limb shortening is mainly rhizomelic and involves both the upper and lower limbs. Less common characteristics include NPMDR, congenital cardiopathy and neonatal death. Less than 20 cases are described in the literature and, based on the multiple cases of affected siblings and on the high frequency of consanguinity, there is little doubt about its autosomal recessive inheritance. We report the case of two siblings, the children of young and consanguineous parents. The first case is a 7-year-old girl; her weight was 2400g at birth, when the rhizomelic shortening of her limbs was noted and the diagnosis of achondroplasia was suggested. The patients face displays no phenotypic deviations, she presents rhizomelic shortening of the limbs with extension limitation of elbows and knees, her hands and feet are normal, NPMD is normal, her height is 89.2cm (P2)her upper/lower segment ratio is 1.87 (VR-1.06), span 75cm, CP is 49cm (P2), and the echocardiogram showed persistence of the arterial channel and dilation of the pulmonary stem. The second case is a 5-year-old boy, who had rhizomelic shortening of the limbs noted at birth, and the diagnosis of achondroplasia was suggested. He does not display facial phenotypic deviations, but he has rhizomelic shortening of the limbs with extension limitation of elbows and knees, normal hands and feet, normal NPMD, height of 91.5cm (P2), an upper/lower segment ratio of 1.40 (VR-1.19), span of 67cm, CP of 49cm (P2), and the echocardiogram showed a bicuspid aortic valve. The X-ray study of both patients showed a shortening of the humerus, radioulnar diastasis at the level of the elbows, shortening of radius and ulna, shortening of the femur with a rounded and deviated proximal portion (clubbing). These clinical-radiological characteristics are typical of omodysplasia, and our cases reinforce the autosomal recessive inheritance pattern, whose typical presentation is the involvement of the upper and lower limbs.

Genetics of obesity and its dietary interactions. *L. Perusse* Dept. Preventive Medicine, Laval University, Ste Foy, PQ, Canada.

The yearly updates of the obesity gene map published over the past 10 years provide a good indication of the progress accomplished in the past decade in the search for genes and DNA sequence variations associated with human obesity. According to the most recent version of the map, a total of 426 studies involving 127 different candidate genes have reported positive associations with obesity phenotypes. Despite the large number of genes potentially influencing obesity, only a small fraction of them have been the object of replications in at least five studies. The difficulty to replicate findings of association studies in obesity could be partly explained by the failure of most studies to consider the presence of gene-environment interactions in determining the risk of obesity. This presentation will review the role of genetic factors in obesity and provide an overview of the scientific evidence supporting the key role of gene-diet interactions in the susceptibility to obesity and related metabolic complications. A review of the genes involved in interactive effects with dietary factors will also be presented. Finally, the implications of nutrigenetics in the prevention and treatment of obesity will be discussed.

Genetic Variants in ADIPOR2 are Strongly Associated with Triglyceride and Adiponectin levels in Mexican Americans. *D.K. Richardson[1], J. Schneider[2], J. Blangero[2], M.P. Stern[1], R.A. DeFronzo[1], R. Duggirala[2], C.P. Jenkinson[1]* 1) Department of Medicine, University of Texas Health Science Center at San Antonio, TX; 2) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

Adiponectin is an adipocyte-derived hormone implicated in energy homeostasis, and insulin resistance. Two receptors for adiponectin have been identified (ADIPOR1 and ADIPOR2) both of which are abundantly expressed in skeletal muscle and liver. We genotyped single nucleotide polymorphisms (SNPs) in the ADIPOR2 gene in Mexican American subjects (N=439) from the San Antonio Family Diabetes Study, and performed association analysis of insulin resistance syndrome-related traits. Of 38 SNPs genotyped, 24 were polymorphic in this population. The average proportion of shared variation between SNPs, measured by the pairwise correlation was 0.31 (range 0-0.99). Of these 24 SNPs, 14 were significantly associated with fasting plasma triglyceride and 10 with adiponectin levels ($P<0.05$). Most minor alleles were associated with decreased triglyceride and increased adiponectin levels. Notably, 4 SNPs (rs10848569, rs929434, rs3809266 and rs12342) were in high pairwise linkage disequilibrium ($r2=0.99$) and were strongly associated with triglyceride levels ($P=0.00029$, 0.00016, 0.00027 and 0.00021). After adjusting for the effects of BMI and HOMA-%S on triglyceride concentrations, the association significance increased to $P=0.000060$ for SNP rs929434. Bayesian Quantitative Trait Nucleotide analysis was used to examine all possible models of gene action. SNP rs929434 provided the strongest statistical evidence of an effect on triglyceride concentrations. Haplotype information did not improve the association. The ADIPOR2 locus is close to chromosome 12p13.31 where we reported linkage of triglyceride levels. Linkage analysis conditional on rs929434 decreased the LOD score from 1.85 to 0.98. Thus, 47% of the evidence for linkage, at 12p13.31, was explained by rs929434. In summary, these results provide strong evidence for association of several genetic variants in ADIPOR2 with triglyceride and adiponectin levels in Mexican Americans.

