The Mouse Genome Informatics Database (MGI, http://www.informatics.jax.org/) is a comprehensive, integrated information resource for the genetics, genomics and biology of the mouse. At the core of MGI are DNA and protein sequence data, descriptions of genes/gene products and their functions, orthologous gene relationships between mouse and other mammals, and genetic and physical mapping data. Integrated with this core are other data. Phenotypes are described for nearly 16,000 alleles, including spontaneous, mutagen-induced, targeted and conditional mutations, transgenes, and 2,900 QTL. Association of parallel mouse and human data aids genotype-to-phenotype comparisons and relates mouse mutants or QTL to human disease. An extensive and growing catalog of mouse SNPs can aid in mapping disease-associated mutations and localizing QTL. The database may be queried for gene-, tissue- or developmental stage-specific expression patterns.

MGI's utility has recently been enhanced by a number of additions and modifications. Perhaps most obvious is the representation of phenotype data; each phenotypic detail now is annotated to a term from the Mammalian Phenotype (MP) ontology, a hierarchically structured vocabulary. Online Mendelian Inheritance in Man (OMIM) is used to make similarity assertions between mouse models and human diseases. These and additional controlled vocabularies (ontologies) for anatomy, molecular functions, biological processes and cellular components (the latter three comprising the Gene Ontology, GO) permit querying the database simultaneously for any combination of these parameters. Such queries also may incorporate expression, sequence, polymorphism and/or mapping data. For example, one might ask for any gene of which there are mutations that cause deafness and whose product is associated with the plasma membrane and has signal transduction activity. To search for modifiers mapping to a particular genomic region, one might display SNPs in that region. Use of ontologies in annotating phenotypes, diseases, alleles and genes support data mining *via* such complex queries. Supported by NIH grants HG00330, HG02273, HD33745, CA89713.

Association of Innate Immune Response Candidate Genes in Primary Sjögrens Syndrome. *D.C. Patel, P.S. Ramos, S.M. Rao, E.S. Emamian, L.M. Tobon, T.W. Behrens, P.M. Gaffney, A.J.W. Huang, N.L. Rhodus, B. Segal, K.L. Moser*
Dept Medicine, Univ Minnesota, Minneapolis, MN.

Sjögrens Syndrome (SS) is one of the most prevalent inflammatory autoimmune diseases, characterized by an infiltration and focal accumulation of lymphocytes in exocrine glands. The underlying etiology is thought to be complex, involving multiple genes and influenced by environmental factors. Microarray analysis of primary SS patients has shown dysregulation of expression levels for genes involved in several key biological pathways, including a prominent signature defined by genes known to be inducible by Type I interferons. In this study, we chose candidate genes related to pathways that are dysregulated in SS and tested them for genetic association using a case-control cohort. We evaluated interleukin 1 receptor antagonist (IL1RN), the 2-prime,5-prime oligoadenylate synthetase (OAS) cluster, Toll-like receptor 2 (TLR2) and 52-kD Ro/SSA (TRIM21/Ro52). Single nucleotide polymorphisms (SNPs) covering at least 80% of the total variation across each gene were genotyped in 98 Caucasian primary SS cases and 175 Caucasian controls. We found at least one variant in each candidate gene whose genotype frequencies were significantly different between cases and controls ($p < 0.05$). Association with TRIM21/Ro52 was found with a variant in the mRNA/UTR (p-value = 0.0004) and a second SNP in intron 2 ($p = 0.0027$). In the OAS cluster, we observed evidence of association with an upstream SNP ($p = 0.0176$) in OAS1, and an intronic SNP in OAS3 ($p = 0.0065$). We also observed evidence of association of a variant in the mRNA/UTR region of TLR2 ($p = 0.0013$) and a variant upstream of IL1RN ($p = 0.036$). Our studies support the hypothesis that dysregulated gene expression levels of these genes may be due to underlying genetic variants that are associated with primary SS. Further investigation of these genes for a role in this complex disease is warranted.

Linkage studies in autosomal dominant lateral temporal lobe epilepsy: searching for the alternative locus. *F.R. Torres, N.S. Ferreira, R. Secolin, M.C. Gonsales, E. Kobayashi, L.A.C. Sardinha, F. Cendes, I. Lopes - Cendes* Dept Medical Genetics, UNICAMP, Campinas, Brazil.

The objective of this study was to localize the major *locus* causing autosomal dominant lateral temporal lobe epilepsy (ADLTLE) in a kindred with no mutations in the *LGI1* gene and no linkage to chromosome (ch) 10q. We studied 23 affected individuals from a single family segregating ADLTLE. In addition, all 23 patients had high resolution MRI scans. As an initial strategy we chose the candidate gene approach. A total of 42 family members were genotyped for 15 polymorphic dinucleotide repeat markers flanking the *LGI2*, *LGI3*, *LGI4* and *MASS1* genes. Two-point lod scores (Z) were calculated using the LINKAGE package. Auditory auras were reported by 18 of 23 patients (78%). *Deja-vu* phenomena, associated to auditory auras, were reported by 13/18 (72%). Three individuals had only isolated frequent *deja-vu* episodes, and two individuals had only generalized tonic clonic seizures. MRI scans of all 23 patients in this kindred were normal and two-point lod scores were significantly negative ($Z < -2.00$) for all 15 markers tested. Most affected individuals in this kindred have *deja-vu* phenomena suggesting involvement of mesial aspects of temporal lobe structures as well. This clinical characteristic is not a common feature in ADLTLE families with mutations in the *LGI1 gene*. In addition, we found that mutations in the *LGI2*, *LGI3*, *LGI4* and *MASS1* genes are not causing ADLTLE in the family studied. A wide genome search is under way in order to identify the causative gene in this kindred.

Genetic Analysis of Osteoarthritis. *B.H. Reck[1], A. Philip[1], M. Chiano[2], U. Atif[3]* 1) Genetics Analysis, GlaxoSmithKline, RTP, NC; 2) Genetics Analysis, GlaxoSmithKline, UK; 3) Medical Genetics, GlaxoSmithKline, RTP, NC.

Osteoarthritis (OA) is the most common cause of musculoskeletal disability in most developed countries. The site that causes the greatest burden of disability in public health terms is the knee, which is estimated to result in pain and loss of function in 10% to 15% of men and women aged over 45 years. The etiology and pathogenesis of the condition, however, remain largely unknown. It is more common in and has been strongly associated with several environmental risk factors including obesity, previous injury, meniscectomy, and other physical and metabolic factors. Although environmental factors have traditionally been thought to be the main influences, there are few data to support this. Between 39% and 65% of Osteoarthritis in the general population can be attributed to genetic factors. Identification of the genes concerned could have a large impact on the disease in terms of prevention and new therapeutic approaches. GlaxoSmithKline has undertaken a series of genetic studies on Osteoarthritis which consist of a combination of linkage and association analysis on multiple OA phenotypes. An initial whole-genome scan identified broad chromosomal regions which were possibly linked to OA. A Linkage Refinement analysis performed in these regions produced two peaks, one on chromosome 9 and one on chromosome 18, meriting further investigation. An association analysis was performed on these regions using a dense set of SNP markers, and association was seen in these regions for a number of SNPs using different phenotypes. Although the high density association analysis suggests some genes which may be involved in OA susceptibility, a replication analysis that is currently being planned will be necessary to confirm these findings. We will describe this project from the original scan through the high density association analysis, focusing on the patient collection studies, OA radiographic phenotypes investigated and methods implemented. The objective of this study is to gain increased understanding of osteoarthritis, leading to the identification of novel susceptibility genes and drug target pathways.

Association study between asthma and candidate genes identified by microarrays. *K. Tremblay[1,2], M. Lemire[3], A. Montpetit[3], D. Daley[4], AJ. Sandford[4], PD. Paré[4], TJ. Hudson[3], C. Laprise[1,5]* 1) University of Montreal Community Genomic Medicine, Chicoutimi, Canada; 2) Laval University, Quebec, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montreal, Canada; 4) University of British Columbia, Vancouver, Canada; 5) Université du Québec à Chicoutimi, Chicoutimi, Canada.

RATIONALE: Asthma is a heterogeneous complex trait. To date, knowledge about its genetic risk factors remain largely unknown. Microarrays allowed us to identify new or known genes relevant to asthma. We selected 9 differentially expressed genes (SFRP1, CX3CR1, IL2RB, IL7R, CXCL12, TNFRSF7, NOS2A, CD14, ALOX15) and 8 candidate genes based upon the biological plausibility of inflammation and immunity pathways (STAT6, MS4A2, IL1B, IL4, IL4R, IL6, IL13, IL15). **AIM**: To conduct a candidate gene association study in a founder population sample from Northeastern Quebec. **METHODS**: TagSNPs were selected from the HapMap database with minor allele frequency .10 and an r2.80 for each gene (mean of 10 tagSNPs/gene). Asthma was defined used the American Thoracic Societys criteria and 1139 individuals (n=260 families) were included. Genotyping was performed using Illumina SNP chip (AllerGen network). Genetic analyses were done using the TDT as implemented in the FBAT program. **RESULTS**: Additive and dominant models were used to test for association with asthma and related phenotypes. In the additive model, analyses showed positive association with IL13 only (asthma, p=0.007). In dominant model, analyses show positive associations for three common alleles of SFRP1 (IgE, p0.004), two common alleles of CX3CR1 (asthma and atopy, p0.002), two common alleles of IL2RB (atopy and airway hyperresponsiveness, p0.005), one minor allele of CXCL12 (IgE, p=0.009) and for one minor allele of IL13 (asthma, p=0.006). **CONCLUSIONS**: These results await further replication studies and refined statistics. Indeed, we currently working on haplotype analyses and models that allow for gene-gene and gene-environment interactions. Nevertheless, our preliminary results show a potential benefit to use microarrays in the selection of candidate genes for asthma association studies.

Development of Clinical Molecular Genetics Testing for Primary Ciliary Dyskinesia. *M.A. Zariwala, M. Langley, M.W. Leigh, J. Booker, M.R. Knowles, K. Weck* Dept Pathology/Lab Medicine, Medicine, Pediatrics, University of North Carolina-Chapel Hill, Chapel Hill, NC-27599.

Primary ciliary dyskinesia (PCD) is a rare, autosomal recessive genetic disorder associated with abnormalities in the structure and function of cilia of the respiratory tract and flagella of sperm. Phenotype includes oto-sinu-pulmonary disease, situs inversus (50% of patients) and male infertility. Diagnosis has relied upon compatible clinical phenotype and tests such as ultrastructural studies of cilia, nasal nitric oxide and ciliary beat frequency measurements. Recent work (Hornef et al, 2006 and our unpublished data) has identified mutations in two ciliary outer dynein arm genes (*DNAI1* and *DNAH5*) in approximately 38% of PCD patients. Due to the large size, full gene sequencing may prove to be cumbersome. Although allelic heterogeneity has been noted, there are eight exons where mutation clusters reside including exons 34, 50, 63, 76, 77 of *DNAH5* and exons 1, 16 and 17 of *DNAI1*. We have developed a sequenced based clinical molecular genetics panel for PCD. We designed primers specific for each of the targeted eight exons such that PCR and sequencing reactions could be run in parallel. Using positive controls for each of the known mutations, the UNC Molecular Genetics Laboratory devised and validated sequencing assays using consistent conditions that would be robust in a clinical setting. Final assay conditions were determined based on the quality of sequence data in multiple runs. Eight exons with a total of 18 different mutations were analyzed with complete concordance between the data from research and the clinical labs. In conclusion, we have developed and validated a robust clinical sequencing assay with consistent reaction conditions that will aid in the diagnosis of PCD. Based on our previous experience, this strategy will allow the identification of a causative mutation on at least one allele in approximately 23% of well-characterized PCD patients. Ours is the first CLIA and CAP-approved laboratory to offer genetic testing for PCD on a clinical basis. This abstract was funded in part by GCRC#00046, MO1 RR00046-42, 1 RO1 HL071798, 5 U54 RR019480, NIH/ORD CETT.

An Association Analysis of Cannabinoid Receptor 1 Gene with Bipolar Disorder. *J. Shi, J.A. Badner, E.S. Gershon, C. Liu* Dept Psychiatry, Univ Chicago, Chicago, IL.

Several lines of evidence implicate cannabinoid receptor 1 gene (CNR1) as a candidate for bipolar disorder (BD). First, CNR1 is mapped to chromosome 6q14-q15, a potential BD linked region. Second, cannabinoid receptors in the central nervous system regulate mood and anxiety. Blockade of these receptors engenders antidepressant-like neurochemical changes and behavioural effects consistent with antidepressant/antistress activity in rodents. Third, increased CNR1 levels were found in the hippocampus and prefrontal cortex of the post-mortem brains of patients with major depression. Finally, polymorphisms of CNR1 were reported to be associated with schizophrenia, substance addiction/abuse, and depression in patients with Parkinson's disease. The present study analyzes four tag SNPs in the CNR1 gene in 240 Caucasian BD families, which comprise the Clinical Neurogenetics (CNG) pedigrees with 45 samples (7 trios and 6 quads) and the National Institute of Mental Health (NIMH) Genetics Initiative for Bipolar Disorder waves I-IV with 868 samples (40 trios and 187 quads). Neither allelic nor haplotypic association with BD is found in our study (Sib-Transmission/Disequilibrium test for allelic association: rs12720071, $P = 0.64$; rs806368, $P = 0.92$; rs1049353, $P = 0.69$; rs806370, $P = 1$; TDTPHASE for haplotype consisting of rs12720071, rs806368 and rs1049353: global $P = 0.45$). Our sample has 80% power at $P < 0.01$ to detect an odds ratio (OR) > 1.6 for allele frequency of 0.1 and an OR > 1.4 for allele frequency of 0.5, under a multiplicative model. Thus it is unlikely that the CNR1 gene plays a major role in the susceptibility to bipolar disorder.

Ovotestes and XY sex reversal in a female with an interstitial 9q33.3-q34.1 deletion encompassing NR5A1 and LMX1B. *S. Schlaubitz[1, 9], S. Yatsenko[1], L. Vissers[3], L. Smith[4, 5], K. Keller[5], D.A. Scott[1], W.W. Cai[1], W. Reardon[6], O. Abdul-Rahman[7], E. Lammer[8], E. Magenis[4], J. Veltman[3], P. Stankiewicz[1], B. Zabel[8], B. Lee[1, 2]* 1) Dept. of Mol. & Human Genetics, Baylor College of Medicine, Houston, TX; 2) HHMI, Baylor College of Medicine Houston, TX; 3) Dept. of Human Genetics, NCMLS, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands; 4) Sect. of Medical Genetics & Mol. Genitopatellar syndrome (GPS [MIM 606170]) is a rare multiple anomaly syndrome characterized by renal and genital anomalies, congenital contractures, aplastic/ hypoplastic and often displaced patellae, dysmorphic facial features, and mental retardation. Reported individuals have significant delays in gross motor development and expressive language. Because animal models have shown that limb and genitourinary development share common genetic pathways, we collected blood from seven GPS patients to perform a systematic molecular analyses. This involved mutation screening of the coding regions of WNT4, WNT7A, TBX4 and LMX1B, CGH using a high density BAC array consisting of 32,447 clones, and FISH. We found a microdeletion of chromosome 9q that includes LMX1B and NR5A1 in a child who has features of GPS along with true hermaphroditism and a 46,XY karyotype. This microdeletion, causing haploinsuffiency of LMX1B and NR5A1, was not seen in other patients with GPS by FISH. LMX1B is essential in dorso-ventral patterning of the developing limb and is mutated in nail patella syndrome, while NR5A1 is required for male sexual differentiation and is mutated in different forms of XY sex reversal. These data suggest that the etiology of GPS is heterogeneous and may include microdeletions associated with haploinsufficiency of LMX1B and NR5A1.

Identifying the Molecular Basis of Morphological Variation in Beaks. *K. Powder[1], S. Brugmann[2], J. Helms[2], M. Lovett[1]* 1) Washington University, St Louis, MO; 2) Stanford University, Stanford, CA.

Avian beaks show extreme species-specific variability in morphology, though they develop from the same primordial structures. Understanding the molecular and developmental bases of these variations enhances our insights into evolution and provides a unique model for investigating human craniofacial disorders. In both humans and birds, cranial neural crest cells are the primary source of mesenchyme for the frontonasal prominence; previous work has shown that these cells contain species-specific patterning information. To determine the molecular basis of avian craniofacial patterning, we measured changes in gene expression between cranial neural crest cells from the frontonasal prominence of three bird species (chickens, quails, and ducks) at two different developmental stages. Samples were dissected before (HH20) and after (HH25) morphological distinctions between the species are evident. A total of 55 comparative hybridizations were conducted on a custom microarray, which contains oligonucleotides designed for cross-species comparisons of most transcription factors plus a wide range of signaling pathways. Our data indicate that by HH20, prior to any overt morphological differences, cranial neural crest cells have established a species-specific expression profile and this profile is largely maintained, with very few changes, to HH25 when morphological differences are evident. Over 280 genes were found to be differentially expressed (>2-fold with p-values < 0.05) between the three species, with fold changes ranging from a 30-fold up-regulation of ZNF334 to a 17-fold down-regulation of ZNF2 in duck versus chicken. Of the seventy genes that exhibited the largest changes, ten percent are known components of WNT signaling and another ten percent are parts of the TGF/BMP signaling pathways. Several of the other genes have also been previously implicated in human craniofacial morphogenesis (e.g. OSR1, OSR2, SATB2, and Jagged2). This set of genes provides a list of valuable candidates to investigate the molecular mechanisms that lead to species-specific craniofacial form, and also underlie a number of human craniofacial anomalies.

Glucocerebrosidase Mutations in Sporadic Parkinson Disease. *E. Sidransky[1], M.J. Eblan[1], U. Gutti[1], B. Stubblefield[1], O. Goker Alpan[1], A.B. Singleton[2]* 1) Molec Neurogen,MGB/NHGRI/NIH, Bethesda, MD; 2) Molecular Genetic Unit NIA,NIH< Bethesda, MD.

Background: An association between glucocerebrosidase, the enzyme deficient in Gaucher disease, and the synucleinopathies has been suggested both by the development of parkinsonism in Gaucher probands and carriers and by the presence of mutations in the gene for glucocerebrosidase (GBA) in different series of subjects with synucleinopathies. An open access Parkinson repository was used to better establish the incidence of GBA mutation in cohorts with sporadic Parkinson disease (PD). Methods: The glucocerebrosidase gene (GBA) was sequenced in samples collected from 92 Caucasian Parkinson disease patients from the United States and 92 Chinese Parkinson disease patients from Taiwan and in 184 clinically screened controls, matched for age and ethnicity. Findings: Among the Caucasian cohort, 5.4% of subjects carried mutations in GBA, while there were no carriers among the matched controls. The frequency of GBA mutations among the Chinese PD probands was 4.3%, in contrast to 1.1% in Chinese controls. Mutant alleles identified included the known mutations N370S (3 cases), L444P, D409H, T323I and three novel mutations, R262H, L174P and Q497R. Conclusion: These results, ascertained in two ethnically diverse cohorts collected in a standardized and clinically rigorous fashion by an open access Parkinson disease repository, and screened by direct sequencing of GBA, demonstrate that GBA mutations are encountered in subjects with sporadic PD at a higher frequency than most known PD genes. These findings suggest that the presence of this mutant lysosomal protein contributes to the neurodegenerative process, perhaps via enhanced protein aggregation.

Candidate gene medical sequencing: Fast identification of causitive variant candidates in genetically heterogeneous cardiac disease. *S.E. Scherer[1], T. Xu[2], Z. Yang[2], N.E. Bowles[2], J.A. Towbin[2], G. Weinstock[1], R.A. Gibbs[1]* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Cardiac Genetics, Dept. of Pediatrics, Baylor College of Medicine, Houston, TX.

We applied candidate gene medical sequencing to the cardiac disease, Arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) to define the scope of gene variation and highlight potential functional pathways leading to the observed phenotype. ARVD/C is characterized by sudden cardiac death and associated with nine genetic loci. Four genes have been linked to the defect, two of which encode proteins present in cardiac desmosomes and adherens junctions. Five desmosome genes as well as genes encoding sarcomeric, sarcolemma-sarcomere link and ion channel proteins were sequenced across 234 ARVD/C registry patients, including 146 unrelated probands and 250 healthy, ethnic matched controls. We identified 47 heterozygous variants in the desmosome genes while observing no variants in non-desmosome genes and low frequency in controls. Kindred analysis of PKP2 results suggested that the incomplete penetrance observed in this disease might be due in part to compound and/or digenic heterozygosity. Preliminary functional analyses are underway. These studies demonstrate the power and speed of candidate gene medical sequencing over traditional approaches in defining variant frequency and functional pathways involved in heterogeneous disease phenotypes.

Mutations in FGF Signaling Pathway Genes Contribute to Cleft Lip and Palate. *B.M. Riley[1], M.A. Mansilla[1], L. Raffensperger[1], B. Maher[2], M.L. Marazita[2], M. Mohammadi[3], J.C. Murray[1]* 1) Dept Pediatrics, U of Iowa; 2) Ctr for Craniofacial and Dental Genetics, U of Pittsburgh; 3) Dept Pharmacology, NYU School of Medicine.

Nonsyndromic cleft lip and palate (NSCLP) is a complex birth defect resulting from a combination of genetic and environmental factors. We hypothesize that members of the fibroblast growth factor (FGF) signaling pathway family contribute to NSCLP. Genotyping of SNPs in the FGF and FGFR candidate genes found significant P-value associations between NSCLP and FGF3, FGF7, FGF10, FGF18, and FGFR1 and the FGF3-FGF4 haplotype. Gene x gene interaction data supports interactions between members of the FGF family, such as FGF3/FGF18 and FGF10/FGF18, but also interactions with other NSCLP candidate genes. Medical resequencing of the coding regions of these genes in 184 NSCLP patients identified 7 novel mutations: FGFR1 M369I, E467K, R609X; FGFR2 R84S, D138N; FGFR3 V329I; and FGF8 D73H. Structural modeling of these proteins has elucidated possible functional roles for several of the mutations. Modeling of the D73H mutation indicates reduced biological activity due to disruption of FGF8 protein conformation and critical ligand-receptor binding interactions. These findings predict D73H to be a loss-of-function mutation. The E467K mutation may influence recruitment and phosphorylation of downstream signaling molecules due to its close proximity to Y463, one of FGFR1's autophosphorylation sites. Models of the V329I mutation predict that this mutation should lead to loss-of-function. Specifically, the mutation should destabilize the tertiary folding of the Ig domain 3, resulting in incomplete processing and retention of the mutated FGFR3 in intracellular compartments. These 7 point mutations may contribute to as much as 3-6% of isolated cleft lip and palate. Together with data from IRF6(12%); FOXE1, GLI2, MSX2, SKI, SATB2, and SPRY2(6%); and MSX1(2%), these genes can account for 23-26% of isolated cleft cases and have a significant impact on the clinical diagnosis and genetic counseling of CLP, in addition to providing further evidence that the FGF signaling pathway is important in lip and palate development.

RETINITIS PIGMENTOSA IN COLOMBIA: CLINICAL AND MOLECULAR STUDIES. *L. Urrego[1], N. Gelvez[1], S. Florez[2], D. Medina[2], M. Tamayo[1, 2]* 1) Instituto de Genética Humana, Bogotá, Colombia; 2) Fundación Oftalmológica Nacional, Bogotá, Colombia.

The objective of this study was identify mutations in Rhodopsin, Peripherin and NRL genes. We performed clinical and molecular studies in 115 unrelated Colombian individuals with Retinitis Pigmentosa (RP). A complete ocular examination was performed with ophthalmological exams including ERG, visual field, fluoresceinic angiography and photos of funduscopy. Genomic DNA was amplified by PCR, followed by SSCP-HA analysis and automatic sequencing. Among 115 affected we confirmed Autosomal Recessive inheritance in the 40.9% (47/115), Autosomal Dominant in 9.5% (11/115), recessive X-linked in 3.5% (4/115) and sporadic cases in 46.1% (53/115). The SSCP-HA analysis showed 14 different migration patterns in 85 RP individuals. By sequencing, 6 different polymorphisms were identified, three of them are already reported (Gly338Asp, Lys310Arg and Glu304Gln) and the others (24037 Ins G, Ala351Ala and Thr278Thr), are no reported yet in the literature. The frequency of Gly338Asp was 48.7% (56/115), Lys310Arg 26.9% (31/115), Glu304Gln 13.9% (16/115), 24037 Ins G 41.7% (48/115), Ala351Ala 5.2% (65/115) and Thr278Thr 0.87% (1/115). Although our statistical analysis are not conclusive, the severity of the disease seems to be higher than expected by several mechanism of inheritance. On the other hand, the presence of some polymorphisms could be related with the tendency to present an earlier onset of the disease.

Genotype-phenotype correlations for sub-microscopic copy number variants. *F. Zahir[1], A. Baross[2], A.D. Delaney[2], P. Eydoux[3], H.V. Firth[4], W.T. Gibson[1], S. Langlois[1], H. Martin[4], M. Marra[1,2], R.M. Pettett[5], A-C. Thuresson[6], J. Vermeesch[7], L. Willat[4], SL. Yong[1], J.M. Friedman[1]* 1) Dept Med Genet, Univ BC; 2) BC Genome Sci Ctr; 3) Dept Path & Lab Med, C&W Hosp (1-3 Vancouver, Canada); 4) Dept Med Genet, Addenbrookes Hosp; 5) Wellcome Trust Sanger Ins (4&5 Cambridge, UK); 6) Uppsala Univ Child Hosp, Sweden; 7) Univ Hosp, Ctr Hum-Genet, Leuven, Belgium.

Mental Retardation (MR) is idiopathic in at least half of all cases. Potentially pathogenic de novo, submicroscopic gains/losses of genomic material (copy number variants-CNVs) were identified using Affymetrix GeneChip 100K Whole Genome Sampling Analysis in 10 of 100 children with idiopathic MR. Genotype-phenotype correlations were performed in these 10 cases to establish pathogenicity. Five cases have CNVs with genomic coordinates that overlap with other cases in DECIPHER (http://decipher.sanger.ac.uk), an international database of pathogenic CNVs detected by array genome hybridization. Two of our cases and DECIPHER #CAM126 show overlapping deletions of 14q11.2. These cases exhibit similar facial features: widely-spaced eyes, prominent epicanthic folds, very short nose with flat bridge, long philtrum, prominent Cupids bow, full lower lip, and unusual auricle malformation. The genomic overlap region covers only 3 annotated genes, which can be considered good candidate MR genes. Another child with a 3.6 Mb, 16p13.3 duplication, has a striking phenotypic resemblance to reported cases with cytogenetically apparent duplications of the same region, and with a larger duplication in DECIPHER #CGH237, indicating the critical genomic region lies in our patient's lesion. Other cases show a deletion 22q12 matching DECIPHER #CHG758 and a deletion 7p21 matching DECIPHER #UPP969. The fact that half of our de novo CNVs show overlap with others reported in DECIPHER supports the pathogenicity of these lesions for MR. High resolution Array Genome Hybridization permits identification of new chromosomal abnormality syndromes and provides insight into copy-number-sensitive genes affecting embryonic brain development.

Thirty percent of *LMNA* cardiomyopathy families manifest complex disease in which some mutation negative family members are phenotype positive. *S. Parks[1], J. Kushner[1], D. Nauman[1], D. Burgess[1], S. Ludwigsen[1], A. Peterson[1], D. Li[1], P. Jakobs[1], M. Litt[2], R. Hershberger[1]* 1) Divison of Cardiovascular Medicine, Oregon Health & Science University, Portland, OR; 2) Department of Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR.

As many as one half of all cases of idiopathic dilated cardiomyopathy (IDC) may be familial dilated cardiomyopathy (FDC), which is thought to be caused by rarely occurring, single base mutations in any of several different genes. The lamin A/C gene (*LMNA*), known to cause progeria, AD Emery-Driefuss muscular dystrophy, lipodystrophy and other disorders, is also a well known cause of FDC. To evaluate the risk of lamin A/C cardiomyopathy in patients with FDC versus those with non-familial IDC, blood was collected from 324 probands, of whom 138 had IDC and 186 had FDC. Genomic DNA was PCR amplified and sequenced for nucleotide alterations in *LMNA*. Likely disease causing mutations were followed up by evaluating additional family members, when possible.

LMNA mutations were observed in 20 of the 324 probands (6.2%), including 6 of 138 (4.4%) with IDC and 14 of 186 (7.5%) with FDC. Conduction system disease, which is commonly observed in *LMNA* cardiomyopathy, was evident in 19 of the 20 probands (95%). Unexpectedly, we found that in 6 of the 20 *LMNA* cases, (30%) there was at least one additional family member with dilated cardiomyopathy who did not carry the *LMNA* mutation, a condition we refer to as complex disease. This suggests that an additional factor, such as a second disease gene, is involved, and indicates that genetic dilated cardiomyopathy may have a more complex basis than previously appreciated. These findings challenge disease models suggesting that a mutation in a single gene is generally sufficient to explain FDC. The implications are profound for providers and patients, especially in the interpretation of clinical molecular genetic results, as neither a negative nor a positive *LMNA* sequence finding may provide a definitive explanation. We suggest extreme caution in the interpretation of clinical genetic testing results for lamin A/C cardiomyopathy.

A worldwide survey of linkage disequilibrium and haplotype variation in the human genome. *J.K. Pritchard[1], D.F. Conrad[1], G. Coop[1], M. Jakobsson[2], X. Wen[1], J.D. Wall[3], N.A. Rosenberg[2]* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Department of Biological Sciences, University of Southern California, Los Angeles, CA.

Although recent genome-wide surveys have provided high-resolution information about haplotype structure in a small number of human populations, little is known about the extent to which these populations are representative of global haplotype diversity. We report haplotype structure across 12 megabases of DNA sequence in a sample of 927 individuals from 52 human populations. The geographic distribution of haplotypes strongly reflects human history, with a loss of haplotype diversity as distance increases from our species ancestral range in Africa. Although there is dramatic variation across populations in the extent of linkage disequilibrium (LD), considerable sharing of haplotype structure exists, and the locations of inferred recombination hotspots generally match across diverse human populations. The four samples studied by the International HapMap Project contain the majority of haplotypes found in most populations: averaging across the 52 populations, 83% of common haplotypes in a population are also common in the most similar HapMap sample. Consequently, although the efficiency of tag-SNPs based on the HapMap is reduced in low-LD African populations and in Eurasian populations distant from those studied in the HapMap, the HapMap will be helpful for the design of genome-wide association mapping studies in nearly all human populations.

A mutation of -Actin responsible for a new neurological syndrome associated with dystonia and deafness alters actin dynamics and mitochondrial bioenergetics. *V. Procaccio[1], G. Salazar[2], S. Ono[2], M. Styers[2], M. Gearing[2], A. Davila[1], R. Jimenez[1], J. Juncos[2], C. Gutekunst[2], G. Meroni[3], B. Fontanella[3], E. Sontag[4], J.M. Sontag[4], V. Faundez[2], B. Wainer[2]* 1) Center for Molecular and Mitochondrial Medicine, Univ California, Irvine; 2) Departments of Cell Biology and Pathology, Laboratory Medicine and Neurology, Emory Univ School of Medicine, Atlanta; 3) Telethon Institute of Genetics and Medicine, Naples; 4) Department of Pathology, Univ of Texas Southwestern Medical School, Dallas.

Actin is a major cytoskeletal protein in neurons, and the dynamics of its assembly affect many aspects of cell motility and membrane turnover, representing a major ATP-consuming process in cells. Actin protein is one of the most highly conserved proteins. Actin is co-transported with actin-binding proteins, including ADF and cofilin, which are essential for rapid turnover of actin filaments in vivo. An extensive actin aggregation in the brains of identical twins with generalized dystonia and deafness associated with multiple developmental abnormalities was previously reported. We recently found a missense mutation in a non-muscle form of the actin gene, -actin, resulting in an arginine to tryptophan substitution at position 183 in a highly conserved domain of the protein. Cellular studies of a probands lymphoblastoid cell line showed altered actin depolymerization dynamics in response to latrunculin A, an actin momomer sequestering drug. In addition, DNA microarray studies of mitochondrial gene expression using our Mitochip and real-time quantitative PCR in brain tissues showed increased expression of several genes including actin, cofilin, genes involved in apoptosis and mitochondrial reactive oxygen species (ROS) scavenging enzymes in response to increased mitochondrial ROS production. Expression of genes involved in mitochondrial ATP production was down-regulated in brain cortex. Actin turnover requires ATP consumption and actin depolymerisation is the rate limiting step for actin turnover. Hence the actin mutation may affect the integrity and function of the ATP-binding site, altering energy production and increasing free radical generation.

Angiotensinogen gene polymophism predicts blood pressure response to an angiotensin converting enzyme inhibitors therapy. *X. Su[1], L. Lee[2], X. Li[1], J. Lu[2], Y. Hu[2], S. Zhan[2], W. Cao[2], ling. Mei[1], YM. Tang[1], R. Krauss[3], J. Rotter[1], H. Yang[1]* 1) Medical Genetics, Cedars-Siniai Medical Center, Los Angeles, CA; 2) Department of Epidemiology, School of Public Health, Peking University Health Science Center, Beijing, China; 3) Children's Hospital Oakland Research Institute, Oakland, CA.

Bacground-Angiotensinogen(AGT), one of the major structural candidate genes in the Renin-Angiotensin-Aldosterone System pathway, was evaluated for its association with BP response to ACEI therapy in a large sample of Chinese hypertensives by utilizing a haplotype approach in a two-stage design. Methods and Results-1447 hypertensives ascertained from a Chinese community-based screening for hypertension and underwent the benazepril treatment as sole therapy for 3 years were randomly assigned into two groups, an exploratory set(n=733) and a confirmatory set(n=714). Four SNPs, -6 A/G, T207M, M268T and C11537A, were selected based on the TagSNP approach and previous reports. In the exploratory set, all 4 common haplotypes and SNPs were analyzed. Haplotype 2 (H2) carriers had a borderline significant increase in diastolic BP(DBP) reduction than those without H2, p=0.086 after adjusting for baseline BP, gender, age, kidney function and dose of benazepril received. Among the four SNPs, C11537A in the 3 untranslated region(3-UTR)of the AGT gene was significantly associated with DBP response to ACEI therapy(P=0.028). The A allele carrier had a greater DBP reduction than CC homozygotes. Since the H2 is the only common haplotype contained the A allele at C11537A suggests that the observed borderline H2 association is likely driven by A allele in the SNP. In the confirmatory set, we observed a significant association (p=0.018) after adjusting for the same covariates. Electrophoretic mobility shift assay demonstrated that this SNP located on AP4 specific binding site and that the binding affinity was significantly higher with the C than the A allele. Conclusion-We identified that a SNP in 3-UTR of the AGT gene is associated with DBP response to an ACEI therapy and suggest its potential function might be related to its effect on AP4 binding.

Development of High Multiplex TaqMan MicroRNA Assays. *R. Tan, C. Chen, K. Guegler* Applied Biosystems, Foster City, CA.

MicroRNAs (miRNAs) are endogenous small non-coding RNAs averaging ~22- nucleotides. MicroRNAs down-regulate gene expression by inducing endonucleotic cleavage or translational repression of specific target mRNAs, and play important regulatory roles in many cellular processes. More than 1,000 miRNAs have been identified, and the number of discovered miRNAs is still growing. The explosion of interests in miRNAs has created a demand for experimental tools to identify, quantify and profile miRNAs. A stem-loop RT-based TaqMan miRNA assay has been developed at Applied Biosystems for miRNA quantification. Recently, we have optimized the condition of the RT-based high multiplex TaqMan miRNA assay. To further improve the rate of throughput, we have developed a ligation-based full plex TaqMan miRNA assay, in which all miRNAs can be multiplexed together to perform ligation, digestion and reverse transcription in a single tube, followed by individual real-time PCR. The relative quantification results of ligation-based assay are similar with those of RT-based assay. Both RT-based and ligation-based high multiplex TaqMan miRNA assays have provided powerful tools to profile miRNAs sensitively and cost effectively in high through put manner.

Detection of genomic copy number variations (CNV) using the SNPlex genotyping system. *M. Wenz[1], F. de la Vega[1], R. Koehler[1], A. Tobler[1], T. Hemming Karlsen[2], A. Franke[3], S. Schreiber[3], J. Hampe[3]* 1) Applied Biosystems, 850 Lincoln Centre Drive, Foster City, CA, USA 94404; 2) Institute of Immunology, Rikshospital et University Hospital, N-0027 Oslo, Norway; 3) Institute for Clinical Molecular Biology, Christian-Albrechts-University, Schittenhelmstr. 12, 24105 Kiel/Germany.

Genome copy number variations (CNVs) are far more frequent than originally expected, and many of them affect gene copy numbers. Several genetic disorders are the result of CNVs, however because of technical limitations, the extent to which such contribute to phenotypic variations is still poorly understood. We recently introduced the SNPlex Genotyping System to address the need for accurate genotyping data, high sample throughput, study design flexibility, and cost efficiency. The system uses oligonucleotide ligation/polymerase chain reaction (OLA/PCR) and capillary electrophoresis (CE) to analyze single nucleotide polymorphism (SNP) genotypes (Tobler et al. J. Biomol. Tech. 16(4), 2005). Here we demonstrate the feasibility of an adaptation of the SNPlex Genotyping System, to analyze CNVs by comparing the intensity ratios of OLA reactions in test and reference regions. We will present the copy number analysis of DNAs with known chromosomal duplications. Specifically, we studied 88 genomic DNAs, 7 of which contained duplications of the chromosomes 9, 13, 18 or X. On each duplicated chromosome we analyzed at least 10 test OLA reactions, and differences in intensity ratios confirmed all known chromosomal duplications. The assay further identified male (XY) and female (XX) DNA samples due to their copy number difference of the X chromosome. In addition to identifying known chromosomal duplications, we analyzed copy numbers changes of the RCCX module of the human MHC complement gene cluster.

A mouse model for Sjögren-Larsson syndrome produced by targeted knockout of the ALDH3A2 gene encoding fatty aldehyde dehydrogenase. *W.B. Rizzo[1], G. Carney[1], J. Bridger[1], R. Spieker[1], L. Bunnell[1], L. Spaulding[2], J.A. Stribley[2], J.M. Salbaum[2]* 1) Dept Pediatrics; 2) Dept Genetics, Anatomy and Cell Biology, Univ Nebraska Med Ctr, Omaha, NE.

Sjögren-Larsson syndrome (SLS) is an inherited neurocutaneous disorder characterized by ichthyosis, mental retardation and spasticity. The disease is caused by mutations in the ALDH3A2 gene encoding fatty aldehyde dehydrogenase (FALDH), an enzyme that catalyzes the oxidation of aliphatic aldehydes derived from metabolism of fatty alcohol and other lipids. To investigate the biochemical pathogenesis of SLS and explore therapeutic options, we produced an FALDH-deficient mouse strain by gene targeting methods that introduced a mutation in the ALDH3A2 gene that completely abolishes enzyme activity. ALDH3A2$^{-/-}$ mice showed undetectable (<0.05% of wild-type) FALDH activity in liver using octadecanal as substrate, but variable amounts of residual enzyme activity in intestine (7 3%), brain (35 12%) and skin (60 5%) probably due to other tissue-specific aldehyde dehydrogenase enzymes. Heterozygous mice expressed a partial FALDH deficiency in liver (42 8 % of the wild-type). Fatty alcohol (hexadecanol and octadecanol) levels in tissues from the ALDH3A2$^{-/-}$ mice were increased in liver (7-fold), skin (3-fold) and brain (11-fold) compared to wild-type animals. The mutant mice were fertile and appeared to have a normal lifespan. The clinical phenotype of the ALDH3A2$^{-/-}$ mice was variable on a mixed 129 genetic background, suggesting the presence of modifier genes. Approximately one-fourth of the mutant mice developed ichthyosis at 6-12 months of age, whereas a small number of mutant mice, all products of homozygous crosses, showed congenital ichthyosis. Some mice displayed self-mutilation with loss of ear tissue due to excessive scratching that resembles the pruritus seen in SLS patients. ALDH3A2$^{-/-}$ mice performed poorly on Rotorod testing compared to wild-type mice. This animal model of SLS should prove valuable for elucidating the biochemical pathogenesis of the disease, exploring modifier genes and developing new therapeutic approaches.

Bivariate Linkage Analysis Identified Genomic Regions for Body Fat Mass and Bone Mineral Density. *P. Xiao*[1], *Z.H. Tang*[2], *H. Shen*[3], *H.W. Deng*[3] 1) Osteoporosis Research Center, Creighton University, Omaha, NE, USA; 2) Laboratory of Molecular and Statistical Genetics, College of Life Sciences, Hunan Normal University, Changsha, Hunan, P. R. China; 3) Departments of Orthopedic Surgery and Basic Medical Science, School of Medicine, University of Missouri-Kansas City, Kansas City, MO, USA.