Narrowing in on the genotype-phenotype correlation in 1q terminal deletion syndrome. *N. Scribanu[1], J. Meck[2], C. Kozma[1], J. Blancato[3], L. Matyakhina[2]* 1) Pediatrics, Georgetown University Children's Medical Center, Washington, DC; 2) Obstetrics & Gynecology, Georgetown University Hospital, Washington, DC; 3) Oncology, Georgetown University Medical Center, Washington, DC.

To date, 30 cases of 1q terminal deletion have been reported, the majority of which are deleted from 1q42 or q43 to the terminus (q44). G-banding of lymphocyte chromosomes from a 2-month-old female patient demonstrated an apparent terminal deletion at 1q44. The abnormal chromosome 1 had a significantly diminished signal using a 1q subtelomere FISH probe (Vysis). The remainder of that signal was not noted on any other chromosome, ruling out translocation of the 1q material. This probe is within 300 kb of 1q terminus suggesting that the deletion of 1q is confined to only a portion of 1q44. The baby was delivered at term by C-section to a 35-year-old G1P1 following a pregnancy complicated by IUGR. All growth parameters were below the 5th percentile. Multiple congenital abnormalities were noted including brachycephaly, retromicrognathia, a single umbilical artery, posterior cleft palate, congenital heart defects, bilateral postaxial polydactyly of the lower extremities, and severe unilateral calcaneovalgus deformity. Also noted were a unilateral single transverse palmar crease, mild bilateral clinodactyly, and index finger overlapping the third finger. The baby had symmetrical failure to thrive with increased extensor tone, exaggerated DTR, a high-pitched cry, and mottled skin. Brain MRI revealed pachygyria. To better characterize this chromosome abnormality, a complete subtelome FISH panel is being performed because of the possibility that a portion of another subtelomere has been translocated to 1q terminus. BAC mapping to refine the breakpoint and assist in regional gene identification are in progress. Furthermore, to determine de novo vs. inherited status of the structural abnormality, parental karyotyping and FISH are planned. The phenotype of our patient is strikingly similar to that of patients with larger 1q deletions. Based on our FISH findings and reference databases, it appears that the phenotype of terminal 1q deletion is primarily due to haploinsufficiency of fewer than 8 genes.

Exploring the Reversibility of the Smith-Magenis Syndrome (SMS) Phenotype. *K. Walz[1], J. Molina[1], A. Cardenas[1], P. Carmona[1], J.I. Young[1], J.R. Lupski[2]* 1) Centro de Estudios Cientificos, Valdivia, X Region, Chile; 2) Human Molecular Genetics, Baylor College of Medicine, Houston, Texas, USA.

SMS is a contiguous gene syndrome (CGS) associated with a microdeletion of ~4 Mb within chromosome 17 band p11.2. The clinical phenotype includes craniofacial abnormalities, brachydactyly, self injurious behavior, sleep abnormalities, seizures and mental retardation. Mutations in RAI1 (one of 19 genes present in the deleted region) have been identified as causative of SMS, and seem to be responsible for most of the phenotypes present in SMS. Human chromosome 17p11.2 is syntenic to the 32-34 cM region of murine chromosome 11. By chromosome engineering we have generated a mouse model for SMS, Df(11)17/+, that carries a 3 Mb deletion and presents craniofacial abnormalities, seizures, obesity, alterations in circadian rhythm and hypoactivity. The objective of this work is to restore the normal gene dosage of Rai1 at an appropriate time to study if it is possible to prevent the development of at least some of the phenotypes seen in the mouse model for SMS. For this purpose we are generating mice that bear an inducible wild-type Rai1 allele in a mutant Df(11)17/+ genetic background. We tagged a wild type copy of Rai1 cDNA with HA and subcloned it downstream of a bidirectional tetracycline-responsive promoter (EGFP-pBI-Rai1-HA) to generate transgenic mice that bear an extra copy of Rai1. We will then cross the Rai1 transgenic mice with those expressing tTA under Rai1 promoter regulation. For this purpose we have generated a modified BAC, by recombineering, expressing the tetracycline-inhibitable transcription factor (tTA) under the control of Rai1 specific promoter sequences (BAC-tTA). Both transgenes, EGFP-pBi-Rai1-HA and BAC-tTA are being injected, and double transgenic mice will be mated in the Df(11)17/+ mice genetic background to be analyzed. (Supported by NIH FIRCA TW007536-01 to KW -and FONDECYT No. 1061067, Chile to KW).

Practical solution for population stratification in genome-wide association scans and targeted studies. *A.L. Price[1,2], N.J. Patterson[2], R.M. Plenge[2,3], M.E. Weinblatt[3], N.A. Shadick[3], J. Butler[1,4], C.D. Campbell[1,4], A. Ramos[1,4], A. Ruiz-Linares[5], J.N. Hirschhorn[1,2,4], D. Reich[1,2]* 1) Harvard Medical School; 2) Broad Institute of MIT & Harvard; 3) Brigham & Women's Hospital, Boston; 4) Children's Hospital, Boston; 5) University College London.

Population stratification-allele frequency differences between cases and controls due to systematic ancestry differences-can cause spurious associations in disease association studies. Stratification is a concern both in genome-wide scans of hundreds of thousands of markers, and in targeted studies of selected markers. Here, we introduce a new method and software to correct for stratification and describe a new resource, 160 markers highly informative for within-Europe ancestry, which can be used to correct for stratification in targeted studies on European Americans. Our method, EIGENSTRAT, uses principal components analysis to explicitly model ancestry differences between cases and controls. This approach has significant advantages over Genomic Control, whose uniform correction for all markers is insufficient at markers that are unusually differentiated in frequency across populations, and Structured Association, which runs too slowly to be practical on large data sets. Furthermore, simulations show that EIGENSTRAT retains higher power to detect true associations than either of those methods. The method provides an effective correction for stratification in genome-wide scans, as we demonstrate on a real data set of 488 European American samples.

Correcting for stratification is an even greater challenge in targeted studies, due to the limited number of markers for inferring ancestry. A solution is to genotype additional ancestry informative markers. We designed a set of 160 markers highly informative for within-Europe ancestry, which we further validated using 300 samples from Italy, Spain, Sweden, England and Poland. We genotyped these markers in 368 European American samples discordant for the height phenotype, in which stratification had previously been shown to cause a spurious association. Using these markers, EIGENSTRAT successfully corrects for stratification.

HNF-1 mutation search in families of the Polish Nationwide Registry of MODY. *J. Skupien[1], M.T. Malecki[1], T. Klupa[1], S. Gorczynska-Kosiorz[2], D.K. Moczulski[2], J. Sieradzki[1]* 1) Department and Chair of Metabolic Diseases, Jagiellonian University Medical College, Krakow, Poland; 2) Department of Internal Medicine, Diabetology and Nephrology, Silesian School of Medicine, Zabrze, Poland.

Introduction: Maturity-onset diabetes of the young (MODY) is an autosomal dominant form of diabetes characterised by beta-cell defect and early age of diagnosis. The most frequent MODY3 subtype is caused by mutations in the HNF-1 gene. **Aim:** To determine the frequency of diabetes due to mutations in the HNF-1 gene in MODY families from the Polish Nationwide Registry and to provide its clinical characteristics. **Methods:** We identified 37 families with the early onset, autosomal dominant form of diabetes that meet the criteria of MODY. The 10 exons and promoter region of the gene were screened for sequence differences by direct sequencing of DNA from the probands of these families. **Results:** So far, during a screening of probands from MODY families of Polish origin, we identified twelve mutations. They segregated with diabetes in the families where they were identified. In eight probands, previously described mutations were found. Among them there were three missense mutations (R131Q, R271W, and P447L), three were frameshift mutations (S225fsdelC, P291fsinsC, and P378fsdelT), and one was the cryptic splice acceptor site mutation IVS7nt-6G>A resulting in skipping exon 7 and the premature termination of translation. In addition, we found one previously reported nonsense mutation R171X. Moreover, we found four novel mutations. There were two missense mutations (S249P and N257T). In another proband, we identified a splice mutation IVS2nt+1G>A. Interestingly, another novel mutation was a duplication of a 7 base pair motif (GGGTTGG) in the 5-UTR of the gene, between -164 and -165 base pairs upstream from ATG. This family was characterized by a severe phenotype with no response to sulphonylurea in some mutation carriers. **Conclusion:** MODY3 constitutes about one third of the Polish Nationwide Registry. In addition, the Pro291fsinsC mutation was encountered only once in our group, while it is the most frequent mutation, constituting a hot-spot in other well characterised European and Asian populations.

Classical Sotos syndrome with a Mutation in the NSD1 gene in a Two Generation Family. *AhmadS. Teebi, ReganE. Klatt, Tawfeg. Ben-Omran* Division of Clinical and Metabolic Genetics, Hospital for Sick Children, University of Toronto, Toronto, Canada University of Toronto,, toronto, on, Canada.

Sotos syndrome (OMIM#117550) is a well recognized overgrowth syndrome characterized by a typical facial gestalt, pre- and post-natal excessive growth including macrocephaly, advanced bone age, and variable degrees of developmental delays. Other clinical manifestations include neonatal jaundice, seizures, scoliosis, strabismus, conductive hearing loss, congenital heart disease, renal anomalies, and behavioral problems. Mutations and deletions of NSD1 (the nuclear-receptor-binding SET-domain-containing protein 1) at 5q35 are associated with Sotos syndrome. A few cases of parent-to-child transmission of Sotos syndrome have been published so far with only 15 familial cases have documented NSD1 mutations. Here, we describe the clinical and molecular findings in a family (father and 2 children) with autosomal dominant segregation of classical Sotos syndrome. This family will further contribute to our understanding of genotype-phenotype correlation and the scope of intrafamilial variability in Sotos syndrome. Familial examples offer more precise genetic counseling including risk figures and long term prognosis.