Body fat mass (BFM) is a predictor of bone mineral density (BMD). It was also suggested that BFM and BMD are highly correlated. However, knowledge on specific genes influencing both BFM and BMD is limited. To identify genomic regions affecting both BFM and BMD, we performed a bivariate linkage analysis involving 4,126 subjects from 451 families on BFM and BMD at spine, hip and wrist, respectively. The highest LOD score of 2.69 was achieved on 7q21 for BFM and spine BMD. Another interesting suggestive linkage was detected on 6q27 for both BFM and spine BMD (LOD = 2.42) and BFM and hip BMD (LOD = 2.30). In addition, suggestive evidence was also found on 2q32 for BFM and hip BMD, and 6p22 and 11p13 for BFM and wrist BMD. Our results suggest that there may be pleiotropic genes on chromosome 2, 6, 7, and 11 for BFM and BMD at different skeletal sites.

Gene-environment interactions between maternal stress and Factor 5 polymorphisms on preterm delivery. *H.-J. Tsai[1,2], Y. Yu[1,2], X. Wang[1,2]* 1) The Mary Ann and J. Milburn Smith Child Health Research Program, Children's Memorial Hospital and Children's Memorial Research Center, Chicago, IL; 2) Department of Pediatrics, Feinberg School of Medicine, Northwestern University, Chicago, IL.

Preterm delivery (PTD, < 37 weeks of gestation) is a major public health concern and a leading cause of infant mortality and morbidity. PTD has been recognized as a complex trait, but the etiology is still unclear. Previous results have suggested that genetic effects, environmental factors and gene-environment interactions may play an important role in PTD. However, only very few studies have examined genetic effects, gene-gene and gene-environment interactions. In this study, we genotyped seven single nucleotide polymorphisms (SNPs) of Factor 5 gene in 337 mothers with PTD and 527 mothers with term deliveries in multiple racial groups at the Boston Medical Center. Of these, 4 SNP variants resulted in non-synonymous amino acid changes. We only carried out association tests for 4 SNPs with major allele frequencies more than 10%. We adjusted maternal age, race, education, marital status, parity, passive smoking, and infant gender in all analyses. Significant genotype associations of PTD were observed with two SNPs 6 and 7 (p=0.04 and 0.02, separately). Locations of SNP 6 and 7 are in an intronic region and His107Asp, respectively. Moreover, we examined genetic effect of SNPs 6 and 7 in PTD stratified by lifetime stress and stress during pregnancy, respectively. We found that SNP 7 was significantly associated with PTD among women with low-to-medium, but not high lifetime stress (p=0.01 and 0.92, separately). Similarly, significant association between SNP 7 and PTD was only observed among women with low-to-medium stress during pregnancy (p=0.01). Our results have demonstrated gene-environment interactions between maternal stress and Factor 5 genetic variants on PTD. We are planning to examine whether F5 SNPs are associated with PTD related traits such as low birth weights, and account for potential confounding effect due to population stratification in future analyses.

A new estimator for locus-specific genetic effect from case-control data based on generalized linear model. *G. Zhang[1], R. Chakraborty[1], L. Jin[2,3,1]* 1) Center for Genome Information, University of Cincinnati, Cincinnati, OH; 2) School of Life Sciences, Fudan University, Shanghai, China; 3) CAS-MPG Partner Institute of Computational Biology, Shanghai, China.

Genetic architecture underlying complex disease is governed by loci that have quantitative genetic effects. Their locus-specific effects can be stated in terms of amounts of variation; i.e., the fraction of the phenotypic variation attributable to certain DNA variant(s) between individuals. However, for binary traits, the continuous liability is a latent variable, which makes the variation attributable to certain DNA variant(s) cannot be readily calculated. Instead, the most widely used measures for genetic contribution or effective size of genetic variant(s) are based on penetrance, such as genotypic relative risk, odds ratio or heritability of penetrance. These measures evaluate the outcomes of a complex disease as zero or one, which neglect the underlying gradation of some attribute related to the disease causation. Furthermore, these measures fail to reflect the intrinsic effects of disease allele frequency or disease prevalence. Consequently, these measures are not directly comparable between different diseases, or even between different genetic variants of a same disease. In this presentation, we develop a method to estimate locus-specific genetic effect of certain genetic variant(s) from case-control data based on a generalized linear model (GLM). The proposed estimator is less sensitive to allele frequency or disease prevalence. We show analytically that the estimator is proportional to the Wald statistic, which brings another favorable property of it - it can serve as a direct index for the power of association study. We evaluate the performance of the Wald test on the proposed estimator and show that the power is greater or equal to those of the traditional ^{2} or Hotelling's T^2 tests. In addition, this estimator can be extended to multi-locus or haplotype settings for estimating the genetic effect of a haplotype block. Finally, the potential usage of this estimator to study genetic epistasis as departure from additivity of variance explained by single-locus effects is discussed.

The Prader Willi-like phenotype in Fragile X syndrome. *F. Tassone[1,2], S.T. Nowicki[2], M-F. Croquette[3], P.J. Hagerman[1], R.J. Hagerman[2]* 1) Department of Biochemistry and Molecular Medicine, University of California, Davis, School of Medicine, Davis, CA, 95616, USA; 2) M.I.N.D. Institute, UC Davis, Sacramento, 95817, CA, USA; 3) Department of Neuropediatrics, Centre Hospitalier Regional et Universitarie de Lille, France.

Fragile X syndrome (FXS) is a single-gene disorder with a broad spectrum of involvement and a strong association with autism. The spectrum of involvement in fragile X is likely related to molecular variations both within the FMR1 gene, within the genes that FMR1 protein (FMRP) regulates and in other background genes in addition to environmental factors. Indeed FMRP is a translational regulator, whom absence leads to dysregulation of a number of other genes. FMRP binds to additional proteins, including CYFIP1 and CYFIP2, in carrying out its role as a transporter and regulator of translation of mRNAs. CYFIP1, which has been recently mapped to the critical region of 15q (Prader Willi/Angelman region)is an important protein that interacts with Rac1 in an activity dependent manner and acts as a link between two processes that underlie synaptic remodeling, including the cytoskeleton reorganization regulated by Rac1 and control of local protein translation via FMRP. A subgroup of patients with FXS has a Prader-Willi phenotype (PWP), which includes severe hyperphagia, obesity, hypogonadism. Here, we describe a group of 13 of these patients who present with severe hyperphagia, severe behavioral problems but most striklingly a high rate of autism compared to individuals with FXS only. In addition, our preliminary molecular studies demonstrate a significant dysregulation of CYFIP1, at both RNA and protein level, in the majority of patients with FXS and PWP suggesting that abnormal expression of CYFIP1 and/or contiguous genes may be associated with autism and with the PWP in fragile X syndrome. Since synaptic remodeling problems are seen in subgroups of patients with autism, particularly those with newly discovered X-linked MR genes, the PWP in FXS may be a model disorder for understanding the link between FXS and other forms of autism.

Association testing of candidate genes in the anabolic neuropeptide pathway with obesity among the Samoans of Polynesia. *D.T. Smelser[1], G. Sun[1], R. Kaushal[1], P. Pal[1], S. Viali[2], J. Tufa[3], R. Chakraborty[1], D.E. Weeks[4,5], S.T. McGarvey[6], R. Deka[1]* 1) Center for Genome Information, Department of Environmental Health, University of Cincinnati, Cincinnati,OH; 2) Department of Health, Government of Samoa, Apia, Samoa; 3) Department of Health, American Samoa Government, Pago Pago, American Samoa; 4) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 5) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 6) International Health Institute, Brown University, Providence, RI.

The Samoans of Polynesia have a high prevalence of obesity (84% in women and 78% in men in American Samoa and 59% in women and 29% in men in Samoa). Samoans living in the independent nation of Samoa lead a traditional lifestyle, while American Samoans in the US territory have taken on a Western way of life. We have tested for association of variants in eight genes in the anabolic neuropeptide pathway with obesity in this population. This pathway stimulates appetite, increases feeding behavior and decreases metabolic rates, leading to overeating and obesity. DNA analysis was performed on a total of 991 samples (456 American Samoans and 535 Samoans) using a total of 45 tagging SNPs covering eight genes (AGRP, GAL, GHRL, INS, LEP, NPY, PMCH, RETN). All SNPs were found to be in Hardy Weinberg equilibrium. We found significant differences in allele frequencies at two SNPs in NPY when comparing the two populations. We found significant associations with BMI (adjusted for age and sex) in the American Samoan population for the following genes and SNPs: LEP rs3828942 (p=0.03), PMCH rs7973796 (p=0.01), PMCH rs10860845 (p=0.01) and PMCH rs10507144 (p=0.03). For the Samoan population, significant associations with BMI were seen in GHRL rs1642977 (p=0.05) and GHRL rs26310 (p=0.05). The American Samoans and Samoans are genetically similar, so the difference in the results is likely due to gene-environment interactions brought on by the variance in lifestyles between the populations. Further haplotype analysis is currently being conducted in this study.
This research is supported by NIH R01 DK59642.

Families with multiple types of Idiopathic Interstitial Pneumonia (IIP) have decreased survival. *A. Wise[1,2], M. Steele[1,2], M. Speer[2], J. Loyd[3], K. Brown[4,5], A. Herron[1], L. Burch[1], M. Schwarz[4,5], D. Schwartz[1,2]* 1) NIEHS, Research Triangle Park, NC; 2) Duke University, Durham, NC; 3) Vanderbilt University School of Medicine, Nashville, TN; 4) National Jewish Medical and Research Center, Denver, CO; 5) University of Colorado Health Sciences Center, Denver, CO.

Previously, it was thought that non-Usual Interstitial Pneumonia (UIP) forms of IIP were inflammatory and would either resolve or eventually evolve into the more fibrotic UIP phenotype. Thus, families with multiple types of IIP (heterogeneous) were thought to have the same underlying genetic basis as families with only UIP (homogeneous). To determine whether the consistency of IIP within families with Familial Interstitial Pneumonia (FIP) defined a specific phenotype, we evaluated the type of IIP within 146 families with two or more cases of IIP. Among these families, 74 of the families presented as homogeneous, while 72 exhibited a heterogeneous phenotype. Current age, age at diagnosis, age at death, mortality, sex, dyspnea, vital capacity, Dl_{CO}, smoking status, and for smokers, pack years and cigarettes per day smoked; were evaluated in affected individuals. Surprisingly, survival was decreased in the heterogeneous (47%) compared to the homogeneous (61%) families ($p<0.01$). In order to assure that this difference was not due solely to the different IIP diagnoses present in the heterogeneous families, the UIP affected individuals only from the heterogeneous families were compared to the individuals from the homogeneous families. Decreased survival in the heterogeneous families was also seen in the UIP only individuals (39% vs. 61%, $p<0.001$). Additionally, the mean age of death was significantly lower ($p<0.01$) in both heterogeneous (64 +/-12) and UIP only heterogeneous individuals (64 +/-12) when compared to individuals with UIP from homogeneous families (69 +/-10). Therefore, homogeneous and heterogeneous families may, in fact, represent two distinct phenotypic groups with heterogeneous families presenting with more aggressive disease. This difference in disease progression may also indicate genetic heterogeneity in FIP with variable genetic susceptibility leading to different disease outcomes.

A method for screening susceptibility genes and modeling gene-gene and gene-environmental interactions in large-scale candidate gene association studies. *N. Tanaka[1], K. Tokunaga[2], T. Miki[3]* 1) Dept Clinical Bioinformatics, Grad Sch of Medicine,Univ Tokyo, Tokyo, Japan; 2) Dept Human Genetics, Grad Sch of Medicine, Univ of Tokyo,Tokyo,Japan; 3) Dept Geriatric Medicine, Ehime Univ Sch of Medicine, Ehime, Japan.

Virtually any common human disease results from the genetic susceptibility factors and modifiable environmental factors. Then a large number of candidate genes can be subjected to whole genome candidate gene association studies with various diseases. Nevertheless, it is often the case that the candidate genes for further analysis are selected based on statistical analyses on disease associations for single genes. Recently several approaches have been proposed to identify gene-gene interactions. However, these approaches may be inadequate for identifying high-order interactions in the absence of the gene effects of which marginal effects are large enough to be detectable from high dimensional data, and generally do not permit us to control for potential confounders. Furthermore the interaction effects of most common disease are assumed to be non-linear. We propose here a novel screening method for case-control association studies to select candidate genes, which is composed of combined resampling methods and semiparametric additive mixed modeling. The proposed heuristic approach can handle a large number of inputs and take into account both categorical and continuous variables. We evaluate the performance of the procedures through simulation studies and illustrate their application with data from an extensive multi-institutional case-control association study on hypertension in Japanese. The proposed method provides a flexible statistical framework for controlling potential confounders and screening combinations of multiple genes and environmental factors that are associated with the disease onset.

Novel mutation in the triple helical coding domain of the *COL1A1* gene of type I collagen (R780L) causes a mild form of osteogenesis imperfecta (OI). *G. Sun, D. Chen, P. Byers* Dept. of Pathology, Univ Washington, Seattle, WA.

OI is a clinically and genetically heterogeneous disorder characterized primarily by osseous fragility. The clinical range is from very mild to lethal in the perinatal period. About 90% of affected individuals are heterozygous for mutations in one of the type I collagen genes, COL1A1 and COL1A2. Most mutations result in substitution for any one of the 338 glycine residues in the triple helical domain (Gly-Xaa-Yaa)338, alterations at splice sites, frameshifts with premature termination codons, and mutations that affect assembly of the trimer of the procollagen molecule. In a woman with a mild form of OI (25th percentile in height, blue sclerae, modest number of fractures, and some bowing of the tibias) we identified a unique mutation, c.2873G>T, that resulted in substitution of the arginine at position 780 of the triple helical domain (970 of the chain from the initiator methionine) by leucine (R780L), a Y-position substitution. Sequence of the full length of the cDNA from both genes revealed no additional mutations. Neither of her parents was affected. She had one pregnancy with the same mutation that had a large encephalocele as well as evidence of bony abnormalities. A healthy infant who did not receive the mutant allele was born subsequently. Cultured dermal fibroblasts from the proband produced some normal type I procollagen molecules and others that had been overmodified amino terminal to the region of the mutation. The mutation was cloned and expressed in the context of a full length cDNA and the expressed protein had a mobility shift that reflected the charge change. Of the 31 leucine residues in the triple helical domains of the pro1(I) and pro2(I) chains of type I procollagen only one occurs in the Y-position. Substitution experiments in peptides suggest that leucine may destabilize the helix when in the Y-position, and may slow helix propagation in a local region. This is one of a very small class of mutations in the X or Y-positions that leads to OI. Both overmodification and disruption of interactions with other matrix molecules may be important in producing bone abnormalities.

Cluster analysis of extended Y-STR haplotypes leads to discovery of a large and widespread subclade of Y Haplogroup J2. *B.E. Schrack[1], T.W. Athey[2], J.F. Wilson[3]* 1) College of Information Studies, University of Maryland, College Park, MD; 2) Retired, Brookeville, MD; 3) Public Health Sciences, University of Edinburgh, Scotland.

Cluster analysis of extended Y-STR haplotypes within Y Haplogroup J2 has led to the identification of a new subclade of J2 that is widespread, and substantial in size. The new subclade is defined by a deletion that includes part of the Y-STR marker, DYS445. The presence of the deletion is revealed when testing of DYS445 results in apparent repeat values of six, or rarely seven, instead of the values of 11 or 12 typically found in J2. Testing of Y-SNPs within haplogroup J2 in a selected group of subjects has shown that the new subclade is within Haplogroup J2a1 (as defined by Sengupta et al, Am J Hum Genet, 78:202-221, 2006). We have named the clade J2a1k. J2a1k represents approximately one-fifth of all J2 Y chromosomes in northwest Europe. An analysis of the geographic origins of members of the subclade shows that J2a1k is widely distributed within the range of Haplogroup J2 in Europe and Turkey.

Development of a high-throughput assay for the identification of small molecule inhibitors of human galactokinase. *K.J. Wierenga, K. Lai* Dr John T Macdonald Fndn Ctr Med Gen, Univ Miami, Miami, FL.

Introduction. Classic galactosemia (OMIM 230400) is caused by deficiency of galactose-1-phosphate uridylyltransferase (GALT; EC 2.7.7.12), resulting in the unique accumulation of galactose-1-phosphate (gal-1-p). Due to endogenous production of galactose adherence to galactose-free diet does not prevent long-term sequelae, which include developmental delay, ataxia, speech dyspraxia and premature ovarian failure. Since galactokinase deficiency (OMIM 230200) is a comparatively benign condition not associated with complications other than cataracts, we hypothesized that an inhibitory molecule of galactokinase (GALK, EC 2.7.1.6) activity will reduce conversion of endogenously produced galactose to gal-1-p, and potentially prevent long-term sequelae in patients with classic galactosemia. **Materials/Methods.** Human galactokinase was purified using Nickel affinity chromatography on a lysate from E. coli strain BL21 (DE3) (Novagen) over-expressing the human GALK gene (cDNA clone obtained from I.M.A.G.E. consortium, ID: 3501788). We used PlateMate Plus High Throughput 384-Channel Automated Pipetting System (Matrix Technologies Corporation) and EnVision Multilabel Plate Reader (PerkinElmer) to miniaturize the GALK assay: galactose + ATP gal-1-p + ADP. The ATP not consumed during the reaction was measured using Kinase-Glo Luminescent Kinase Assay (Promega): ATP + luciferin luminescence. Z factor was used to assess the suitability for high-throughput screening (HTS) of kinase inhibitors. Inhibition of GALK was tested using the ATP-analog adenosine 5-O-(3-thio)triphosphate (ATPS). **Results.** The optimized assay contained 0.15g GALK, 5mM $MgCl_2$, 60mM NaCl, 20mM HEPES, 30mM galactose, 500mM DTT, 0.5% DMSO and 5M ATP. Assay volume per well was 30L prior to adding Kinase-Glo. Z score was 0.91. There was a 96-fold difference in luminescence between this assay, and a similar assay without GALK. An assay with added ATPS revealed increasing inhibition of GALK activity with increasing concentration of ATPS. **Conclusions.** We established a miniaturized assay for HTS of inhibitors of GALK activity using 0.15g GALK and 5M ATP. The assay identified inhibition by ATPS.

Analysis of Transcriptomes: A Genomics Multimedia Module. *M.I. Roche[1,2], D.J. Lofland[1]* 1) Instructional Media Group, Morehead Planetarium and Science Center, UNC, Chapel Hill, NC; 2) Department of Pediatrics, UNC, Chapel Hill, NC.

Analysis of Transcriptomes is an engaging, inquiry-based module designed for advanced high school students and undergraduates. The module begins by posing the paradoxical question: how can the cells in a single organism look and behave differently even though they all share the same genome? Challenged to compare the transcriptional profiles of genes from dividing cells to those from quiescent cells, students conduct a DNA microarray experiment. After setting up the experiment, they observe the construction of the DNA microarray, obtain samples from experimental and control cells, apply the samples to the microarray, and visualize the data obtained by a laser scanner. When presented with four previously uncharacterized genes, students apply their knowledge to classify each into a functional category. Through an integrated series of narrated audio, 3D graphics, FLASH movies, and interactives, students work at their own pace and check their understanding after each subsection. A final assessment allows instructors to measure student understanding. The summary reiterates the powerful role microarrays play in answering fundamental genomic questions. Delivered over the Internet and accessed using any standard browser equipped with the Macromedia Flash plug-in, the customized, centralized delivery enables easy management and allows real-time updates to the content. The system maintains a constant connection to a back-end server, facilitating the storage and retrieval of student data. Automated tracking allows instructors to identify students' interactions with each aspect of the content and provides Web access to student scores. The module has been evaluated at a math and science high school, a major research university, and two historically, underserved minority colleges (N=95). Results from student and teacher surveys showed high levels of satisfaction with both content and delivery at all sites. Pre-test performance indicated low levels of knowledge about microarrays in comparison to the post-test assessment. This module was supported by NHGRI grant #: 5R42HG002983-03.

Designing optimal two-stage genome-wide association studies. *A.D. Skol, L.J. Scott, G.R. Abecasis, M. Boehnke* Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Genome-wide association (GWA) is a promising approach to identify common genetic variants that predispose to human disease. Because of the high cost of genotyping hundreds of thousands of markers on thousands of subjects, GWA studies will often follow a staged design in which a proportion ($_{samples}$) of the available sample is genotyped on a large number of markers in stage 1, and a proportion ($_{markers}$) of these markers are followed up by genotyping them on the remaining samples in stage 2. We describe a strategy to identify cost-effective two-stage GWA designs that preserves the power of the one-stage design while minimizing the study cost. We explore how the optimal design and study cost is influenced by differences between stage 2 and stage 1 genotyping costs, the desired genome-wide false-positive rate, and power measured as a proportion the one-stage design's power.

We find that the ratio R of stage 2 to stage 1 per genotype cost dramatically influences both the optimal design and study cost. Increasing R shifts the genotyping burden, and much of the studys cost, to stage 1, both by increasing the proportion of the samples genotyped in stage 1, and by decreasing the proportion of markers to follow-up in stage 2. When stage 1 per genotype costs are constant, increasing R can increase study costs substantially. This cost increase can be partially mitigated by adopting a design with reduced power or by increasing the false-positive rate (while preserving power).

For example, when R is 5 an optimal two-stage GWA study which retains 95% of the one-stage design's power to detect a disease variant of modest effect will genotype 40% of the sample in stage 1 and follow-up 2% of the markers in stage 2 and costs 46% of the one-stage design. If R is 25, the optimal design genotypes 50% of the sample in stage 1, follows up 0.5% of the markers into stage 2, and costs 55% of the one-stage design. By allowing 5 rather than 1 false-positive genome-wide, this study's cost decreases to 50% of the the one-stage design's cost.

Array comparative genomic hybridization analysis of 20 first-trimester spontaneous abortions with normal karyotype. *O. Shimokawa[1,2,3], N. Harada[2,3], N. Miyake[1,4], K. Satoh[4], T. Mizuguchi[3,4], N. Niikawa[1,3], N. Matsumoto[3,4]*
1) Department of Human Genetics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 2) Kyushu Medical Science, Nagasaki, Japan; 3) Solution-Oriented Research for Science and Technology (SORST), JST, Kawaguchi, Japan; 4) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan.

We performed array comparative genomic hybridization (aCGH) analysis to detect genomic copy-number changes in 20 first-trimester spontaneous abortions with normal G-banding chromosomes. DNA was extracted directly from frozen villous samples of 20 first-trimester spontaneous abortions (46,XY karyotype: 10 cases; 46,XX karyotype: 10 case). A microarray, containing 2,173 BAC clone with a 1.5-Mb resolution, was constructed and used in the analysis. Two deletions were identified: a 1.4-Mb deletion at 3p26.2-p26.3 and a 13.7-Mb deletion at 13q32.2-qter. Re-examination of chromosome preparations from the sample with the 13q deletion showed a mixture of cells with the 13q- chromosome and those mostly with 46,XX chromosomes, the latter of which is likely to have been derived from maternal decidual cells. Detection rate of genomic imbalance in this series is thus 10% (2/20). The aCGH could successfully detect submicroscopic copy number changes and may overcome drawbacks of tissue culturing and chromosomal analysis, such as tissue culture failures or overgrowth of maternal cells.

Sequencing of *BBS2, BBS4* and *BBS5* genes in non-syndromic obesity patients reveals a small contribution of these genes that is likely to involve a multifactorial model. *A. Slavotinek[1], B. Bogert[2], A. Moshrefi[1], M. Skhiri[3], A. Landin Malt[1], C. Vaisse[3], K. Ashrafi[2]* 1) Dept Pediatrics, UCSF, San Francisco, CA; 2) Dept Physiology, UCSF, San Francisco, CA; 3) Diabetes Center, UCSF, San Francisco, CA.

Bardet-Biedl syndrome (BBS) is a genetically heterogeneous malformation syndrome comprising obesity, retinal dystrophy, polydactyly, learning disability, hypogonadism and renal anomalies. Mutations in eleven genes have been identified with the encoded proteins shown to be involved in ciliary formation; the role of these genes in non-syndromic obesity has not been established. We used RNAi to target the *BBS1-BBS8* gene orthologues in C.elegans and used Nile Red fluorescence to examine the fat content of mutant worms. Inactivation of the worm orthologues of the *BBS1*, *BBS2*, *BBS5* and *BBS8* genes resulted in enlarged fat droplets in the wild-type strain N2 Bristol compared to vector controls at 72 hours after plating. C. elegans mutants for the orthologues of *BBS1*, *BBS7* and *BBS8* also showed a moderate increase in fat. Based on these results and the literature, we screened *BBS2*, *BBS4* and *BBS5* for mutations in human subjects with non-syndromic obesity. We sequenced the coding regions of each gene in 188 severely obese patients with a median BMI of 49 kg/m^2. For *BBS2*, we identified one missense alteration predicting p.R539W that was absent in more than 600 control chromosomes. For *BBS4* and *BBS5*, we have identified six novel sequence alterations that we are examining in controls. The data on BBS gene variations and obesity is so far inconclusive; one study sequenced *BBS6* in 60 men with obesity and identified the rare p.A242S mutation in two families, showing partial segregation of this mutation with the obesity phenotype and concluding that a major role for *BBS6* in non-syndromic obesity was unlikely. However, it has been noted that p.A242S could increase susceptibility to obesity in combination with other predisposing gene variants and it is plausible that the alterations in *BBS2*, *BBS4* and *BBS5* could interact with other genetic or environmental factors to produce obesity according to a multifactorial model of disease. .

Transferability of Tag SNPs between CHB and JPT: A Warning of Performing tSNPs across Genetically Close Populations. *R. Yang*[1], *S. Xu*[1], *L. Jin*[1, 2] 1) MOE Key Laboratory of Contemporary Anthropology and Laboratory of Theoretical Systems Biology, Institute of Genetics, School of Life Science, Fudan University, Shanghai, China; 2) CAS-MPG Partner Institute of Computational Biology, SIBS, CAS, Shanghai, China.

International HapMap project made an effort to generate a whole genome single-nucleotide polymorphisms (SNPs) data base in the hope of providing researchers with tag SNPs (tSNPs) to be used in association studies. Many recent studies evaluated the performance of tSNPs between HapMap populations and those outside the project, all supporting the use of HapMap data in other populations. Here we present a result of evaluating the transferability of tSNPs between CHB and JPT, which are two samples used in HapMap project and put together in all the studies for their genetically close relationship. Our results are based on the data of ten 500-kb ENCODE regions and focused on SNPs with minor allele frequency of more than 15%. We found that the transferability of tSNPs between CHB and JPT is not as high as expected, only 84.9% (80.2-89.5%) from CHB to JPT and 86.8% (83.1-90.4%) from JPT to CHB, in contrast to the higher transferability across Caucasian populations (90-95%). Although the transferability of tSNPs between genetically close populations is higher than that of between those genetically distant (72.6% [60.4-84.8%] from CEU to CHB and 68.5% [55.5-81.6%] from CEU to JPT), our results indicate that people should keep in mind about the information loss when applying tSNPs from one population to others, even between those genetically close populations.

Development of objective tools to assess the number and volume of dermal neurofibromas in adults with Neurofibromatosis 1. *A. Theos[1], A.M. Shih[3], Y. Ito[3], B.S. Burns[2], B.R. Korf[2]* 1) Department of Dermatology; 2) Department of Genetics; 3) Department of Mechanical Engineering, University of Alabama at Birmingham, Birmingham, AL.

Purpose: To evaluate standardized digital photography and surface laser scanning as objective tools for quantifying the number and volume of dermal neurofibromas in adults with NF 1.

Methods:(1) Standardized digital photography was used to assess neurofibroma density. A 100 cm^2 frame was applied to predetermined regions on the back, abdomen, and thigh of adults with NF1. Discrete dermal neurofibromas that measured 2 mm in diameter were marked with a washable marker and counted. Standardized digital photographs were taken. Tumor density was calculated for each of the three body regions.(2) Surface laser scanning was used to calculate the volume of dermal neurofibromas. A defined 100 cm^2 area containing discrete dermal neurofibromas was scanned 4 separate times with a Minolta Vivid 9i laser scanner, which has an accuracy of 0.05 mm. The scanned data was converted to a 3-D triangulated mesh and the volume of three random tumors in each patient was calculated using Rapidform software. The reproducibility of this method was determined.

Results:(1) 31 patients with NF1 were evaluated with standardized digital photography. Tumor density ranged from 0-2.1/cm^2. Significantly higher tumor burden was observed on the back and abdomen.(2) 3 adults with NF1 were evaluated with surface laser scanning. This method proved to be rapid and easy to use. The reproducibility was assessed and the coefficient of variation ranged from 1 to 7.28.

Conclusion: The lack of objective methods for following the growth of dermal neurofibromas is a significant impediment to the study of new preventative and therapeutic measures in NF1. Based on our pilot studies, we conclude that standardized digital photography and surface laser scanning are useful methods for quantifying the number and volume of dermal neurofibromas.

Delineation of breakpoints in patients with 9q34.3 chromosomal rearrangements using fosmid array-CGH. *S. A. Yatsenko[1], S. W. Cheung[1], C. Shaw[1], F. Scaglia[1], A. Patel[1], T. Sahoo[1], G.M. Weissenberger[1], C. Chinault[1], J.R. Lupski[1,2,3]* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine; 3) Texas Children Hospital, Houston, TX.

Cryptic unbalanced subtelomeric rearrangements are emerging as an important cause of mental retardation and malformation syndromes. Constitutional disorders of 9q34.3 including terminal and interstitial microdeletions, duplications, derivative chromosomes and complex rearrangements are relatively frequent. Recently, we presented the FISH mapping of breakpoints in 11 patients with 9q34.3 microdeletion syndrome using BAC clones, and identified an ~700 kb critical region encompassing *EHMT1* (euchromatic histone methyltransferase) and *CACNA1B* associated with a minimal phenotype (Yatsenko et al, 2005). To further refine the location of the breakpoints and gain insight into the recombination mechanisms leading to 9q34.3 chromosomal instability we constructed a CGH-microarray using 239 fosmid clones spanning ~ 8 Mb of the most distal 9q region as well as subtelomeric regions of all chromosomes. Using this approach we studied a total of 14 rearrangements of 9q34.3 including 8 deletions, 2 duplications, 3 derivative chromosomes and an unbalanced translocation in a fetus. The majority of 9q34 rearrangements occur *de novo*, except in one patient who inherited a der(9)t(9;13)(q34.3;p12) from a balanced carrier mother. A CGH-based rapid identification of cytogenetically undetected 9q34 chromosomal imbalances demonstrates their complexity, and delineates the breakpoints to a 30-40 kb resolution in each case studied. Our investigation reveals that duplications of 9q34 vary considerably in size, in contrast with deletions that appear limited to the 9q34.3 region; for both types of rearrangement there is no single common breakpoint. Further cloning and sequencing of breakpoints is ongoing to gain insights concerning the mechanism of formation of terminal rearrangements and to unravel dosage sensitive genes potentially responsible for the observed phenotypes.

The role of inflammatory genes in a gastric precancerous lesion. *Y.Y. Tsai[1], S.W. Wang[2], I.C. Wu[2], R. Wu[1], D.C. Wu[2], S.H. Juo[1,3]* 1) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Taiwan; 2) Division of Gastroenterology, Kaohsiung Medical University Hospital, Taiwan; 3) Department of Clinical Research, Kaohsiung Medical University Hospital, Taiwan.

INTRODUCTION: Intestinal metaplasia (IM) is a precancerous lesion of gastric cancer. Inflammation may play a role to initiate the gastric carcinogenesis, and therefore, inflammation may also be involved in the development of IM. The aim of the study is to evaluate the relationship between three inflammatory genes and IM.

METHODS: A case-control study with 190 IM and non-IM subjects was conducted. All controls did not have IM pathological findings for two or more consecutive biopsy examinations during a 3-year or longer follow-up. Single nucleotide polymorphisms (SNPs) were selected for genotyping using the Taqman technology. We selected one functional promoter SNP (i.e. SNP1) and one tSNP (i.e. SNP2) at the COX-2 gene, two tSNPs (SNP3 and SNP4) at the IL-6 gene and, two tSNPs (SNP5 and SNP6) at the IL-10 gene from the HapMap project. The genotype data were analyzed by using chi-square test. We also used the Hap-clustering program to perform the haplotype analysis.

RESULTS: The six SNPs in cases and controls were all in Hardy-Weinberg equilibrium. The statistical results showed significant association at IL-6 SNP3. Compared with the reference TT genotype, the G carriers had an OR of 1.62 (95%CI: 1.07~2.46, p=0.024). A borderline significance was found at IL-6 SNP4:the G carriers of SNP4 had an OR of 1.51(95%CI: 0.98~2.32, p=0.06) compared with the reference AA genotype. The haplotype analysis for IL-6 polymorphisms also reached a statistical significance (p=0.046). However, there was no statistical significance for either of the COX-2 or IL-10 polymorphisms.

CONCLUSIONS: The IL-6 gene may play a moderate role in the development of IM in the Taiwanese population. More subjects will be recruited in the near future to provide a more solid result.

Allele frequencies of CYP2C19 and CYP2D6 in a Japanese population. *T. Uemichi[1], T. Suzuki[1], T. Nobori[2], N. Yasui-Furukori[3], M. Mizuno[4], S. Shirahama[5], Y. Miyoshi[6]* 1) Kinki Central Hospital, Itami, Japan; 2) Department of Laboratory Medicine, Mie University School of Medicine, Tsu, Japan; 3) Department of Neuropsychiatry, Hirosaki University School of Medicine, Hirosaki, Japan; 4) Department of Neuropsychiatry, Toho University School of Medicine, Tokyo, Japan; 5) SRL, INC., Hachioji, Japan; 6) Roche Diagnostics K.K., Tokyo, Japan.

Cytochrome P450 (CYP) 2C19 and 2D6 play important roles in drug metabolism. Recently, polymorphisms in the genes coding these proteins have been shown to be associated with the decreased, or lack of, enzyme activity. To promote the individualized pharmacotherapy based on the genetic difference, the knowledge of the allele frequency of these genes in various ethnic groups is essential. In this study, we have examined the CYP2C19 and CYP2D6 allele frequency in a large-scale Japanese population. This study was conducted at four hospitals located on Honshu, the main island of Japan. One thousand and two subjects participated in the study. CYP2C19 and CYP2D6 genotypes were determined using DNA chip (AmpliChip, Roche Diagnostics) which was designed to detect 3 allelic variants of *CYP2C19* and 32 of *CYP2D6*. DNA sequencing analysis was carried out when the result of genotyping by DNA chip was not conclusive. *CYP2C19* analysis showed that allele frequencies of *1, *2, and *3 in this population were 0.57, 0.36, and 0.13, respectively. According to the result, extensive metabolizers (*1/*1, *1/*2, *1/*3) were 82% while poor metabolizers (*2/*2, *2/*3, *3/*3) were 18%. The *CYP2D6* allele frequencies of *1, *10, *2, *5, *41, and others were 0.40, 0.38, 0.13, 0.06, 0.01, and 0.02, respectively. For CYP2D6, 76.7% of the Japanese population were considered extensive metabolizers, 22.0% intermediate metabolizers, 0.2% poor metabolizers, and 1.1% undetermined phenotype. This is the first study to demonstrate the allele frequencies of the CYP2C19 and CYP2D6 genes in over a thousand Japanese subjects. The CYP2D6 gene shows a number of allelic variants including SNPs, deletions, and duplications in Japanese as previously described in other ethnic groups, and DNA chip is expected to be a powerful tool for genotyping CYP2C19 and CYP2D6 in individualized medicine.

The Effects of Recombination and Mutation on Patterns of Variation surrounding the -globin HbS allele. *E. Wood[1], D. Stover[2], M. Nachman[1], M. Hammer[1,3]* 1) EEB, Univ Arizona, Tucson, AZ; 2) Arizona State Univ, Tempe, AZ; 3) Division of Biotechnology, Univ Arizona, Tucson, AZ.

A longstanding question in population genetics is whether the malarial-resistance -globin HbS allele originated multiple times via recurrent mutation or if the HbS mutation arose once and moved to different haplotypic backgrounds through recombination. We PCR-cloned and sequenced a 5.2-kb region spanning the -globin recombinational hotspot and gene in a sample of 46 HbA and 31 HbS chromosomes. We estimate that recombination rates in the hotspot, which encompasses the HbS allele, are >50-fold higher than the genome average. We infer that a single mutation followed a crossing-over event is sufficient to explain the origin of Senegalese and Bantu HbS haplotypes, while Benin haplotype may have arisen via independent mutation or gene conversion. These results underscore the importance of recombination (crossing-over or gene conversion) in generating haplotypic diversity surrounding the HbS allele.

Audiological manifestations in mexican patients with Down syndrome. *L.Acosta Ramos[1], G. Garcia Sanchez[4], S.G. Juarez Garcia[2], L. Hernandez Gomez[3]* 1) Depto. de Comunicación Humana, CRIS Ameca Ameca, Edo. Mex,; 2) Servicio de Neuropsicologia Infantil. Instituto Nacional de Rehabilitación Mexico D.F; 3) Servicio de Audiologia. Instituto Nacional de Rehabilitación Mexico D.F; 4) Depto. de Investigación. Instituto Nacional de Rehabilitación. Mexico, D. F.

The syndrome of Down is a very frequent trisomía, with an incidence of 1 in 700 births, characterized by facies typical dismórfica with depressed nasal bridge, epicanto, anterior_posterior brachycephaly, variable orofaciales anomalies, fold simiano, mental weakness hipotonía generalized, mental weakness, hipotonía generalized, defects cardiac, from the 40 to 77% of the patients with this syndrome they present/display hearing problems that can be of conductivo type, sensorial or mixed due to congenital malformations and infections of superior respiratory routes due to its anatomical alterations. This study of made with 40 patients with syndrome of Down, to that interrogation was made to them, physical exploration, timpanometría and conventional audiometría, 25 patients were of masculine sex (62%) and 15 Feminine ones (38%), with an age average of 15 years and 5 months, of which 22 presented/displayed superficial normal hearing (55%) and 15 (36%) 12 of conductivo type and flat profile and 3 of sensorial type and slowly descendent pattern, 2 of moderate degree (5%) of conductivo type and flat pattern and 1 (2.5%) of sensorial type and descendent neurosensorial pattern. Most of our patients they presented/displayed hipoacusia of superficial degree of conductivo type and flat audiometrico pattern and a minority of deep degree of sensorial type and descendent superficial slowly descendent pattern as well as some cases of sensorial that they suggest data of presbiacusis.

Chromosome Microarray Analysis (CMA) Detects a Large X Chromosome Deletion Including *FMR1* and *IDS* in a Female Patient with Mental Retardation. *F.J. Probst[1], E.R. Roeder[2], V.B. Enciso[2], M.L. Cooper[1], P. Eng[1], J. Li[1], Y. Gu[1], A.C. Chinault[1], Z. Ou[1], C.A. Shaw[1], S.W. Cheung[1], D.L. Nelson[1]* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Genetics and Metabolic Disorders, Department of Pediatrics, The University of Texas Health Science Center at San Antotonio, San Antonio, TX.

Chromosome Microarray Analysis (CMA) by array-based comparative genomic hybridization (CGH) is a new clinical test that can screen for hundreds of different submicroscopic chromosomal deletions and duplications. We report here a 6-year-old girl who presented for evaluation of mildly dysmorphic facies and marked developmental delay. She did not walk until 24 months of age and did not speak her first words until 5 years. Physical examination revealed overgrowth, a prominent forehead with nevus flammeus, mildly upslanting palpebral fissures, and a flat nasal bridge. Previous studies included a normal brain MRI; a normal 46, XX karyotype; and Fragile X studies yielding a single allele of 30 CGG repeats. CMA showed a loss in copy number of four clones from the genomic region cytogenetically defined as Xq27.3-Xq28. This loss was also seen by FISH analysis. Further studies have confirmed a complete loss of one copy each of the *FMR1* and *FMR2* genes (which are mutated in Fragile X Syndrome and FRAXE Syndrome, respectively) and at least a partial deletion of one copy of the *IDS* gene (which is mutated in Hunter Syndrome). Skewed X-inactivation has been previously reported in females with deletions in this region and can lead to a combined Fragile X/Hunter Syndrome phenotype in affected girls. A possible diagnosis of Hunter Syndrome is therefore being pursued, as enzyme replacement therapy is possible for this disease. Currently, efforts are underway to define precisely the childs deletion breakpoints, to determine this childs X-inactivation status (normal vs. skewed), and to assess her IDS activity. This clinical case demonstrates the utility of CMA for both making the diagnosis of a submicroscopic chromosomal deletion and for suggesting further testing that could possibly lead to therapeutic options for patients with developmental delay.