CHARGE syndrome: genotype-phenotype correlations and mutational hot-spots at the CHD7 locus. *D. Sanlaville[1,2], S. Audollent[1], G. Goudefroye[1], J. Amiel[1], V. Abadie[3], C. Baumann[4], H. Dollfus[5], D. Genevieve[1], C. Thauvin[6], S. Marlin[7], A. Toutain[8], C. Cruaud[9], H. Etchevers[1], J. Weissenbach[9], A. Munnich[1], T. Attié-Bitach[1], S. Lyonnet[1]* 1) Dept de Génétique and INSERM U781 , Hôpital Necker Enfants Malades, Paris, France; 2) Service de Cytogénétique, Hospices Civils de Lyon, Hôpital Edouard Herriot, Lyon; 3) Service de Pédiatrie générale, Hôpital Necker-Enfants Malades, Paris; 4) Service de Génétique, Hôpital Robert Debré, Paris; 5) Service de Génétique, Hôpital de Hautepierre, Strasbourg; 6) Centre de Génétique, Hôpital d'Enfants, Dijon; 7) Service de Génétique, Hôpital Trousseau, Paris; 8) Service de Génétique, Hôpital Bretonneau, Tours; 9) Genoscope and CNRS UMR8030, Evry, France.

Introduction: CHARGE syndrome is a dominantly inherited multiple congenital anomalies (MCA) syndrome defined by ocular coloboma (C), heart disease (H), choanal atresia (A), retarded growth and/or anomalies of the central nervous system (R), genito-urinary defects and/or hypogonadism (G), ear anomalies and/or deafness (E). Recently, *CHD7* gene mutations have been identified in 55 to 60 % of CHARGE patients. **Methods:** We studied, by direct sequencing, a series of 164 cases in whom the diagnosis was suspected based on the criteria proposed by Pagon or Blake. **Results:** The diagnosis was confirmed in 91 cases (55 %) by the identification of a *CHD7* heterozygous mutation. We identified 29 (32 %) stop codon mutations, 38 (42 %) frameshift mutations leading a premature codon stop, 19 splice site mutations (18 %) and 8 missense mutations (9 %). More half of mutations were identified in 6/38 exons (exons 2, 10, 21, 26, and 36), whereas no mutation could be identified in 11/38 of the 38 exons of *CHD7* gene. **Discussion:** Our data support that almost only truncation mutation at the CHD7 locus result in full-blown CHARGE syndrome. However, some apparently milder missense mutations were observed in milder cases, sometimes with dominant inheritance and variable expression suggesting a careful genetic counselling. Interestingly 60 % of mutations were localized in only 6/38 exons. Our results allowed us to propose a strategy to screen mutations in *CHD7* gene.

The Development of Genomic SELEX for the Identification of Direct Transcriptional Targets of Pax3, FKHR and the Oncogenic Fusion Protein Pax3-FKHR. *A. Sidhu, K.E. Johanson, R.J. Scioneaux, A.D. Hollenbach*
Department of Genetics, LSU Health Sciences Center , New Orleans, LA.

Alveolar rhabdomyosarcoma (ARMS, MIM 268220) is a soft tissue tumour, arising primarily in the trunk and extremities of adolescents and young adults. The four year overall survival rate is less than 30% for ARMS, with a lower incidence of survival in patients with metastases and bone marrow involvement. ARMS is an aggressive malignancy most commonly characterized by a t(2;13) (q35;q14) chromosomal translocation, which results in the fusion of two transcription factors important for myogenesis, Pax3 and FKHR. The resulting oncogenic fusion protein, Pax3-FKHR, is a potent transcriptional activator and functions as a dominant acting oncogene. Thus, screening for target genes of Pax3, Pax3-FKHR, and FKHR would be of great significance in determining the molecular basis of this disease and its clinical outcome. Therefore, the long term goal of this work is to identify the direct transcriptional targets of Pax3 and FKHR and to determine how gene expression differs in the presence of Pax3-FKHR. We will address this goal with the development of a Genomic SELEX technique, through a modification of the standard SELEX, in order to identify promoter elements directly bound and regulated by Pax3 and FKHR. We will then confirm, identify, and evaluate the promoter elements that are bound by Pax3 and FKHR. Lastly, we will determine how Pax3-FKHR alters the expression of the identified genes in the physiologically relevant mouse primary myoblasts. The identification of physiologically relevant genes whose expression is altered by the presence of Pax3-FKHR will allow us to elucidate the cellular pathways that contribute to ARMS tumor progression. The knowledge of these aberrantly expressed genes will provide us with critical information that will allow the development of novel therapies for the treatment of ARMS.

Increased *Hprt* deletions in *Blm* hypomorphic mice *in vivo* are mediated by illegitimate recombination. *I.V. Tereshchenko[1], Y. Chen[1], L.D. McDaniel[2], R.A. Schultz[2], J.A. Tischfield[1], C. Shao[1]* 1) Genetics Department, LSB, Rutgers University, Piscataway, NJ; 2) University of Texas Southwestern Medical Center at Dallas, Dallas, TX.

BS (Blooms syndrome) is an autosomal recessive disease with the phenotype of growth retardation, sunlight sensitivity and a predisposition to cancer. BS is caused by mutations in BLM, a RecQ DNA helicases that has both DNA-stimulated ATPase and ATP-dependent DNA helicase activities. Homozygous null Blm mutation is embryonic lethal in the mouse. To study the role of BLM in the maintenance of genomic integrity in vivo, we characterized the spontaneous Hprt mutations in T cells and fibroblasts in Blm hypomorphic mice. The Blm hypomorphic mice carry a null allele (L) and a hypomorphic allele containing insertion of an extra exon (T). The Hprt mutants were detected as cell colonies resistant to 6-thioguanine (6-TG). We found that the frequency of Hprt mutants was increased about ten fold in T cells of Blm hypomorphic mice (L/T) when compared to T/+ mice, but to a lesser extent in fibroblasts. Multiplex PCR of Hprt exons indicates that many of the mutations were caused by deletions of one or more exons. Sequencing analysis of break junctions revealed that deletions were flanked by short stretches of homologous sequences, indicating that illegitimate recombination is responsible for the deletions. Thus, in addition to increased chromosomal instability and sister chromatid exchanges, deletions from illegitimate recombination are also elevated when BLM is reduced.

Generation and characterization of Elovl4 Y270X knockin mouse. *Z. Tong, D. Gibbs, S. Kamaya, H. Chen, Z. Yang, C. Wang, D.J. Cameron, Y. Chen, A. Praggastis, E. Pearson, K. Howes, K. Zhang* Moran Eye Center, Department of Ophthalmology, University of Utah, Salt Lake City, UT. 84112.

Purpose: ELOVL4 was first identified as a disease-causing gene in Stargardt macular dystrophy. To date, three ELOVL4 mutations have been identified including Y270X, all of which result in truncated proteins. However, the specific role of ELOVL4 in photoreceptors and the degenerative events caused by dominant ELOVL4 mutations are not well understood. The purpose of this study is to generate Y270X knockin mice which will provide a mouse model to examine the dominant pathogenic mode of degeneration in human STGD3 patients. Methods: A mouse Elovl4 knockin targeting construct was generated containing a neo cassette flanked by loxP sites, and a Y270X mutation and HA tagged Elovl4 fragment introduced into exon 6. For gene targeting, the targeting vector was electroporated into mouse embryonic stem (ES) cells derived from 129. Clones in which homologous recombination resulted in targeted replacement of exon 6 were identified by PCR and by Southern blotting. Chimeric mice will be bred with wild type C57Bl/6 mice for germline transmission of the recombinant Elovl4 gene. Results: Twenty-one positive recombinant ES cell clones have been identified. Injections have yielded eight chimeric mice so far. Chimeric mice are currently being mated with C57Bl/6 mice to generate heterozygous knockin mouse. Conclusions: We have generated chimeric mice which will be used to generate the Elovl4 Y270X knockin mutation. Characterization of retinal phenotypes associated with Y270X knockin mutation will be presented. These mice will provide an important animal model for examining autosomal dominant macular degeneration in STGD patients.

Myotonic Dystrophy 1: CUG repeats alter phosphorylation-dependent functions of CUG triplet repeat binding protein, CUGBP1. *L.T. Timchenko[1], C.H. Huichalaf[1], K. Sakai[1], H. Nguyen[1], E. Salisbury[2], N.A. Timchenko[2]* 1) Medicine, Section of Cardiovascular Sciences, Baylor College of Medicine, Houston, TX; 2) Huffington Center on Aging and Department of Pathology, Baylor College of Medicine, Houston, TX.

Myotonic Dystrophy 1 (DM1) is a multisystemic disease associated with skeletal muscle weakness, progressive wasting and myotonia. The most severe and deadly form of disease, congenital DM1, is characterized by a delay of muscle development and differentiation. DM1 is caused by an expansion of polymorphic CTG repeats in the 3 UTR in DMPK gene. Major symptoms of DM1 are mediated by the mutant RNA CUG repeats which affect two RNA-binding proteins, CUGBP1 and MBNL. In DM1 patients, CUGBP1 levels are increased due to stabilization of CUGBP1 by CUG repeats. Examination of animal models showed that the unscheduled elevation of CUGBP1 is toxic and might be a major cause of DM1 pathology. In transgenic mice, the elevation of CUGBP1 results in a significant delay of muscle development and myofiber fusion. Our data and observations from other labs suggest that CUGBP1 plays a significant role in several aspects of RNA metabolism including splicing, translation and mRNA stability. Such diverse functions of CUGBP1 in RNA metabolism suggest that CUGBP1 might regulate a large number of mRNAs. We have found that the RNA binding activity of CUGBP1 and protein-protein interactions of CUGBP1 are regulated by specific phosphorylation at different residues within CUGBP1 molecule. In normal cells, biological activities of CUGBP1 are differently regulated in proliferating and in differentiating muscle cells. Examination of phosphorylation status of CUGBP1 in DM1 muscle cells supports hypothesis that, in addition to elevation of CUGBP1, CUG repeats also change signal transduction pathways which phosphorylate CUGBP1. We suggest that a synergistic effect of these alterations dramatically changes processing of multiple mRNAs in DM1 tissues.