The quantification of the allelic variations of gene expression in peptidylarginine deiminase type 4 (PADI4). *A. Suzuki[1], Y. Kochi[1], K. Kobayashi[1], K. Hayashi[2], R. Yamada[1, 3], K. Yamamoto[1, 4]* 1) SNP Research Center, RIKEN, Yokohama City, Kanagawa, Japan; 2) Division of Genome Analysis, Research Center for Genetic Information, Kyushu University, Fukuoka, Japan; 3) Center for Genomic Medicine, Kyoto University, Kyoto, Japan; 4) Department of Allergy and Rheumatology, Graduate School of Medicine, the University of Tokyo, Tokyo, Japan.

Recently, multiple studies have shown that human single nucleotide polymorphisms (SNPs) affect gene regulation, resulting allelic imbalances of gene expression. The finding of these regulatory SNPs leads to understanding phenotypic diversity and the identification of alleles that modify disease risks. Therefore, it is important to quantify the allelic variations of gene expression in vivo for identification of regulatory SNPs. For measurement of these variations, we performed TaqMan real-time RT-PCR system and PLACE-SSCP system using cDNA from tissues of heterozygous individuals. In this study, we examined allele-specific gene expression in PADI4, which was reported to be associated with rheumatoid arthritis (RA), and of which allelic imbalance of the gene expression was observed. We used TaqMan probes, rs11203366 (G/A) as a marker located in exon and also used this SNP as a target for PLACE-SSCP analysis. Briefly, we measured the signal intensity using cDNA and DNA from heterozygous individuals, and calculated allele-specific gene expression ratio. We performed these analyses using cDNA from peripheral blood leukocyte of heterozygous individuals and showed difference of allele-specific PADI4 expression in vivo. This data supported the hypothesis that expression levels of PADI4 are associated with RA susceptibility. In this study, we also indicated that TaqMan assay was available for quantification of the allelic variation in gene expression with high accuracy. In addition, the method based on TaqMan assay can be used for the high-throughput assay of allelic gene expression in vivo. Further advances of analysis of allele-specific gene expression will contribute to understanding of transcriptional gene regulation and will provide strategies for studying complex traits, including common diseases.

A lethal autosomal dominant defect of mitochondrial and peroxisomal fission. *H.R. Waterham[1], J. Koster[1], C.W.T van Roermund[1], P.A.W. Mooijer[1], J.V. Leonard[2], R.J.A. Wanders[1]* 1) Laboratory Genetic Metabolic Diseases (FO-224), Academic Medical Center/Univiversity of Amsterdam, Netherlands; 2) Department of Pediatrics, Institute of Child Health, University College London, United Kingdom.

Mitochondria form a dynamic network which is subject to continuous fusion and fission processes for which several proteins involved have been identified. We report a deceased newborn female who had microcephaly, abnormal brain development, optic atrophy and hypoplasia, failure to thrive, persistent lactic academia, and raised plasma very long chain fatty acids. Extensive laboratory investigations revealed a defect in the fission of both mitochondria and peroxisomes due to a single heterozygous, but dominant negative c.1184C>A (p.A395D) mutation in the DLP1 gene. DLP1 codes for the dynamin-like protein DLP1, previously shown to be involved in the fission of these two organelles. Over-expression of mutant 395D-DLP1 in control fibroblasts resulted in the aberrant mitochondrial phenotype, whereas over-expression of normal 395A-DLP1 in fibroblasts of the patient reversed the aberrant mitochondrial phenotype to normal. The autosomal dominant inheritance of the observed defect was confirmed by the absence of the c.1184C>A mutation in the DLP1 gene of the patients parents. Our finding represents the first patient from a new class of disease with a combined defect in both mitochondria and peroxisomes.

Pseudoxanthoma Elasticum-like disorder with generalized cutis laxa and clotting deficiency represents a novel genetic entity. *O.M. Vanakker[1], L. Martin[2], D. Gheduzzi[3], B.P. Leroy[1], V. Guerci[4], P. Coucke[1], I. Pasquali-Ronchetti[3], A. De Paepe[1]* 1) Ctr. Medical Genetics, Ghent University Hospital, Belgium; 2) Dept. of Dermatology, Porte-Madeleine Hospital, France; 3) Biomedical Sciences Dept., University of Modena and Reggio Emilia, Italy; 4) IRCCS Burlo Garofalo, Metabolic Disorders, Italy.

OBJECTIVE: Pseudoxanthoma Elasticum (PXE) is an autosomal recessive disorder characterized by oculocutaneous and cardiovascular manifestations. The causal ABCC6 gene (chrom. 16p13.1), encodes an ATP-dependent transmembrane transporter. We performed mutation analysis in over 150 patients and identified mutations in all but five individuals. Although these patients showed fragmented and calcified elastic fibres typical for PXE, they revealed a severe, progressive and generalized skin laxity (resembling cutis laxa) but only mild retinopathy. Moreover, all five had a deficiency of the vitamin K-dependent clotting factors. We performed a detailed study to determine whether this condition is genetically distinct from PXE. MATERIAL AND METHODS: Direct sequencing was performed for ABCC6. In addition, , we also performed molecular analysis of VKORC1 and GGCX. Both candidate genes cause hereditary deficiency of the vitamin K-dependent clotting factors (VKCFD1&2). RESULTS: Although microscopical findings in the dermis were indistinguishable from PXE, at the ultrastructural level the organization of the mineralized elastin was found to be different. Direct sequencing revealed causal mutations neither in ABCC6, nor in VKORC1. In contrast, GGCX harboured missense mutations in four out of five patients. The GGCX enzyme, important for -carboxylation of gla-proteins such as the vitamin K-dependent clotting factors, is involved in bone mineralization and in preventing calcium precipitation in soft tissue. As such, it may play a role in the aberrant elastic fibre mineralization in this phenotype. CONCLUSION: In view of the differences in clinical and ultrastructural findings and the absence of ABCC6 mutations, we conclude that this disorder is genetically separate from PXE or cutis laxa. Our data suggest GGCX as a good candidate gene for this disorder.

Determination of parental origin of *de novo* mutations that were detected in the past protein studies of Atomic bomb survivors children. *Y. Satoh, E. Nishikori, N. Takahashi* Dept. Genetics, RERF, Hiroshima, Japan.

We have studied the effects of atomic bomb radiation on human germ cells. During 1975 to 1984, a large-scale survey was conducted at RERF to detect genetic effect of radiation by screening serum and erythrocyte proteins with altered electromobility on starch gel electrophoresis in the offspring (and the parents), which is most likely due to amino acid substitutions. Total five *de novo* mutations [phosphoglucomutase 2 (PGM2), nucleoside phosphorylase (NP), 6-phosphogluconate dehydrogenase (6PGD), adenosine deaminase (ADA), and glutamic-pyruvate transaminase (GPT) genes] were detected after testing more than 1 million loci from about 23,000 offspring consisted of over .005 Gy exposed group and under .005 Gy control group. Although it was not possible in those days to determine the parental origin of the mutations, it is now possible to do it in the post genomic era. For this purpose, lymphoblastoid cell lines consisting of offspring-mother-father trios were established from 4 families. The observed electrophoretic mutations were confirmed by base sequencing followed by determination of polymorphic sequences located near the mutation sites to determine the parental origin. About NP, offspring had a G747A (Arg > His) mutation which is consistent with the electrophoretic phenotype, and parents did not have. And then neighboring SNPs of NP mRNA were examined. G266 and C286 existed on the same chromatid which mutation existed. They were inherited only from father not mother to offspring. It suggests that this mutation occurred in a gamete of paternal origin. 6PGD and GPT had a T1049G (Leu > Arg) and G699A (Gly > Arg) mutation respectively, which are consistent with the electrophoretic phenotypes. But, there have not been distinguishable neighboring inherited SNP among the family, so far. In this study, these methods can detect the parental origin of *de novo* mutation. Further characterization experiments are underway to distinguish mutation rate of exposed and non-exposed gametes.

Chromatin immunoprecipitation identifies direct neural targets of a gene implicated in human speech and language disorder. *S.C. Vernes[1,2], E. Spiteri[3], J. Nicod[2], M. Groszer[2], K.E. Davies[1], D. H. Geschwind[3], S.E. Fisher[2]* 1) Physiology, Anatomy & Genetics, University of Oxford, UK; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 3) UCLA Department of Neurology, UCLA, USA.

Heterozygous mutations in the human FOXP2 transcription factor cause problems with sequencing orofacial movements during speech (verbal dyspraxia) plus a wide-range of expressive and receptive language deficits. Mutations reported include a missense change yielding a substitution in the DNA-binding domain, and a nonsense mutation that dramatically truncates the protein. Identification of neural genes regulated by FOXP2 will shed light on molecular pathways that can go awry in verbal dyspraxia, suggest novel candidate genes for mutation testing in language-related disorders, and provide fundamental insights into the neurogenetic bases of speech and language. Here, we detail the isolation of candidate targets in neuronal-like cell culture using chromatin immunoprecipitation (ChIP), followed by validation of these candidates in these cells and in mice carrying Foxp2 point mutations mimicking those implicated in the human disorder (*Groszer et al, manuscript in preparation*). We adopted two FOXP2-ChIP strategies; i) immunoprecipitated chromatin was characterised via shotgun sequencing. *In silico* analysis was used to prioritise fragments near 5 ends of coding regions and containing predicted FOXP2 binding sites, ii) DNA from FOXP2-ChIP was applied to promoter arrays for high-throughput identification of target sites (ChIP-chip). This technique provided more rapid and comprehensive screening but promoter arrays usually cover only 1-5 kb spanning the start site of a subset of genes. Therefore shotgun screening allows for detection of genomic regions not covered by the arrays and the two techniques represent complementary approaches. Validation included the use of EMSA binding assays, and quantitative RT-PCR to demonstrate regulation of candidates by FOXP2. The biological significance of candidates was evaluated *in vivo* by studying CNS expression of Foxp2 mutant mice, providing the first *in vivo* confirmation of Foxp2 targets.

Balanced 1;21 translocation associated with Kleine Levin syndrome. *B. Tuysuz[1], L. Telvi[2], O. Kaya[1], N. Mütevelli[3], H. Kaynak[4]* 1) Istanbul University,Cerrahpasa Medical School, Department of Pediatric Genetics Istanbul, Turkey; 2) Hôpital St. Vincent de Paul, Laboratoire de Cytogénétique Constitutionnelle, Paris, France; 3) Istanbul University, Istanbul Medical School, Department of Child Psychiatry, Istanbul, Turkey; 4) Istanbul University, Cerrahpasa Medical School, Department of Neurology, Istanbul, Turkey.

The Kleine-Levin hibernation syndrome (MIM 148840) is a rare disorder that usually affects males and is characterized by episodic hypersomnia, increased feeding and aberrant behavioral / psychiatric disturbances. The case of an adolescent boy (13 year-old) was referred to our department with a diagnosis of Kleine-Levin syndrome. He was presenting with recurrent sleepiness and hyperphagia. He had a sleeping and eating period for 7-10 days followed by an awakeness period. Between episodes he was normal. He had fall down from 10 meter when he was 2 year-old. On physical examination, weight, height and head circumference were (>97p), (50-75p) and (97p), respectively. He had no major and minor abnormalities. At the end of two years, he had episodes with progressively milder manifestations under lithium and valproate therapy. Chromosome analysis from blood lymphocyte revealed de novo balanced translocation [46,XY, t(1;21)(p12;q22.2)]. FISH analysis was done using two whole chromosomes 1 and 21 painting probe and confirmed the balanced translocation. Etiology and pathogenesis of this syndrome are unknown. Precipitated factors such as infection, head trauma and serious medical and psychiatric diseases in 61% of the patients have been reported. Premature centromere division with chromatid puffing in area of constitutive heterochromatin only in a women with periodic hypersomnia had been described. She had also short stature and late menarche like Turner syndrome clinical findings and her chromosomes showed a mosaicism in 45,X/46,XX. Other chromosomal abnormalities had not been reported in Kleine-Levin syndrome up to date. The balanced translocation may be a coincidence in this patient. On the other hand, Kleine-Levin syndrome-associated genes can be localized to the breakpoints on the chromosome 1 and 21.

Estimation of allele frequencies of 100K SNPs in 500 individuals by combination of the pooled DNA method and the 100K SNP Array: Identification of a possible susceptibility gene for Parkinsons disease. *W. Satake[1], S. Ishikawa[2], M. Yoshida[1], I. Mizuta[1], M. Yamamoto[3], N. Hattori[4], M. Murata[5], H. Aburatani[2], T. Toda[1]* 1) Div Clinical Genetics, Osaka Univ Grad Sch Med; 2) Div Genome Sci, RCAST, Univ Tokyo; 3) Dept Neurol, Kagawa Pref Central Hosp; 4) Dept Neurol, Juntendo Univ Sch Med; 5) Dept Neurol, NCNP, Japan.

Genotyping large numbers of SNPs on large sample sizes is required to perform genome-wide association studies, but is very expensive and laborious. To solve this problem, we combined Affymetrix 100K SNP Array (100K Array) with the pooled DNA method, and made it possible to estimate allele frequencies of 100K SNPs in 500 individuals in a short period and by low cost. In order to assess the reliability of quantification of the 100K Array, we mixed 2 DNA samples at various proportions (1:4, 2:3, 3:2, 4:1), assayed these mixed samples on the 100K Array, and compared the relative allele signals (RAS) with the calculated allele frequencies. The RAS were highly correlated with the calculated allele frequencies (average of 0.989). We concluded that allele frequencies of the pooled DNA could be estimated using RAS. We therefore used this approach in order to identify susceptibility genes for idiopathic Parkinsons disease (PD). A PD pool and a control pool were prepared from the DNA of 500 PD patients and 500 controls respectively. Each pool was assayed on six separate 100K arrays to average experimental variances. We estimated allele frequencies with RAS, and selected SNPs which shows associations with PD. A SNP in -*synuclein*, which we recently reported to be a susceptibility gene for PD (HMG 15, 2006), was also included with the significant association (estimated $P10^{-8}$). Selected SNPs were genotyped individually for more than 800 PD patients and controls respectively using TaqMan assay. One SNP showed a significant association ($P=6.6x10^{-4}$). We performed association studies with the tagSNPs surrounding this SNP, and found one with a more significant association ($P=5.7x10^{-5}$). Our approach made it possible to perform effective genome-wide association studies in a short period and by low cost.

Identification of new and recurrent glucokinase mutations in Belgium and Luxembourg. *W. Wuyts[1], D. Beckers[2], M. Craen[3], C. de Beaufort[4], K. Dahan[5], M. Giri[6], A. Van den Bruel[7], C. Mathieu[8], L. Vits[1]* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Department of Paediatrics, University of Louvain (Yvoir) and University of Leuven (KUL), Belgium; 3) Department of Paediatrics, University Hospital Ghent, Belgium; 4) DECCP, Department of Paediatrics, CHL, Luxembourg; 5) Centre for Human Genetics, Université Catholique de Louvain, Brussels; 6) Department of Internal Medicine and Endocrinology, Algemeen Ziekenhuis Sint Jan, Brugge, Belgium; 7) Department of Endocrinology, University Hospital Gent, Belgium; 8) Department of Endocrinology, University of Leuven (KUL), Leuven, Belgium.

Glucokinase (GCK) is a key regulatory enzyme in the pancreatic beta cell acting as a glucose sensor which regulates insulin secretion. Mutations in the GCK gene encoding the glucokinase protein are responsible for the autosomal dominant Maturity Onset Diabetes of the Young type 2 (MODY2). After clinical examination, 161 Belgian and Luxembourg patients belonging to 124 families were selected for their clinical characteristics suggestive for MODY. Biochemical and clinical parameters including fasting glucose, HbA1c, BMI, age of diagnosis and treatment are presented. Molecular analysis of the GCK gene was performed by sequencing analysis of exon 1a and exons 2-9. In 33 probands, 19 different GCK mutations were identified, of which 11 have not been described previously. Among these, 6 were missense mutations (p.Phe152Leu, p.Ala188Val, p.Met202Arg, p.Asn231His, p.Leu315Phe and p.Cys434Phe), 3 were frameshift mutations resulting in premature termination of translation (c.171delG, c.1261delG and c.663-673dupGGTCGGCATGA) and the last two novel alterations were the splice site mutations IVS6-1 G/A and IVS6-6 C/A. Two recurrent mutations, p.Cys129Tyr and p.Ala378Thr, were identified in our patient population where they represent 42.4% of the GCK mutations identified. In our study 26,6 % of the 124 probands showed a GCK mutation, demonstrating that GCK mutations are a frequent cause of MODY presentation in the Belgian/Luxembourg diabetic patient population.

Severe myoclonic epilepsy of infancy: the impact of a mutation screening service on clinical management. *S. Stenhouse[1], R. Birch[1], L. Conlin[1], S. Zuberi[2]* 1) Inst Medical Genetics, Yorkhill Hosp, Glasgow, United Kingdom; 2) Fraser of Allander Neurosciences Unit, Royal Hospital for Sick Children, Glasgow, United Kingdom.

Severe Myoclonic Epilepsy In Infancy (SMEI) / Dravets Syndrome is an epilepsy syndrome characterised by early onset prolonged generalised, or unilateral clonic seizures usually induced by fever. During the first few years of life a number of seizure types arise, these include; generalised tonic-clonic seizures (GTCS), generalised clonic seizures (GCS), alternating unilateral clonic seizures, myoclonic seizures, atypical absences, obtundation status, and focal seizures. Developmental delay and/or regression occur concurrently with onset of first seizure. Mutations in the sodium channel gene SCN1A are commonly found in SMEI patients and the discovery of such mutations allows a definitive diagnosis to be made much earlier in the progress of the disorder. Having a diagnosis can in turn guide the clinical management of the patient allowing the clinician to focus on the few medications that have been shown to be helpful in this syndrome. These are rarely used in other epilepsies and include stiripentol and the bromides. Better seizure control may potentially prevent or ameliorate the cognitive decline associated with SMEI with obvious benefits to the patient. With the help of a grant from the Muir-Maxwell Fund, SCN1A mutation searching has recently been established in the West of Scotland Regional Molecular Genetics Department for patients suffering from SMEI. This service has been set up as a collaboration between the molecular genetics service in Glasgow and Dr Sameer Zuberi, Consultant Paediatric Neurologist and lead clinician for Scottish Paediatric Epilepsy Managed Clinical Network. SCN1A has 26 exons (7848bp) which are amplified in 40 fragments. A pre-screen is performed using Conformational Sensitive Capillary Electrophoresis (CSCE) and fragments containing apparent changes are sequenced. To date we have tested and reported on 51 individuals including 7 parents of children with SMEI. 7 mutations have been identified in affected patients but none in the parents confirming previous evidence that the majority of mutations are de novo. (Claes et al 2001) Unless their seizures were previously well controlled the finding of a mutation in a patient allows treatment to be altered. Three patients who are now on revised treatment as a result of finding a mutation already show clear improvement. Others are still being titrated up on dosage but early signs are hopeful. From this initial study it is clear that mutations are found in those patients who exhibit particular clinical features and in order to target testing most effectively Dr Zuberi has designed a questionnaire for referring clinicians which is now in use. We will report further on mutation detection rates before and after the use of the questionnaire. Claes et al, 2001. De novo mutations in the sodium channel gene SCN1A cause severe myoclonic epilepsy of infancy. Am J Hum Genet. 68:1327-1332.

Extensive in silico analysis of pathogenic *NF1* splicing defects identified by RNA-based mutation analysis uncovers predictors for splicing outcome of 5 splice-site disruption. *K. Wimmer[1], X. Roca[2], H. Beiglboeck[1], T. Callens[3], R.R. Atmakuri[2], J. Etzler[1], C. Fonatsch[1], L. Messiaen[3]* 1) Department of Human Genetics, KIMCL, Medical University of Vienna, Austria; 2) Cold Spring Harbor Laboratories, Cold Spring Harbor, NY; 3) Department of Genetics, UAB, Birmingham, AL.

Here we describe 94 pathogenic *NF1* gene alterations identified in a cohort of 97 Austrian neurofibromatosis type 1 patients meeting the NIH criteria. All mutations were fully characterized both at the genomic and mRNA transcript level. Thirty-six (38%) of the identified mutations altered pre-mRNA splicing and fall into five groups: exon skipping as a result of mutations at the authentic splice-sites (type I), cryptic exon inclusion caused by deep intronic sequence alterations (type II), creation of novel splice-sites causing loss of exonic sequences (type III), activation of cryptic exonic and intronic splice-sites due to the disruption of the natural splice-sites (IV) and exonic sequence alterations causing exon skipping (type V). The splice-site strengths of all wild-type, mutated and cryptic splice-sites were estimated using four different algorithms. With very few exceptions, they readily predict a dramatic decrease in splice-site strength upon mutation and an increase at sites of sequence alterations creating novel splice-sites. However, cryptic splice-sites used upon disruption of the natural splice-sites generally have a substantially lower calculated strength than natural splice-sites. Extensive *in silico* analyses of 37 *NF1* exons and their surrounding intronic sequences uncovered that the availability of a cryptic splice-site combined with a strong natural 3 splice-site are the main determinants for cryptic splice-site activation upon 5 splice-site disruption. Furthermore, the exonic sequences downstream of authentic exonic cryptic 5 splice-sites resemble more intronic than exonic sequences with respect to ESE/ESS density, providing an additional predictive parameter. In summary this study identifies valuable predictors for the outcome of 5 splice-site disruption, but also underscores the indispensable application of RNA-based techniques for most effective and reliable *NF1* mutation analysis.

A R184Q mutation in the GJB2 gene causes autosomal dominant nonsyndromic hearing impairment in a large Chinese Family. *R. Yang[1], G.R. Zhang[2], X. Ren[1], C. Zhou[2], J.Y. Liu[1], Q.K. Wang[1,3], M.G. Liu[1]* 1) Center for Human Genome Research and College of Life Science and Technology, Huazhong University of Science and Technology, Wuhan, Hubei, 430074, P.R. China; 2) The first affiliated hospital of jilin university, Jilin, P.R. China; 3) Department of Molecular Cardiology, The Cleveland Clinic Foundation, Cleveland, OH 44195, USA.

Approximately one in 1000 children is affected by severe or profound hearing loss at birth or during early childhood. GJB2 on chromosome 13q11, which encodes the gap-junction protein Connexin 26 (Cx26), is the most important deafness causative gene. Mutations in the GJB2 gene not only responsible for as much as 50% cases with autosomal recessive Hearing loss, but also cause autosomal-dominant hearing loss in a small number of families. In this study, we identified a 8 generation Chinese family with congenital autosomal dominant nonsyndromic hearing impairment, 74 individuals in the family are affected with bilateral, moderate to severe hearing impairment, exhibiting intrafamilial variability for the onset and severity of hearing loss. Linkage analysis revealed that the causative mutation in the family is linked to the DFNA3 locus. Direct DNA sequence of whole coding region and exon -intron boundary of GJB2 showed a heterozygous G to A transition at nucleotide 551, resulting in an arginine to glutamine substitution at codon 184 (R184Q). PCR-RFLP analysis showed that the R184Q mutation co-segregated with all affected individuals, and was not present in unaffected members in the family and 200 controls. Our data first provide strong evidence suggested that R184Q mutation of GJB2 gene can cause autosomal dominant nonsyndromic hearing impairment.

A computerized interactive database for diagnosis and study of Atypical Spinal Muscular Atrophies. *L. Viollet[1], I. Maystadt[2], N. Brahimi[1], S. Quijano-Roy[3], A. Munnich[1]* 1) INSERM U781, Hopital Necker, Paris, France; 2) Universite Catholique de Louvain, Bruxelles, Belgique; 3) Hopital Raymond Poincaré, Garches, France.

Atypical Spinal Muscular Atrophies (SMA), also named non-5q-linked-SMAs, form a very heterogeneous group of rare disorders characterized by progressive anterior horn cell degeneration, paralysis, denervation, and amyotrophy. Diagnosis of Atypical SMA is assessed upon clinical and electrophysiological critera and classification is based on the distribution of paralysis, age at onset and mode of inheritance. To date, many phenotypes have been described in case reports or series but the diagnosis of these rare disorders is usually hardly made. The main reasons are the lack of information due to the rarety of the phenotypes and the lack of an easily accessible and well documented database for clinicians. Only few genes have been identified and genetic research is hampered by the small number of informative families. To proceed in Atypical SMAs, we intend to set up an international interactive computerized database, allowing the collection of clinical and biological data from patients of both sexes and of all ages, though they may be few and dispersed geographically and in time, facilitating the emergence of research projects. These informations will allow to study the natural history of the diseases and to construct correlations genotype/phenotype, improving the quality of diagnostic approach. The database will be accessible to neurologists, neuropaediatricians and geneticists of the Neuromuscular Centers in France and Europe and could be extended to the worldwide community. The project vill be granted by the french Agence Nationale Pour la Recherche and the Association Française contre les Myopathies. The goal of this project is to improve the knowledge of the mecanisms leading to motor neuron degeneration by the identification of novel proteins involved in motor neuron disorders. Characterization of novel mutations in Atypical SMAs should allow a better understanding of the motoneuronal physiopathology, an important step towards the developement of specific treatments. Email: viollet@necker.fr.

Expression variation of HSA21 genes in Down syndrome and control individuals: understanding phenotypic variability in DS patients. *P. Prandini[1], R. Lyle[1,2], M. Gagnebin[1], C. Gehrig[1], S. Deutsch[1], S.E. Antonarakis[1]* 1) Dept Genetics & Development, Univ Geneva, Geneva 4, Switzerland; 2) Norwegian Institute of Public Health, Oslo, Norway.

Down Syndrome (DS) individuals display considerable phenotypic variability. Major goals in DS research are the identification of the underlying causes of phenotypic variation and of genes involved in specific DS phenotypes. Since DS is a disease caused by alterations of gene dosage, gene expression variation of human chromosome 21 (HSA21) genes in DS and normal individuals is likely to have a substantial impact on pathogenesis and phenotypic penetrance. We studied gene expression variation on 14 lymphoblastoid (LCLs) and 17 fibroblast cell lines from DS individuals and an equal number of age, sex and ethnic matched controls. Gene expression was assayed using Taqman qRT-PCR on a total of 105 HSA21 expressed genes and 20 non-HSA21 genes. Analysis of expression levels in LCLs, revealed a general over-expression of HSA21 genes in DS patients compared to normal. Around 43% of genes showed a statistically significant difference between DS and normals ($p<0.005$), with an average upregulation of 1.66 fold. According to the expression levels, we broadly classified genes in three categories: (a) 60 genes with no significant differences in gene expression between DS and controls, (b) 40 genes with significant over-expression and minor overlapping distributions and (c) 5 genes with significant over-expression in DS individuals but with largely overlapping distributions. We hypothesize that genes in category (b) could be involved in the constant features of trisomy 21, while genes in category (c) are likely to be involved in variable DS traits. We are currently performing a similar analysis in the fibroblasts cell lines. This study provides the first extensive data set on HSA21 gene expression variation in DS and addresses its potential role in underlying phenotypic variability observed in this disorder.

Screening for mutations in NEMO in a large cohort of Incontinentia Pigmenti patients. *M.V. Ursini, F. Fusco, G. Fimiani, A. Pescatore, G. Napolitano, M.G. Miano, M. D'Urso* "Institute of Genetic and Biophysics A.B. Traverso" CNR, Naples, Italy.

Incontinentia Pigmenti (IP) is an X-linked genodermatosis, lethal for males and presents in females with abnormal skin pigmentation and high variable clinical signs. IP results from mutations in NEMO. This gene encodes for the NF-kB essential modulator/IKKgamma (IkB kinase-gamma) required for the activation of the transcription factor NF-kB, which is central for many immune and apoptotic pathways. The genomic deletion of exons 4-10 of NEMO accounts for 80% of molecular IP phenotype. Loss-of-function mutations are lethal in males while the females survive for an extremely skewed X-inactivation pattern. Less deleterious mutations that preserve the NEMO activity can result in male affected by EDA-ID. A non-functional copy of the gene, pseudoNEMO, identified in opposite direction to NEMO, maps 22kb distal to NEMO and only contains exons 3-10. We report on 150 patients diagnosed with IP for which we revealed the presence of the recurrent NEMO 4-10 deletion in 81 females. By using a PCR diagnostic methods to discriminate between NEMO gene and pseudo-gene, we found that 4 patients carried also a pseudoNEMO 4-10 deletion. In addition 4 IP females had only pseudoNEMO deletion. Whether or not this deletion has a pathological effect will be discussed. Mutational analysis of all NEMO coding exons in the remaining 65 patients revealed the presence of 13 new mutations. We will report on the role of those protein-affecting-mutation on the function of NEMO protein and therefore, on the activity of IKK complex. Finally we identified a new class of IP males with clinical characteristic typical of IP in females, and exclusion of EDA-ID diagnosis. This cohort is composed of 17 males, 2 of them were post-mytotic mosaics for a loss-of-function deletion of NEMO, while all the others present no NEMO protein-affecting mutations in their DNA. We will present data supporting the hypothesis that other gene/pathway may be involved in this IP-like pathology in males.

RECQL4: One gene behind three syndromes with an increased risk for malignancies. *H.A. Siitonen[1], H. Kääriäinen[2], M. Kestilä[1]* 1) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Department of Medical Genetics, University of Turku, Turku, Finland.

RAPADILINO, Rothmund-Thomson (RTS) and Baller-Gerold (BGS) syndromes are caused by mutations in the RECQL4 gene. These syndromes are chracterised by growth retardation and bone malformations, mainly hypo- or aplasia of thums, radius and patellae. Differential diagnosis in these three syndromes relies on two cardinal features. The first is poikilodermatous rash seen in RTS and BGS but never in RAPADILINO. The second feature craniosynostosis is unique to BGS. RTS patients are also known for their elevated osteosarcoma incidence. We have recently found out that RAPADILINO patients may have increased susceptibility to develop lymphoma. We have mainly investigated RAPADILINO syndrome which is overrepresented in Finnish population where all patients are either homo- or heterozygous for the IVS7+2delT mutation. This mutation leads to inframe skipping of exon seven and causes a 44 amino acid deletion out of 1208 amino acid protein. The mutations in RTS and BGS are mainly truncating mutations and the outcome of these mutations could be unfunctional protein which could explain the elevated osteosarcoma risk in RTS. In contrast the IVS7+2delT mutation might preserve some of the proteins function. Hence we are studying the genotype-phenotype correlation in order to further understand the role of RECQL4 defects. RECQL4 is one of the five human RecQ homologs and mutations in three of them, RECQL4, BLM and WRN, are known to be associated with cancer predisposition. RECQ proteins are helicases with a role in maintaining genomic stability. RECQL4 is the only human RECQ protein that does not possess helical activity. Yet it has been suggested to have role as a genome caretaker and thus the defect in maintenance of genomic stability which could explain the elevated cancer incidence. When transfecting HeLa and COS-1 cells with wt and mutant (lacking exon seven) constructs we observed mislocalisation of the mutant constructs. Other studies at the protein level are in progress. We are currently analysing genomewide expression arrays to furter understand the role of RECQL4 defect in RAPADILINO.

Silencing of the oncosuppressor gene FHIT in normal cells leads to dysregulation of mitosis related pathways. *L. Roz, F. Andriani, G. Sozzi* Dept Experimental Oncology, Ist Nazionale Tumori, Milano, Italy.

The inactivation of the tumor suppressor gene Fhit in many epithelial cancers has been reported in several studies. Restoration of Fhit expression in Fhit-negative cancer cells results in reduction of tumorigenicity and induction of apoptosis, however the precise mechanism of action remains to be elucidated. In this study we used small interfering RNAs technology to transiently inhibit the endogenous Fhit expression in 293-HEK cells and in normal bronchial epithelial cells (NHBE) and thereby investigate the effect of its inactivation in the regulation of various critical cellular processes that lead to tumorigenesis. After reduction of the FHIT transcript, we tested by real-time PCR the expression of some of the target genes already identified in a microarray experiment which demonstrated the involvement of Fhit in the regulation of processes related to DNA replication and synthesis, cell cycle control and mitosis. The decrease of Fhit transcript was associated with a regulation of more than 50% of the selected genes, including TOP2A, HEC, CCNB1, BUB1, KNSL1 and CENPF, suggesting a putative role of the Fhit protein in mitosis control also in non-transformed human epithelial cells. The effect of Fhit repression on regulation of these genes was also investigated using retroviral-mediated long term silencing in human bronchial epithelial cells-KT (HBEC-KT), an immortal cell line generated from normal cells by stable expression of cyclin dependent kinase-4 (CdK4) and hTERT. Real-time PCR showed a marked reduction of the level of FHIT gene expression and regulation of 8/12 (67%) proliferation-related genes (CCNA2, CCNB1, CCNB2, KNSL1, CENPF, STK12, BUB1, PKMYT). These results demonstrate a good reproducibility of gene regulation obtained with different approaches and provide further support for the relevance of the Fhit gene in proliferation control. Interestingly HBEC-KT cells carrying both Fhit knockdown and p53 knockdown cassettes showed a more evident regulation of the same genes compared to cells with wild type p53, suggesting a putative cross-talk of these oncosuppressor genes in the control of different pathways related to the tumorigenesis process.

Microdeletion encompassing the MAPT gene at chromosome 17q21.3 is associated with developmental delay and learning disability. *C. Shaw-Smith[1], A. Pittman[2], L. Willatt[3], H. Martin[4], L. Rickman[5], S. Gribble[5], R. Curley[5], S. Cumming[4], C. Dunn[3], D. Kalaitzopoulos[5], K. Porter[5], E. Prigmore[5], A. Krepischi-Santos[6], M. Varela[7], C. Koiffman[7], A. Lees[2], C. Rosenberg[6], H.V. Firth[1], R. de Silva[2], N.P. Carter[5]* 1) Medical Genetics, University of Cambridge, Cambridge, United Kingdom; 2) Reta Leila Weston Institute of Neurological Studies, University College, London UK; 3) Regional Cytogenetics Laboratory, Addenbrooke's Hospital, Cambridge, UK; 4) Regional Molecular Genetics Laboratory, Addenbrooke's Hospital, UK; 5) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 6) Department of Genetics and Evolutionary Biology, Institute of Biosciences, Sao Paulo, Brazil; 7) Human Genome Study Centre, Department of Genetics and Evolutionary Biology, University of Sao Paulo, Brazil.

Recently, the application of array-based comparative genomic hybridization (array-CGH) has improved rates of detection of chromosomal imbalances in patients with mental retardation. Here, we describe three individuals with learning disability and a heterozygous deletion at chromosome 17q21.3, detected in each case by array-CGH. There are some clinical similarities between the three patients: low birth-weight, neonatal hypotonia and feeding difficulties were present in each case, as well as moderate to severe learning difficulties. FISH analysis demonstrated that the deletions occurred as de novo events in each patient and were between 500 kb and 650 kb in size. A recently described 900 kb inversion which suppresses recombination between ancestral H1 and H2 haplotypes encompasses the deletion. We show that, in each trio, the parent of origin of the deleted chromosome 17 carries at least one H2 chromosome. This region of 17q21.3 exhibits complexity of genomic architecture with well-described low copy repeats (LCRs). We show that the orientation of LCRs flanking the deleted segment in inversion heterozygotes is likely to facilitate the generation of this microdeletion by the mechanism of non-allelic homologous recombination. We believe this to be the first microdeletion syndrome to be described in which all the patients have been ascertained by array-CGH.

Landmark study of LD in a genetic Sardinian isolate using 500k SNP: prerequisite for GW association approach.

N. Pirastu[1], E. Mocci[1], G. Mancosu[1], L. Casula[1], M. Cosso[1], F. Marras[1], M. Pirastu[1,2], A. Angius[1,2] 1) Shardna Spa, Pula (CA), Cagliari, Italy; 2) Inst. Population Genetics, CNR, Alghero, Italy.

The knowledge of the genetic features such as linkage disequilibrium (LD) patterns in isolated populations has acquired a great importance to determine the feasibility of genome wide association studies to map genes that underlie complex traits. We analyzed 500K SNPs (Affymetrix) in 50 unrelated individuals (kin<0.0625) from the village of Urzulei (URZ) in Ogliastra region of eastern Sardinia. This isolate (~1000 inhabitants) is characterized by a low number of founders, high endogamy (95%;) and slow demographic growth with very little immigration. 83.5%; of the SNPs were informative with a mean MAF of 0.18 and heterozigosity of 0.3. For comparison we selected a subset of 300,000 SNPs typed both in URZ and in 60 unrelated Caucasian individuals obtained from the HapMap project. Genomewide LD patterns were calculated using pairwise D' and r2 in both populations. The average distribution of LD was very similar (=0.9), although in the URZ it was uniformly higher. We constructed metric LD maps for both populations for the whole genome and found similar patterns of LD blocks and recombination hot spots. Differences in length of the LDU maps imply that LD extends twice as far in the URZ population than in the CEU; on average 129 kb vs 62.75 kb, respectively. Although LD Blocks shared by both populations show similar haplotypes with highly correlated frequencies (=0.9), their distribution within each block shows that more than 50%; differ significantly in the 2 samples independently from LD block sizes, possibly due to genetic drift. Using Gene Ontology, we compared the distribution of genes involved in 40 biological processes (BP) within high and low LD regions vs the whole genome gene distribution. 18 BPs in URZ, mostly shared with CEU, showed a significant difference between the observed and the expected distribution suggesting a correlation between gene function, LD distribution and evolution of the village. These results suggest that this isolate, while resembling the general population, posses an enhanced LD power to detect the genetic make up of the biological processes.

Cost-optimal two-stage designs for genome-wide association studies. *H. Schaefer, H.H. Mueller* Inst Medical Biometry, Philipps Univ, Marburg, Marburg, Germany.

Genome-wide association studies for complex diseases have become practical since genome-wide SNP chips are available. To reduce the cost of genome-wide association studies, two-stage designs with intermediate substantial reduction of the marker set after the first stage have been proposed (Satagopan et al.,2002,2003,2004; Thomas et al.,2004). Efficient statistical analysis strategies for two-stage studies have recently been proposed (Skol et al.,2006). We present cost-optimal two-stage designs for case-control association studies. These designs are based on the methodology of group sequential tests as known from clinical trials. For case-control studies using 500k SNP markers and achieving 80% power at genome-wide type I-error rate of 0.05, overall study costs can be reduced by more than 60% as compared to one-stage designs and by about 25% as compared to two-stage designs proposed in the literature (Satagopan,2003). Only the most promising 5% of the total marker set must be genotyped in the whole sample in the second stage of the study. As in the work by Satagopan et al.,2003, the cost function used for design optimisation includes both sampling and genotyping costs, with user specified cost ratio. In addition it was extended to fit different costs in the two stages, e.g., lower genotyping costs per marker in the first stage due to high throughput chip technology. Patterns of admixture in Latino populations. *A. Ruiz-Linares[1], S. Wang[1], G. Bedoya[1], C. Bortolini[2], H. Nicolini[3], W. Klitz[4], J. Molina[5], N. Freimer[5], R. Barrantes[6], G. Mazzotti[7], C. Gallo[7], J. Dipierri[8], E. Alfaro[8], N. Bianchi[8], G. Bailliet[8], F. Rothhammer[9], F. Salzano[2], M. Feldman[10], N. Rosenberg[10]* 1) Dept Biol, Wolfson House, Univ Col London, London, United Kingdom; 2) Departamento de Genetica, Univ Federal do Rio Grande do Sul, Porto Alegre, Brazil; 3) Department of Neuropsychiatry, Neurological Emergencies of the National Institute of Neurology and Neurosurgery, Mexico City, Mexico; 4) School of Public Health, Univ California, Berkeley, CA; 5) Univ California, Los Angeles, Los Angeles, CA; 6) Dept Genetics, Escuela de Biol, Univ de Costa Rica, San Jose, Costa Rica; 7) Univ Peruana Cayetano Heredia, Lima, Peru; 8) IMBICE, La Plata, Argentina; 9) Faculty Medicine, Univ Chile, Santiago, Chile; 10) Univ Michigan, Ann Arbor, MI.

We examined the diversity of 13 Latino populations from seven countries (Mexico, Guatemala, Costa Rica, Colombia, Chile, Argentina and Brazil) typing 745 autosomal microsatellite markers in 250 individuals. Estimates of genetic ancestry for these populations varied substantially. Native American ancestry varied between 19.6% and 70.3%, European ancestry between 26.9% and 70.6%, and African ancestry between 1.1% and 9.8%. Genetic structure analysis provides evidence of a genetic continuity between pre- and post-Columbian populations for specific geographic regions. For instance, a Chibchan-Paezan ancestry is detectable in Latinos from lower Central America and northwest South America. Individual admixture estimates vary considerably between populations. Some Latinos (e.g. Mexico City) show marked variation in individual admixture, whereas others (e.g. Antioquia and Costa Rica) show little variation. This variation is likely to reflect the history of admixture of each geographic region examined: some Latino populations are still undergoing substantial admixture whereas others underwent admixture mostly in early colonial times. These results have important implications for admixture mapping and association mapping studies in Latino populations.