3D morphometric analysis of the craniofacial complex in first degree relatives of individuals with orofacial clefts.
S.M. Weinberg, B.S. Maher, M.P. Mooney, K. Neiswanger, M.I. Siegel, M.L. Marazita University of Pittsburgh, Pittsburgh, PA.

Numerous studies have described altered patterns of craniofacial form in the unaffected relatives (URs) of those with oral clefts. Results from these studies have been highly variable and have failed to provide a reliable method for discriminating at-risk relatives from controls. In the present study, we compare craniofacial shape between a sample of URs (33 females; 14 males) from CL/P multiplex families and an equal number of age/sex matched controls. A total of 16 x,y,z facial coordinates derived from 3D photogrammetry were analyzed via Euclidean Distance Matrix Analysis (EDMA), while 14 additional linear distances from direct anthropometry were analyzed via t-tests. Variables identified as significantly different (p .10 from EDMA; .05 from t-tests) were then entered into a discriminant function analysis. All analyses were carried out for each sex separately. Female URs demonstrated increased facial width, midface reduction and lateral displacement of the alar cartilage. A single discriminant function was derived (canonical correlation = .43; p = .01) which correctly classified 70% of female URs and 73% of female controls. Male URs demonstrated increased facial and cranial base width, increased lower facial height and decreased upper facial height. Again, a single discriminant function was derived (canonical correlation = .79; p < .001) which correctly classified 86% of male URs and 93% of male controls. In both males and females, facial width contributed most to the discriminant function (loading > .60). These results suggest that the craniofacial shape differences characterizing URs are largely sex-specific and perhaps more pronounced in males. Importantly, the pattern of relative-control differences observed in both sexes is in broad agreement with previous findings from both humans and animal models. Although preliminary, these results suggest that a relatively simple phenotypic assessment may provide a tool for the identification of at-risk individuals within CL/P multiplex families. NIH grants R01-DE016148 and P50-DE016215.

High throughput mutation screen of human ion channel genes in episodic neurological disorders. *J.F. Poulin[1], R. Lafrenière[1], M. Simoneau[1], N. Gupta[1], F. Lafrenière[1], K. Boisvert[1], A. Anton[1], S. McLaughlan-Edwards[1], G. Ebers[2], Z. Cader[3], J. Sequeiros[4], J.M. Pereira Monteiro[5], G. Turecki[6], M. Alda[6], P. Grof[7], S. Chouinard[8], B. Brais[8], P. Cossette[8], G. A. Rouleau[1,8]* 1) Emerillon Therapeutics, Inc., Montreal, Quebec, Canada; 2) Wellcome Trust Centre for Human Genetics, Oxford, UK; 3) Oxford University, Oxford, UK; 4) UNIgene, IBMC, University of Porto, Porto, Portugal; 5) Hospital Santo António, Porto, Portugal; 6) McGill University, Montreal, Canada; 7) University of Ottawa, Ottawa, Canada; 8) Universite de Montreal, Montreal, Canada.

Common neurological conditions such as epilepsy and migraine are episodic disorders showing significant heritability. Mutations in several ion channel genes have been identified as the genetic basis of these disorders in some patients. Additional diseases such as bipolar disorder, essential tremor and Tourette syndrome share some aspects of episodic disorders, and may be caused by dysfunction of ion channel genes. In an effort to identify relevant drug targets for these neurological disorders, we have initiated a high throughput mutation detection screen of brain-expressed human ion channel genes. To date, we have screened 140 ion channel genes in a panel of 368 unrelated patient samples using dHPLC and have identified a total of 1266 different variants. Sequence variants are prioritized and genotyped in additional cohorts of patients and controls to determine allelic frequencies. Statistical analyses (Fishers Exact test, Hardy-Weinberg equilibrium test, etc) are then automatically performed on each genotyped variant to test any possible association with a particular disease. Infrequent variants are genotyped in extended pedigrees to test for co-segregation of the variant with affected family members. These genotype data allow us to better assess the possible relevance of these variants for each of the diseases studied. The most interesting candidate genes/variants will be presented, including preliminary biochemical validation data. Identification of genetic factors causing these neurological disorders will benefit patients and families through better molecular diagnosis and improved therapeutics.

Simulating association studies: a data-based resampling method for candidate regions or whole genome scans. *F. Zou[1], H. Huang[1], X. Guan[2], K. Gamiel[2], C. Jeffries[2,3], W.T. Barry[1], F. Pardo-Manuel[4], P.F. Sullivan[4], K.C. Wilhelmsen[4], F.A. Wright[1]* 1) Department of Biostatistics, University of North Carolina, Chapel Hill; 2) Renaissance Computing Institute,UNC Chapel Hill; 3) School of Pharmacy,UNC Chapel Hill; 4) Department of Genetics,UNC Chapel Hill.