The human X chromosome in the etiology of Premature Ovarian Failure (POF): epigenetic control of the critical region on autosomal genes translocated to the X chromosome. *F. Rizzolio[1], C. Sala[1], S. Bione[1,2], V. Causarano[1], S. Alboresi[1], M. Goegan[1], O. Zuffardi[3], D. Toniolo[1]* 1) Dept of Molecular Biology and Functional Genomics, DIBIT-HSR, Milano, Italy; 2) Institute of Molecular Genetics, CNR, Pavia, Italy; 3) Dept. of Pathology and Medical Genetics, University of Pavia, Pavia, Italy.

Premature Ovarian Failure (POF) is a disorder characterized by lack of ovulation and elevated gonadotropin level before 40 years of age. POF has a frequency of about 1% among females and has become a relevant cause of female infertility. A genetic component of the disorder was demonstrated by numerous familial cases and by the frequent observation of X chromosome rearrangements. Mapping of chromosomal rearrangements associated with POF led to the definition of a POF critical region in Xq. Characterization of the POF critical region by FISH mapping of a large panel of X chromosome rearrangements showed that most of the breakpoints mapped to a 16 Mb gene poor region corresponding to Xq21, where only 3 genes were interrupted by POF associated breakpoints. Expression analysis of X-linked genes surrounding some of the X;autosome balanced translocation breakpoints did not reveal ovary-specific genes. Surprisingly, analysis of the corresponding autosomal regions showed in all instances genes with a specific expression in mouse ovaries, in granulosa cells and/or in oocytes. Investigation of the position effect of the breakpoints on chromatin organization of X chromosome and autosomal regions, showed chromatin alterations occurring exclusively at the promoters of the autosomal genes translocated to the X. The data demonstrates a role of the X chromosome critical region on ovarian gene expression, during oogenesis and follicular maturation, when the global active X chromosome gene expression is down regulated .

Exact type I error rate for association study using SNPs. *A. Takahashi[1], T. Nakamura[1], N. Kamatani[1,2]* 1) Laboratory for Statistical Analysis, SNP Research Center, RIKEN, Japan; 2) Institute of Rheumatology, Tokyo Women's Medical University, Japan.

Association study using single nucleotide polymorphisms(SNPs) is one of the methods to discover genes related with diseases. Large number of marker SNPs over the genomes have become available by the HapMap project. Large number of tests are performed in association study generally. Therefore problem of multiple testing has to be considered. Bonferroni's correction is one of the corrections for multiple testing. However it is well known that Bonferroni's correction is too conservative. We derived the equation of exact type I error rate for association study using SNPs. We calculated the probability of distributing all samples to case and control groups on the condition that the size of both groups had fixed. Exact type I error rate is depend on sample size, the number of SNPs and significance level of test. Exact type I error rate can be calculated computationally in principle. However if sample size is too large, it is difficult to calculate this rate because calculation time becomes very long. Markov chain Monte Carlo methods was developed to calculate type I error rate by the approximation. The results of simulated data will be reported. We will discuss the relation between our results and other correction methods.

Development of a new assay for monitoring the *in vivo* effects of drugs on *SMN* mRNA in clinical trials of spinal muscular atrophy. *M. Vezain[1], P. Saugier-Veber[1,2], J. Melki[3], A. Toutain[4], E. Bieth[5], M. Husson[6], J.M. Pedespan[6], L. Viollet[7], I. Pénisson[8], S. Férenbach[2], J. Bou[1,2], T. Frebourg[1,2], M. Tosi[1]* 1) Inserm U614, Faculty of Medicine, Rouen, France; 2) Department of Genetics, University Hospital, 76031 Rouen, France; 3) Laboratory of Molecular Neurogenetics, Inserm E.0223 and University, 91000 Evry, France; 4) Department of Medical Genetics, University Hospital, 37044 Tours, France; 5) Department of Medical Genetics, University Hospital, 31079 Toulouse, France; 6) Unit of Child and Teenager Neurology, University Hospital, 33076 Bordeaux, France; 7) Department of Medical Genetics, Necker-Enfants Malades Hospital, 75743 Paris, France; 8) Department of Neurology, University Hospital, 49033 Angers, France.

Spinal muscular atrophy (SMA) mainly results from homozygous deletion or gene conversion of the survival motor neuron (*SMN1*) gene. All patients have at least one copy of the highly homologous *SMN2* gene. Two main mRNA isoforms are produced from the *SMN2* gene: a full length (FL) mRNA, and mRNA lacking the exon 7 sequence (7mRNA). An inverse correlation between *SMN2* copy number and disease severity has been reported, suggesting the possibility of treating SMA patients by increasing FL *SMN* mRNA levels produced from the *SMN2* gene. We have developed a sensitive assay based on multiplex fluorescent RT-PCR which allows to determine in the same reaction the levels of FL mRNA, 7 mRNA and total *SMN* mRNA, and to calculate directly the FL/7 mRNA ratio. This assay, applied to blood samples of 75 unrelated control subjects and 48 SMA patients, allowed us to show that, in both SMA patients and controls, the levels of 7 mRNA are linearly dependent on the number of *SMN2* copies. In addition, we show that FL mRNA levels are linearly dependent on *SMN2* copy number in SMA patients. We also show that, in patients, the FL/7 ratio is approximately 1 in blood cells and 0.5 in muscle. These data indicate that the FL/7 mRNA ratio is regulated according to tissue. This new assay should be valuable as a biomarker for monitoring the *in vivo* effects of various drugs on *SMN2* in forthcoming clinical trials of SMA.

Detection by functional analysis of splicing mutations in hereditary nonpolyposis colorectal cancer. *I. Tournier[1], M. Vezain[1], F. Charbonnier[1], A. Martins[1], M-P. Buisine[2], S. Olschwang[3], Q. Wang[4], T. Frebourg[1,5], M. Tosi[1]* 1) Inserm U614, Faculty of Medicine, Rouen, France; 2) Laboratory of Biochemistry and Molecular Biology, University Hospital, Lille, France; 3) Inserm UMR 599, Institut Paoli-Calmettes, Marseille, France; 4) Molecular Oncology Unit, Centre Léon Bérard, Lyon, France; 5) Department of Genetics, University Hospital, Rouen, France.

Hereditary nonpolyposis colorectal cancer (HNPCC) results from germline mutations of the *MMR* genes, especially *MLH1*, *MSH2* and *MSH6*. Numerous variants of unknown biological significance such as missense, silent, or intronic mutations have been found in these genes, which limits the molecular diagnosis and genetic couselling of HNPCC. A fraction of these variants may have an effect on RNA splicing by disturbing splicing regulatory sequences like exonic or intronic splicing enhancers and silencers (ESE, ESS, ISE, ISS). In order to determine the consequences of these variants on splicing, we have undertaken a systematic screening of these variants using a functional assay of exon inclusion or exclusion, performed on genomic DNA. This assay is based on an expression vector, containing a CMV promoter and exons 2 and 3 of the *SERPIN/G1* gene, separated by their natural intron, into which we have inserted appropriate cloning sites. For each family, mutant and wild-type exons to be tested are PCR amplified from genomic DNA, including about 150 bp of flanking sequences on both sides, and are inserted into the expression vector and transfected transiently into HeLa cells. The effects of mutations on splicing are evaluated by RT-PCR on total RNA and by direct sequencing of the relevant RT-PCR products. We have presently examined 53 different *MLH1* or *MSH2* mutations (32 missense, 9 silent, 2 deletions of a single codon and 10 intronic mutations). We found that 17 of these mutations affect splicing, including 5 exonic mutations that indicate the presence of ESE (exonic splicing enhancer) or ESS (exonic splicing silencer) elements. This assay should contribute to the molecular diagnosis and genetic counselling of HNPCC and can be easily applied to other genetic diseases.

Genomic diversity and population structure of Native Americans. *S. Wang[1], M. Jakobsson[2], S. Ramachandran[3], G. Bedoya[1], W. Rojas[1], M. Parra[1], J. Molina[4], G. Mazzotti[5], C. Gallo[5], D. Labuda[6], W. Klitz[7], R. Barrantes[8], C. Bortolini[9], F. Salzano[9], F. Rothhammer[10], M. Feldman[3], N. Rosenberg[2], A. Ruiz-Linares[1]* 1) Dept Biol, Univ Col London, London, United Kingdom; 2) Univ Michigan, Ann Arbor, MI; 3) Stanford Univ, Stanford, CA; 4) Univ California, Los Angeles, Los Angeles, CA; 5) Univ Peruana Cayetano Heredia, Lima, Peru; 6) Univ Montreal, Montreal, Canada; 7) School of Public Health, Univ California, Berkeley, CA; 8) Dept Genetics, Escuela de Biol, Univ de Costa Rica, San Jose, Costa Rica; 9) Univ Federal do Rio Grande do Sul, Porto Alegre, Brazil; 10) Faculty Medicine, Univ Chile, Santiago, Chile.

We examined 745 autosomal microsatellite markers in 432 individuals sampled from 24 indigenous populations in the Americas. These data were analyzed jointly with similar data available in 54 other indigenous populations from across the world (including an additional 5 Native American groups). The populations from the Americas show lower diversity and more differentiation than populations from other continental regions (global Fst=0.08). Signals of long-range linkage disequilibrium are detectable to a greater extent in Native Americans than in other populations, as are signals of recent bottlenecks followed by population growth. A negative correlation is observed between population diversity and geographic distance from the Bering Strait, an observation consistent with the north-to-south dispersal of humans upon initial entry into the continent. A higher diversity is observed in western vs. eastern South American populations, potentially reflecting differences in long-term effective population size or in colonization routes within South America. Phylogenetic trees relating Native American populations show a marked differentiation between Canadian and other Native populations. Canadian natives also show a detectable shared ancestry with contemporary Siberian populations, which is less visible for more southerly Americans. A substantial agreement is observed between phylogenetic relatedness and population affiliation according to the linguistic classification of Greenberg.

Prevention of oculopharyngeal muscular dystrophy-associated nuclear protein aggregation with intracellularly expressed camelid-derived antibody domains. *S. van der Maarel[1], P. Verheesen[2], A. de Kluijver[2], S. van Koningsbruggen[1], H. de Haard[2], G. van Ommen[1], T. Verrips[2]* 1) Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands; 2) Dept Mol Cell Biology, Utrecht University, Utrecht, Netherlands.

Oculopharyngeal muscular dystrophy (OPMD) is considered a paradigm for neurodegenerative protein aggregation disorders. OPMD is caused by extensions of the N-terminal polyalanine stretch in the nuclear polyA-binding protein 1 (PABPN1) leading to the presence of intranuclear aggregates in skeletal muscle. Intranuclear aggregation of mutant PABPN1 is also observed in animal and cell models for OPMD, and these models support a direct role for protein aggregation in OPMD pathogenesis. We have isolated camelid-derived single domain antibody reagents (VHH) against different epitopes in PABPN1 from a non-immune phage display library. These VHH specifically detect and label normal and mutant endogenous PABPN1. When expressed intracellularly as intrabodies, autofluorescent VHH specifically recognize endogenous PABPN1. In a cell model for OPMD, aggregation was prevented in a dose-dependent manner by some of these intrabodies. These intrabodies were also able to reduce already existing aggregates. Currently, the intrabodies are being used in living cells to study the spatiotemporal behaviour of normal and mutant PABPN1. Given the domain specificity of VHH-mediated aggregation interference, this approach facilitates definition of the nucleation kernel in aggregation-prone proteins, thus providing etiological insight into this and other protein aggregation disorders. It may also provide useful therapeutic agents.

Male-to-female sex reversal due to an ~250 Kb deletion upstream of *NR0B1 (DAX1)*. *M. Smyk[1,2,*], J.S. Berg[1,*], A. Pursley[1], F. Curtis[3], B. Fernandez[3], G.A. Bien-Willner[1], J.R. Lupski[1], S.W. Cheung[1], P. Stankiewicz[1,2]* 1) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 3) Disciplines of Medicine and Genetics, Memorial University of Newfoundland. *Equally contributing authors.

Sex determination and differentiation is a complex cascade involving a number of dosage sensitive genes. Although mutations in many of these genes were identified, the cause for sex reversal remains unknown in the majority of patients. *NR0B1 (DAX1)* is a dosage sensitive gene on Xp21.2 that plays a critical role in the development of the reproductive and adrenal systems. Deletion of *NR0B1* results in congenital adrenal hypoplasia, whereas *NR0B1* duplication in 46,XY individuals leads to gonadal dysgenesis and a female phenotype. We describe a 20 year old 46,XY female manifesting primary amenorrhea, a small immature uterus, and ovotestis, in whom analysis by array-CGH showed a loss in copy number detected by one BAC interrogating clone RP11-662D2 that harbors *NR0B1*. No signs of adrenal insufficiency were present in the patient. Surprisingly, FISH with this clone showed the fluorescence signal on Xp21. Using PCR, we found that *NR0B1* was present in the patient; however, we identified a 257,782 bp deletion located 11,320 bp upstream (proximal) to *NR0B1* and 75 kb distal to *GK1*. The deletion truncated 53% of the BAC RP11-662D2, which explains the discrepancy between array-CGH and FISH results. No additional nucleotides were found at the junction. The deletion was also found in the patients mother. Using bioinformatics and comparative genomics, we identified within the deletion several potential *cis*-acting regulatory elements upstream of *NR0B1* as well as 17 potential consensus-binding sites for SF1; the latter is thought to be a negative regulator of *DAX1*. Loss of regulatory sequences apparently resulted in a position effect up-regulation of *NR0B1* expression. We propose that this genomic region and by extension those surrounding the dosage sensitive *SRY, SOX9*, and *SF1* genes, should be examined for copy number variation in patients with sex reversal.

Apolipoprotein E polymorphism in patients with amyotrophic lateral sclerosis. *H. A. Idrisoglu[1], A. Sazci[2], G. Akpinar[2], E. Ergul[2], O. Ozsarac[1]* 1) Department of Neurology, University of Istanbul, Faculty of Medicine, Istanbul, Turkey; 2) Department of Medical Biology and Genetics, Faculty of Medicine, University of Kocaeli, Umuttepe, 41380, Kocaeli,Turkey.

Amyotrophic lateral sclerosis(ALS) is the most common adult onset neurodegenerative disorder affecting the motor neurons. ALS is considered a multifactorial disease, though its etiopathogenesis is still unknown. We were interested to know whether apolipoprotein E polymorphism play a role in the susceptibility to ALS in a turkish population.We used a PCR-RFLP method to determine the genotypes of 113 ALS patients and 406 healthy controls. The frequency of the 2,3, and 4 alleles of ApoE gene was 8.37%, 84.61% and 7.02% in the controls and 7.52%, 83.18% and 9.29% in ALS cases respectively. There was no allele association between ALS cases and controls (Chi2= 6.333; df=5; P=0.275). The ApoE3/4 genotype had a 1.666 -fold increased risk for ALS when compared to the controls (OR=1.666; 95%CI= 0.903-3.074; Chi2=2.716;df=1;P=0.99), though it was statistically insignificant. And also, the ApoE4/4 genotype had a 1.811-fold increased risk for ALS as compared to the controls. However it was statistically insignificant (OR=1.811;95%CI=0.327-10.015; X2=0.476; df=1; P=0.490). The individuals with the APOE2/3 genotype had a 1.107-fold increased risk for ALS as compared to the controls (OR=1.107; 95%CI=0.615-1.992; X2=0.114;df=1;P=0.735), though the results were statistically insignificant. In conclusion, individuals with the ApoE3/4,4/4 and 2/3 genotypes showed increased risk for ALS in the turkish population. However the results did not reach the statistical significant level. The study should be carried out on a large sample size in the future.

Recurrent campomelic dysplasia due to a mosaic *SOX9* deletion in a father. *E. Obersztyn[1], M. Smyk[1], B. Nowakowska[1,2], E. Bocian[1], S.W. Cheung[2], T. Mazurczak[1], P. Stankiewicz[1,2]* 1) Dept of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 2) Dept of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Campomelic dysplasia (CD) is a fully penetrant autosomal dominant semilethal skeletal malformation syndrome with or without XY sex reversal caused by mutations in *SOX9*, a dosage-sensitive gene that plays a critical role in the development of the skeletal and reproductive systems. To date, multiple intragenic *SOX9* mutations and 19 chromosomal rearrangements have been identified in patients with CD: two entire gene deletions, one deletion upstream of *SOX9*, 14 translocations and one inversion with breakpoints scattered up to 1 Mb 5' to *SOX9*, and one translocation with breakpoint mapping 1.3 Mb downstream of *SOX9*. We present a family with two children diagnosed with CD. From the first pregnancy a child with CD was born in the 31st week of gestation and died after one hour of life. During the second pregnancy, an ultrasound examination showed an increased nuchal translucency (NT) and amniocentesis revealed a normal fetal karyotype. A child with CD was born in the 35th gestational week and died on day of life 3 due to upper respiratory insufficiency. Postmortem array CGH study revealed a >600 kb deletion involving the entire *SOX9* gene. During the third pregnancy, a slightly increased NT was observed; however, no evidence of the deletion was found by FISH in amniocytes. The second ultrasound at 24th weeks of gestation was normal. FISH analysis of the parental samples revealed that the father was a carrier of a *SOX9* deletion present in 66% of lymphocytes. He had short stature (<3rd centile). We are currently studying the grandparental samples and determining the size and tissue distribution of the deletion. This is the first report of mosaic deletion of *SOX9*; few familial CD cases with germline and somatic mutation mosaicism have been described. Our findings reveal the utility of aCGH in the evaluation of SAB and indicate that for a more accurate estimate of the recurrence risk for a completely penetrant autosomal dominant disorder, parental somatic mosaicism should be considered in healthy parents.

Locus specific mutation databases for human genetics: catalogue and survey of curators. *C. Talbot[1], R. G. H. Cotton AM[2], O. Horaitis[2], M. Phommarinh[3], K. Phillips[2], Consortium to collect mutations* 1) Inst Genetic Medicine, Johns Hopkins Sch Medicine, Baltimore, MD; 2) Genomic Disorders Research Centre, St. Vincent's Hospital, Australia; 3) McGill University Health Centre (MUHC), Montreal Children's Hospital.

Complete and accurate information on mutations in disease genes is required for efficient delivery of genetic health care. Whilst possible to obtain this information by surveying scientific journals and/or data mining, it is well known that many variations are unpublished for numerous reasons. Information in scientific journals does not have all the information that those dealing with patients or research need. Curators of locus specific databases (LSDBs) collect mutations and their effect in an organised manner usually collecting unpublished mutations.

The HGVS (www.hgvs.org) has been collecting LSDB lists with the first list available in 1998. We recently updated this and found 571 genes have an LSDB (www.hgvs.org/dblist/glsdb.html).

We surveyed the curators of these databases. Whilst their existence is essential to those dealing with research and patients, funding and content is variable. 125 curators were sent a questionnaire and we received 47 responses. Some individuals performed curation on up to 69 genes. Time spent on curation was variable, varying from no time to up to five curators spending over four hours per week. Funding estimated for proper curation ranged from USD 600-4,500 per year. A majority of databases were stimulated by the HUGO-Mutation Database Initiative (now-HGVS) using their guidelines. Many reported unpublished and all but one reported errors in the literature. Of the 13 who reported hits, nine reported over 52,000 per year. The need for expert curation is underlined by the fact that curators found an enormous error rate in the literature and many contained unpublished mutations.

Detection of Duplication/Deletion of the PMP22 Gene in Patients with Charcot-Marie-Tooth Disease Type 1A and Hereditary Neuropathy with Liability to Pressure Palsy. *M. Rostami, M. Dehghanmanshadi, S.M. Seyedhasani, A. Ebrahimi, M. Tonekaboni, M. Houshmand* medical genetic, NIGEB, Tehran, Tehran, Iran.

Charcot-Marie-Tooth (CMT) disease is a clinically and genetically heterogeneous group of hereditary peripheral neuropathies. The clinical characteristics of the disease include distal symmetric muscle weakness, atrophy, bilateral pes cavus, and diminished or absent deep tendon reflexes. Peripheral nerve conduction velocities are often severely reduced. In hereditary neuropathy with liability to pressure palsy (HNPP), recurrent peripheral nerve palsies (e.g., ulnar nerve, median nerve, and peroneal nerve palsies) occur because of minor compression trauma, whereas foot deformity is less frequently observed than it is in CMT. Nerve conduction velocities are significantly reduced at compression sites of peripheral nerves. Charcot-Marie-Tooth disease type 1A (CMT1A) is the most common form of CMT (1, 2). A 1.5-Mb duplication on chromosome 17p11.2-p12 (CMT1A duplication) caused by a misalignment of the CMT1A repeat sequences (CMT1A-REPs) is associated with Charcot-Marie-Tooth disease type 1A (CMT1A). A hotspot of crossover breakpoints located in a 3.2-kb region of the CMT1A-REPs accounts for three-quarters of the rearrangements in CMT1A patients. In contrast, deletion of the PMP22 characteristically results in HNPP. Point mutation in the PMP22 may result in CMT1A or HNPP. Thus heterozygous carriers of the deletion (HNPP) or duplication (CMT1A) have one or three copies of the PMP22, respectively.We used some methods for study of this gene: PCR-based diagnostic method to detect a recombination Hotspot associated with the CMT1A duplication Methods for molecular diagnosis of CMT1A use Southern blot and/or amplification by PCR of polymorphic poly (AC) repeats(microsatellites) located within the duplicated region, or the detection of junction fragments specific for the duplication. Real-time quantitative PCR using SYBR Green I to detect the PMP22 duplication and deletion.

Alleles of reelin gene show association with working memory in Finnish schizophrenia families. *J.O. Peltonen[1], A. Tuulio-Henriksson[2], A. Loukola[1], J. Ekelund[1,2], T. Paunio[1,2,4], T. Varilo[1,3,5], J. Suvisaari[2], T. Partonen[2], J. Lönnqvist[2,3,4], L. Peltonen[1,3,5]* 1) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Department of Mental Health and Alcohol Research, National Public Health Institute, Helsinki, Finland; 3) Department of Medical Genetics, University of Helsinki, Finland; 4) Department of Psychiatry, University of Helsinki, Finland; 5) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA.

Using a large, well-characterized nationwide collection of schizophrenia families we have obtained evidence for multiple genetic loci, including 7q22. The initial linkage evidence emerged from 52 families (n=236). We later replicated this finding in an independent sample of 352 families (n=1626).

RELN gene on 7q22 encodes the reelin protein critical for neuronal development. It regulates neuronal migration by guiding neurons and glia to their positions during brain development, and is expressed in brain regions with synapse remodelling. No reports exist for genetic association of *RELN* with the clinical diagnosis of schizophrenia. However, specific alleles of *RELN* have been suggested to contribute to response to antipsychotics.

We hypothesized that since *RELN* takes part in essential brain functions it might associate with cognitive traits affected in schizophrenia. We collected detailed neuropsychological data from 186 schizophrenia families (n=618) and tested association with five microsatellites in *RELN* using sex, age, and affection status as covariates. This revealed associations (p=0.002 to 0.000001) with traits related to working memory, controlled by the frontal brain areas and known to be impaired in schizophrenia. Carriers of the most associated allele scored lower in the visual working memory (p=0.0005) and verbal working memory tests (p=0.000008), as well as in learning (p=0.001) and memory tests (p=0.0002). Our findings suggest a role of *RELN* in frontal brain functions and raise the possibility that some allelic variants of this gene might contribute to cognitive disturbances related to schizophrenia.

A study of common SNP variation around 10 genes in the SREBP and HMG CoA reductase pathway and a testing of their association with BMI in a Caucasian case control panel. *E.K. Speliotes[1,2], H. Lyon[2,3], J.L. Butler[3], J.A. Drake[2,3], J. Nemesh[2,3], M.J. Daly[1,4], D. Altshuler[1,2,4], S. Purcell[1], J.N. Hirschhorn[2,3,4]* 1) Massachusets General Hospital, Boston MA; 2) Broad Institute, M.I.T., Cambridge MA; 3) Children's Hospital, Boston MA; 4) Harvard Medical School, Boston MA.

Obesity is a heritable risk factor for significant illness and death in the U.S. and worldwide. The genetic variants that predispose some but not other individuals to becoming obese are largely unknown. We with others recently showed that the SNP rs7566605, located 10 kb upstream of INSIG2 (insulin induced gene 2), is associated with BMI in multiple human populations (1). Data from animal studies suggest that INSIG2 regulates the localization of the SREBP transcription factor and the stability of HMG CoA reductase, which in turn control lipid and cholesterol biosynthesis pathways. Using HapMap data, we selected a set of tagged SNPs that capture most of the common variation in individuals of European ancestry for 10 genes in these pathways: INSIG1, SCAP (SREBP cleavage activating protein), SREBF1(SREBP1), SREBF2(SREBP2), LXRA (LXR alpha), LXRB (LXR beta), HMGCR (HMG CoA reductase), MBTPS2(site 2 protease), FASN (fatty acid synthase) and ACAS2 (acetyl coA reductase). We genotyped 94 SNPs in over 2800 individuals from the United States and Poland drawn from the near-extremes of the population distribution of body mass index (BMI). One SNP upstream of the LXRB showed a nominally significant association with obesity in both samples (Mantel-Hanzel p-value 0.006 and OR 0.83). We are genotyping this SNPs in additional samples to determine whether this nominal association with BMI is reproducible. We will also be testing for gene-gene interactions between SNPs in this pathway, with a particular focus on rs7566605. (1) Science. 2006 312(5771):279-83.

Genetic Heterogeneity and Genetic Interaction study of Parkinsons Disease in Seventy-Six Multiplex Tunisian Families. *L. Warren[1], R. Gibson[1], L. Ishihara[2], S. Thomas[1], R. Amouri[3], N. Gouider-Khouja[3], M. Kefi[3], M. Zouari[3], S. Sassi[3], S. Yahmed[3], E. Euch-Fayeche[3], A. Roses[1], L. Middleton[1], F. Hentat[3]* 1) GlaxoSmithKline, Res Triangle Park, NC; 2) Department of Public Health and Primary Care, University of Cambridge, Cambridge CB2 2SR, United Kingdom; 3) Service de Neurologie, Institut National de Neurologie, La Rabta, Tunis 1007, Tunisia.

Parkinsons disease (PD) is the second most common neurodegenerative disease after Alzheimers disease. To identify genetic causes of the disease, GSK has established a unique PD family-based collection from Tunisia. This collection is characterized by having large consanguineous pedigrees, excellent clinical assessment and a relatively homogenous population background. All of these factors have provided a great opportunity for genetic research to identify regions harboring PD susceptibility genes. Whole genome linkage scan was conducted in 76 consented PD families with 455 individuals genotyped for 1000 4cM-spaced microsatellite markers. Five major linkage regions have been identified with highly significant statistical support (LOD > 3). Of particular interest is the region on Chromosome 12 (LOD = 3.64), where a single mutation (G2019S) within the LRRK2 gene has been confirmed. The objective of the current study is to identify genetic interactions among these major linkage loci and examine genetic heterogeneity in the data set, with the potential to identify additional novel linkage regions. Linkage analyses stratified by LRRK2 G2019S mutation were performed and a significant linkage peak on Chromosome 13 (LOD = 3.05) was identified in families without the LRRK2 G2019S mutation. A series of Ordered Subset Analyses (OSA) were performed by treating the per-family linkage scores as covariates in non-parametric linkage analyses. A possible genetic interaction between genes under chromosome 1 and chromosome 13 was identified (permutation-based P-value = 0.017). Detailed results will be presented at the meeting. These results warrant further molecular follow-up work for confirmation and validation.

Animal Model of Fabry disease: new findings. *L.G. Rodrigues[1], M. Pais-Vieira[2], M.J. Ferraz[1], M.C. Sá-Miranda[1]* 1) UniLiPe, Institute for Molecular and Cellular Biology, Porto, Portugal; 2) Morphophysiology Unit, Institute for Molecular and Cellular Biology, Porto, Portugal.

Purpose: Fabry (Fb) disease is an X-linked inherited disorder of glycolipid metabolism resulting from deficient activity of the lysosomal enzyme, a-galactosidase A. Neutral glycosphingolipids, predominantly globotriaosylceramide, accumulate several tissues. Pain is one of the most distressing and less understood symptoms. As far as we know to date the Fb knockout mouse model was not used to study the pain mechanism.

Methods: All animals analysed were genotyped and two different ages, 24 and 48 weeks (wks), were analysed and only males were used. We characterised the behaviour of Fb knockout mice and their respective background (C57BL/6) by subjecting them to a primary behavioural screen (SHIRPA protocol). Sensitivity to noxious heat stimuli was measured with a hot plate (HP) test. Morphological and ultrastructural studies in myelin of sciatic nerves were carried out examining cross sections between Fb mice and controls with the light and electron microscope.

Results: When screening for the SHIRPA protocol it was found: a higher body weight for the Fb mice at 24 wks but these effects were not found at 48 wks; it was also found for both ages studied a decreased in locomotor activity and an increased in righting reflex for the Fb mice when compared with their respective aged matched controls. When compared Fb mice to their respective controls for the HP test it was found for both ages studied that Fb mice respond to a higher temperature. In the 24 wks Fb mice only responded approximately 4ºC above their respective controls and for the 48 wks group the difference was even higher, 5ºC. Its seems also to be a decreased in the ratio of myelin/unmyelin number of fibres in the sciatic nerve of the 48 wks Fb mice when compared with their respective aged matched controls.

Conclusions: An important conclusion from this study is that the nociception phenotype of the Fb mice is mainly one of hypoalgesia. The significance of this finding remains to be established.

Prevalent and uncommon filaggrin mutations cause ichthyosis vulgaris. *A. Terron-Kwiatkowski[1], A. Sandilands[1], F.J.D. Smith[1], M. van Geel[2], M.A.M. van Steensel[2], W.H.I. McLean[1]* 1) Human Genetics Unit, University of Dundee, Scotland, UK; 2) Department of Dermatology, University Hospital Maastricht.

The aim of this study was to identify filaggrin (FLG) mutations that cause ichthyosis vulgaris (IV) and that predispose individuals to atopic dermatitis (AD). The 400 kDa polyprotein profilaggrin is the major protein of keratohyalin granules and its proteolytically processed end-product, filaggrin, is essential for skin barrier function. Prevalent loss-of-expression mutations in FLG were recently shown to cause IV and predispose carriers to AD and other atopic phenotypes in European populations. Exon 3 of FLG contains multiple filaggrin repeat units arranged in tandem. These highly repetitive DNA sequences make PCR amplification and diagnostic re-sequencing of this gene problematic. Furthermore, the number of repeats has been shown to vary from 10-12 in the population. By designing repeat-specific primers we were able to develop a range of overlapping PCR fragments each of which spans a few filaggrin repeats. Here we analysed the FLG gene in several families with IV and found that mildly affected patients were heterozygous for the previously reported mutations R501X or 2282del4, whereas severely affected individuals were homozygous for either mutation, consistent with the suggested semidominant inheritance model. Interestingly, three individuals with the marked IV presentation were found to be heterozygous for R501X or 2282del4. Further sequencing revealed three novel compound heterozygous mutations: E2422X and 7267delCA, both at the end of filaggrin repeat 6; and 11033del4 in filaggrin repeat 10. All of the novel mutations lead to premature termination codons within exon 3 of the FLG gene. Immunohistochemical and biochemical analysis suggested that although these more distal mutations allow synthesis of several filaggrin repeats, they disrupt profilaggrin processing and therefore act as null-alleles. This strongly suggests that sequences near the C-terminus of profilaggrin are required for correct processing to occur. These data confirm the role of the FLG gene in IV and suggest that other family-specific or population-specific mutations should be sought in IV and AD.

Copy number variation of immune genes. *S.J. White[1,2], E. van den Akker[1], E. van de Vosse[3], A.W. de Visser[3], J.T. den Dunnen[1], M.H. Breuning[1]* 1) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Immunohematology and Blood transfusion, Leiden University Medical Center, Leiden, Netherlands; 3) Department of Infectious Diseases, Leiden University Medical Center, Leiden, Netherlands.

Recent studies have revealed a new type of genetic variation encompassing relatively large genomic segments, referred to as copy number variation (CNV). CNV is significantly associated with segmental duplicons, defined as stretches of DNA (>1 kb) with a high degree of homology (>90%) present in at least two copies in the genome. These duplicons are enriched for genes, particularly those involved in the immune system. We have searched for CNV in immune-related genes present in segmental duplicons using Multiplex Ligation-dependent Probe Amplification (MLPA), which is currently the best method available to analyze duplicons in a high-throughput, high-resolution manner. A large proportion (1142 of 1562) of the genes in the Immunogenetic Related Information Source (IRIS) was screened for the presence of exon containing segmental duplications. Analysis showed that 137 (12.0%) of the immune related genes tested were completely (n=73, 6.4%) or partially (n=64, 5.6%) located within one or more segmental duplicons. At least two MLPA probes were designed for 41 target genes, preferentially within two outmost exons, each on one end of the particular gene. These probes were used to screen genomic DNA from healthy individuals. CNV was detected for SIGLEC5 and C4A/C4B, and suspected for several other loci. We are currently confirming the potential CNV detected, as well as expanding the number of genes to be tested. Our results demonstrate that CNV occurs in at least some immune genes with segmental duplicons, which may be associated with disease susceptibility.

Mapping recombination hotspots in the three Indian consanguineous communities. *M.S. Song[1], H.S. Savithri[2], X.M. Lu[1], X. Li[3, 4], B.S. Gong[4], H.S. Venkatesha Murthy[5], A.H. Bittles[6], N. Appaji Rao[2], W. Wang[1,3]* 1) Department of Biology, Graduate School of the Chinese Academy of Sciences, Beijing, PR China; 2) Indian Institute of Science, Bangalore; 3) Capital University of Medical Sciences, Beijing, PR China; 4) Bioinformatics Department, Harbin Medical University, Harbin, PR China; 5) Annapurna Clinic, Bhadravati, India; 6) Edith Cowan University, Perth, Australia.

Mapping recombination hotspots should ultimately illuminate the as yet mysterious factors that direct the location and frequency of recombination and aid in understanding the genomic landscape of human evolution. Previous studies have shown that uniform genetic background and controlled breeding schemes can avoid the variability which often confounds genetic effects such as environmental effects, therefore the sample size required to identify the specific gene in question will be decreased and fewer biomarkers needed owing to increased linkage disequilibrium (LD) and decreased allelic diversity. Here we studied recombination rates of chromosomes 13, 15, 16, 17 and 18 by genotyping of 67 STR loci in the three 4-generation Indian consanguineous communities (Sankethi kindreds A, B and C) with a total of 128 individuals (69 males and 59 females). The results evidenced the extreme local recombination rate variations on individual chromosomes among the isolated Sankethi kindreds, indicating that it is essential to look at patterns of recombination rates in the consanguineous populations.

LADD syndrome is caused by mutations that reduce the tyrosine kinase activity of FGFR2. *E. Rohmann[1, 2], I. Lax[3], E.D. Lew[3], V.P. Eswarakumar[3], H.G. Brunner[4], Y. Li[1, 2], H. Kayserili[5], J. Schlessinger[3], B. Wollnik[1, 2]* 1) Center for Molecular Medicine Cologne (CMMC), Cologne, Germany; 2) Institute of Human Genetics, University of Cologne, Cologne, Germany; 3) Department of Pharmacology, Yale University School of Medicine, New Haven, CT, USA; 4) Department of Human Genetics, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands; 5) Medical Genetics Department, Istanbul Medical Faculty, Istanbul University, Istanbul, Turkey.

Lacrimo-auriculo-dento-digital (LADD) syndrome is an autosomal dominant disorder mainly affecting the lacrimal system, the ear-shape and hearing, teeth development, and digit patterning. We recently identified the molecular basis of LADD syndrome and found heterozygous missense mutations in LADD families in FGFR2, and FGFR3, and FGF10, one of FGFR2 ligands. Notably, the mutations in the FGF-receptor molecules were located in regulatory regions of the tyrosine kinase domain of the receptors. Previous studies have shown that different craniosynostosis syndromes are caused by gain-of-function mutations in FGFR2 which result in elevated tyrosine kinase activity of FGFR2. We have compared the tyrosine kinase activity of three LADD FGFR2 mutations and demonstrated that their intrinsic tyrosine kinase activity is reduced as compared to the tyrosine kinase activity of wild type FGFR2 or to the constitutively activated tyrosine kinase activity of FGFR2 mutant responsible for Pfeiffer syndrome. Furthermore, stimulation with a LADD FGF10 mutant protein led to a decreased FGFR2 activation and to compromised MAPK stimulation as compared to stimulation of these responses induced by wild type FGF10. We conclude that FGFR2- and FGF10-LADD mutations lead to reduced FGFR2 autophosphorylation and diminished cell signaling via FGFR2 and that the reduced tyrosine kinase activity of FGFR2 is a hallmark underlying the molecular basis of LADD syndrome.

Phenotypic Variability of Vascular Ehlers-Danlos Syndrome in a Pedigree with a COL3A1 Mutation. *J. Yang*[1], *W. Chen*[2], *J. Tran*[1], *N.B. McDonnell*[2], *C.A. Francomano*[2,3] 1) Laboratory of Genetics, National Institute on Aging/NIA, Baltimore, MD; 2) National Institute on Aging, NIH, Baltimore, MD; 3) Harvey Inst Hum Genetics, GBMC, Baltimore, MD.

Vascular Ehlers-Danlos Syndrome (VEDS) is a rare genetic disorder affecting approximately 1 in 100,000 individuals, resulting from mutations in the gene for type III procollagen (COL3A1). Affected patients are at risk for arterial, bowel, and uterine rupture and have a significantly reduced life expectancy. We describe a pedigree in which a single base pair substitution leading to a G786R mutation in Col3A1 was detected in a 55 year old proband and her 30 year old son. Previously performed protein gel electrophoresis analysis on a clinical basis found abnormal type III procollagen motility. A review of the family history revealed that at least 10 additional members of the family are affected with VEDS. A total of 6 premature deaths (age range 14-55) were reported due to aneurysms and bleeding complications. However, there was no history of uterine rupture or pregnancy- related death in five affected females with a total of ten pregnancies. A vascular work-up including MRI/MRA imaging and echocardiography in the 30 year old son who carries the G786R mutation was completed and did not reveal any abnormalities. A review of the clinical history in affected family members revealed variability in the facial characteristics as well as musculoskeletal features of the disorder, in addition to the vascular presentation. The phenotypic variability speaks to the role of environmental interactions as well as possible influence of modifier loci. The study of modifying influences may lead to the identification of therapeutic approaches to reduce the complications of VEDS.

Aortic smooth muscle reactivity in -galactosidase A knockout mice. *P. Rozenfeld[1], M. Frtiz[1], A. Kulkarni[2], R. Brady[2], C. Fossati[1], G. Rinaldi[1]* 1) Univ Nacional de La Plata, Argentina; 2) National Institutes of Health, USA.

Introduction: Fabry disease results in deposition of glycosphingolipids, particularly in vascular endothelium and smooth muscle cells, leading to vessel occlusion and ischemia. Previous reports demonstrated increased endothelium-mediated vascular reactivity in Fabry disease. We used the -galactosidase A knockout (AGA null) mice as a murine model to study the pathophysiology of the vasculopathy in Fabry disease. The aim of this work was to evaluate the aortic reactivity in AGA null mice compared with wild type littermates (WT). Methods: Contraction forces (in milligrams of force per milligram of tissue, mgF/mgT) of aortic rings from AGA null and WT mice were measured after exposure to either 80 mM KCl or 1 M norepinephrine (NE). The relaxant agents acethylcholine (Ach) and sodium nitroprusside (SNP) were added to the bath when the maximum force of the agonists was attained, and the relaxation was expressed as a percent of that contraction. The effect of L-NAME in Ach-induced relaxation was also studied. Results: Aortic rings from AGA null mice developed a higher contractile force than WT mice in 80 mM KCl (1526 169 vs. 1083 117 mgF/mgT, $P<0.05$); and with NE (1412 119 vs. 1174 141 mgF/mgT,). After the addition of Ach, the relaxation was significantly greater in AGA null mice. L-NAME inhibited Ach-induced relaxation to a similar extent in both groups. The percentage of relaxation with SNP was lower in AGA null mice than in WT mice ($p<0.03$). Conclusions: 1) Aortic smooth muscle of AGA null mice exhibited augmented contractile response upon activation of either voltage-operated or receptor-operated channels. 2) An exaggerated response to Ach was observed, demonstrating an increased endothelium-dependent vasodilation. 3) SNP-induced relaxation was significantly decreased in AGA nulls with respect to WT. 4) A similar blunting of Ach response after L-NAME was observed in both groups. These findings indicate an augmented contractile response and a higher vasodilation response in AGA null mice mediated mainly by non-NO endothelial mediators.

DNA microarray-based resequencing analysis of LRRK2 in familial Parkinsons disease. *H. Tomiyama[1,2], N. Seki[2], Y. Takahashi[2], J. Goto[2], E. Rogaeva[3], A. Lang[3], M. Murata[4,5], T. Toda[5,6], M. Yamamoto[5,7], M. Funayama[1], Y. Mizuno[1], N. Hattori[1,5], P.S. George-Hyslop[3], S. Tsuji[2]* 1) Neurology, Juntendo University School of Medicine, Japan; 2) Neurology, University of Tokyo, Japan; 3) Centre for Research in Neurodegenerative Diseases, Dept of Medicine, University of Toronto, Canada; 4) Neurology, Musashi Hospital, National Center of Neurology and Psychiatry, Japan; 5) CREST, Japan; 6) Functional Genomics, Osaka University Graduate School of Medicine, Japan; 7) Neurology, Kagawa Prefectural Central Hospital, Japan.

Objectives: LRRK2, the causative gene for PARK8, is a large gene with 51 exons containing 7584bp. Recently, we have established a custom-made DNA microarray-based high throughput resequencing system for the comprehensive mutational analysis of genes of familial Parkinsons disease (PD). To clarify the molecular epidemiology of mutations in the large LRRK2 gene, we applied the microarray-based resequencing system to extensive mutation analysis of LRRK2. Methods: We determined the nucleotide sequences of all the 51 coding exons and the splice junctions of LRRK2 of 42 autosomal dominant PD (adPD) probands from Japan (23 families) and Canada (19 families) using the microarray-based resequencing system. Results: We found one patient with R1514Q from Canada. The R1514Q has been described in adPD patients of Norway, thus confirming as the causative mutation. The G2385R was found in 21.7% (=5/23) of Japanese adPD probands, while it was not identified in adPD patients from Canada. The G2385R was also present in 4.8% (=22/457) of Japanese normal controls. Discussions: High throughput DNA microarray-based resequencing system is highly useful for comprehensive mutational analysis of causative genes for PD, especially for genes containing numerous exons like LRRK2. Very recently, the frequency of heterozygotes G2385R has been reported to be higher in sporadic PD patients (10.0%) than in controls (4.8%) in Taiwan. Given the much higher overrepresentation of the G2385R in Japanese adPD probands (21.7%), the results strongly support that LRRK2 G2385R is a common genetic risk factor for PD in Asian but not in Caucasian.

Dilated Cardiomyopathy In Propionic Acidemia Patients. *S. R. Romano[1], V. V. Valayannopoulos[1], F. L. Lacaille[1], D. B. Bonnet[1], D. R. Rabier[3], A. R. Rotig[2], A. M. Munnich[2], G. T. Touati[1], P.dL de Lonlay[1,2]* 1) Department of Pediatrics Hôpital Necker-Enfants Malades, Paris, France; 2) Department of Medical Genetics and INSERM U-393Hôpital, Necker-Enfants Malades, Paris,France; 3) Department of Biochemistry Necker-Enfants Malades, Paris,France.

Objective. Dilated cardiomyopathy is now a well known complication of propionic acidemia (PA) even if it has been reported in only a small number of PA patients. We reviewed PA patients for evidence of cardiomyopathy and we described follow up and management of these patients. Methods. Five patients with PA had the diagnostic criteria of cardiomyopathy and were treated with standard therapy. For each patient we detailed clinical follow up, age at the onset of cardiomyopathy and medical management. Endomyocardiac biopsy (EMB) was performed for mitochondrial respiratory chain investigation (two patients). Results. Dilated cardiomyopathy occurred at age height (n=1), six (n=1), nine (n=1), and five (n=2). All patients had neonatal onset of PA (neonatal coma) except one (10 months). Complex III deficiency was identified for one patient and complex II deficiency for the other. Liver transplantation (LT) was performed for two patients. The first was transplanted thirteen years ago. Cardiac echography was normal one year after the transplantation. The second child has been transplanted one month ago and shortening fraction was 28 % before LT. Cardiac echography is now normal. Conclusion. Dilated cardiomyopathy in propionic acidemia is a severe complication due to secondary Oxphos deficiency. A toxic accumulation of metabolites excreted in PA probably is implicated as the cardiac defect was reversible after liver transplantation for two patients.

Are periventricular intracranial cysts on prenatal MRI an early diagnositic feature for mitochondrial depletion syndrome? *M. Rohrbach[1], D. Chitayat[1, 2], G. Maegawa[1], G. Davidzon[3], S. Shanske[3], K. Chong[1, 2], S. Blaser[4]* 1) The Hospital for Sick Children, Department of Pediatrics, Division of Clinical and Metabolic Genetics, University of Toronto, Toronto, ON, Canada; 2) Mount Sinai Hospital, The Prenatal Diagnosis and Medical Genetics Program, University of Toronto, Toronto, Ontario, Canada; 3) Department of Neurology, Columbia University College of Physicians and Surgeons, New York, USA; 4) The Hospital for Sick Children, Department of Pediatrics, Divisions of Neuroradiology, University of Toronto, Toronto, ON, Canada.

Mitochondrial DNA (mt DNA) depletion syndrome (MDS) refers to a quantitative defect in mtDNA in which affected tissues have markedly reduced mtDNA copy number. MDS is inherited as an autosomal recessive trait and mutations in a number of nuclear genes involved in mtDNA replication and nucleotide metabolism have been reported in patients. We describe a patient who first presented at 27 weeks gestation with isolated prenatal MR findings of bilateral periventricular/subependymal cysts adjacent to the frontal horns, and fetal diffusion-weighted-images which showed restriction. The pregnancy was continued and resulted in a boy, who presented with severe lactic acidosis, elevated lactate/pyruvate ratio (56.6) and methylmalonic aciduria. Postnatal MRS revealed high lactate peak and MRI confirmed prominent periventricular cysts with no other brain abnormalities. Muscle biopsy showed low activities for multiple respiratory chain complexes, suggesting MDS. Quantitative PCR analysis in muscle showed a severe reduction of mtDNA, a depletion of approximately 90%. However, sequencing of two of the genes affected in some patients, thymidine kinase (TK2) and polymerase gamma (POLG) did not reveal any mutations. The karyotype was 46,XY. To our knowledge this is the first report correlating fetal MRI abnormalities and mitochondrial depletion syndrome. Due to unfavorable prognosis, prenatal recognition of this disorder would be very useful for counseling.

Chromosome 16p duplications: phenotype and microarray analysis. *J. Puechberty[1], M. Noruzinia[3], A. Schneider[1], G. Lefort[1], J. De Vos[2], C. Coubes[1], P. Blanchet[1], V. Cacheux[1], P. Sarda[1]* 1) Genetique Medicale, CHU Arnaud de Villeneuve, MONTPELLIER, Languedoc, France; 2) Institut de Recherche en Biotherapie, CHU Hopital Saint-Eloi, MONTPELLIER, Languedoc, France; 3) School of Medical Sciences, Tarbiat Modarres University, Teheran, Iran.

Partial trisomy 16p is a rare chromosomal anomaly. Duplications of chromosome 16p are often the products of unbalanced maternal reciprocal translocations and consequently the phenotype of patients is not typical of pure partial trisomy 16p. The cytogenetic difficulty is to determine the precise limits of duplicated regions, which is important for predicting the phenotype. We report an analysis of eleven cases of pure partial duplications of chromosome 16p, six from the literature and five new cases from our laboratory. This study determines three groups of duplications. The first group includes patients with short proximal 16p11-p12.1 euchromatic duplication considered as a silent duplication without phenotypical expression. Two of our patients fall into group 1. Two other patients belong to group 2 which corresponds to patients with larger 16p11-p12/p13 duplications. Phenotype is characterized by severe mental retardation, dysmorphism, variable malformations and recurrent infections. The third group includes patients with terminal 16p13-pter duplication and is not well defined to date due to the difficulty of comparing published reports. Our last patient falls into this category. The correlation phenotype-karyotype is difficult to define according to the data presently reported in the literature. In our patients, studies using SNP microarrays (Affymetrix) have permitted to define the borders of the duplications and have led to the discovery of an additional unexpected micro-rearrangement in one case.

Carnitine palmitoyltransferase-1b (CPT-1 muscle isoform) deficiency in the mouse. *P.A. Wood[1], S. Ji[1], D.A. Hamm[1], J. Kerner[2], C.L. Hoppel[2], T.R. Schoeb[1], W.S.H. Chick[3], Y. You[3]* 1) Dept Genetics, Univ Alabama at Birmingham, Birmingham, AL; 2) Depts Pharmacology & Nutrition, Case Western Reserve Univ, Cleveland, OH; 3) Oak Ridge Nat Lab, Oak Ridge, TN.

Carnitine palmitoyltransferase-1 (CPT-1) catalyzes the rate-limiting step of mitochondrial beta-oxidation of long chain fatty acids. CPT-1b, also known as the muscle isoform, is expressed in skeletal and cardiac muscle, as well as brown fat, and to a lesser extent in other tissues. Patients with CPT-1b deficiency have been extremely rare. In order to better understand the function of this gene, we have developed a mouse model with CPT-1b deficiency by gene targeting a deletion of exons 1-3 in the mouse CPT-1b gene (*Cpt-1b*). To date we have not detected any homozygous CPT-1b deficient pups, suggesting that homozygous mutants do not survive to birth. There were no CPT-1b homozygous mutant embryos detected from heterozygous matings at 9.5 dpc (n=10) and 11.5 dpc (n=8). In both male and female CPT-1b heterozygous mice, the total CPT-1 enzyme activity in skeletal muscle was reduced to ~60 percent of that in wild-type littermates, whereas no change in total CPT-1 activity was seen in liver. This is consistent with the predominate tissue-specific expression of CPT-1b in skeletal muscle but not liver. Following an 18 hour fast, adult CPT-1b heterozygous mice showed significant fatty change in brown adipose tissue only, whereas skeletal muscle and heart appeared unaffected as compared to CPT-1b wild-type controls. Furthermore, there were no significant differences in fasting blood glucose and triglyceride concentrations. The development of this model will provide an important tool to investigate the role of CPT-1b in many disease conditions including type 2 diabetes.

Histological Findings in GUCY2D-/- x PDErd10/rd10 Double Mutant Mice Suggest a Protective Effect of cGMP Depletion in Photoreceptors Lacking Rod-Specific PDE Function. *J.M. Rozet[1], I. Perrault[1], K. Bigot[2], A. Provot[2], L. Vede[2], G. Pivert[3], A. Munnich[1], M. Abitbol[2], J. Kaplan[1]* 1) INSERM U781, Hopital des Enfants Malades, Paris, France; 2) CERTO, Faculte de Medecine Necker, Paris, France; 3) IRNEM, Faculte de Medecine Necker, Paris, France.

This purpose of this study was to characterize the phenotype of a mouse lacking both GUCY2D and rod-specific PDE functions. GUCY2D knock-out mice were crossed with homozygous PDErd10/rd10 mice to generate double mutant GUCY2D-/- x PDErd10/rd10 mice. Comparative histological studies of the retinas of rd10 and double mutant mice were performed at ages 2, 3, 4, 5, 6, 7 weeks. For that purpose, the animals eyes were fixed in paraformaldehyde, embedded in wax, sectioned at 4m and coloured in HES. As soon as 4 weeks of age, the retinas of homozygous PDErd10/rd10 mice showed a massive reduction of the outer segment, inner segments layer and outer nuclear layers. Conversely, the retina of double mutant mice of the same age demonstrated slower photoreceptor degeneration. In PDErd10/rd10 mice a dramatic degeneration was noted in both central and peripheral retina (one or two rows of photoreceptors). In double mutant mice the degeneration followed a concentric gradient from the central retina to the peripheral retina where a significant number of photoreceptors was still present up to 7 weeks of age, especially in the superior retina. In conclusion, it has been shown that the invalidation of GUCY2D in mice resulted in severe cone degeneration. Rods do not degenerate but are functionnaly impaired. On the other hand, the missense mutation in the rod-specific beta-subunit of the PDErd10/rd10 mice resulted in a fast degeneration of both rods and cones. Interestingly, in mice lacking both the GUCY2D and PDE functions, the degeneration of photoreceptors was less severe than in rd10 mouse. Although preliminary, these data suggest that the retinal-specific guanylate cyclase gene might play a role in rod photoreceptors of mouse and that the lowering of cGMP synthesis might partially protect these cells from degeneration.

Genome wide linkage analysis of two Norwegian families with epilepsy. *K.K. Selmer[1], T. Egeland[1], M.H. Solaas[1], K. Brandal[1], K.O. Nakken[2], L.A. Corey[3], D.E. Undlien[1]* 1) Inst. of Medical Genetics, University of Oslo, Norway; 2) National Center for Epilepsy, Sandvika, Norway; 3) Dept. of Human Genetics, Virginia Commonwealth University, Richmond, VA, USA.

Epilepsy is one of the most common brain disorders with a prevalence of ~1%. Most forms of epilepsy are considered to be of multifactorial origin and the clinical expression of the different subtypes is very heterogeneous. During the past decade mutations in several different genes have been detected as a cause of some monogenic forms of epilepsy. The aim of our study is to identify mutations leading to the development of epilepsy. More than 40 families with assumed monogenic epilepsy were ascertained from the population based Norwegian Twin Panel. Epilepsy classifications were done by experienced neurologists according to the International League Against Epilepsy classification, based on clinical and family interviews and medical records. Further selection of 12 families for genome wide linkage analysis was based on power analyses and clinical diagnoses. 3862 SNP markers were genotyped in 285 persons using the ABI Linkage Mapping Set 4K. Analyses of two of the families were performed in Merlin, which takes linkage disequilibrium (LD) between markers in clusters into account to reduce possibly inflated LOD scores due to LD between markers. The remaining 10 families will be analyzed in Simwalk2 due to pedigree size. Altogether, the two families consist of 46 members, in which 11 are affected by either epilepsy or febrile seizures. Estimated maximum LOD scores (based on power estimations) were 1.8 and 1.5 respectively and parametric analyses assuming autosomal dominant mode of inheritance with penetrance of 0.80 indicated linkage to chromosomal region 14q31.1 with LOD scores in the same range. Suggestive linkage to other loci was also found in the two families, but the linkage peak on chromosome 14 was the only one the two families had in common. Our study provides evidence for linkage to chromosome 14 in two Norwegian families with epilepsy and further analyses of the remaining 10 families with a similar form of epilepsy are planned to see if we can confirm the linkage to this locus.

A method for finding risk haplotypes using cases and their parents. *M. Shi, D.M. Umbach, C.R. Weinberg*
Biostatistics Br, NIEHS, RTP, NC.

We propose a method for association studies based on dense SNP markers using cases and their parents. Our approach uses the genotypes of affected individuals and their parents directly, without requiring the user either to know or to estimate haplotypes and their phases. Our testing procedure works by comparing the affected offspring with their corresponding complement through permutations, where the complement is the equally likely hypothetical offspring of the same parents that would have received the sequences of DNA un-transmitted to the affected offspring. We describe a method, the max_Z2 test, for testing the hypothesis that the inherited diplotype is not associated with the disease phenotype under study. The max_Z2 is based on the difference vector between the childs and complements genotypes, and P-values are obtained by referring to a permutation distribution, derived by randomly assigning disease status to either the offspring or their complement. This method can be used when there are missing SNPs or individuals with entirely missing genotypes. To take advantage of different testing procedures we propose an approach to effectively combine different tests. Our approach can be easily extended to test for maternal effects. When the null hypothesis is rejected, a subsequent procedure permits identification of the informative risk-haplotype tagging SNPs, to enable discovery of the haplotype that is associated with the phenotype under study. We characterize the performance of the proposed approach and compare it with several competing procedures through realistic simulation studies of case-parent triads based on the haplotype frequencies and structures for four genes, derived from the HAPMAP project. We apply this method to data from an orofacial cleft study.

Molecular Studies on *DYX1C1* a candidate gene for dyslexia. *I. Tapia-Paez*[1], *S. Massinen*[2], *J. Kere*[1,2] 1) Biosciences and Nutrition, Stockholm, Stockholm, Sweden; 2) Dept. of Medical Genetics, Biomedicum, University of Helsinki, Finland.

Dyslexia is a complex disorder characterized by reading disability despite normal intelligence, senses and education; it affects 5-10% of the population. Genetic studies have repeatedly pointed out loci linked to dyslexia on at least chromosomes 2, 3, 6, 11, 15 and 18. Until now, four genes have been associated with dyslexia: *DYX1C1*, *DCDC2*, *KIAA0319*, and *ROBO1*. These genes are involved in neuronal migration or brain development and their functional role in dyslexia remains to be elucidated. The *DYX1C1* gene on chromosome 15 (Taipale et al. PNAS 2003) was the first gene implicated in dyslexia, cloned based on a translocation t(2;15)(q11;q21) that cosegregated with dyslexia in a Finnish family. Two sequence changes in *DYX1C1* showed association with dyslexia in unrelated families, one that introduced a stop codon truncating the protein by four amino acids, and the second in 5UTR, close to the translation initiation site. The association of *DYX1C1* with dyslexia has been ambiguous in replication studies, prompting us to look for new SNPs in the promoter of the *DYX1C1* gene. Two new SNPs were found, and when combined with additional results from German samples, they showed supportive evidence for *DYX1C1* as a candidate dyslexia gene (Dahdouh F et al. manuscript). To understand possible functional consequences of these changes, we made constructs to study the binding of proteins in electrophoretic mobility shift assays. Allele-specific differential retardation of mobility was observed with the promoter and 5UTR SNPs, suggesting a functional effect of these variations. We also prepared constructs for reporter assays in pGL3 basic and promoter vectors using the -3G/A polymorphism. We could detect differences in luciferase expression, suggesting that a repressor molecule binds to the -3 position and that this effect is stronger when the -3G variation is present. In another approach, to study protein-protein interactions we have created a stable cell line overexpressing constitutively native DYX1C1. Elucidation and understanding of the biology behind *DYX1C1* and the other genes related to dyslexia may open new pathways in the study of brain function.

The polymorphism of *INSIG2* is associated with fatty liver, hypertriglyceridemia and insulin resistance in type 2 diabetes. *M. Zenibayashi, Y. Hirota, K. Miyake, T. Teranishi, K. Kouyama, K. Sakaguchi, T. Ohara, M. Kasuga*
Division of Diabetes and Digestive and Kidney Diseases, Department of Clinical Molecular Medicine, Kobe University Graduate School of Medicine, Kobe, Japan.

Introduction Insulin-induced gene (Insig) 1 and 2 are closely related proteins that block proteolytic activation of sterol regulatory binding proteins (SREBPs). We studied the association of polymorphisms in Insig genes with type 2 diabetes and its relation to lipid parameters in type 2 diabetic patients. **Method** We screened 5' flanking region (1000bp) and the coding region of the human *INSIG1* and *INSIG2* in 16 diabetic subjects by direct-sequencing. 5 SNPs in *INSIG1* and 2 SNPs in *INSIG2* were identified. We also extracted 4 SNPs around *INSIG1* and 9 SNPs around *INSIG2* from the public databases for analyzing linkage disequilibrium (LD) in 87 non-diabetic subjects. We selected 3 SNPs of *INSIG1* and 7 SNPs of *INSIG2* based on allele frequencies and LD patterns. We genotyped these SNPs in 340 Japanese patients with type 2 diabetes and 180 non-diabetic subjects. We evaluated hepatic lipid content by ^{1}H-Magnetic Resonance Spectroscopy. **Results** None of SNPs or haplotypes in both genes was associated with type 2 diabetes. We also tested their association to the lipid parameters of 100 patients with type 2 diabetes. We found one haplotype of *INSIG2* was significantly associated with hepatic lipid content (p=0.015) and serum triglyceride level (p=0.016). This haplotype was determined by -231G>A polymorphism (nucleotide number of the SNP is counted from the transcriptional start site), so we examined whether this SNP affects serum triglyceride level and HOMA-IR in 308 patients with type 2 diabetes. We found A allele carriers had significantly higher levels of serum triglyceride (p=0.031) and HOMA-IR (p=0.008) than non-carriers. These differences remained after adjusting for sex, age and BMI using multiple regression model. We found no association of this polymorphism with BMI in these 308 patients. **Conclusion** These results suggest that the -231G>A polymorphism of *INSIG2* is associated with fatty liver, hypertriglyceridemia and insulin resistance in type 2 diabetes.

Therapeutic perspectives for the treatment of breathing dysfunctions in Rett syndrome. *J. C. Roux, E. Dura, A. Moncla, J. Mancini, L. Villard* Génétique Médicale, INSERM U491, Faculté de Médecine de la Timone 13385 Marseille, France.

Rett syndrome is a severe X-linked neurological disorder, in which most patients carry a mutation in the gene encoding methyl-CpG binding protein 2 (MECP2). The clinical course of the disease consists of normal in utero and neonatal development followed by a period of regression showing signs of neurodevelopment defects (arrest of brain development, loss of acquisitions such as speech and walk, apparition of behavioural troubles). Twenty six percent of deaths in Rett girls occur with sudden respiratory arrhythmia. We investigated breathing dysfunction in Rett syndrome using an animal model deficient for the Mecp2 gene. We performed experiments on wild-type and Mecp2-deficient mice to understand the role of the Mecp2 gene in respiration and bioaminergic systems. We have previously shown that adult mice deficient for the Mecp2 gene have erratic breathing with highly variable respiratory rhythm and frequent apneas likely due to reduced norepinephrine content and a drastic decrease of tyrosine-hydroxylase (rate limiting enzyme in the catecholaminergic synthesis) expressing neurons in the medulla. Recently, using TUNEL method, no apoptotic cells have been identified at the brainstem level indicating that the neurons did not die and probably lost their ability to synthesize tyrosine-hydroxylase protein. We are currently investigating the stimulation of noradrenergic metabolism in the same animal model using specific norepinephrine reuptake inhibitors. Our results show that we can improve both, the respiratory rhythm of the mutant animals and increase significantly their lifespan. Moreover, we determined that our treatment significantly increased the number of tyrosine-hydroxylase expressing neurons which could explain at least in part the breathing improvement. In conclusion, these results open new perspectives for the treatment of the respiratory deficits of Rett syndrome children.

Evidence of a single founding event responsible for the infertility phenotype macrocephalic spermatozoa. *P.F. Ray[1], K. Dieterich[1], J. Perrin[1], S. Hennebicq[1], B. Ben Amar[2], M. Zahi[2], S. Rousseaux[3], B. Sèle[1], J. Lunardi[1]* 1) Dpt Génétique et Procréation, CHU de Grenoble, France; 2) Rabat, Morocco; 3) INSERM U309,Grenoble.

Rare cases of infertile men have been reported presenting with 2-3 fold enlarged spermatozoa with an aneuploidic content observed by FISH. The anomalies suggested a segregation defect during meiosis I and II and a failure of nuclear division. The remarkable likeness of i) the spermatograms, ii) the morphological aspect of the spermatozoa and iii) the FISH results strongly suggested a common genetic etiology for this rare phenotype. We investigated four unrelated French patients (3 from Algier and one from Tunisia), all born to first cousins, and ten patients from the Rabat region in Morocco. All showed oligoasthenoteratozoospermia with 100% abnormal spermatozoa with macrocephalia and a variable number of flagella. An autosomic recessive transmission was suspected, potentially due to a founder effect. A microsatellite whole genome scan was realized to identify homozygous regions common to the patients. DNA was extracted from blood and a genome-wide scan was realized for the 22 autosomes with the 10cM Linkage Mapping v2.5 Applied Biosystems. Homozygosity ranging from 1 to 6 adjacent kit markers (<10 - 58 Mb) was observed on chromosome 19 in 9/14 patients. Detailed polymorphisms analysis confirmed the region homozygosity for the nine patients and allowed to identify a smaller region in 3 other patients that had passed unoticed with the first low coverage screen. A 1Mb critical interval with a common haplotype was identified in all 12 patients. In conclusion our data indicate that 12/14 patients have inherited two copies of a common genetic event localized on chromosome 19. All four French patients have inherited the "Rabats haplotype"; indicating that the genetic event is probably at least 10 generations old. We are currently sequencing a candidate gene expressed in the testis. Preliminary results indicate that this gene is likely to be involved.

This work was supported in part by the Fond d'Aide à la recherche Organon (FARO) and the DRC of Grenoble CHU.

GOLDsurfer2: A comprehensive tool for the analysis and visualization of whole genome association studies. *F. Pettersson[1], A.P. Morris[1], P.S. Derwent[2], M.R. Barnes[2], L.R. Cardon[1]* 1) Dept Bioinformatics, Wellcome Trust Centre, Oxford, United Kingdom; 2) GlaxoSmithKline Pharmaceuticals, Genetic Bioinformatics, Harlow, Essex, UK.

With recent advances in the efficiency of high-throughput single nucleotide polymorphism (SNP) genotyping technology, genome-wide association studies are now routinely undertaken with the sample sizes necessary to detect the modest genetic effects we expect for complex diseases. There is now a clear demand for efficient analysis tools that allow data pre-treatment, together with evaluation, visualization and interpretation of results. To meet these demands, we have further developed the GOLDsurfer software [1]. GOLDsurfer2 can be used for pre-filtering of genotype data, using user-defined quality control thresholds based on Hardy-Weinberg disequilibrium, missing genotype rates and minor allele frequencies, and for statistical association analysis. Interactivity in terms of both visualization and data management are key concepts in the user-friendly GUI. Basic statistical calculations, including single-locus and pairwise models of SNP association with disease, are built in. The architecture is written to accommodate methods for more complex analyses as external modules. Functional annotation is of great importance for design of studies and evaluation of statistical results. GOLDsurfer2 can link to extract annotation from public databases such as the UCSC genome database and it also supports browsing of gene ontologies. A core feature is the 3D interactive visualisation of linkage disequilibrium (LD) which has been further developed to function on a genome wide level. Extended regions of disease association within LD blocks can suggest regions for further investigation in order to find putative causal alleles. To this end, we include a capability to functionally weight SNPs characterized by the International HapMap project. GOLDsurfer2 is implemented in Java and distributions are available for Mac OS X, Linux and Windows. References. [1] Pettersson, F., Jonsson, O. and Cardon, L.R., GOLDsurfer: three dimensional display of linkage disequilibrium. Bioinformatics. 2004;20(17):3241-3.

A polyalanine contraction in HOXD13 is associated with complex brachydactyly. *X. Zhang[1], X. Zhao[1,2], M. Sun[1,3], W. Yang[1], X. Zeng[1], W.H.Y. Lo[1], E.W. Jabs[3], X. Shan[2]* 1) Department of Medical Genetics, Peking Union Medical College, Beijing, China; 2) Southeast University, Nanjing, China; 3) The Johns Hopkins University, USA.

HOXD13, the homeobox-containing gene located at the most 5 end of the HOXD cluster, plays a critical role in limb patterning and growth. Mutations in human HOXD13 may give rise to different limb malformations. Polyalanine expansions in HOXD13 cause synpolydactyly (SPD [MIM 186000]) while missense mutations in the homeodomain are associated with brachydactyly types D and E. SPD was the first disease in which a polyalanine expansion was identified as the disease-causing mechanism. This novel type of mutation has been found in nine different human genetic diseases. Unequal crossing-over has been suggested as the mechanism for polyalanine expansion. Polyalanine contraction, the alternative allele of unequal crossing-over, has not yet been confirmed to cause a human genetic disease. We identified a large seven-generation Chinese family with an autosomal dominant complex brachydactyly phenotype to discover the disease gene. Fifty-seven family members, including 27 affected individuals (10 males and 17 females), were clinically investigated. The constant phenotypic feature in the family is bilateral generalized brachydactyly with limb features overlapping brachydactyly types A, D and E. Forty-five members were recruited for linkage and mutation analysis. Two-point linkage analysis was performed using 31 microsatellite genetic markers at chromosome 2q. A maximal LOD score of 6.46 (=0) was obtained at D2S2314. Haplotype analysis defined a region between D2S1379-D2S324 where HOXD13 was located. A deletion of 21 bp in the polyalanine encoded by exon 1 of HOXD13 was detected. This polyalanine contraction of 7 residues was shown to completely cosegregate with the disease phenotype and was not detectable in all unaffected individuals in the family and controls. Our data establish the association of a polyalanine contraction with a genetic disease.[This work has been supported in part by the International Collaborative Genetics Research Training Program (NIH D43 TW 06176)].

Antidepressant treatment response in mood disorders is associated with a brain-derived neurotrophic factor haplotype. *V. Soria[1], M. Gratacos[2,3], J.R. Gonzalez[2,3], M. Bayes[2,3], R. de Cid[2,3], J.M. Crespo[1], M. Urretavizcaya[1], X. Estivill[2,3]* 1) Mood Disorders Clinical and Research Unit, Psychiatry Dept, Hospital Universitari de Bellvitge. Catalonia. Spain; 2) Genes and Disease Program, and National Genotyping Center (CeGen), Center for Genomic Regulation, Catalonia, Spain; 3) Department of Health and Life Sciences, Pompeu Fabra University, Barcelona, Catalonia, Spain.

To test whether BDNF is a susceptibility locus for mood disorders phenotypes and antidepressant treatment response, we performed a case-control study with eight TagSNPs (including the Val66Met functional variant), covering the entire BDNF region. We have genotyped 342 control subjects and a clinical sample of 374 patients with mood disorders diagnosed according to DSMIV criteria. Single SNP case-control association analysis considering the mood disorder phenotype identified a significant association to a SNP located in the 5 upstream region of the gene ($p = 0.029$), which did not remain significant after Bonferroni correction. We further investigated the association of this nominal positive SNP with the antidepressant treatment response phenotype. Patients were allocated to one of two groups according to Thase and Rush staging scheme: those with clinical remission after major depressive episode treated with adequate antidepressant monotherapy were denoted responders. After testing for five genetic models of inheritance, the additive model was the one that best fit the data. Thus, patients heterozygous for variant allele have almost 3-fold probabilities of being responders and almost 6-fold if they are homozygous carriers (OR = 2.95; CI95% = 1.48-5.88; $p = 0.0025$). We have further identified a haplotype conferring risk to this particular phenotype through a 3 SNPs sliding window approach (OR = 2.71; CI95% = 1.30-5.63; $p = 0.0078$). While our results failed to detect a positive association of BDNF with mood disorders diagnosis, they support the implication of BDNF in the therapeutic response to antidepressants.

Clinical evaluation of Prader-Willi syndrome treated with growth hormone in early infancy. *H. Yoshihashi[1], D. Ariyasu[1], T. Hasegawa[1], K. Samejima[2], K. Kurosawa[2]* 1) Pediatrics, Tokyo Metropolitan Kiyose Children's Hospital, Tokyo, Japan; 2) Division of Medical Genetics, Kanagawa Children's, Medical Center, Yokohama, Japan.

Prader-Willi syndrome (PWS) is characterized by infantile hypotonia, obesity in childhood, small hands and feet, hypogonadism, mental retardation, and occurs at a frequency of 15,000 births. The major pathogenic mechanisms are a deletion of a paternal chromosome 15(q11-q13)(70%) or maternal uniparental disomy(UPD) of chromosome 15(25%). The majority of patients with PWS can be diagnosed by using methylation analysis, even if in the neonatal period. Growth hormone replacement therapy is known as one of the treatments, after assurance that sleep apnea and respiratory compromise are not present. The age for starting growth hormone replacement is still controversial. We evaluated for the effects of growth hormone replacement therapy to three PWS female babies, including 2 cases with mUPD15 and 1 case with deletion, diagnosed in early infancy (13-62day). Hypotonia, feeble fetal activity, poor suck, labial hypoplasia, hip-joint abduction are common to these cases. Data are presented on perinatal events, dysmorphic features, body composition, development, and cytogenetics. Growth pattern is estimated in comparison with growth charts representing Japanese patients with PWS (Nagai T et al. Am J Med Genet. 2000) . All cases, who started on growth hormone replacement therapy (0.25mg/kg/week) at 7-18month, grow well on treatment and especially improve in development. In one case, facial and body phenotype are almost normal. There are no adverse effects. It is appropriate to start growth hormone replacement therapy in early infancy . Further study may provide insight into the consideration of the indication of replacement therapy.

Unexpected results of molecular diagnostics in a patient with CDG Ia. *K. Vesela[1], T. Honzik[1], H. Hansikova[1], E. Schollen[2], G. Matthijs[2], J. Zeman[1]* 1) Pediatric Department, 1st Medical Faculty, Charles University, Prague, Czech Republic; 2) Center for Human genetics and Center for Metabolic Diseases, University of Leuwen, Belgium.

Congenital disorders of glycosylation represent a heterogeneous group of disorders affecting assembly or processing of the glycoproteins. Up to now, 24 distinct subgroups of CDG syndrome have been identified. We present unexpected results of molecular analyses of PMM2 gene in 16-year old boy with CDG Ia syndrome and persisting thrombocytopenia and leucopenia. Methods: We analyzed (PCR, RFLP and sequencing analysis) coding sequence and 59 SNPs around in gDNA from whole blood, cultivated fibroblasts, buccal cells, urinary sediment, isolated platelets and CD3+, CD19+, CD15+ and CD14+ cells separated from fresh blood sample and cDNA from whole blood. Results: Molecular analyses confirmed the diagnosis CDG-Ia, but according to found mutation layout, the exact hereditary transfer is unclear. First analysis of gDNA from whole blood revealed novel homozygous mutation IVS2+3A>T. Analysis of parental DNA showed this mutation only on one fathers' allele, mother carried heterozygous form of common mutation 422G>A. Therefore we continued in analyses of other tissues. In cultivated fibroblasts, buccal cells, urinary sediment we confirmed the presence of both mutations in heterozygous forms, but in separated blood cells we found lower proportion of 422G>A only in platelets, the other cells carried homozygous IVS2+3A>T. Discussion: We assume that there is a mosaic in the stem cells. DNA differences between platelets and other cells might correlate with patients' symptoms. Mechanisms of forming cells with homozygous IVS2+3A>T is unclear. Existence two different genotypes in one blood cell lineage might be explained by unknown selection benefit of blood cells carrying homozygous mutation IVS2+3A>T compare to the cells with IVS2+3A>T/422G>A, or by alternative model of haematopoieses. Supported by GAUK 33/2005/c, GAUK 18/2004/c and LSHM-CT-2005-512131.

Genetic association of LDLR SNP with plasma low density lipoprotein cholesterol level. *H. Zhu[1], H.M. Tucker[1], R.K. Gopalraj[1], J. Simpson[1], L.A. Cupples[2], A.K. Manning[2], S. Estus[1]* 1) Department of Physiology and Sanders-Brown Center on Aging, University of Kentucky, Lexinton, KY; 2) Department of Mathematics and Statistics, Boston University, Boston, MA.

Alternative splicing increases transcript diversity and maximally utilizes genome sequence. Single nucleotide polymorphisms (SNPs) may locate in exonic splicing enhancers (ESEs) and act as cis genetic components to modulate mRNA splicing efficiency. Recently, our lab identified a low density lipoprotein receptor (LDLR) SNP that was associated with a lower proportion of full length LDLR transcript in both human brain and minigene transfection experiments. In this study we further evaluated the association of this SNP with plasma LDL cholesterol level in a Framingham Offspring Study (FOS) series of 1716 individuals. Genomic DNA was extracted from peripheral blood leukocytes. ApoE genotypes were determined by a restriction fragment length polymorphism approach. SNP genotyping used a TaqMan approach designed by Applied Biosystems. Briefly, genomic DNA was denatured at 95º for 10min, and then amplified for 40 cycles by using 92ºC for 15sec and 60ºC for 1min. Genotypes were determined using an ABI PRISM 7000 sequence detection system (Applied Biosystems). The SAS General Linear Model (GLM) procedure was used to evaluate genotypic association of LDL cholesterol level with this LDLR SNP. The resulting p values were considered significant if less than 0.05. Our results suggested that LDLR SNP rs688 was significantly associated with a higher plasma LDL cholesterol level in pre-menopausal women and that this effect was dominant (p=0.0129) when adjusting for age, BMI, apoE, estrogen level, menopause. Hence, this LDLR SNP needs further study for its functional mechanism and may represent a good genetic biomarker for cardiovascular disease.

Are we providing excellent care? Development of novel quality measures for clinical genetics. *A. Shealy, C. Scacheri, M. Mettler, R. Rerko, D. Clements, C. Clough, C. Eng, M.R. Natowicz* Center for Personalized Genetic Healthcare, Cleveland Clinic Genomic Medicine Institute, Cleveland, OH.

Many medical specialties have already developed outcomes measures, parameters to evaluate operational aspects of clinical practice. These provide a structured, often quantitative, means to determine the quality of care provided by clinicians, facilitate standardization of healthcare delivery, and offer a way to monitor improvement over time. They also allow one to assess patient-oriented parameters including patient satisfaction and education. Finally, they may facilitate reimbursement when the clinical value of a program can be documented. To our knowledge, quality measures specific to clinical genetics have not been published. However, standardization of the delivery of genomic medicine is critical. We are using two broad categories of quality measures: structure and outcome. Structural measures evaluate an institutions infrastructure to assess whether resources and logistics are sufficient to provide high-quality care. Examples of our structural measures are: (1) parameters relating to the consultations physical setting, including space accessibility and (2) the number of relevant personnel (eg, schedulers, board eligible/certified genetic counselors, physician geneticists) in total and per 100 patients seen. Outcome measures evaluate the quality and effectiveness of patient care. Examples of our outcome measures include: (1) the amount of time before consultation letters are sent to the physician and patient; (2) several standard measures of patient satisfaction; and (3) patient education as measured by evaluating pre- and post-counseling knowledge. We are accessing patient-related outcome data through questionnaires submitted either electronically or by mail after the appointment. Quality control is imperative in the practice of medicine, especially in evolving fields like clinical genetics. We believe outcomes measures such as these will enable clinical genetics programs to objectively evaluate their performance, provide a tool with which to longitudinally measure improvement of clinical services, and facilitate intra-and inter-institutional standardization.

Genetic Analysis of Benign Positional Paraoxysmal Vertigo. *L.R. Peddareddygari[1], M. Gizzi[1], D. Gordon[2], A. Dutra[1], M. Hirano[3], A. Abubakr[1], R.P. Grewal[1]* 1) New Jersey Neuroscience Institute, Edison, NJ; 2) Department of Genetics, Rutgers, The State University of New Jersey, Piscataway, NJ; 3) Columbia University College of Physians & Surgeons, New York, NY.

Vertigo is a common neurological symptom, occurring in up to 42% of the general population. One form of vertigo, benign positional paroxysmal vertigo (BPPV), is characterized by recurrent episodes of a violent whirling sensation lasting less than 30 seconds. These episodes are typically triggered by a change in body position. It is estimated that BPPV is present in up to 17% of patients reporting dizziness.

The risk factors for developing this disorder are not known and may include environmental and/or genetic factors operating alone, or gene/environmental interactions. Family histories of patients with BPPV indicate that multiple family members are often affected, suggesting a genetic contribution to the pathophysiology of this disorder.

We ascertained a large family three-generation Caucasian-American family in which BPPV segregates as an autosomal dominant trait with incomplete penetrance. Nine individuals are definitely affected. We performed a genome-wide scan with a set of 400 microsatellite markers spaced at 10cM (Weber lab screening set 13, Prevention Genetics Inc., Marshfield, WI). Linkage analysis revealed a maximum 2-point LOD score of 2.47 at theta=0. Recombinations identified through haplotype reconstruction indicates that the BPPV gene in this family maps to a critical chromosomal interval of 25 MB.

A Genomic Approach to Neurofibromin Function. *A. Pemov*[1], *L. Messiaen*[2], *D. Stewart*[1] 1) Dept GDRB, NHGRI/NIH, Bethesda, MD; 2) UAB, Birmingham, AL.

Background: Neurofibromatosis type 1 (NF1) is a monogenic disorder of dysregulated tissue growth. The causative gene, NF1, encodes a 220 kD protein called neurofibromin. Neurofibromin is a tumor suppressor but its other putative functions are not well understood. We hypothesized that a genomic approach characterizing gene expression differences between NF1-affected and NF1-unaffected individuals could offer insight into the function of neurofibromin. We reasoned that gene expression profiling in a single large NF1 pedigree could benefit from limited heterogeneity of NF1 mutations. Methods: 1) We obtained genome-wide expression profiles of 33 lymphoblastoid cell lines (LCLs) from an NF1 pedigree from the Coriell Cell Repository. Twelve LCLs were from NF1-affected individuals and 21 LCLs were from NF1-unaffected family members. Total RNA was isolated from the LCLs, reverse-transcribed to cDNA and labeled with Cy3. Universal human RNA (Stratagene) was labeled with Cy5. Both were then hybridized to in-house printed microarrays containing 34,580 oligos representing known and putative human genes. 2) We analyzed the coding region of the NF1 gene for mutations in the proband. Results: 1) We compared genome-wide expression profiles from NF1-affected to NF1-unaffected family members. Of all probes on the microarrays, three corresponded to three different exons of the NF1 gene. We found that two of the three NF1 probes had the two highest t-scores. The third one had a t-score in top 30 probes. Accordingly, quantitative RT-PCR data showed that the level of NF1 mRNA was consistently lower in NF1-affected individuals. Although there were no other statistically significant genes in the list, some of them are potentially biologically relevant in NF1. 2) We detected a 4 bp deletion in exon 28 in one of the NF1 alleles; the mutation co-segregated with affected individuals. Conclusions: 1) The modest changes in the level of NF1 gene expression in heterozygous NF1 LCLs were detected by microarray technology and validated by qRT-PCR; 2) genes whose expression is affected by NF1 haploinsufficiency likely require a larger sample to detect; 3) LCLs may prove to be convenient tool for studying cellular and molecular mechanisms in NF1.