Reductions in genotyping costs have heightened interest in performing whole genome association scans and in the fine mapping of candidate regions. Improvements in study design and analytic techniques will require the simulation of datasets with realistic patterns of linkage disequilibrium and allele frequencies for typed SNPs. We describe a general approach to simulate genotyped datasets for standard case-control or affected child trio data, by resampling from existing phased datasets. The approach allows for considerable flexibility in disease models, potentially involving a large number of interacting loci. The method is most applicable for diseases caused by common variants that have not been under strong selection, a class specifically targeted by the International HapMap project. Using Phase I/II HapMap CEU data as a testbed for our approach, we have implemented the approach in HAP-SAMPLE, a web-based simulation tool. With HAP-SAMPLE, we can perform simulations that effectively mimic data from whole-genome platforms. For example, 94.4% of the SNPs on the Affymetrix 100K platform are among the Phase I/II HapMap CEU data. Further, as an intermediate step, we developed a simple phasing approach suitable for genome-wide phasing of parent-child trios. Our phasing algorithm has competitively low error rates in comparison with the official HapMap phased version, and is so fast that the entire Phase II dataset can be phased in a few hours on a single PC.

CNS Tumors, Melanosis and More: A Lesson in the Value of Research and Longitudinal Genetic Counseling. *K. Zbuk, A. Shealy, C. Eng* Genomic Medicine Institute, Cleveland Clinic Foundation, Cleveland, OH.

We often counsel based on case reports or rare case series in uncommon syndromes. These reports are usually based on data obtained at a single snapshot in time. This case family illustrates the importance of longitudinal patient follow-up and participation in research. In 2003, the proband, a 12yo female, was referred for a posterior fossa paraganglioma (PGL). Her father and paternal uncle had hemangiomas (pedal and hepatic, respectively) and a paternal first cousin once-removed reported a brain tumor of unknown type. We offered *SDHD* and *VHL* gene testing; both were negative. Consequently, we requested further medical records on the relative's brain tumor. However, the family was lost to follow up until this year (2006). The patient was recently diagnosed with primary acquired melanosis of the conjunctiva and cornea and was referred back to our Center for Personalized Genetic Healthcare. Updated family history revealed that the brain tumor in the first cousin once-removed was reportedly a chordoma. While this could be a chordoma, chordomas could be histologically mistaken for PGLs. The patient is currently being tested for *SDHB* and *SDHC* mutations on a research protocol that additionally allows DNA to be stored for 20 years to be used in any relevant future research. We are now able to consider several new differential diagnoses. NF1 is a consideration given that the patient has 3 cafe-au-lait spots, as does the mother who also has axillary freckling, and the history of paragangliomas, melanosis, and cutaneous and liver hemangiomas. Posterior fossa neuroectodermal tumors are reminiscent of a syndrome characterized by *SNF5* mutations. Finally, if the chordoma was a misdiagnosed PGL, consideration is given to *SDHC*-related PGL syndrome, which is enriched for head and neck PGLs. While *SDHB* is in the differential, it is less likely than *SDHC* because the former is enriched for abdominal, extra-adrenal PGL. Since the chordoma was diagnosed in adulthood, tuberous sclerosis complex is unlikely. This case illustrates the value of following complicated families over time and aggresively utilizing research studies which ultimately enhance clinical care.

First report of two siblings with SMS due to maternal mosaicism. *A.C.M. Smith[1,2], B.A. Pletcher[3], J. Spilka[2], J. Blancato[2], J. Meck[2]* 1) SMS Research Unit, OCD/NHGRI/NIH, Bethesda, MD; 2) Georgetown Univ Medical Center, Washington, DC; 3) New Jersey Medical School, Newark, NJ.

Smith-Magenis syndrome (SMS) is a clinically recognized MCA/MR syndrome associated with interstitial deletion of chromosome 17p11.2 in the majority of cases. The deletion usually occurs de novo. Only one case of SMS with transmission from a partially affected mosaic mother has been reported (Zori et al.,1993). We report a 2nd family with SMS due to maternal mosaicism that, to our knowledge, represents the first report of SMS recurrence in siblings. Case Report: The 37y proband (P) is the youngest and his 54y sister (S) the oldest in a sibship of 9 that includes 2 miscarriages & 5 healthy siblings. Both carried a diagnosis of Down syndrome (DS) since infancy. Cytogenetic confirmation of DS was not pursued until adulthood, when the DS "diagnosis" was challenged. Both siblings were confirmed to have SMS (del 17p11.2). Parental karyotyping on lymphocytes confirmed normal chromosomes in the father; however, the mother was mosaic for the deletion [31/50 (62%) cells with del 17p11.2]. Record review and recent genetic evaluation of P and S confirm psychomotor and speech delays, moderate/severe MR, self-injurious and maladaptive behaviors, sleep disturbances, and many physical findings classically seen in SMS. S also has Type 2 diabetes, hypothyroidism, seizures, and bipolar disease. Their 80y mother in her youth was cognitively normal with a sociable personality and loved attention, but also had behavior and emotional problems (i.e., immaturity, poor self-esteem) with aggressive mood swings (bipolar); she is currently being evaluated for early signs of dementia. Summary: This family illustrates several points for discussion and genetic counseling: 1) Delays in diagnosis and suspicion of DS in infancy are common in SMS emphasizing the need to consider cytogenetic testing; 2) parental chromosome studies are indicated in all newly diagnosed cases of SMS; 3) parental somatic/germline mosaicism for del 17p11.2 may be more common than originally thought with implications for genetic counseling; and 4) del 17p11.2 mosaicism may be associated with a milder phenotype than classic SMS.