Genome scan follow up studies provide further evidence for a primary open angle glaucoma loci on chromosome 14q11-q22 and 15q11-q15. *J.L. Wiggs[1], R.R. Allingham[2], M.A. Hauser[3], L. Olson[4], C. Santiago-Turla[2], E.A. DelBono[1], K. Abramson[3], F. Lennon[3], M.A. Pericak-Vance[3], J.L. Haines[4]* 1) Dept Ophthalmology, Harvard Medical Sch, MEEI, Boston, MA; 2) Dept Ophthalmology, Duke University School of Med, Durham, NC; 3) Center for Human Genetics, Duke University School of Med, Durham, NC; 4) Center for Human Genetics Research, Vanderbilt University School of Med, Nashville, TN.

Primary open angle glaucoma (POAG) is a genetically and phenotypically heterogeneous disorder that causes irreversible damage to the optic nerve and is a leading cause of blindness worldwide. Three genes have been identified as factors that contribute to POAG and 7 additional loci have been localized using mendelian approaches. Using a collection of affected sibling pairs, we have previously completed a genome scan that provided evidence for POAG loci on chromosomes 2, 4, 14, 15, 17 and 19. Using additional sibling pairs (total of 195) and additional markers in the regions of interest, we have performed follow-up studies to further define these loci. Model dependent and model free linkage analysis gave highest values for markers D14S264 (LOD = 3.71) and D15S165 (LOD = 2.43). Haplotype sharing using additional markers in the areas of peak linkage identified a 50 cM interval on chromosome 14q11-q22 extending from marker D14S72 to D14S274 shared by affected individuals in 53% of the pedigrees. An 18 cM region extending from D15S122 to D15S219 was identified on chromosome 15q11-15, and coincides with the chromosome 15 region previously identified using age of onset ordered subset analysis. 38% of the pedigrees were found to share both the chromosome 14 and chromosome 15 affected haplotypes which suggests that the genes located in these regions may have an additive effect, and that together these two loci represent a significant portion of the genetic contribution to POAG in this population.

Paucity of mutations in *GJB2* and *GJB6* in African American and Caribbean Hispanic populations. *J.M. Samanich[1,2], R. Burk[3], C. Lowes[2], S. Shanske[4], A. Shanske[1], B.E. Morrow[2]* 1) Center for Craniofacial Disorders, Childrens Hospital at Montefiore, Bronx, NY; 2) Department of Molecular Genetics, Albert Einstein College of Medicine, Bronx, NY; 3) Department of Pediatrics, Albert Einstein College of Medicine, Bronx, NY; 4) Laboratory of Molecular Neurogenetics, Columbia University, New York, NY.

Approximately 1/1,000 children are born with hearing impairment, half due to genetic and half to environmental causes. Autosomal recessive non-syndromic sensorineural hearing impairment (ARNSHI) comprises 80% of familial cases. Approximately half of familial cases result from coding mutations in the Connexin 26 gene, *GJB2*, in Caucasian populations. Heterozygous mutations in the single coding exon of *GJB2* occasionally co-occur with a deletion in the Connexin 30 gene, *GJB6*. Few studies have focused on the mutation frequency of these in African American (AA) and Caribbean Hispanic (CH) admixture populations. In this study, we performed bidirectional sequencing of the *GJB2* gene and PCR screening for the common *GJB6* deletion in 109 predominantly simplex individuals of mostly minority ethnic backgrounds. The hearing impairment ranged from unilateral mild to bilateral profound. None of the AA patients and only one CH patient had a bi-allelic mutation in *GJB2*. Variations found were T101C (M34T; 1/109), G109A (V37I; 1/109), 35delG (mutation; 6/109, 2/6 CH), 167delT (mutation; 1/109), G139T (mutation; E47V; 1/109 homozygous, CH), C-15T (1/109, AA), G79A (V27I; 10/109, 3/10 CH, 1/10 AA, 1/10 CH/AA), G380A (R127H; 4/109), A670C (Indeterminate; K224Q; 1/109 CH), A503G (novel; K168R; 3/109, 2/3 CH) and C684A (novel; 1/109 CH). None had a *GJB6* deletion. Bi-directional sequencing of *GJB2* was performed in 187 AA and Hispanic healthy individuals. Our results reveal that *GJB2* mutations and *GJB6* deletions may not be a significant cause of HI in these minority admixture populations.

Resequencing of the 3UTR of SLITRKs and potential targets of miRNAs in patients with obsessive-compulsive disorder. *E. Saus[1], M. Gratacos[1,2], M.P. Alonso[3], J.R. Gonzalez[1,2], J.M. Menchon[3], C. Segalas[3], M. Bayes[1,2], J. Labad[3], J. Vallejo[3], X. Estivill[1,2,4]* 1) Genes and Disease Program, Center for Genomic Regulation, Barcelona, Barcelona, Spain; 2) Center for Genomic Regulation, Barcelona, Barcelona, Spain; 3) OCD Clinic, Department of Psychiatry, Hospital Universitari de Bellvitge, LHospitalet de Llobregat, Barcelona, Spain; 4) Department of Health and Life Sciences, Pompeu Fabra University, Barcelona, Catalonia, Spain.

Obsessive-compulsive disorder (OCD) is characterized by recurrent unwanted thoughts and/or repetitive behaviors, with prevalence estimate of 2.5% in the Spanish population. Recently, Abelson et al. (2005) studied SLITRK1 as a candidate gene for Gilles de la Tourette Syndrome (GTS) on chromosome 13q31.1, and identified two mutations in SLITRK1 in three out of 174 GTS probands. One of these mutations was a base change in the 3UTR of the gene, and corresponds to a highly conserved nucleotide within the predicted binding site for a miRNA, hsa-miR-189. Due to the overlap between GTS and OCD, it has been postulated that, in some cases, OCD and GTS may be alternative manifestations of the same underlying illness. We hypothesized that OCD patients may carry sequence variants in the 3UTR of the family of SLITRK genes, especially in the regions predicted to be targets for miRNAs. We have performed re-sequencing of the six genes of the SLITRK family (Slit and Trk-like family, members 1-6) in 86 OCD patients. We have identified four previously described SNPs and eight sequence variants not found in public available databases. We performed a case-control analysis between known and new SNPs in 95 control samples to test if the presence of these variants confers susceptibility to the development of OCD. Finally, conservation and miRNA target prediction programs have been used to define the potential disruption of the complementarities between known miRNAs expressed in the central nervous system and nuclotide changes affecting the 3UTR of SLITRK genes.

Unusual presentation of partial hypoxanthine phosphoribosyltransferase deficiency in a female patient. *I. Sebesta[1,2], O. Martincova[1], B. Stiburkova[1], L. Dvorakova[1], M. Hrebicek[1], J. Minks[1], Z. Vernerova[3], I. Rychlik[4]* 1) Institute of Inherited Metabolic Disorders; 2) Institute of Clinical Biochem. and Lab. Diagnostics,1st Faculty of Medicine, Charles University; 3) Depatment of Pathology; 4) 1st Department of Medicine,3rd Faculty of Medicine,Prague,Czech Republic.

Partial deficiency of hypoxanthine-guanine phosphoribosyltransferase (HPRT), described as Kelley-Seegmiller syndrome is an X-linked inborn error of purine metabolism. Marked uric acid overproduction resulting in hyperuricemia, nephrolithiasis and gout are common features. Female carriers have somatic cell mosaicism of HPRT activity, and are healthy with enzyme activity in erythrocytes within normal limits. Only one female with partial HPRT deficiency was described recently. We report 50-years old women, the sister of the proband with Kelly - Seegmiller syndrome, who did not experience neither gout, nephrolithiasis nor hyperuricemia. She was never on allopurinol. Uric acid was quantified by specific enzymic method and red cell enzyme with plasma purine metabolites were measured by HPLC methods. Results: Purine biochemical investigations few months ago revealed in repeat serum uric acid concentrations within normal limits (31412 mol/); increased plasma levels of hypoxanthine:19.8 mol/l (control values 2.51.0 mol/l) and xanthine: 7.5 mol/l (control values 2.40.7 mol/l); HPRT activity in erythrocyte lysate was surprisingly very low: 8.6 nmol/h/mg Hb (control values :113 11 nmol/h/mg Hb). Mutation analysis using direct sequencing revealed heterozygous form of previously described mutation in the 3rd exon of HPRT gene, c.215AG (Y72C). Our preliminary results showed skewed X-inactivation ratio in favour of mutant allele (25:75), which could explain enzyme defect. Although enzyme deficiency with urate overproduction (presenting as high plasma oxypurines) is evident, the reason for normal serum urate concentrations remains uncertain. Such results have not been reported in a female with HPRT deficiency. In conclusion our finding shows the need of detailed purine metabolic investigation in asymptomatic female members of family with partial HPRT deficiency. (Supported by grants - MSM 0021620806, VZ 64165 CZ).

A family longevity selection score. *P. Sebastiani[1], E. Hadley[2], M. Province[3], A. Yashin[4], K. Christensen[4], J. Vaupel[4], C. Kammerer[5], W. Rossi[2], T. Perls[6], A. Ash[1]* 1) Biostatistics, Boston Univ Sch Pub Health, Boston, MA; 2) Geriatrics, Boston Univ Med Cntr, Boston, MA; 3) Biostatistics, Washington Univ, St Louis, MO; 4) Public Policies Stud, Duke Univ, Durham, NC and Univ S. Denmark; 5) Epidemiology, Univ Pittsburgh, Pittsburgh, PA; 6) Geriatrics and Clin Gerontology, Natl Inst Aging, Bethesda, MD.

The Long Life Family Study requires a score to rank sibships as to their desirability for recruitment due to being unusually long-lived and having good numbers of old living members. We propose a family longevity selection score denoted by S, as a measure with several desirable properties: all family members, both living and dead, contribute; a sib's contribution to S increases sharply with very old age; a deceased sib adds less than a living sib of the same age, sex and birth cohort; sibs dying young decrease S. S has two parts: total sibship exceptionality(TSE) which depends on all members of the sibship, and living sibship exceptionality (LSE), which depends only on living members. Let A denote the age and C the sex and birth-year cohort of a sib; then LSE is defined as the sum over all living sibs of: max(-ln(Probability of survival past age A for a sib in birth cohort C) - Threshold, 0) Threshold is a tuning parameter that adjusts the tradeoff between the desire for more subjects and for older subjects in defining LSE by giving positive credit only for sibs with ages exceeding a percentile of the relevant survival distribution. If, say, Threshold = -ln(0.25), then s is only positive when a sib's age exceeds the 75th percentile of survival for a person of the same sex and decade of birth. TSE is calculated similarly, but by summing over all sibs and using the age at death for A for deceased sibs while replacing actual ages of living sibs by their expected ages A* at death, given their birth and sex cohorts. Finally, S is defined as a weighted average of LSE and TSE, the relative weight being a second tuning parameter. We used Danish family data to choose tuning-parameter values so that families with above-median values of S are slightly larger than average, but with high mean ages for both total and living sibships.

Robotic Microscopy of Amniotic Fluid Cells for the Fully-Automated Quantitation of FISH Signals. *T. Tafas*[1], *M.W. Kilpatrick*[1], *J. Tepperberg*[2], *S.M. Sharp*[1], *P. Tsipouras*[1] 1) Ikonisys Inc, New Haven, CT; 2) LabCorp of America, Research Triangle Park, NC.

FISH analysis is a valuable adjunct to cytogenetics that provides a rapid screen for common abnormalities. However, FISH is expensive, labor intensive, and requires a high skill level and subjective signal interpretation. A fully automated system for FISH analysis could improve laboratory efficiency and potentially reduce errors and costs. Ikonisys fastFISH is a fully robotic fluorescence microscopy platform requiring only that slide-containing cassettes are loaded into the instrument. Each slide is scanned and returned to its cassette with no requirement for user input. Images of cells are digitally captured and automatically analyzed for the presence of specific FISH signals, that are enumerated and reported, along with the Test Outcome from analysis of 50 selected nuclei. A gallery displaying the image of each cell and its FISH signals is provided, so that the operator can confirm the diagnostic relevance of the data reported. Slides were prepared and probed for chromosomes 13, 18, 21, X, and Y. The accuracy of the automated FISH dot counting was first evaluated by blindly comparing images of a total of 1129 chromosomes obtained using the fastFISH Auto System with the automated dot count of the same images. The agreement between the manual and automated FISH dot count ranged from an average of 76.9% for chromosome 18 to one of 95.3% for the Y chromosome. Subsequently, 161 amniocentesis samples were split and two slide sets were prepared per sample. One set was evaluated using standard manual microscopy and the other using the fastFISH Auto application. An automated diagnostic outcome was produced for 155 of the 161 amniocentesis samples, including a trisomy 21 and an X0. 100% concordance was observed between the results obtained using manual microscopy and the Test Outcome generated from automated FISH dot-count analysis. This data suggests that the automated system is capable of providing accurate detection and quantitation of FISH signals and has potential where the reliability and speed offered by an automated system would be of benefit.

Fetal stability of the 8893T>G mtDNA mutation load has implications for the feasibility of prenatal diagnosis in NARP syndrome. *J. Steffann[1], N. Gigarel[1], J. Corcos[1], M. Bonnière[1], F. Encha-Razavi[1], Y. Dumez[2], A. Yamgnane[2], R. Frydman[3], S. Prevot[3], J.P. Bonnefont[1], A. Munnich[1]* 1) Department of Genetics, Inserm U781, Hopital Necker, Paris, France; 2) Obstetrics, Hopital Necker, Paris, France; 3) Obstetrics and foetopathology, Hopital Béclère, Clamart, France.

Mitochondrial DNA (mtDNA) mutations cause a wide range of serious genetic diseases with maternal inheritance. Due to a high transmission risk and the absence of efficient therapy in these disorders, at risk couples often ask for prenatal diagnosis (PND). However, because loads of heteroplasmy (coexistence of mutant and wild type mtDNA) may vary among tissues and with time, the possibility that a single fetal sample may not reflect the whole organism impedes prenatal diagnosis of mtDNA disease. We carried out 13 prenatal diagnoses for the NARP (Neurogenic weakness, Ataxia, Retinitis Pigmentosa) m.8993T>G mtDNA mutation. Analyses were carried out from chorionic villous (CVS) and/or amniocytes (AS) samples, using a method enabling quantification of low DNA amounts. Maternal mutant loads ranged from 0 to 65% in blood and had no predictive value for the fetus status except for women with no detectable mutant DNA whose fetuses were constantly mutation free. In 8/13 PND, mutant load was below 30%. These children are healthy at 1 to 6 years of age. In 5/13 PND, mutant load ranged from 65 to 95% and parents elected to terminate the pregnancies (15-17 weeks of gestation). Single-cell analysis of 7 trophoblastic cells and 21 amniocytes from one fetus found a mutant load of 725%, and 767%, very close to the overall CVS and AS mutant loads (70% and 70%, respectively). m.8993T>G mutant load, assessed in 5, 7, and 11 different tissues from 3 termination products, was identical in all tissues from a given fetus (mean 631%, 752.8%, and 910.4%for the 3 fetuses, respectively). Our results suggest that the placental/amniotic mutant loads do reflect the NARP mutant mtDNA load in the whole fetus even when the sample amount is small. While these data establish the feasibility of PND for this mutation, assessing more precisely the correlation between mutant load and disease severity should further help interpreting PND results.

Uncommon Rearrangements and De Novo Mutations Associated With Leber Congenital Amaurosis (LCA). *I. Perrault[1], S. Hanein[1], N. Delphin[1], S. Gerber[1], J.L. Dufier[2], J. Kaplan[1], J.M. Rozet[1]* 1) INSERM U781, Hopital Necker-Enfants Malades, Paris, France; 2) Service d'Ophtalmologie, Hopital Necker-Enfants Malades, Paris, France.

The purpose of this study was to understand the uncommon segregation of RPE65 and RDH12 mutations in four unrelated LCA patients. Two unrelated patients whom clinical history strongly suggested the involvement of the RPE65 gene and two unrelated patients suggesting the involvement of the RDH12 gene, respectively, were screened for mutation using DHPLC and direct sequencing. Subsequently, haplotype analyses at the RPE65 or RDH12 loci on chromosome 1p31 and 14q23, respectively, were carried out using polymorphic markers flanking both genes. The paternity was checked for all four patients using markers of chromosomes 1 and 14 as well as 8 highly polymorphic markers localized on 4 distinct chromosomes. This study alowed to identify i) a partial maternal isodisomy of chromosome 1p31 carrying a RPE65 splice-site mutation (c.11+5G>A) responsible for the disease in the affected child of this woman, ii) a paternal de novo RPE65 mutation in an affected child carrying a maternal mutation in this gene, iii) two RDH12 deletions resulting in apparent homozygosity in two patients born to non-consanguineous parents; one of them was inherited from the father while the second consisted in a large intragenic paternal deletion. In conclusion, we report four families with unconventional mutations in two of the nine hitherto identified LCA genes. It is worth noting that a paternal isodisomy of the whole chromosome 1 responsible for LCA has been already reported. This study emphasizes the existence of not uncommon pitfals in the transmission of disease alleles in autosomal recessive LCA.

Characterization of a 1q21:6q25 Translocation Associated With Congenital Glaucoma. *K.V. Ramchand[1], M.D. Tocyap[1], J.L. Haines[2], J.L. Wiggs[1]* 1) Dept Ophthalmology, Harvard Medical School/MEEI, Boston, MA; 2) Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN.

Congenital glaucoma can be inherited as an autosomal recessive or autosomal dominant trait. One gene for the autosomal recessive form of the disease, CYP1B1, has been identified. The purpose of this study is to identify genes that are disrupted by a 1q21:6q25 translocation in a patient with congenital glaucoma and evaluate those genes as candidates for autosomal dominant forms of the disease. To facilitate the identification and sequencing across the translocation breakpoints, somatic cell hybrids were constructed from a lymphoblastoid cell line derived from a patient with congenital glaucoma and a cytogenetically detectable translocation involving chromosomes 1q21 and 6q25. Using a PCR approach, the breakpoints were initially found between microsatellite repeat markers D1S2612 and D1S2347, and D6S1655 and D6S1581. Using the human genome sequence for design of PCR assays, the locations of the breakpoints were further refined to intron 1 of the KIAA0460 gene located at 1q21 and in intron 5 of the VILLIN2 gene located on chromosome 6q25. The breakpoint sequence of both derivative chromosomes was obtained by direct genomic sequencing after PCR amplification across the breakpoints. Secondary chromosomal abnormalities were not identifed. These data suggest that the form of congenital glaucoma affecting this patient may be the result of disruption of genes located at the translocation breakpoints. Mutation screening of these genes in a population of early onset glaucoma patients is currently underway.

Hyaluronan synthetase 2 is a target gene of human SIM2 transcription factor. *Y. Shimizu[1], A. Yamaki[1], S. Asai[1], A. Ueno[1], J. Kudoh[2], N. Shimizu[2]* 1) Department of Medical Genetics, Kyorin University School of Health Sciences, Tokyo Hachioji, Tokyo, Japan; 2) Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan.

The study using Sim2 knockout mouse has indicated that Sim2 contributes to neuroendocrine hormone gene expression in the anterior hypothalamus and craniofacial development. Human SIM2 gene locates on chromosome 21q22.2, Down syndrome chromosomal region. It belongs to the family of bHLH (basic helix-loop-helix)/PAS (Per-Arnt-Sim) transcription factor and interacts with ARNT or ARNT2 to repress the expression of unknown target genes. To find the target genes of SIM2, we established stable cell lines which overexpress SIM2 or SIM2/ARNT2. Then, we performed a differential display analysis using RNA from these cell lines (HeLa, HeLa-mock, HeLa-SIM2 and HeLa-SIM2/ARNT2). We identified 26 potential target genes of SIM2 and SIM2/ARNT2 and confirmed the expression by real-time PCR analysis. Transcription of Hyaluronan synthase 2 (HAS2) was inhibited drastically by overexpression of SIM2 and SIM2/ARNT2. Furthermore, we performed the promoter analysis of HAS2 using dual Luciferase assay and 11 deletion constructs which contain various parts of promoter regions, nt-4401~nt-480. We found that the inhibitory activity locates in the regions, nt-3114 ~ nt-1974 and nt-1767~nt-1751. In these regions, three binding sites for SIM2/ARNT2 heterodimer were estimated. To examine the cis-elements in HAS2 promoter, we made constructs that have two base substitutions in the consensus sequence. The mutations of nt-2421G>A, nt-2420T>A and nt-2309A>T, nt-2308C>T, made to increase the promoter activity. These data suggest that two cis-elements exist in 5 franking region of HAS2 gene and that HAS2 gene is a target of SIM2 transcription factor.

Integrated Analysis of Genetic and Proteomic Data Improves the Prediction of Adverse Drug Reactions. *D.M. Reif[1,2], A.A. Motsinger[1], B.A. McKinney[1,2], J.E. Crowe Jr.[1], J.H. Moore[2]* 1) Vanderbilt University, Nashville, TN; 2) Dartmouth Medical School, Lebanon, NH.

Complex clinical phenotypes such as adverse drug reactions (ADR) arise from the coordinate interaction among a myriad of genetic, genomic, proteomic, metabolic, and environmental factors. We propose as a working hypothesis that our ability to predict ADRs and other pharmacodynamic endpoints will be improved by jointly considering candidate biomarkers from multiple different levels of the biological hierarchy that maps the genome to a given phenotype. The goal of this study was to develop and evaluate an analytical strategy using random forests (RF) for modeling multiple different types (e.g. discrete and categorical) and sources (e.g. genetic and proteomic) of data. The RF approach generates thousands of decision trees on bootstrapped samples of the data for the purpose of selecting important variables. Selected variables can then be modeled using a decision tree or any other classification method on the entire dataset. In this study, we characterized the performance of RF on a range of simulated genetic and/or proteomic datasets. The simulated datasets are based upon real genetic data (genotypes at 1442 SNPs across 500 genes) and real proteomic data (circulating levels of 108 cytokines and chemokines) collected to identify biomarkers associated with ADR following smallpox vaccination of n=108 human subjects. This simulation strategy allowed us to evaluate RF with a known genetic/proteomic model while at the same time preserving the complex correlation structure of the real data. We compared the performance of RF for identifying relevant biomarkers when given genetic data alone, proteomic data alone, or a combined dataset of genetic plus proteomic data. Across all simulated datasets, the integrated RF analysis of both the genetic and the proteomic data yielded the most power for identifying functional biomarkers. Our results support the hypothesis that the integrated analysis of genetic, genomic, proteomic, metabolic, and environmental data will improve our ability to predict ADR. (Supported by NIH R01 AI59694, PI-Moore).

Molecular analysis of *SPG7* in patients with Hereditary Spastic Paraplegia. *H.G. Yntema, M. Ruiterkamp-Versteeg, J. Bokhorst, G. Schobers, H. Scheffer, W.M. Nillesen, E.A. Sistermans* Dept of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

Hereditary Spastic Paraplegia (HSP) comprises a genetically heterogeneous group of inherited diseases, characterized by weakness and spasticity of the lower limbs. HSP types have been divided in pure HSP and complicated HSP, which is accompanied by additional neurologic symptoms. Genetic studies have revealed more than 30 different chromosomal HSP loci. Six loci for autosomal recessive complicated HSP have been identified, and four of these genes have been cloned: *SPG7*, *SPG20*, *SPG21*, and *SACS*. SPG7 (MIM 607259) is caused by mutations in the *SPG7* gene, which encodes paraplegin. *SPG7* belongs to the same gene family as *SPAST* (encoding spastin), which is mutated in SPG4, the most common form of autosomal dominant HSP. Both paraplegin and spastin are highly homologous to yeast mitochondrial ATPases and in muscle tissue of some patients morphological and functional abnormalities typical of mitochondrial OXPHOS defects have been described. As in other mitochondrial diseases, the clinical spectrum of paraplegin defects is variable. In this study, 170 patients with pure or complicated recessive HSP have been tested for mutations in the *SPG7* gene by a combination of DGGE, direct sequencing and MLPA. In 12 of these patients two mutations in *SPG7* have been detected. In total 14 different mutations were identified, 12 of which have not been reported in literature before. These novel mutations contained mostly missense mutations (9), but also splice site mutations (2), and one frameshift mutation were detected. One of the reported mutations, c.1454_1462del, was detected in 7 alleles, making it the most common mutation in our population. Furthermore, based on our results, c.1529C>T (p.Ala510Val), which was detected 4 times, is indeed a pathogenic mutation, as has recently been suggested by Elleuch et al (Neurology 2006:654). In conclusion, in this population, SPG7 mutations account for 7% of HSP families compatible with recessive inheritance. This percentage is slightly higher than the 5% reported by Elleuch et al (2006).

Prenatal diagnosis of a rare European Cystic Fibrosis (CF) mutation in a fetus of Jewish descent. *R. Shtoyerman, A. Kaftori, Z. Appelman* The Genetic Institute, Kaplan Medical Center, Rehovot and the Hebrew University, Jerusalem, Israel.

A 25 weeks pregnant woman (P1G0) of a Jewish-Turkish ethnic background, was referred to our clinic due to echogenic bowel in a level II ultrasound performed in the community. Repeated ultrasound in our facility confirmed intestinal obstruction due to meconium ileus. The father, of a combined Jewish Ashkenazi and Jewish Bulgarian background, was a known CF mutation carrier, as detected in routine carrier testing performed elsewhere. DNA fetal testing following amniocentesis confirmed the fetus carried the paternal W1282X mutation. Despite negative carrier status for the mother, as based on the routine ten mutation panel offered to non-Ashkenazi Jews (Orgad et al., 2001; Gazit et al., 2001), the couple opted to terminate the pregnancy with CF being the most probable diagnosis. Pathological examination following termination confirmed meconium ileus. In order to provide genetic counseling for future pregnancies, the mothers DNA was further analyzed at Genzyme Genetics, for an additional panel of 87 mutations (http://www.genzymegenetics.com/pdf/cf_physician_brochure.pdf). This revealed she carries the S1251N mutation. The same mutation was also detected in the fetal sample. S1251N was previously described only in European patients (Kalin et al., 1992; Mercier et al., 1993), thus this is the first report of this mutation in a Jewish subject. Carrier testing for CF is offered in Israel for Jews of most ethnic backgrounds, with an estimated detection rate of 85% for Jews originating from the Balkan countries. We suggest that when meconium ileus is diagnosed prenatally, and the fetus carries a known CF mutation, it is highly suggestive of CF, even when one of the parents is considered a non-carrier. The assumption in these cases should consider the fact that CFTR is a large gene with over a thousand mutations described to date (http://www.genet.sickkids.on.ca/cftr), and the other parent may be a carrier of an unknown/undetected mutation. Future analysis will determine if S1251N is a common mutation in Jews of this ethnic background, or a case of a private mutation.

Genomic Study of Human Complex Disorders Using Twins: Design Options and Sample Size. *F. Zhang[1], N. Whitehead[1], P. Levy[1], L. Corey[2], V. Vannappagari[3], P. Chulada[4], P. Blackshear[4]* 1) RTI International,Resarch Triangle Park,NC; 2) Virginia Commonwealth University, Richmond,VA; 3) GlaxoSmithKline,Research Triangle Park,NC; 4) National Institute of Environmental Health Sciences, Research Triangle Park,NC.

Twin studies have been a powerful tool for investigating the relative importance of genetic susceptibility and environment in the development of complex disorders or traits. As molecular technology advances, molecular geneticists are increasingly interested in determining specific genes that are responsible for the development of a certain disorder. Twin studies have recently received increased attention as a tool in the genomic study of human disorders and have increased focus upon the availability of established twin registries worldwide. In this study we evaluated several study designs and carried out the explicit calculation of sample size required:(1)Dizygotic(DZ)twin pairs are siblings of the same age. Statistical power will be increased in a linkage study where the trait varies by age. Although monozygotic(MZ) twin pairs, who are genetically identical, do not contribute to the detection of linkage in conjunction with DZ pairs they can improve power in linkage analysis.(2) DZ discordant twin pairs can serve as an ideal case-control study, which is believed to be more powerful in detecting susceptibility genes than is a population-based case-control study.(3)MZ discordant twin pairs are particularly powerful for detecting epigenetic effect in that the relative importance of genetic, environment, and epigenetic effects can be estimated.(4)Population-based twin cohort can be used to investigate the association of human disorders or traits with genetic variants. This design can reduce selection bias that is often concerned in case-control design. We have evaluated the sample size and power for an association study using discordant twin pairs. In population-based twin cohort design, twin pairs can be considered as a repeated measurement. Sample size can be calculated using longitudinal design while taking into account the correlation between twin pairs. Sample size increases remarkably with the intra-pair correlation.

Mutational model leading to Polyalanine expansions and contractions revisited. *D. Trochet, L. De-Pontual, B. Keren, A. Munnich, S. Lyonnet, J. Amiel* Dept Genetics, Hosp Necker-Enfants Malades, Paris, France.

Alanine stretches (AS) are common in all proteomes studied with the longer stretches being found in mammals. AS are coded by degenerated codons (GCN) and characterized by rapidly evolving nucleotidic sequences with high rates of expansions and contractions: the longer and more pure the sequence, the higher the length polymorphism of the AS in the population. These genic sequences are frequent in transcription factors and have recently been proposed as facilitators of evolution. Hitherto, polyalanine expansions and contractions have been ascribed to 9 human diseases, either autosomal dominant or X-linked. Considering both that : i) AS are coded by mixed (GCN)n codons and, ii) that transmission over generations is stable, a polymerase slippage mechanism is unlikely. A mechanism of unequal allelic homologous recombination has thus been proposed. Worth noting, expansions have been identified in asymptomatic parents for 3/9 disease causing genes namely HOXD13, ZIC2 and PHOX2B for which mutations account for synpolydactyly, holoprosencephaly and congenital central hypoventilation syndromes respectively. In the latest case, 5% of the asymptomatic parents from our series harbor an alanine expansion in their leucocytes. We tested carrier parents either by cloning the PCR fragment when a heterozygous SNP was present or by QMPSF. We show that, as speculated, carrier parents are somatic mosaics for the mutation. However, instead of the 3 alleles (wild-type, expansion and contraction) expected according to the mutational model, only 2 are observed in mosaic parents (wild-type and expansion). Therefore, an alternative mutational model to generate alanine expansions and contractions will be proposed.

Potential role of UBE3A and ATP10A, positional and functional candidate genes, in the aetiopathogenesis of the autistic disorder. *S. Russo[1], MT. Bonati[1], A. Gessi[1], G. Guffanti Masetti[2], M. Marchi[1], F. Cavalleri[1], F. Cogliati[1], M. Elia[3], M. Estienne[4], L. Larizza[1,5], F. Macciardi[2]* 1) Ist.Auxologico Italiano,Milano, Italy; 2) Polo LITA,University of Milan,Italy; 3) LOasi-Troina (EN),Italy; 4) Ist.C.Besta,Milano,Italy; 5) Hosp.S.Paolo,University of Milan,Italy.

Autism is a common neurodevelopmental disorder characterized by severe impairments in reciprocal social interactions and communication and restricted/stereotypical patterns of interests and behaviour. The complex genetic aetiology of autism has not been elucidated; however, the most common chromosomal abnormality seen in 1% of children with autism is gain of chromosome 15q11-q13 caused by interstitial duplication of this region or supernumerary marker chromosomes deriving from proximal 15q. Moreover genetic and epigenetic alterations of 15q11-q13 region, causing the lack of expression of the maternally inherited copy of the imprinted UBE3A gene, are responsible for Angelman syndrome, which features, such as severe mental retardation, absence of speech, abnormal EEG/epilepsy, inappropriate social behavior, overlap with those often seen in AD (Clayton-Smith and Laan, 2003). In 2001 a study of Nurmi et al. reported a significant evidence for marker D15S122, located at 5 end of UBE3A and autism, which was never replicated. Also SNPs in the nearby imprinted gene, ATP10A, were investigated to disclose association with autism without coming to relevant evidence.We here refer on the analysis of D15S122, and ATP10A,SNP3(intron12)-D15S1534 (intron 8)markers and D15S135 (intron 18) in a sample including 54 trios from idiopatic autism and 13 among non deleted Angelman patients,RTT and fragile X syndrome with autistic traits selected for displaying autistic traits.TDT test was used for statistical evaluation.Our results are consistent with a potential role of UBE3A and ATP10A in showing a significant association for D15S122 and for the haplotype including D15S122. Other tagged 18 SNPs in the region are under analysis to streghten these preliminary results.

Results of a whole genome association study for Major Depressive Disorder (MDD). *H. Sakul*[1], *D.A. Hinds*[2], *K.A. Frazer*[2], *D.R. Cox*[2], *C. Hyde*[1] 1) Pfizer Global R&D, CT; 2) Perlegen Sciences, CA.

Many genetic and environmental factors affect response to treatment with an SSRI or placebo in MDD clinical trials. While many candidate genes have been studied, results are often discordant and difficult to interpret due to small sample size, multiple testing, etc. The primary objective of this study was to identify genes affecting SSRI or placebo response, as well as time-to-response, to improve the design of MDD trials. DNA from 1,024 Caucasian subjects from 8 MDD trials were genotyped using 250,000 SNPs and analyzed using various statistical models. Primary endpoints were Total HAMD, and three subscales: Core Depression, Anxiety and Insomnia. Statistical significance was based on overall false discovery rate (q-value). The following numbers of SNPs were significant across binary, quantitative or time to response variables and annotated as CNS-relevant or novel based on the literature: For Placebo, 16 CNS and 466 Novel; for SSRI, 33 CNS and 440 Novel. False discovery rates were also computed for 11 CNS candidate genes and SNP rs10891539, located in the TTC12 gene (11q23.1) within 50 kb of the D2 dopamine receptor (DRD2), was the most significant marker. This SNP is a part of a 3 SNP haplo-block spanning both genes (D>0.9). Most literature reports for DRD2 highlight associations with the bipolar disorder while our data is from unipolar depression. As such, our finding may have a significant impact on MDD trials. Further, the effects of each allele of this SNP suggested that with all studies combined, screening out subjects homozygous for the reference allele results in SSRI treatment significance that is double the observed value without screening. For 2 of the 5 trials where SSRI treatment response was not significant, such screening would result in significant SSRI response. In conclusion, we have identified several genes with significant effects on either SSRI or placebo response in MDD trials. Our analyses also demonstrate that even the large sample size of this study has limited statistical power for replication, and we anticipate that our results will facilitate external replication studies and possible collaborations to join datasets.

Haplotype Trend Regression (HTR) Analysis of *OPRD1*, *OPRK1* and *GPR7* in Alcohol or Drug Dependence. *H. Zhang[1,2], H.R. Kranzler[3], BZ. Yang[1,2], J. Gelernter[1,2]* 1) Dept Psychiatry, Yale Univ Sch Med, New Haven, CT; 2) VA CT Healthcare System, West Haven, CT; 3) Dept Psychiatry, Univ CT Sch Med, Farmington, CT.

We investigated whether variation in the genes encoding the human and -opioid receptors and G-protein coupled receptor 7 (*OPRD1*, *OPRK1* and *GPR7*) could influence risk for substance dependence (SD). Eight single nucleotide polymorphisms (SNPs) spanning *OPRD1* were examined in a sample of 621 European Americans (EAs) affected with SD [557 with alcohol dependence (AD), 225 with cocaine dependence (CD), and 111 with opioid dependence (OD)] and 443 EA healthy controls. Statistically significant associations of SNP1 (F27C in exon 1) with OD only (both allelic and genotypic), SNP4 (in intron 1) with AD (genotypic), CD (genotypic) and OD (allelic), and SNP5 (in intron 1) with AD (genotypic) and CD (genotypic) were observed. The association of SNP1 with OD remained significant after correction for multiple testing. Although haplotype frequency distributions did not differ significantly between cases and controls, haplotype trend regression (HTR) analyses indicated that a specific haplotype GCAATACT, which harbors susceptibility alleles of SNP1 (G-allele), SNP4 (A-allele) and SNP5 (T-allele), may confer vulnerability to SD. The frequency of haplotype GCAATACT was 3.7% (control subjects), 6.4% (AD subjects), 8.1% (CD subjects) and 12.4% (OD subjects). When confounding factors, sex and age, were considered, the haplotype GCAATACT still showed a risk effect for OD (=3.20, *P*=0.011), but not for AD and CD. Population structure analyses with genotype data from 38 ancestry informative markers excluded population stratification artifact. Additionally, seven SNPs covering *OPRK1* and two SNPs covering the intronless *GPR7* were examined in most of the above samples. No significant difference in allele, genotype or haplotype frequency distributions was found between cases and controls. Nevertheless, HTR analyses revealed a possible risk effect of a specific *OPRK1* haplotype GGCTTCT on AD (=0.69, *P*=0.007). In summary, our findings suggested a positive association between *OPRD1* variants (especially the functional F27C) with OD, and a possible haplotypic association between *OPRK1* and AD in EAs.

A genome-wide scan of non-synonymous SNPs in a phase III clinical trial identifies variants influencing outcome in chronic lymphocytic leukemia. *G.S. Sellick[1], R. Wade[2], M.F. Rudd[1], S. Richards[2], D. Catovsky[3], R.S. Houlston[1]* 1) Section of Cancer Genetics, Institute of Cancer Research, Sutton, Surrey, UK; 2) Clinical Trial Service Unit, University of Oxford, Oxford, UK; 3) Section of Haemato-Oncology, Institute of Cancer Research, Sutton, Surrey, UK.

B-cell chronic lymphocytic leukemia (B-CLL) is a heterogeneous disease with a variable clinical course. Staging systems are useful for predicting survival and treatment requirements, however, even for patients with same-stage disease there is variability in clinical outcome. Germline sequence variation may influence disease prognosis. We undertook a genome-wide scan of non-synonymous SNPs (nsSNPs) in 425 CLL patients participating in a phase III trial (UK LRF CLL4) established to compare the efficacy of fludarabine, chlorambucil, and fludarabine and cyclophosphamide as a first-line treatment for patients with Binet stage B, C and A-progressive disease. The 990 nsSNPs in 870 genes were selected for their relevance to cancer biology and were strongly biased towards those likely to be functionally deleterious. Genetic data was linked to individual patient outcome and response to chemotherapy. The effect of genotype on progression free survival (PFS) and overall survival (OS) was assessed and the relationship between nsSNPs and PFS and OS was evaluated. Our study shows that germline variation influences CLL survival and identifies a number of variants that provide insight into the biological determinants of prognosis.

Maturation process of SUMO1 and SUMO4 in different cell lines. *W.Z. WEI, Y. WANG, C.Y. WANG* CBGM, Medical College of Georgia, Augusta, GA.

Sumoylation carried out by the small ubiquitin-related modifiers (SUMO1-4) is a newly identified mechanism contributing to the dynamic regulation of protein functions, implicated in DNA repair and synthesis, RNA processing, protein degradation, and glucose metabolism. SUMO proteins are synthesized as precursors that need the maturation process to expose the C-terminal glycine-glycine residues. This di-glycine motif is prerequisite for covalent conjugation of its substrates. Maturation process of SUMO1-3 by SUMO specific peptidase has been demonstrated, except for the newly identified isoform, SUMO4, which could be a susceptibility gene for human type 1 diabetes. In this work, in vitro maturation process of full-length SUMO1, SUMO1-P94, SUMO4 and SUMO4-Q90 were studied in different cell types, including HEK293, human monocytes, DC2.4, Hela, CM, and Jurket cells. Our results demonstrated that in HEK293 cells, the rates and efficiency of full-length SUMO4 and SUMO4-Q90 mutant were similar, but both of them are much slower or lower than those of full-length SUMO1, while SUMO1-P94 could not be processed. In addition, SUMO1 and SUMO4 maturation showed cell-type specificity by comparative studies among different cell types. Therefore, different SUMO peptidases should be responsible for SUMO1 and SUMO4 maturation, respectively.

Ciliary disfunction underlies cystic kidney in Oral-Facial-Digital Type I (OFD1) syndrome. *A. Zullo[1], A. Barra[1], A. Indrieri[1], A. Cantone[2], N. Messaddeq[3], G. Capasso[2], P. Dollé[3], P. Igarashi[4], B. Franco[1,5]* 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Nephrology Dept., Second University of Naples, Naples, Italy; 3) Institut de Génétique et de Biologie Moléculaire et Cellulaire, Illkirch, France; 4) Internal Medicine Dept., University of Texas Southwestern Medical Center, Dallas, Texas, USA; 5) Medical Genetics, Department of Pediatrics, Federico II University, Naples, Italy.

Oral-facial-digital type I syndrome is characterized by a distinctive X-linked dominant male-lethal pattern of inheritance, craniofacial and limb abnormalities, and cystic kidney of glomerular origin (30% of cases). We previously demonstrated that the responsible gene *Ofd1* is a centrosomal/basal body protein. More recently, we generated *Ofd1*-knockout animals, which reproduced the main features of the human disease. Renal cysts of glomerular origin were observed starting from E16.5 in heterozygous females and immunofluorescence and ultrastructural studies demonstrated defective cilia formation implicating ciliogenesis as a mechanism underlying cyst development. To overcome the problem of embryonic male and perinatal female lethality we generated a mouse line with kidney-specific inactivation of *Ofd1* by crossing the *Ofd1*-floxed line with a transgenic line (cre^{Ksp}) that expresses cre recombinase in renal tubular epithelial cells. Kidney-specific inactivation of *Ofd1* led to viable offspring that developed kidney cysts of tubular origin from P14. By P35 the renal parenchyma was completely replaced with large cysts and by P70 the mutant mice exhibited lethargy and growth retardation. Progressive GFR impairment was observed from P28. Specific tubular markers staining revealed that the cysts originated from the distal nephron and we demonstrated the absence of primary cilia exclusively in cells that lined the cysts. These data show that OFD1 is important in different segments of the nephron and that *Ofd1* inactivation results in cyst formation in the distal tubules as well as in glomeruli. The animal model generated represents an additional tool to dissect the molecular basis of cystic kidney disease and the relationship between renal cysts and primary cilia dysfunction.

A novel statistic to test for gene-environment interaction. *X. Zhou[1], M. Xiong[2]* 1) Dept Internal Medicine, University of Texas Health Science Center at Houston,TX; 2) Biostatistics, University of Texas Health Science Center at Houston, TX.

Most phenotypic variations, including those involved in complex diseases and differences in drug response, are generated by integrated actions of multiple genetic and environmental factors, through dynamic, epigenetic, and regulatory mechanisms. Despite growing consensus on the importance of testing for gene-environment interactions in genetic studies of complex diseases, there is still lack of powerful test statistics for detection o gene-environment interaction. A comprehensive delineation of the complicated interplay between genetic and environmental factors that influences complex traits will require complete characterization of DNA variation in the population and the development of mathematical tools for unraveling the interaction between genetic variation and environmental exposures. In this report, we study how gene-environment interactions create the linkage disequilibrium (LD) in the disease populations and develop a statistic to test for gene-environment interaction by comparing differences in LD between cases and controls. We perform simulations to investigate null distribution of the proposed statistic and calculate its type 1 error rates. We compare the power of the newly developed statistic and existing statistics for detection of gene-environment interactions. To further evaluate its performance the proposed statistic is applied to several real data sets. The results are encouraging. They demonstrate that the P-values of the proposed statistic are much smaller that that of other approaches.

High-throughput genotyping for detecting structural genomic variation in healthy African Americans. *S.W. Scholz[1], M. Matarin[1], H.C. Fung[1], J. Simon-Sanchez[1], D. Hernandez[1], A. Britton[1], J.R. Gibbs[1], A. Singleton[1], A.B. Zonderman[3], M.K. Evans[2]* 1) Laboratory of Neurogenetics, National Institute on Aging, Bethesda, MD, USA; 2) Health Disparities Research Section, Clinical Research Branch, National Institute on Aging, 5600 Nathan Shock Drive, Baltimore, MD 21224, USA; 3) Cognition Section, Laboratory of Personality and Cognition, National Institute on Aging, 5600 Nathan Shock Drive, Baltimore, MD 21224, USA.

Objective: To determine the frequency, distribution and size of structural variation in healthy African-Americans using whole genome genotyping.

Background: Illumina SNP genotyping technology has emerged as a powerful technique to study genomic variation in Caucasian populations. However, the applicability of this technology to study structural variation in non-Caucasian populations is unclear.

The African American population represents 13.4% of the population of the US and is known to be an admixture of Africans, Caucasians, and Native Americans. Studying genomic structure and regions of extended homozygosity in this non-Caucasian population may provide valuable insights into the role of these variations in human disease and clinical phenotypes.

Methods: A cohort of 147 healthy African-Americans was studied. Over 400,000 SNPs were genotyped for each individual using Sentrix HumanHap 300 Genotyping and Sentrix Human-1 Genotyping Beadchips (Illumina Inc., San Diego, CA).

Results: We identified 179 large-scale structural changes (111 duplications, 66 deletions) ranging in size from 47kb to 2.61Mb. Extended tracts of regions of homozygosity and V(D)J recombination in the T-cell receptor alpha locus were also detected.

Conclusion: This is the first whole genome SNP genotyping study of healthy African Americans. The data demonstrates the ability of SNP chip technology to detect structural genomic alterations (40kb in size) and extended regions of homozygosity in African-Americans.

Correcting for the winners curse in genetic association studies. *R. Xiao, M. Boehnke* Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Studies of gene-disease association are now commonly used to localize genetic loci that impact disease susceptibility. It is also of interest to estimate the genetic effect of each identified locus. It is known that the initial positive findings of the genetic effect estimate tend to be upwardly biased, a phenomenon known as the winners curse. In our study, we model the winners curse in the context of case-control genetic association studies. We quantify its impact on the naïve estimators of the allele frequency difference between cases and controls as a function of several factors including sample size, minor allele frequency in controls and cases, and the chosen statistical significance level. We also propose a maximum likelihood method to improve the estimate of the allele frequency difference corrected for the ascertainment. Initial analytical and simulation results indicate that our method substantially reduces the observed overestimation, allowing better estimation of locus-specific effect, and more appropriate design for follow up studies.

Association study of CRP gene polymorphisms with serum CRP level and cardiovascular risk in the NHLBI Family Heart Study. *Q.W. Wang[1], S.C. Hunt[2], Q. Xu[1], M.A. Province[3], J.H. Eckfeldt[4], J.S. Pankow[5], Q. Song[1, 6]* 1) Cardiovascular Research Inst, Morehouse School of Medicine, Atlanta, GA; 2) Cardiovascular Genetics Division, University of Utah, Salt Lake City, UT, USA; 3) Division of Biostatistics, Washington University, St. Louis, MO, USA; 4) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN, USA; 5) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN, USA; 6) Clinical Research Center, Morehouse School of Medicine, Atlanta, Georgia, USA.

Objective: Recent epidemiological studies indicated that baseline C-reactive protein (CRP) levels may have value in prediction of cardiovascular risk. Methods and results: Using 6 TagSNPs selected from our complete list of single nucleotide polymorphisms (SNP) on the CRP gene, we investigated the association of CRP genotypes with plasma CRP levels and cardiovascular risk in the NHLBI Family Heart Study (FHS) cohort (1296 Caucasians, male 48.5%, age 54.712.8 years). There was a significant trend towards association of CRP haplotypes with CRP levels (p=0.045). Single-SNP analysis indicated a highly significant association of SNP-757 (rs3093059, p=0.0004) and SNP-286 (rs3091244, p=0.0065) and a borderline association of SNP-7180 (rs1341665, p=0.06) with CRP levels. Neither CRP haplotypes nor individual SNP genotypes were associated with IMT of the common carotid arteries, internal carotid arteries, or at the bifurcations of the carotid arteries. Conclusion: These results indicated a strong impact of local SNPs of the CRP gene on plasma CRP levels, but there was no direct evidence that these genetically-controlled CRP elevations by local CRP SNPs contributed to cardiovascular disease phenotypes.

Mutation analysis approach to uncover the gene responsible of an autosomal recessive spastic ataxia associated with frequent white matter changes that map to 2q33-34. *I. Thiffault[1], M. Tetreault[1], L. Loiselle[1], J. Mathieu[2], M. Vanasse[3], G.A. Rouleau[4], J.P. Bouchard[5], J. Lessage[6], B. Brais[1,2,3]* 1) Laboratoire de neurogénétique , Center for the study of brain CHUM-Notre Dame Hosp, Montreal, PQ, Canada; 2) Clinique des maladies neuromusculaires, Carrefour de la Santé de Jonquière, Saguenay, QC, Canada; 3) Clinique des maladies neuromusculaires, Centre de réadaptation Marie Enfant, CHU Mère Enfant Sainte-Justine, Montreal, QC, Canada; 4) Laboratoire de neurogénétique, Center for the study of brain diseases, Centre de recherche du CHUM, Montreal, QC, Canada; 5) Service de neurologie, Hôpital de lEnfant-Jesus, Université Laval, Quebec, Qc, Canada; 6) Radiology Department, Centre hospitalier de lUniversité de Montréal, Montreal, QC, Canada.

Recessive ataxias are a heterogeneous group of diseases. To date, the mutated genes for ten recessive ataxias have been uncovered and two others have been mapped. The combination of pyramidal and cerebellar signs has been observed in a few recessive ataxias, complicated paraplegias, leukodystrophies and cerebral palsy. We recently reported the identification of a group of 23 French-Canadian cases from 17 families affected by an autosomal recessive spastic ataxia associated with frequent white matter changes (ARSAL) that map on 2q33-34. Candidate gene mutation analysis was performed in parallel with the fine mapping. The UCSC March 2006 freeze predicts that 23 genes lie in the conservative 2.51 cM haplotype-defined candidate region. A total of eight candidate genes on chromosome 2q33-34 were studied for mutations: ALSIN, EEF1B2, NRP2, NDUFS1, ALS2CR19, GPR1, KLF7 and ADAM23 (entire coding and a minimum of 30 bp of intronic flanking sequences. Primers used to amplify exonic and flanking sequences were designed using ExonPrimer. Preliminary results suggest that these candidate genes are unlikely the genetic cause of ARSAL. Further gene screening is on-going to identify the causal mutations. The uncovering of the mutated gene may point to a common pathway for pyramidal and cerebellar degeneration as both are often observed in recessive ataxias and complicated paraplegias.

Expression pattern of *Lgi1* gene in mouse brain during development suggests a possible function. *P.A.O. Ribeiro*[1], *L. Sbragia*[2], *R. Gilioli*[3], *F. Cendes*[4], *I. Lopes-Cendes*[1] 1) Medical Genetics, UNICAMP, Campinas, Brazil; 2) Pediatric Surgery, UNICAMP, Campinas, Brazil; 3) CEMIB, UNICAMP, Campinas, Brazil; 4) Neurology, UNICAMP, Campinas, Brazil.

Mutations in *LGI1* gene were described in patients with autosomal dominant lateral temporal lobe epilepsy and preliminary functional studies point to a possible involvement of *LGI1* with migration and/or neuronal proliferation. However, the precise function of *LGI1* remains unknown. The objective of the present study was to determine the expression pattern of the *Lgi1* gene in mice brain during development and in adult animals. Programmed mating was carried with Balb/c mice in order to obtain embryos of different ages. The brains of three animals at the following ages were removed: E15, E17, E18 days (E: embryo), P1, P7, P14, P28, P42 and P56 days (P: post-natal). Gene expression assays were carried out using real time PCR with the TaqMan system. In addition we used an endogenous control (*Gapdh* gene) and all experiments were performed in duplicates. *Lgi1* gene expression was significantly low during the intrauterine ages increasing gradually until P56 (adult animal). Samples from P28, P42 and P56 presented a seven fold increase in expression as compared to E15 samples. The pattern of *Lgi1* gene expression that we observed suggests a predominantly inhibitory function during development of the central nervous system (low expression during embryonic stages). In addition, we may speculate that in more advanced ages, when neurons are already differentiated, its inhibitory function could be also essential, which can be suggested by the high expression in adult mouse brain.

Proximal 10q trisomy syndrome resulting from a paternally inherited insertion of 10q11.2 to q21.3 with normal growth and ophthalmologic findings: implications for possible localization of gene(s) involved in growth regulation and/or eye development at 10q22. *M.N. Strecker, A.M. Slavotinek* Division of Genetics, Department of Pediatrics, UCSF, San Francisco, CA.

There have been ten reported cases of proximal 10q trisomy syndrome with varying cytogenetic breakpoints within the region of 10q11-10q22. The phenotypic consequences of this trisomy include mild to moderate developmental delay, postnatal growth retardation, microcephaly, long slender limbs, and craniofacial dysmorphism characterized by a prominent forehead, deep-set eyes, epicanthic folds, an upturned nose, dysplastic helices, a bow-shaped mouth and micrognathia. We report an 18 year-old male with an extremely mild phenotype constituting mild developmental delay (categorized as a sensory integration disorder), long thin limbs, and subtle facial dysmorphisms, including down-slanting palpebral fissures, flattened helices, a narrow maxilla, and a bow-shaped mouth. His karyotype by high resolution GTG banding was 46,XY,der(17)ins(17;10)(p13;q11.2q21.3), resulting from an interstitial insertion of chromosome 10q11.2-10q21.3 into chromosome 17p13. Parental chromosome analysis revealed that the father was a balanced carrier of this insertion, with a karyotype of 46,XY,ins(17;10)(p13;q11.2q21.3). In contrast to previous cases, our patient has a smaller and more proximal duplication without involvement of chromosome band 10q22, whereas all of the previously reported proximal 10q trisomy patients have had duplication of 10q21 to 10q22. Clinically, our patient also differed from the majority of other patients in that he had normal growth without microcephaly and was without ocular abnormalities. Our patient's karyotype and mild phenotype imply the possible localization of gene(s) involved in growth regulation and/or eye development at chromosome 10q22 that contribute to the proximal 10q trisomy phenotype. Candidate genes include COL13A1, a gene expressed in connective tissue of unknown function, and P4HA1, a component of the enzyme prolyl 4-hydroxylase involved in collagen synthesis.

Associations of gene expression variation with SNPs and copy number variants (CNVs) in the HapMap samples.

B.E. Stranger[1], M. Forrest[1], M. Dunning[2], C. Ingle[1], C. Beazley[1], R. Redon[1], C. Lee[4], C. Tyler-Smith[1], A.G. Clark[5], N. Carter[1], S.W. Scherer[3], S. Tavare[2], P. Deloukas[1], M.E. Hurles[1], E.T. Dermitzakis[1] 1) Wellcome Trust Sanger Inst, Hinxton, UK; 2) Department of Oncology, Cambridge University, UK; 3) Program in Genetics and Genomic Biology, The Hospital for Sick Children and Department of Molecular and Medical Genetics, University of Toronto, Toronto, Ontario, Canada; 4) Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA; 5) Department of Molecular Biology and Genetics, Cornell University, NY, USA.

Gene expression variation is likely a major determinant of phenotypic variation and susceptibility to disease in humans. The goal of this work is to identify and characterize functionally variable regions that contribute to gene expression variation. We have screened mRNA levels for ~48,000 transcripts in lymphoblastoid cell lines from 270 individuals of the HapMap Project. Approximately 15,000 transcripts gave a detectable expression signal relative to background. We used SNP genotypes and a recent set of copy number variants (CNVs) genotypes for the HapMap samples to correlate with gene expression. We used methodologies that consider each population separately, and are implementing methods that consider all populations together. We have detected significant associations for about 800 and 60 genes per population with SNPs and CNVs in regions nearby the genes. About 75% of the SNP and CNV associations are population-specific, while 25% of the associations are replicated in at least 2 populations. About 15% of the CNV associations are captured by SNP associations suggesting that phenotypic variation caused by CNVs may be tractable by SNPs in some cases. We have also identified genomic associations with genes whose expression exhibit significant population differentiation. Finally, we infer that the CNV effects on gene expression are of similar magnitude as the SNP effects. This is the first detailed analysis of associations of gene expression variation with both SNPs and CNVs in multiple human populations and is proving to be highly informative for the structure of genetic variation in human populations.

Familial Noonan syndrome with high intelligence associated with an isoform-specific KRAS mutation. *S. Unger[1,2], D. Horn[3], K. Lehmann[3], M. Zenker[4], C. Kratz[5]* 1) Institute for Human Genetics, Univ Freiburg, Freiburg, Germany; 2) Division of Clinical and Metabolic Genetics, Sick Kids, Toronto, Canada; 3) Institute for Medical Genetics, Humboldt University, Berlin, Germany; 4) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany; 5) Department of Pediatrics and Adolescent Medicine, University of Freiburg, Germany.

Noonan syndrome (NS) (MIM163950) is an autosomal dominant disorder whose main features are mild short stature, congenital heart disease (pulmonic valve stenosis), and webbed neck. Developmental delay of a variable degree is seen in one third of the patients. Approximately 50% of Noonan syndrome individuals have a mutation in the PTPN11 gene encoding for SHP-2, a phosphatase that relays growth signals from activated growth factor to other signaling molecules including Ras. Downstream partners in the same signaling pathway as SHP-2 were natural candidates genes for the remaining NS patients. Recently, we have identified de novo missense mutations in the KRAS oncogene in several sporadic cases of NS. We report a multigeneration family with typical features of NS. All affected individuals had mild short stature and facial features consistent with NS and all were of normal/high intellect. Several affected individuals had scoliosis, some had multiple lentigines and one person had pulmonic valve stenosis. The proband, who has an IQ of 133, was found to carry a G179S KRAS mutation. This change is located in exon 5 and is thus expressed only in the A isoform of KRAS, which is in contrast to other mutations reported thus far. The precise mechanism by which this mutation disrupts Ras function is currently unknown. The G179S mutation is likely to interfere with Ras processing and cellular localization, but does not alter a residue known to be involved in the GTPase activity of Ras. We speculate that the location of this mutation is responsible for the relatively mild phenotype, in particular for the absence of developmental delay.

Identification of three potential candidate genes for autosomal dominant mental retardation. *A.K. Srivastava[1], S.D. Menon[1], G.F. Guzauskas[1], V.S. Vervoort[1,2], M.R. Vayalapaty[1], F. Zhang[1], S. Ladd[1], K.C. Ukadike[1], A. King[1], B.R. DuPont[1], K. Clarkson[1], R.J. Schroer[1]* 1) Greenwood Genetic Center, Greenwood, SC; 2) Present address: Developmental Neurobiology Department, Burnham Institute for Medical Research, La Jolla, CA.

Mental retardation (MR) is the most common developmental disability, affecting cognitive function in about 2-3% of the human population. The etiology of MR remains poorly understood in the majority of cases. MR may result from alterations in any of a number of genes involved in various pathways and these genes are presumably distributed throughout the human genome. Although the role of X-linked genes in MR is relatively well known, little progress has been made in identifying autosomal MR genes partially due to enormous genetic heterogeneity and the lack of large families for linkage analysis. We utilized patients with MR and balanced autosome;autosome translocations to circumvent some of these obstacles and to identify candidate autosomal MR genes for intensive mutation screening. Here we report the identification of three potential candidate autosomal MR genes: 1) ZNF161, a zinc finger gene at 17q23, was physically disrupted in a female patient with profound MR, 2) C10orf45, a novel gene at 10p13, was disrupted in a female patient with profound MR; and 3) a novel isoform of the CLDN14 gene was disrupted at 21q22 by the translocation breakpoint in a male patient with moderate MR and aggressive behavior. Both chromosomal breakpoints of the translocations were mapped and no additional genes were found to be affected by the second chromosomal breakpoints in these patients. Furthermore, no additional mutations of these genes were identified in the patients with the translocations indicating that the disruption of one copy of the gene in the respective patients does not unmask a recessive mutation in these genes. All three genes are expressed in adult and fetal brain. The three candidate MR genes were further characterized and are presently being screened in a large cohort of patients (500 females and 500 males) with MR of unknown etiology to investigate their potential involvement in some cases of autosomal MR.

Novel mutations in two large Saudi families affected with L-2-Hydroxyglutaric aciduria. *M. Ul Haque[1], E. Faqieh[2], A. Alduraihem[1], N.M. Saleh[1], H.A. Abalkhail[1], M. Al-Owain[2], A. Tbakhi[1], M. Al-Sayed[2]* 1) Molecular Genetics Lab, DPLM, King Faisal Specialist Hosp, Riyadh, Riyadh, Saudi Arabia; 2) Department of Medical Genetics, King Faisal Specialist Hospital & Research Centre, P.O.Box# 3354, MBC# 75, Riyadh 11211, Saudi Arabia.

Here we report 2 extended consanguineous families from different geographical regions of Saudi Arabia, displaying the typical features of L-2-Hydroxyglutaric aciduria encoded by L-2-hydroxyglutarate dehydrogenase (L2HGDH), a rare autosomal recessive neurometabolic disorder characterized by mild psychomotor delay in the first years of life, followed by progressive cerebellar ataxia, dysarthria and moderate to severe mental deterioration. We studied 13 patients, from 2 families with L2HGDH gene and sequenced the entire coding regions and exon-intron boundaries which revealed two different homozygous mutations in both families. In 1st family, we identified a novel single bp deletion A1015 in exon 8, resulting in a frameshift in the translated protein and replacement of 12 novel amino acids before a premature termination. The mutation was found in a homozygous state in all 6 affected individuals and was heterozygous in all unaffected carrier parents. In 2nd family, mutation analysis in 7 affected individuals revealed a homozygous C1319A transition at codon 440, which changes Serine a hydrophilic acidically charged residue to Tyrosine a basically charged residue in a conserve low complexity region of gene. To our knowledge, this is the first report of mutation analysis of the L2HGDH gene from Saudi Arabia.The two mutations are located in a highly conserved area across the multiple species suggest that the substituted residues are important for protein folding and/or enzyme catalysis and may effect the pre- processing and folding mechanism of the protein inside the mitochondria.

Clinical applications of rapid chromosome aneuploidy detection by quantitative fluorescent PCR. *Y. Yang, S. Hondorp, A. Haque, K. Thompson* Molecular Laboratory, Center for Medical Genetics, Houston, TX.

Common fetal chromosome aneuploidies compatible with live births are trisomies 13, 18 and 21 as well as sex chromosome anomalies (such as Klinefelter and Turner syndromes). Typically, detection of these anomalies can be accomplished by conventional cytogenetic analysis of prenatal cells from chorionic villi or amniotic fluids, which usually takes more than seven days. Two rapid approaches are available to provide preliminary results: fluorescence in situ hybridization (FISH) and quantitative fluorescent PCR (QF-PCR). While both methods can be used to detect aneuploidies for chromosomes 13, 18, 21, X, and Y within 24-48 hours, QF-PCR, a molecular genetics based test, has the advantage of being less expensive and requiring less amniotic fluids.
We are reporting here our experience of performing QF-PCR for rapid aneuploidy detection in the past two years. A total of 475 samples have been tested, including 378 amniotic fluid, 8 CVS and 89 newborn blood samples. Two tiers of multiplex QF-PCR were designed. The first tier includes two highly polymorphic STR markers for each chromosome studied and the Amelogenin gene. Trisomies can be detected by the tri-allelic pattern or 2:1 peak ratio of the PCR amplification products. Samples uninformative in the first-tier (about 5%) will be retested using the second-tier STR markers. Of the 475 samples, the abnormal results include 36 trisomy 21, 3 trisomy 18, 2 trisomy 13 and 3 cases strongly suggesting Turner syndrome (45,X). Our results have been compared to those of chromosome analysis and showed excellent agreement with the cytogenetics results: 100% sensitivity and specificity for trisomy detections. Overall our studies showed that QF-PCR is an accurate, efficient and inexpensive method for preliminary aneuploidy detection. By this method, clinicians and patients can have the preliminary results in as early as one day. It should be noted that both QF-PCR and FISH should be used in conjunction with routine chromosome analysis before any irreversible decisions are made.

Treatment of multiple sulfatase deficiency with recombinant human arylsulfatase B (galsulfase, Naglazyme). *S. Sandberg[1], L. Charnas[1], E. Braunlin[1], K. Bjoraker[1], M. Deanching[2], G. Hoganson[2], F. Rimell[1], C. Whitley[1]* 1) University of Minnesota, Minneapolis, MN; 2) University of Illinois, Chicago, IL.

C-alpha-formylglycine (FGly) is the catalytic residue at the active site of eukaryotic sulfatases, is created from cysteine by FGly-generating enzyme, coded by the SUMF1 gene. Mutations result in multiple sulfatase deficiency (MSD), a disorder with features of several lysosomal diseases, eg, increased glycosaminoglycans (GAG), sulfolipids, and steroid sulfates. We encountered a 13-year-old girl whose progressive MSD was life-threatening. Examination showed dysostosis multiplex, hepatomegaly, and ichthyosis. IQ was normal. MRI revealed cervical cord compression but no leukodystrophy. Urine GAG and sulfatides were elevated. Several lysosomal sulfatases were measured at low levels. The patients family declined hematopoietic stem cell transplant, a treatment that would replace several enzymes presumed necessary to halt MSD disease. Lacking other treatment, we considered enzyme replacement therapy (ERT) with human recombinant arylsulfatase B (ASB). After 4 months of galsulfase (Naglazyme) 1 mg/kg/week, urine GAG decreased from 1,023 mg GAG/g creatinine to 80. Liver volume decreased (745 to 581 cc) while spleen size was unchanged (172 to 170, respectively). There was rehabilitation from full-time bedrest, to part-time sitting. The patient became independent of respiratory assistance, by 5 months being free of oxygen and mechanical pressure support. In this patient, ERT demonstrated that deficiency of ASB was causing clinical pathology, and that some features were responsive analogous to Maroteaux-Lamy syndrome. Other features persisted: ichthyosis and sulfatiduria. Arylsulfatase A activity was immeasurable, but not low enough to cause neurologic disease (cf metachromatic leukodystrophy). Other sulfatases were low (ie, iduronate-2-sulfatase deficiency, heparan sulfate sulfamidase) but not so low as to cause Hunter syndrome or Sanfilippo syndrome type A. We speculate that clinical MSD may be the manifestation of only 1, 2 or 3 enzymes which are below a crucial threshold. Naglazyme may be efficacious in patients for whom ASB activity is a critical factor.

Combining information from multiple common susceptibility polymorphisms increases the predictive power of genetic information: a study of replicated type 2 diabetes variants. *M.N. Weedon[1], M.I. McCarthy[2], G. Hitman[3], M. Walker[4], C.J. Groves[2], E. Zeggini[2], N.W. Rayner[2], B. Shields[1], K.R. Owen[1], A.T. Hattersley[1], T.M. Frayling[1]* 1) Peninsula Medical School, Exeter; 2) Oxford Centre for Diabetes, Oxford; 3) Centre of Diabetes & Metabolic Medicine, University of London; 4) School of Medicine, Newcastle upon-Tyne.

A limited number of studies have assessed the risk of common diseases when combining information from several predisposing polymorphisms. In most cases, individual polymorphisms only moderately increase risk (~20%) and they are thought to be unhelpful in assessing subjects risk clinically. The impact of looking at multiple alleles simultaneously is not well studied. This is often because, for any given disease, there are very few confirmed, common risk alleles. Three common variants (K23 of KCNJ11, P12 of PPARG, and the T allele at rs7903146 of TCF7L2) predispose to type 2 diabetes mellitus (T2D) across many large studies. Risk allele frequencies range from 0.30 to 0.88 in controls. To assess the combined effect of multiple susceptibility alleles we genotyped these variants in a large case/control study (3668 controls v 2409 cases). Individual allele odds ratios (OR) ranged from 1.14 (95% CI: 1.05,1.23) to 1.48 (95% CI: 1.36, 1.60). We found no evidence of gene-gene interaction and the risks of multiple alleles were consistent with a multiplicative model. Each additional risk allele increased odds of type 2 diabetes by 1.28 (1.21, 1.35) times. Subjects with all 6 risk alleles had an OR of 5.71 (95% CI: 1.15, 28.3) compared to subjects with 0 risk alleles. The 8.1% of subjects double homozygous for the risk alleles at TCF7L2 and Pro12Ala had an odds ratio of 3.16 (95% CI: 2.22, 4.50), against the 4.3% of subjects with no TCF7L2 risk alleles and either 0 or 1 E23K or Pro12Ala risk alleles. In conclusion, combining information from several known common risk polymorphisms allows the identification of subgroups of the population with markedly differing risks of developing type 2 diabetes compared to when using single polymorphisms. This approach may have a role in future preventative measures for common, polygenic diseases.

E-Selectin Ligand 1 Negatively Regulates TGF in the Golgi during Skeletogenesis. *T. Yang[1], R. Mendoza-Londono[1], H. Lu[1], K. Li[1], B. Keller[1], M. Jiang[1,2], Y. Chen[1,2], T.K. Bertin[1], B. Dabovic[4], D.B. Rifkin[4], J. Hicks[3], A.L. Beaudet[1], B. Lee[1,2]* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute; 3) Department of Pathology, Baylor College of Medicine and Texas Childrens Hospital; 4) Department of Cell Biology, New York University Medical Center.

Transforming growth factor (TGF) signaling plays critical roles regulating growth and differentiation during development and disease. Its context dependent action is specified by numerous control mechanisms at the extracellular level and downstream of ligand-receptor interactions, but little is known about the regulation of its post-translational trafficking. E-Selectin Ligand-1 (ESL-1), the cysteine rich protein originally isolated as a ligand for E-Selectin, was also found to interact with FGFs and to be co-purified with TGF1 in a large protein complex. To elucidate its in vivo function, we generated Esl-1 mutant mice. The newborn Esl-1-/- mice are notably smaller with narrow chests and generalized shortening and thinning of all bony elements. This severe but proportionate growth retardation was observed from embryonic day 15.5 (E15.5) to maturity. By histological analysis, P1 Esl-1-/- mice showed shortening of the growth plates in both the proliferating zone and hypertrophic zone. Moreover, the notable less bone density was also detected in the adult mutant mice. Further molecular assays show that ESL-1 acts as a negative regulator of TGF production by binding TGF precursors via its laternt activation domain (LAP) in the Golgi in a cell autonomous fashion. In vivo, loss of ESL1 function causes increased TGF signaling resulting in decreased cell proliferation and delayed terminal differentiation in the cartilaginous growth plate, independent of effects on BMP and FGF signaling. Moreover, in vivo genetic models of gain vs. loss of TGF signaling in the growth plate confirm this effect. Our data not only identified ESL-1 as a critical regulator for skeletogenesis, cartilage and bone homeostasis, but also revealed a novel mechanism for regulating TGF intracellular pool in these processes.

A novel de novo frameshift mutation of the EDA gene in a Chinese family with hypohidrotic ectodermal dysplasia. *Xin. Tu, Qinbo. Yang, Changzhen. Huang, Tie. Ke, Qing. Wang, Mugen. Liu* Center for Human Genome Research, Huazhong University of Science and Technology, Wuhan, Hubei, China.

Hypohidrotic ectodermal dysplasia is characterized by severe hypohidrosis, hypotrichosis, and hypodontia. It can be inherited in autosomal dominant, autosomal recessive, or X-linked patterns. Mutations in the EDA gene, which encodes ectodysplasin-A (EDA), are responsible for X-linked hypohidrotic ectodermal dysplasia (XLHED). In the present study, we identified a Chinese family with X-linked hypohidrotic ectodermal dysplasia. By linkage analysis we revealed that the causative gene was linked to EDA locus in the family. Direct DNA sequence analysis of whole coding regions and exon -intron boundaries of EDA gene showed this is the only de novo INSERTION mutations of EDA described, and c.573-574 ins T in EDA gene existed in all affected males and carrier females. This mutation resulted in a frameshift leading to altered amino acid structure and early termination of EDA. Further PCR-RFLP analysis suggested that the c.573-574 ins T mutation of EDA gene is a cause for X-linked hypohidrotic ectodermal dysplasia in the family.

Genetic variation in the endothelin converting enzyme-like 1 gene is associated with type 2 diabetes (T2DM) in the Old Order Amish. *Y. Wang[1], X. Shi[1], P.F. McArdle[1], C.M. Damcott[1], Y.C. Chang[1], A.R. Shuldiner[1,2], B.D. Mitchell[1], N.I. Steinle[1]* 1) Department of Medicine, University of Maryland, Baltimore, MD; 2) GRECC, Veterans Administration Medical Center, Baltimore, MD.

T2DM is a polygenic disorder, characterized by gene-gene and gene-environment interactions with onset in adulthood. The endothelin converting enzyme-like 1 (*ECEL1*) gene is located on chromosome 2q37, within a region on the distal arm of chromosome 2 that has identified as a locus of diabetes susceptibility. *ECEL1*, whose substrate is unknown, is highly expressed in skeletal muscle, pancreas and brain, and is localized in the plasma membrane and the endoplasmic reticulum (ER). We tested the hypothesis that variation in *ECEL1* is associated with T2DM and related traits by genotyping 4 common (MAF>0.1) haplotype tagging SNPs (htSNPs), selected from the CEU HapMap database and one rare nonsynonymous SNP Tyr328His (frequency 0.03) in participants from the Amish Family Diabetes Study (AFDS) (n=1205). In our case-control study, we found that the three intronic htSNPs (rs909431, rs1190430 and rs746379) were significantly associated with either T2DM (p=0.005-0.02) or the combined T2DM/impaired glucose tolerance (IGT) trait (p=0.0002-0.02). Furthermore, these three intronic SNPs as well as the promoter htSNP (rs2742072) were strongly associated with higher glucose and insulin area under the curve during an oral glucose tolerance test in a subset of nondiabetic subjects (n=654) ($p<0.0009$ and $p<0.03$, respectively), suggesting that these individuals have impaired insulin sensitivity. Haplotype analysis showed that the intronic SNPs are in one linkage disequilibrium block with one common haplotype (ACG, frequency 0.293) showing strong association with increased risk of T2DM (p=0.002) and the combined T2DM/IGT trait (p=0.00003). Our data provide the first evidence that genetic variation in *ECEL1* is associated with T2DM, IGT and insulin resistance, through mechanisms that are unknown, but possibly related to ER stress.

Molecular characterization of a case with CHARGE syndrome like phenotype and partial 6p trisomy. *I. Ragoussis[1], G. K. Mirza[1], L. Schimmenti[2], R. Clark[2]* 1) Genomics, Wellcome Trust centre for Human Genetics, Oxford, United Kingdom; 2) USC/Keck School of Medicene, Cancer Genetics Units, Norris Comprehensive Cancer Center, Los Angeles, CA 90089.

We present a case diagnosed with CHARGE syndrome based on initial clinical findings (parents were normal). Cytogenetic analysis identified a normal karyotype in lymphocytes but revealed a *de novo* duplication of 6p in fibroblasts and therefore mosaicism. Molecular analysis was carried out using over 40 BAC and PAC clones that had been previously mapped for FISH on nuclei obtained from fibroblast cultures. The analysis confirmed a terminal duplication karyotype: 46,XY,dup(6)(22), with the region of duplication estimated to be 15Mb. Our case presented with heart defects, choanal atresia, bilateral sensorineural and conductive hearing loss, ocular coloboma, submucus cleft palate, and mild retardation, which are pertinent to the phenotypic characteristics of CHARGE syndrome. Of these, heart defects and choanal atresia are also found in 6p duplications. Additional clinical features included facial dysplasia, myopia, ptosis, strabismus, and skin hypopigmentation, which are consistent with 6p duplications. Although hearing defects are associated with CHARGE syndrome, they have not been previously reported in 6p trisomy cases. External ear abnormalities are associated highly with individuals affected with CHARGE syndrome, but no structural defects of the ears were reported in our case. Interestingly the phenotype is more complex than a reported mosaic case with 6p22-pter trisomy, where the trisomy is found in a small proportion of peripheral blood and fibroblast cells (Giardino et al Am. J. Med. Genet. 108:36-40 (2002)). Most affected individuals with CHARGE syndrome, have mutations or deletions involving the chromodomain helicase DNA-binding protein-7 (CHD7) gene on chromosome 8.We have excluded deletion of the CHD7 gene and mutation analysis is in progress in an effort to delineate the phenotype further. In conclusion, this would be the first time that CHARGE syndrome is possibly linked to 6p.

Identification of Novel Deletions of 15q11q13 in Angelman Syndrome by Array-Based Comparative Genomic Hybridization (CGH): Large Segmental Duplicons Flank the Breakpoints. *S. Peters[1], T. Sahoo[1], J.R. German[1], C.A. Shaw[1], L.M. Bird[2], V. Kimonis[3], A.L. Beaudet[1], C.A. Bacino[1]* 1) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 2) Pediatrics, Childrens Hospital San Diego, San Diego, Ca; 3) Boston Childrens Hopsital, Boston, Ma.

Angelman syndrome (AS) is a neurodevelopmental disorder characterized by severe mental retardation, ataxia, and a happy disposition. Deletions of the 15q11q13 region are found in approximately 70% of AS patients. The deletions are sub-classified into Class I and Class II based on their size (~6 to ~6.8 Mb), and their breakpoint involvement, with two different proximal breakpoints and a single common distal breakpoint. Utilizing a chromosome 15-specific genomic microarray, we have determined the deletion sizes and mapped the breakpoints in a cohort of cases (n=44) to identify a common underlying mechanism and derive precise genotype-phenotype correlations. Interestingly four patients of the 44 studied (9.1%) had novel and unusually large deletions. This is the first report of extremely large deletions of 15q11q13 resulting in Angelman syndrome; the largest being >10.6-Mb. These novel deletions involve three different distal breakpoints, two of which have been shown to be involved only in the formation of isodicentric (15)(q11.2). Additionally, precise determination of the deletion breakpoints reveals the presence of segmental duplications in the vicinity of all the recurrent and novel breakpoints identified so far. This genomic organization provides strong evidence for a mechanism that generates the common as well as rare deletion events. Detailed phenotypic characterization of the probands indicates large deletions result a much more severe phenotype. The large deletions result in a loss of a number of genes outside the common AS-PWS critical interval. The impact of the loss of these additional genes requires further characterization. Array-based CGH thus provides very precise information regarding the nature of the recurrent and rare deletion events that result in Angelman syndrome and identifies genomic structures that most likely are involved in the abnormal recombination events resulting in 15q11q13 deletions.

Enhanced Oversight of Genetic Testing Laboratories Needed and Supported: Results of a Survey of Laboratory Directors. *J. Scott[1], G. Javitt[1], J. Murphy[1], D. Kaufman[1], S. Katsanis[2], K. Hudson[1]* 1) Genetics & Public Policy Ctr, Johns Hopkins Univ, Washington, DC; 2) DNA Diagnostic Laboratory, Johns Hopkins Univ, Baltimore, MD.

Introduction: To ensure high quality laboratory testing, the Clinical Laboratory Improvement Amendments (CLIA) mandate proficiency testing (PT) for high complexity tests within CLIA-defined specialty areas. Genetic tests are considered high complexity, but no specialty area exists for molecular and biochemical genetic tests, and no PT is specified. A few voluntary PT programs exist. The federal government has repeatedly recommended creation of a genetic testing specialty under CLIA. A survey of U.S. genetic testing lab directors assessed the relationship between participation in PT and lab quality, and attitudes about oversight. **Methods:** U.S. molecular and biochemical genetic testing lab directors were asked to complete a confidential online survey between December 2005 and March 2006. Relationships between use of PT and lab errors encountered was explored using regression. **Results:** Of 345 eligible lab directors, 190 (55%) responded, and 95% were at CLIA certified labs. Common specialty certifications included pathology (48%) and chemistry (46%)- 16% were not specialty-certified. Nearly two-thirds conducted some PT on all tests offered, however, 26% conducted PT on 50-99% of their tests, 9% on <50% of tests, and 3% conduct no PT. As the percent of tests covered by PT increased, PT deficiencies in the lab declined significantly ($p=0.004$), and as the number of PT deficiencies declined, the number of incorrect test reports issued also declined significantly ($p=0.03$). Labs performing PT on <100% of tests were also more likely to identify an analytic error as their most common error($OR=3.1$ $p=0.02$). Most lab directors (92%) felt that PT improves the quality of genetic testing, and 73% felt a genetic testing specialty should be created under CLIA. **Conclusions:** Lab directors support the creation of a genetic specialty by CLIA, including specific PT programs which 92% find useful. PT testing is strongly correlated with quality-related outcomes, further supporting creation of the CLIA specialty.

MATN3 (Matrilin-3) sequence variation (p.T303M) is a risk factor for osteoarthritis of the CMC1 joint of the hand, but not for knee osteoarthritis. *A. Tagariello[1], O. Pullig[2], A. Schweizer[1], B. Swoboda[2], P. Schaller[3], A. Winterpacht[1]* 1) Inst Human Genetics, Univ Erlangen-Nuremberg, Erlangen, Germany; 2) Department of Orthopaedics, Univ Erlangen-Nuremberg, Erlangen, Germany; 3) Department of Hand Surgery and Plastic Surgery, Kliniken Dr. Erler, Nuremberg, Germany.