Evidence for Association of Interferon Regulatory Factor 2 (IRF2) with Systemic Lupus Erythematosus (SLE).

P.S. Ramos[1], R.R. Graham[2], S.M. Rao[1], C.D. Gillett[1], W.A. Ortmann[1], K.J. Espe[1], R.C. Ferreira[1], T.W. Behrens[1], K.L. Moser[1] 1) Dept Medicine, Univ Minnesota, Minneapolis, MN; 2) Broad Institute of Harvard and MIT, Boston, MA.

SLE is a complex autoimmune disease characterized by dyrsregulation of both innate and adaptive immune responses. Using linkage analysis of intermediate phenotypes defined by autoantibody production in SLE multiplex families, we have mapped a locus related to anti-Ro/SSA and anti-La/SSB to chromosome 4q35.1. This region has been previously implicated through linkage and association studies in psoriasis, atopic dermatitis, multiple sclerosis, and certain clinical subsets of SLE patients with dermatological manifestations, suggesting the presence of a gene involved in multiple autoimmune diseases. Evaluation of potential candidate genes within the 4q35.1 region indicated that IRF2 is a strong candidate gene for SLE. Numerous lines of evidence suggest that pathways influenced by interferons (IFNs) are dysregulated in multiple autoimmune diseases, including SLE. IRF2 plays a repressive role in transcriptional regulation of IFN-inducible genes, and numerous functional studies are consistent with the hypothesis that altered function or expression levels of IRF2 may lead to dysregulation of IFN-inducible pathways as observed in SLE. In order to test for genetic association with SLE, we genotyped over 400 Caucasian SLE pedigrees and assessed association of 16 haplotype tag single nucleotide polymorphisms (SNPs) across IRF2 using family-based association (TDT and PDT) analysis (mean r2=0.6). We also genotyped a SNP previously reported to be associated with psoriasis and atopic dermatitis in our collection of 184 sib-pair and 185 trio SLE pedigrees for TDT and PDT analysis, as well as in 894 controls for a case-control study. We found significant evidence for association of six SNPs in IRF2 with SLE and in subsets of SLE patients with dermatological manifestations ($p<0.05$). Our studies support the hypothesis that IRF2 may predispose to SLE by altering transcriptional regulation of IFN-inducible genes and that disease-associated variants are enriched in patients with certain dermatological manifestations.

Differential influences on maximum likelihood (ACE-A) and intraclass correlation (IC-A) estimators of additive genetic variance from twin studies. *M.T. Stillitano[1], E. Byrne[2], C.J. Williams[3], J.C. Christian[1]* 1) Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 2) Trinity College Dublin; 3) Department of Statistics, University of Idaho, Moscow, ID.

In an attempt to define differences between the two estimators, simulation studies were carried out using 1,000 sets of 50 MZ and 50 DZ twins, with 0.55 additive genetic variance and 0.45 random environmental variance.

The ACE-A and IC-A estimators had a sample correlation of 0.83. In addition, regression analyses of the estimators showed that the total variance of DZ twins (DZTV) explained 13% of the variance in ACE-A estimates. The DZTV was negatively correlated with the IC-A estimator (r = -0.23) and positively correlated with the ACE-A estimator (r = 0.13), resulting in a differential effect on the two estimators.

Because the ACE-A model controls within pair DZ variance, as DZ variance increases there is an expected increase in the DZ covariance, which results in a decrease in the difference between MZ and DZ covariances and a decrease in the ACE-A value of the estimator. In contrast, in increasing DZTV, not influenced by control of the within DZ variance, when the IC-A is calculated results in a decrease in the DZ intraclass correlation, accounting for the differential effect on the ACE-A and IC-A estimates.

The twins were divided into three classes based upon DZTV standard deviation (SD); (MEDIUM = DZTV SD -0.5 to 0.5 from the mean; LOW = greater than 0.5 below the mean; HIGH = greater than 0.5 above the mean). The ACE-A estimator found 52, 54, and 56% significant results in the three classes (LOW, MEDIUM, and HIGH respectively), while the IC-A estimator found 62, 50, and 40% significant results, respectively. This indicates that control of the within pair DZ variance results in the ACE-A estimator being less influenced by random variation in the DZTV than the IC-A estimator.