Osteoarthritis (OA) is the most common musculoskeletal disorder, characterized by progressive degeneration of joint cartilage resulting in joint pain and stiffness. The disorder has a multifactorial etiology. Hand OA is a subtype of OA, for which a strong genetic basis was suggested. Recently, it has been reported that a single nucleotide polymorphism (SNP) in the matrilin-3 (MATN3) gene encoding T303M at a highly conserved position in an EGF-like domain is associated with an increased risk [frequency of 2 %, relative risk of 2.1] of idiopathic hand OA in the Iceland population (Stefansson et al., 2003). We have investigated the SNP in a small but heterogeneous German cohort of patients with radiographic and symptomatic hand OA of the first carpometacarpal joint (CMC1) [n = 50], 177 patients with radiographic and symptomatic knee OA and 356 unrelated Caucasian control individuals from Germany by direct sequencing. We analysed the frequency of the SNP in hand OA patients and in 356 controls and observed a difference in allele frequency (^{2} = 10.84, p = 0.00099). The rare T allele was present in 10 % of the hand OA patients and in 2.5 % of the healthy controls. The estimated relative risk is 4.28 (95% CI, 1.18-14.8), but this value is uncertain due to the small number of patients. No difference in allele frequency and no significant association could be observed between this allele and the occurrence of knee OA in our cohort (Table 1, ^{2} = 0.03, p = 0.85755). Although our cohorts were fairly small, the present data are significant and we could replicate the results for hand OA reported by Stefansson et al. (2003). These data support the importance of the analysed SNP for this specific form of OA, but not for knee OA where no association could be found.

Association Studies Of Oncogenes In Invasive Epithelial Ovarian Cancer. *L. Quaye[1], H. Song[2], S.J. Ramus[1], I.J. Jacobs[1], B.A.J. Ponder[2], A.S. Whittemore[3], E. Høgdall[4], S. Krüger-Kjær[4], P.D.P. Pharoah[2], S.A. Gayther[1]* 1) Gynaecological Oncology, University College London, London, United Kingdom; 2) Department of Oncology, University of Cambridge, UK; 3) Department of Health Research and Policy, Stanford University, USA; 4) Department for Virus, Hormones and Cancer, Danish Cancer Society, Denmark.

Epithelial ovarian cancer (EOC) represents 5% of all cancers in women worldwide, but it is poorly understood. Approximately 5-10% of ovarian cancer cases are caused by highly penetrant susceptibility, primarily BRCA1 and BRCA2. However, these genes are responsible for only 30% of the excess familial EOC risk. The remaining familial risks are thought to be caused by a combination of susceptibility genes of lower risk (i.e. moderate-low penetrance). We are using candidate gene association studies in EOC case-control populations in order to find low penetrance genes. In this study, we have used a single nucleotide polymorphism (SNP) tagging approach to identify SNPs in candidate oncogenes that have previously been shown (or are predicted) to be involved in ovarian cancer development: BRAF, KRAS, ERBB2, PIK3CA, and the NMYC-CMYC interactor gene, NMI. SNPs were selected with an r2 0.8, minor allele frequency 0.05. Genotyping was performed using the multiplex genotyping approach iPLEX (Sequenom) in two different epidemiological based EOC case-control series from Denmark and the UK. Together, these populations comprise approximately 1200 invasive EOC cases and 2100 unaffected, female controls. We identified two SNPs (rs3771882 and rs3854012) in the NMI gene that were significantly associated with decreased EOC risk. For rs3771882 HetOR=0.77 (95% CI 0.65-0.92), HomOR=0.86 (CI 0.70-1.06) P=0.0136 and for rs3854012 HetOR=0.79 (CI=0.66-0.94), HomOR=0.88 (CI 0.72-1.08) P=0.0236. Both of these SNPs are within the same linkage equilibrium (LD) block with an r2=0.08. A multi-centre consortium study with a further 2500 cases and 3500 controls will be conducted to confirm if these SNPs are associated with decreased EOC risk.

Semi-parametric test based on spline smoothing for genetic association study under structured populations. *Q. Zhang, J. Luo, R. Chakraborty, R. Deka* Dept Environmental Health, Univ Cincinnati, Cincinnati, OH.

Statistical methods have been proposed using markers to control for population stratification in genetic association studies. However, these methods either have low power when population stratification becomes strong or can not control for population stratification well under admixture population models. Zhang et al. (Genet Epidemiol 2003, 24: 44-56) and Chen et al (Ann Hum Genet. 2003, 67 : 250-64) proposed semi-parametric tests based on kernel function to detect the association between candidate markers and quantitative traits, and binary traits, respectively. However, their semi-parametric tests based on kernel smoothing are complex and difficult to implement. Here, we propose another semi-parametric test based on penalized spline smoothing to detect association between candidate markers and qualitative traits. Penalized spline smoothing can be expressed in a linear mixed model framework, which allows such model to be fitted using standard mixed models software, and also allows us to fit complex models, such as proportional odds model for ordinal data. Another advantage of penalized spline smoothing is that the smoothing parameter is the ratio of variance component and can be selected in a natural fashion using restricted maximum likelihood estimation (REML). We are conducting coalescence simulations to compare the power and type I error of this test with other existing method. Our initial results show that the type I error of our method is low with acceptable power.

Genomic convergence in Alzheimer disease. *M. Slifer[1], E. Martin[1], H. Munger[1], J. Haines[2], J. Gilbert[1], M. Pericak-Vance[1]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Ctr Human Genetics Research, Vanderbilt Univ Medical Ctr, Nashville, TN.

Late-onset Alzheimer disease (LOAD) is the most common cognitive disorder affecting more than four million Americans. Over the past two decades, hundreds of variations in candidate genes have been reported as associated with LOAD. However, only the apolipoproteinE4 allele has been widely accepted as a risk factor. The deluge of reported susceptibility alleles, limited resources, lack of follow-up, small sample sizes, varying datasets, and differing experimental designs have complicated the search for confirmed LOAD genetic variants. In this study, we use the genomic convergence approach to select candidate genes for systematic follow-up. A gene is declared convergent if significant effects are published from at least three independent experimental methods (e.g. genetic linkage, genetic association, and gene expression). Nineteen candidates (comprising 1.5 Mb of genomic DNA) meet full convergent criteria and have been interrogated in a large independent case-control dataset (n=1000). All cases meet NINCDS/ADRDA criteria for Alzheimer disease as agreed upon by consensus conferences. Controls have no history of cognitive impairment, no family history of LOAD in a first degree relative or and no evidence of dementia on psychometric testing. Using dense SNP genotyping (approximately 1 SNP per 2.5 kb) we examined candidate variants for association with LOAD. Nine of the nineteen convergent genes have SNPs significantly associated with LOAD ($p<0.05$) including multiple SNPs within 3 regions of the amyloid beta (A4) precursor protein gene ($p=0.0002$), and a region proximal to the 3 end of the major histocompatibility complex, class 1, A gene ($p=0.0001$).

Comprehensive analysis of causative and related genes for sporadic ALS using a high throughput DNA microarray-based resequencing system. *Y. Takahashi, J. Goto, S. Tsuji* Dept Neurology, Univ Tokyo, Tokyo, Japan.

[Background] The causes of sporadic amyotrophic lateral sclerosis (ALS) remains unknown. However, recent reports have demonstrated that mutations of causative genes for familial ALS have been identified in a portion of sporadic ALS patients. The molecular dissection through comprehensive analysis of causative genes should contribute to elucidating molecular epidemiology and providing insight into pathogenesis of sporadic ALS. In addition, comprehensive screening for candidate genes may reveal some variations related to genetic risks of ALS. With this background, we have developed a DNA microarray-based high throughput resequencing system for ALS, TKYALS01. [Objectives] To conduct molecular dissection of sporadic ALS and to identify novel variations potentially associated with disease risks or phenotypic variations of ALS. [Methods] Thirty-three sporadic ALS patients were included in this study, consisting of 18 definite ALS, 9 probable ALS, 3 possible ALS, and 3 ALS-plus patients based on the El Escorial and the revised Airlie House diagnostic criteria. We have screened all the exonic and flanking intronic sequences of 3 causative genes (*SOD1* , *ALS2* , and *DCTN1*) and 7 related genes (*SLC1A2*, *SMN1*, *LIF*, *RNF19*, *ADAR2* , *CNTF* , and *VEGF*) for ALS using TKYALS01. [Results] Two causative mutations were identified, including 1 novel *DCTN1* putative mutation in a possible ALS patient and 1 previously known *SOD1* mutation in a definite ALS patient. In addition, 6 novel heterozygous nonsynonymous substitutions, 5 *ALS2* substitutions in 4 definite and 2 probable patients and 1 *VEGF* substitutions in 1 ALS-plus patient, and 1 heterozygous substitution in the 5UTR of *DCTN1* in 1 definite patient, were identified. The remaining novel heterozygous substitutions included 4 synonymous substitutions in *ALS2* , *DCTN1* , *RNF19* , and *VEGF* . [Conclusion] The present study revealed two causative mutations in 6% of the sporadic ALS patients (2/33), suggesting that a portion of sporadic ALS patients have mutations in the causative genes with reduced penetrance or de novo mutations.

The role of NF-B in TNF-regulated transcription of the human COMT in astrocytes. *I. Tchivileva[1], R. Sitcheran[2], A.S. Baldwin[2], W. Maixner[1], L. Diatchenko[1]* 1) Ctr for Neurosensory Disorders, University of North Carolina at Cahpel Hill, Chapel Hill, NC; 2) Lineberger Comprehensive Cancer Ctr, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Catechol-O-methyltransferase (COMT) plays a crucial role in the metabolism of catecholamines. Reduction in COMT activity resulted in increased pain sensitivity in animal models. The main sources of the enzyme in the nervous system are neurons and astrocytes, and astrocytes are activated under conditions associated with enhanced pain responses. In this research, we hypothesized that regulation of COMT in astrocytes could contribute to development of inflammatory and neuropathic pain. We cloned a distal promoter of human COMT (P2-COMT) which is the only one active in the brain into a luciferase reporter vector and transiently transfected the construct into H4 astroglioma cells. We showed that proinflammatory cytokine tumor necrosis factor (TNF) down-regulated the activity of P2-COMT construct. Real-time RT-PCR and Western blot analyses of cell lysates confirmed decreased level of endogenous COMT after TNF treatment at both mRNA and protein levels. We then proposed that this TNF-dependent regulation of COMT expression was mediated by activation of nuclear factor B (NF-B), the pivotal regulator of inflammation and one of the major targets of TNF. In support of this hypothesis, cotransfection of P2-COMT reporter construct with either p65 NF-B subunit, or IKK subunit expression constructs, led to strong repression of luciferase activity. Furthermore, selective NF-B inhibitor PDTC blocked TNF-mediated down-regulation of the P2-COMT construct. Functional deletion analyses of P2-COMT showed that this TNF-dependent effect on COMT expression was mediated by a 155 base pair fragment in the promoter region of COMT that contained the putative EB binding site. Finally, TNF-dependent suppression of endogenous COMT expression and P2-COMT vector activity was abrogated in H4 cells stably expressing IB super-repressor. Collectively, these data strongly suggest that COMT is down-regulated under inflammatory conditions through the NF-B pathway and NF-B activation can lead to persistent pain states.

Dysregulation of Alternative Splicing of Coagulation Factor V Results in Bleeding Disorder, East Texas Type.

L.M. Vincent[1], V. Tran-Fadulu[1], W.P. Dubinsky[3], B. Dahlback[2], D.M. Milewicz[1] 1) Internal Medicine, Univ Texas, Houston, Houston, TX; 2) Laboratory Medicine, Clinical Chem, Univ Hospital, Malmo, Sweden; 3) Integrative Biology/Pharmacology, Univ Texas, Houston, Houston, TX.

Proper control of alternative splicing is speculated to contribute more to human disease than currently recognized. We identified a large family (16 affected) from East Texas with autosomal dominant inheritance of a novel bleeding disorder characterized by easy bruising, excessive bleeding with trauma/surgery requiring transfusions, and menorrhagia in affected women. Laboratory studies demonstrate prolonged PT and/or aPTT and normal activities/levels of all coagulation factors. Linkage analysis maps the defective gene to 1q23-24 (LOD 7.33), which contains coagulation factor V (FV). An alteration(A2440G) in FV in exon 13 segregates with disease and was not present in 62 controls. Exon 13 of FV is highly polymorphic and non-functional with respect to procoagulant function of FV. Interestingly, this alteration falls on the 5 splice site(TA/GT) of a splicing variant confirmed by RT-PCR of control liver and leukocytes. Furthermore, immunoblot analysis demonstrates that this splice variant produces a low abundance, 250kD isoform of FV in control plasma. The A2440G alteration forms a higher efficiency consensus site for splicing(TG/GT). Semi-quantitative RT-PCR confirms this improved efficiency with an increase of splicing seen in patients RNA from leukocytes(n=3) versus controls(n=3). This translates into a 20-fold increase in the 250kD isoform of FV seen in patients plasma(n=6) versus conrols(n=5). Precipitation of Vit-K dependent coagulation factors suggests that this isoform interacts with known FV-interacting proteins. Plasma mixing studies indicate dose-dependent correction, thus suggesting a dominant negative mechanism of impeding coagulation. **These data indicate that A2440G up-regulates an alternatively spliced transcript of FV, and increases a FV isoform that hinders coagulation as opposed to promoting it like its wildtype counterpart.** As verified by this unique mutation, alternative splicing is an important physiological event that can result in disease if its delicate balance is disrupted.

Molecular Diagnostics in Dual Site Ovarian and Endometrial Cancers. *S.J. Ramus[1], K. Elmasry[1], J. Whittaker[2], Z. Luo[3], A. Gammerman[3], N. Singh[4], W.G. McCluggage[5], A. Ayhan[6], K. Lu[7], I.J. Jacobs[1], S.A. Gayther[1]* 1) Dept Gynaecological Oncology, University College London, UK; 2) London School of Hygiene & Tropical Medicine, UK; 3) Royal Holloway, University of London, UK; 4) St.Bartholomew`s and The Royal London, UK; 5) Royal Victoria Hospital, Belfast, UK; 6) Seirei Mikatahara Hospital, Japan; 7) MD Anderson Cancer Center, USA.

Five to eight percent of patients undergoing laparotomy for suspected ovarian malignancies are found to have synchronous tumours of the ovary and endometrium. Patients with dual primary (DP) tumours have a better prognosis than a single primary tumour with metastasis (SPWM). The benefits of a correct diagnosis include the individualisation of patient management, the avoidance of unnecessary treatment and a more accurate prognosis. Currently, the distinction between DP and SPWM involves pathological interpretation and there is often uncertainty when the tumours have the same histological subtype. We have established a collection of 90 synchronous ovarian and endometrial tumours, in which tumour pairs have the same histological subtype. We have developed a molecular genetic test to distinguish between DP and SPWM cases, based on the analysis of microsatellite markers for allelic imbalance and microsatellite instability at 22 microsatellite markers. We compared genetic data with working pathology diagnoses and detailed histopathology review. Of the 39 patients previously diagnosed as DP cases, 31 had the same results for pathology and genetic tests. A further 7 cases were not informative and one case was given a diagnosis of SPWM. Of 25 patients diagnosed as SPWM by pathology, genetic tests identified 17 as SPWM and 3 as not informative. Significantly, 5 cases previously thought to be SPWM by pathology were diagnosed as DP by genetics suggesting these cases may have had more rigorous adjuvant chemotherapy than necessary. There were 26 patients in this study for whom a diagnosis by pathology was uncertain. Genetics analyses diagnosed 20 of these cases as DP, 4 as SPWM and 2 were uninformative. These data indicate that genetic methods can be used as powerful tools to complement existing histopathology for the diagnosis of synchronous cancers.

Functional and genetic analysis of hnRNPA1 as modifier gene in spinal muscular atrophy (SMA) discordant siblings. *A. Vielle-Canonge[1], I. Bagni[1], L. Vallo[1], L. Alias[2], E. Also[2], E. Tizzano[2], M. Bertoli[1], G. Novelli[1], P. Spitalieri[1], E. Bonifazi[1], A. Botta[1]* 1) Department of Biopathology and, University of Roma Tor Vergata, Rome, Italy; 2) Department of Genetics and Research Institute, Hospital Sant Pau, Barcelona, Spain.

Spinal muscular atrophy (SMA), the second most common autosomal recessive disorder, is caused by the absence of or mutations in the Survival Motor Neuron 1 (SMN1) gene, which encodes an essential protein. A nearly identical copy of the gene, SMN2, fails to compensate for the loss of SMN1 because exon 7 is alternatively spliced, producing a truncated, unstable protein. SMN1 and SMN2 differ by a critical C>T substitution at position 6 of exon 7 in SMN2, that causes skipping of this exon producing only low levels of functional SMN protein. The C>T transition creates an exonic splicing silencer (ESS) in SMN2 and functions as a binding site for a known repressor protein, hnRNPA1. The reduction of hnRNPA1 mRNA and protein levels in minigenes assays showed an efficient SMN2 exon 7 inclusion, making this gene an attractive modifying factor in SMA discordant families. We have first studied the effect of hnRNPA1 depletion in culture of CVS derived from SMA patients using synthetic siRNAs. Analysis conducted 48h after lipofection, showed a significant increase of the SMN protein levels and GEMS numbers in nuclei of SMA patients cells, compared to untreated controls. We have therefore analyzed the sequence of the hnRNPA1 gene and of its binding site on the SMN2 gene, in 10 SMA families with sibling showing identical 5q13 haplotypes and a variable clinical phenotypes. DHPLC/SSCP and sequencing analysis has been used to screen the hnRNPA1 gene and the SMN2 exon 7 in SMA discordant siblings. We were able to identify 3 nucleotides differences (c.17-57G>A, c.913+33C>T, c.1066-62C>T) in 3 exons of the hnRNPA1 gene, which have no association to the SMA clinical outcome. No sequence variations was observed in the sequence of the SMN2 genes where the hnRNPA1 protein binds. Our findings suggest that the hnRNPA1 gene, although playing a role in SMN2 exon 7 skipping, does not directly acts as modifier gene of the SMA phenotypes (FIS05-2416).

Allele Frequencies of CYP2C9, CYP2C19 and CYP2D6 in the Ashkenazi Jewish Population. *S.A. Scott, L. Edelmann, R. Kornreich, R.J. Desnick* Department of Human Genetics, Mount Sinai School of Medicine, New York, NY, 10029.

The polymorphic cytochrome P450 (CYP) isoenzymes are involved in the oxidative metabolism of a number of commonly used drug classes and xenobiotics. Their polymorphisms result in marked individual and ethnic variability in the metabolism and disposition of these drugs and are partly responsible for differences in clinical responses to some drugs. We determined the allele frequencies of 29 major CYP2C9, CYP2C19, and CYP2D6 polymorphisms in 250 anonymous, unrelated Ashkenazi Jewish (AJ) individuals from the greater New York metropolitan area. Genotyping of CYP2C9, CYP2C19, and CYP2D6 was performed using Tag-It Mutation Detection Kits (Tm Bioscience) that simultaneously detect nucleotide variants in a multiplex format. Genotype frequencies for each CYP were in Hardy-Weinberg equilibrium. CYP2C9 and CYP2C19 have extensive, intermediate, and poor metabolizer genotypes. In the AJ population there were 60.4% (151) extensive, 33.2% (83) intermediate, and 6.4% (16) poor CYP2C9 metabolizers, and 69.2% (173) extensive, 27.6% (69) intermediate, and 3.2% (8) poor CYP2C19 metabolizers. Similarly, CYP2D6 has ultrarapid, extensive, intermediate, and poor metabolizer genotypes and 12.0% (30) ultrarapid, 78.8% (197) extensive, 4.0% (10) intermediate, and 5.2% (13) poor CYP2D6 metabolizers were identified. CYP2C9 and CYP2C19 allele and genotype frequencies in the AJ subjects were comparable to those in other Caucasian populations and distinct from those previously reported in African and Asian populations. In contrast, the ultrarapid metabolizer frequency in the AJ population (12.0%), which results from a functional CYP2D6 duplication, was 2-3 times higher than that observed in most Caucasians (4-5%). Given the individual, ethnic, racial, and demographic variability in CYP metabolism status, these results support the incorporation of CYP2C9, CYP2C19, and CYP2D6 genotype information into individualized pharmacologic dose recommendations. Moreover, the higher frequency of the ultrarapid metabolizer genotype suggests that AJ individuals should be screened to identify those at risk for adverse drug reactions.

Constriction of the Region for Familial Combined Hyperlipidemia on 11p. *C.L. Plaisier[1], C.J. van der Kallen[2], T.W. de Bruin[3], P. Pajukanta[1]* 1) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) Department of Medicine, CARIM, Academic Hospital, Maastricht, The Netherlands; 3) GlaxoSmithKline, Translational Medicine and Genetics, Research Triangle Park, North Carolina, USA.

Patients with Familial Combined Hyperlipidemia have high levels of serum total cholesterol (TC) and triglycerides (TGs). FCHL is a complex heterogeneous disorder that predisposes these patients to coronary heart disease. The genome-wide linkage scan of Dutch FCHL families identified a locus for FCHL on chromosome 11p with a multipoint LOD score of 2.6. No LOD scores > 3.0 were obtained for this Dutch genome scan, making it unlikely that a single major gene would predispose to FCHL in the Dutch FCHL families. The chromosome 11 finding was replicated in British FCHL families with a LOD score of 2.7 for TGs. This region has also been linked to TC, low-density lipoprotein cholesterol, as well as to obesity and glucose-related traits in multiple studies. In order to fine map the 40cM LOD -1 region defined by the overlapping Dutch and British peaks, we genotyped an additional 33 microsatellites in Dutch FCHL families bringing the marker density down to 1 marker per 2cM. SimWalk parametric multipoint linkage analysis of the microsatellites restricted the LOD -1 to a 9-cM region on 11p between markers D11S1761 and D11S1780. Importantly, this fine mapping approach reduced the number of candidate genes from 745 to 31 known genes. Our future plan is to use the CEPH HapMap data for these 31 genes to select tagging SNPs for association testing in Dutch FCHL families and other Caucasian combined hyperlipidemia study samples for replication.

BBS proteins are necessary for proper function of the regulatory center of the centrosome and spindle pole and for regulation of -tubulin levels. *J. Wei[1], H.J. Yen[1], A. Fedler[3], Q. Qian[2], C. Searby[1], M. Andrews[1], D.Y. Nishimura[2], S. Patil[2], V.C. Sheffield[1,2]* 1) Howard Hughes Medical Institute, Iowa City, IA; 2) Dept of Pediatrics, Univ of Iowa, Iowa City, IA; 3) Univ of Iowa, Iowa City, IA.

Bardet-biedl syndrome (BBS) is a pleiotropic genetically heterogeneous disorder characterized by obesity, retinopathy, polydactyly, renal malformations, learning disabilities, and hypogenitalism. To date, 11 BBS genes have been identified. Some BBS proteins have been reported to localize to the centrosome. A knockin mouse model of BBS1 (*Bbs1*$^{M390R/M390R}$) and knockout mouse models of BBS2 (*Bbs2*$^{-/-}$), BBS4 (*Bbs4*$^{-/-}$) and BBS6 (*Bbs6*$^{-/-}$) have been developed in our laboratory. These mouse models have features of human BBS. In this study, we utilize cultured mouse renal cells to demonstrate that BBS2 is a microtubule-associated protein and concentrated at the converging sites of microtubules during interphase and at the spindle poles during mitosis. In cultured *Bbs2*$^{-/-}$, *Bbs4*$^{-/-}$, and *Bbs1*$^{M390R/M390R}$ renal metaphase cells, we observed that -tubulin is aberrantly associated with spindle microtubules (MTs). Moreover, these mutant renal mitotic cells have aberrant asters that are associated with misalignment of chromosomes. Further investigation of these phenomena revealed that absence of BBS2, or BBS4, as well as the M390R BBS1 mutation, leads to the excessive accumulation of -tubulin. The cause of excessive accumulation of -tubulin was investigated using a MT depolymerization and repolymerization assay. Abnormal regulation of the level of -tubulin was observed in cultured mutant renal cells. In addition, we uncovered the existence of an induced proteolytic pathway that is responsible for the rapid degradation of -tubulin during MT reassembly after the depolymerization of MTs by nocodazole treatment. We propose that BBS proteins are necessary for assembly, maintainence, and disassembly of the regulatory center in the centrosome and spindle poles for rapid regulation of the level of -tubulin. Failure of regulation of level of -tubulin leads to chromosomal misalignment and aneuploidy during mitosis.

A progress report on suspension FISH combined flow cytometry applied to detection of chromosomal abnormalities. *X. Wu[1,2], Z. Chen[3], J.N. Lucas[1]* 1) ChromoTrax, Inc, Frederick, MD, USA; 2) Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, Hubei, China; 3) Cytogenetics Laboratory, Division of Medical Genetics, Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT, USA.

The broad goal of this research is to develop a novel approach of hybridizing chromosomes in suspension with fluorescently-labeled DNA probes, for flow cytometric analysis in order to sensitively, precisely and rapidly quantify chromosomal abnormalities. In this work we have established interphase suspension FISH. We demonstrated the efficacy of our approach by detecting aneuploidy in trisomy 21 human cells with a DNA probe specific for chromosome 21q. After hybridization in suspension, the majority of interphase cells showed distinct signals. In both the normal and patient groups, the signal distribution patterns between FISH in suspension and on slides were very similar. Recently, we applied suspension FISH to interphase lymphocytes combined with flow cytometry to detect trisomy cells from normal cells. Our results showed a peak shift to the right for trisomy cells relative to that for normal cells, consistent with expected fluorescence density increase for trisomy. Finally, we developed a standard protocol for hybridization of chromosomes in suspension. Using the probes 1q21-SO and 3q26-SO, we observed bright, consistent signals after suspension FISH. Currently, we are applying metaphase suspension FISH combined with flow cytometry for detection of metaphase genome abnormalities.

Plasma Adiponectin is associated with Ghrelin receptor in African-Americans. *X. Zhu[1], H.N. Lyon[2,3], T. Bersaglieri[2,3], M. Egyud[4], D. Kan[1], R.S. Cooper[1], J.N. Hirschhorn[2,3]* 1) Preventive Med & Epidemiology, Loyola Univ Medical Ctr, Maywood, IL; 2) Divisions of Genetics and Endocrinology, Childrens Hospital Boston, Massachusetts and Department of Genetics, Harvard Medical School, Boston, Massachusetts; 3) Broad Institute of Harvard and MIT, Cambridge, Massachusetts; 4) Department of Biology, Boston College.

We previously performed linkage analysis and identified strong linkage evidence of 3q27 to obesity in African-Americans. We are now testing SNPs in 3q27 for a role in obesity and on hormone levels, with a particular focus on growth hormone secretagogue receptor (GHSR, Ghrelin receptor) as the best candidate gene in the region. GHSR has been considered to play an important role in signaling energy insufficiency, and was expected to have a significant effect on feeding behavior and body fat deposition. Plasma adiponectin is inversely correlated with body mass index (BMI). We genotyped 28 SNPs located in GHSR in 606 individuals from 170 African-American families. These SNPs were chosen to capture most of common variation in GHSR (77% in HapMap CEU sample and 56% in YRI data). Linkage disequilibrium reveals this gene consists of four 2-SNP haplotype blocks, with other weak correlated SNPs. We tested the association of the four blocks and the weak correlated SNPs with the residual of log transformation of plasma adiponectin level using family based association test (FBAT) and identified a two SNP haplotype that is significantly associated with plasma adiponectin ($p=0.000008$). Although BMI itself was not significantly associated with the identified haplotype, the association evidence was reduced by adjusting for BMI ($p=0.001$). This is the first study that demonstrates variation in GHSR associated with plasma adiponectin modified by obesity. However, further independent studies are needed to confirm the association.

Development of therapeutic siRNAs for treatment of the skin disorder pachyonychia congenita. *F.J.D Smith[1], R. P. Hickerson[2], H. Liao[1], J. Sayers[1], S. A. Leachman[3], D. Leake[4], R. L. Kaspar[2], W.H.I McLean[1]* 1) Human Genetics Unit, University of Dundee, Dundee, Tayside, United Kingdom; 2) Transderm, Santa Cruz, CA, USA; 3) Department of Dermatology, Univeristy of Utah, Salt Lake City, UT, USA; 4) Dharmacon Inc., Lafayette, CO, USA.

Pachyonychia congenita (PC) is a rare autosomal dominant keratin disorder characterised by hypertrophic nail dystrophy, palmoplantar keratoderma, and oral leukokeratosis. PC is divided into two main types; PC-1 is caused by mutations in keratin K6a or K16 and PC-2 by mutations in K6b or K17. Here, we report 8 recurrent and 2 novel mutations in K6a, and present preliminary studies for a therapeutic approach. Currently there is no treatment for PC and the most painful aspect of the disorder is the plantar keratoderma which can result in wheelchair use. RNAi offers a novel approach for treating genetic disorders such as PC. We have designed four siRNAs against the unique 3UTR region of K6a to target K6a in patients with mutations in this gene. We predict that treatment with K6a siRNA resulting in reduction/knockout of both K6a alleles (mutant and wildtype) could alleviate the symptoms of PC at treated sites. We propose that loss of K6a would be compensated for by other keratins, such as K6b, as demonstrated by transgenic mouse models. Here, in a tissue culture model, we were able to knockdown endogenous K6a in the HaCaT keratinocyte cell line by transient transfection of the four independent K6a siRNAs, resulting in almost 100% reduction of K6a as visualised on protein gels and by immunoblotting. Other keratins present in HaCaT cells were unaffected. These siRNAs were shown to be specific for K6a and not for K6b in a cell culture model. Previously, we have shown that specific siRNAs (but not non-specific controls) strongly inhibit reporter gene expression in vivo (intradermal injection into mouse footpads). These 3UTR K6a siRNAs are being tested in similar animal studies.

Whole genome SNP linkage screen for successful aging loci in the Amish. *W.K. Scott[1], P.J. Gallins[1], H.J. Munger[1], J.L. McCauley[2], L. Jiang[2], P.C. Gaskell[1], A.E. Crunk[2], M. Creason[1], L. Caywood[1], D. Fuzzell[2], C. Knebusch[2], M.C. Morey[1], E.R. Hauser[1], C.E. Jackson[3], J.R. Gilbert[1], M. A. Pericak-Vance[1]* 1) Duke University, Durham, NC; 2) Vanderbilt University, Nashville, TN; 3) Scott & White, Temple, TX.

Successful aging (SA) involves avoiding disease and disability, maintaining cognitive and physical function, and being socially engaged throughout the lifespan. Several components of SA have demonstrated heritability in different samples: longevity, upper extremity strength, lower extremity function, and retention of cognitive ability. The oldest Amish communities of Indiana and Ohio were founded in the mid-1800s by few individuals and remain socially and genetically isolated. Isolation and a relatively homogeneous environment make the Amish a suitable population for identifying complex trait loci. We surveyed cognitively intact Amish age 80 and over, collecting DNA, subjective and objective measures of function, cognition, life satisfaction, and social support. Over 150 individuals have been enrolled in the study and 107 were included in a whole-genome SNP linkage screen (Illumina Linkage Panel IVb) of 460 individuals clustered in 13 kindreds of closely related members. Nine kindreds had two or more of the 43 adults meeting our criteria for SA (cognitively intact, not depressed, satisfied with life, little self-reported limitation in activities of daily living or musculoskeletal function, in the top 1/3 of the sample on a lower-extremity physical function battery, and having adequate social support). 5,902 SNPs were analyzed for linkage to SA using SUPERLINK and affecteds-only dominant (q=0.01) and recessive (q=0.3) models. SNPs on 6 chromosomes generated 2-point lod scores meeting criteria for suggestive linkage (lod > 1.5) under the dominant model: 1q24, 1q32, 4q28, 15q23, 16p12, 17q21, 17q25, and 19q13. The region on chromosome 4q28 is within 20 Mb of the region previously linked to longevity, the 19q13 region is 6 Mb from APOE, and 1q32 contains several genes related to musculoskeletal function. These results suggest that several regions of the genome might harbor loci that influence successful aging in the Amish.

Relationship of peroxisome proliferation-activated receptor-gamma C161-T gene polymorphism with coronary artery disease in Han Race Chinese. *Jing. Wan[1], Jianghu. Ren[2], Yexin. Ma[1], Xin. Tu[1], Maoyin. Cao[2], shixi. Xiong[2]* 1) Cardiology department, Tongji Hospital of Huazhong Science and Technology University, Wuhan city, Hubei Province, China; 2) Zhongnan Hospital of Wuhan university, Wuhan City.

Objective: To investigate the relationship between peroxisome proliferation-activated receptor-gamma (PPAR) C161T gene polymorphism and coronary artery disease (CAD). Methods: 292 subjects were investigated in this study, including 89 healthy persons, 203 cases diagnosed as CAD. PPARC161T gene polymorphism was determined by polymerase chain reaction and restriction fragment length polymorphisms, the blood glucose and the blood lipoprotein were detected. The coronary artery lesions were detected by coronary angiography and analysed quantitatively by Gensini score method. The risk factors of CAD were estimated, and the frequencies of PPARC161T genotypes and the T allele in the CAD and healthy groups were observed. Results: 1, In healthy group, T allele frequency was 0.213, and in CAD group T allele frequency was 0.192. There was no significant difference between the two groups. 2, There was a significant association between PPARC161T genotypes and the number of significantly disease vessels. T allele carriers were far more frequent in patients without than those with significantly diseased vessels ($P<0.05$), and the CAD risk in the T allele carries (OR: 0.56, 95%CI: 0.24-0.63) was much lower than that in the CC homozygote (OR: 1.92, 95%CI: 1.09 -2.54). The results showed that Gensini score in patients with CC genotype was markedly higher than that in patients with Tallele ($p<0.05$). 3, apoB was obviously higher in patients with CC homozygote than those with T allele carriers (1.020.22 and 0.940.23, $P<0.05$).Conclusion: In the Han race Chinese, the distributing trend of PPARC161T gene polymorphism in the healthy group is as the same as that in the patients with CAD group; The Gensini score of the coronary artery angiography in persons with CC genotype are significantly higher than that in the persons with T allele. It means that there is a lower risk of CAD in the patients with T allele.

Progressive CNS lesions in (GCase) null with skin rescued mice and conduritol B epoxide injected Gaucher mice.

Y.H. Xu[1], R. Reboulet[1], B. Quinn[1], J. Huelsken[2], G.A. Grabowski[1] 1) Div Human Gen, Children's Hosp Research Foundation and the University of Cincinnati College of Medicine, Department of Pediatrics, Cincinnati, OH; 2) Ecole Polytechnique Fédérale de Lausanne (EPFL), ISREC (Swiss Institute for Experimental Cancer Research), Switzerland.

Gaucher disease types 2 and 3 are neuronopathic, life-threatening disease variants. We developed neuronopathic mouse models, to facilitate understanding of the molecular mechanism of progressive primary CNS involvement. Since complete knock-outs are lethal in mice, a conditional reactivation model, kn-9h, was developed in which a low activity enzyme (<3% wt activity) was reactivated in skin from a neo-containing D409H allele that was null. The floxed neomycin marker in the neo-D409H allele was excised in keratinocytes using Cre driven by the K14 promoter. All other tissues/cells retained the neo-D409H, i.e., null alleles. kn-9h mice survived for 14 days, but developed progressive lethal CNS disease by 10 days. To mimic this phenotype, CBE, a covalent inhibitor of GCase, was injected daily into wild-type or D409V homozygotes. The kn-9h CNS phenotype was recapitulated in either mouse model with seizures, tail arching, shaking, tremor, and quadra-paresis, with death by 14 days. Histologically, the mouse models had storage cells and glucosylceramide in multiple tissues and extensive CNS neuronal degeneration. Neuronal loss and apoptotic neurons were in spinal cord and brain. Importantly, progressive neuronal degeneration continued for >2 months in D409V homozygotes, but not in wild-type mice after discontinuations of CBE injections. Untreated D409V homozygotes do not spontaneously develop CNS disease or histologic lesions. The CNS signs and pathology in these mouse models mimic Gaucher disease types 2 or 3. These results indicate that CNS deterioration can be progressive even after the initiating insults were stopped and have significant implications for therapy of CNS lesions in Gaucher disease.

Discordance between interphase FISH and cytogenetic results of CVS. *G.S. Sekhon, J.B. Ravnan, E.N. McDonald, D.M. Stenberg, A.N. Lamb* Dept Cytogenetics, Genzyme, Santa Fe, NM.87505.

Interphase fluorescence in situ hybridization (FISH) testing has become a commonly used method of screening direct preparations of prenatal specimens for the common aneuploidies involving chromosomes 13, 18, 21, X, and Y, followed by complete cytogenetic analysis on cultured cells. Because the interphase FISH testing is done on direct preparations of the CVS, there is the potential for discordant results with the chromosome results from cultured preparations, just as discordant results are found between direct cytogenetic preparations and the cultured results. Four cases are presented with discrepant results between the FISH from a direct CVS preparation and cytogenetic analysis on cultured cells out of a total of 2743 FISH tests performed. In all four cases, the initial FISH results were confirmed by repeating the FISH testing on a second slide from the same direct preparation. In two of the four cases, additional FISH testing of the separated layers of the chorionic villus showed that results from the outer layer of the villi (cytotrophoblast) were consistent with the initial direct FISH results, while results from the inner portion of the villi (mesodermal core) were consistent with the cultured cytogenetic results. These findings are consistent with confined placental mosaicism as an explanation for the discordant results. Discordant results between direct and cultured CVS preparations are found in approximately 0.5 % of chromosome analyses performed on both tissue types. Our four cases with discordant results represent 0.1 % of the interphase FISH tests performed on CVS specimens. The lower rate of discordance of interphase FISH is most likely due to the limited nature of the abnormalities that can be detected by FISH in comparison with a full chromosome analysis. Interphase FISH has its limitations in prenatal diagnosis of CVS but in conjunction with chromosomes it can provide useful information. Although FISH can provide preliminary information, caution is necessary when rapid analysis is performed on one layer and chromosomes on the other, just as with conventional cytogenetics on direct and culture preparations in CVS.

Long-term renal stabilization and sustained GL-3 clearance in Fabry patients treated with agalsidase beta. *S. Waldek[1], D. Germain[2], R. Abichandani[3], M. Banikazemi[4], P. Lee[5], W. Wilcox[6], N. Guffon[7]* 1) Hope Hospital, Manchester, United Kingdom; 2) Hôpital Européen Georges Pompidou, Paris, France; 3) Genzyme Corporation, Cambridge, MA; 4) Mount Sinai School of Medicine, New York, NY; 5) National Hospital for Neurology and Neurosurgery, London, UK; 6) Cedars-Sinai Medical Center, Los Angeles, CA; 7) Hôpital Edouard Herriot, Lyon, France.

BACKGROUND: Fabry disease, an X-linked lysosomal storage disorder caused by deficient alpha-galactosidase A (-GalA), results in progressive lysosomal accumulation of globotriaosylceramide (GL-3) and ultimately premature death from renal, cardiac, and cerebrovascular manifestations. This study was conducted to determine long-term safety and efficacy of treatment with recombinant human (rh) -GalA (agalsidase beta) in patients (pts) with Fabry disease. METHODS: This was a multicenter, open-label, phase III extension study of 58 pts with Fabry disease who completed a 20-week, double-blind phase III study and transitioned to an extension study to receive biweekly 1 mg/kg rh--GalA infusions for up to 54 months. GL-3 accumulation was evaluated in capillary endothelium of the skin, kidney and heart. Renal function was also assessed. RESULTS: After 54 months of agalsidase beta therapy, continued, (near) complete clearance of the capillary endothelium of the skin was demonstrated. In those pts (N=8) with kidney biopsies similar GL-3 clearance in renal capillary endothelial cells was shown, and clearance was also observed in other renal cell types. Mean plasma GL-3 levels were quickly normalized, and remained in the normal range at Month 54 (N=44). Median serum creatinine and estimated GFR remained stable (normal) at Month 54 (N=41). Six pts had renal disease progression; 4/6 were over 40 years and 5/6 had significant proteinuria and/or >50% glomerular sclerosis at baseline. Infusion-associated reaction was the most common drug-related AE. CONCLUSIONS: Long-term rh--GalA therapy in pts with Fabry disease results in sustained clearance of capillary endothelial cells, multiple renal cell types, and reduction of GL-3 in the plasma,. Long-term rh--GalA therapy stabilized renal function in patients without advanced renal disease at baseline.

Epidemiology of Congenital Malformations in Scotland. *A.D. Rasalam[1], J.C. Dean[1], D. Clark[2], R. Dobbie[2], D. Tennyson[2]* 1) Department of Medical Genetics, Aberdeen, Scotland; 2) Information Services Division, Edinburgh.

Most large prospective or population based studies have suggested a malformation rate in children exposed to Anti-Epileptic Drugs (AEDs) before birth of around 6-9%, compared with a background risk of 3%. In our previous population based study in Aberdeen, the malformation rate was 14% in those exposed to AEDs, and 5% in unexposed siblings. We suggested this higher rate might be due to the longer follow-up period in our study. A recent register based study reported a substantially lower malformation rate of 2.2 - 6% for exposed children, but used a different definition (Eurocat) of major malformation. In Scotland, all malformations collated from routine administrative data are notified to the Information Services Division (ISD) at birth and during subsequent hospital admissions. Maternal illnesses are similarly coded and notified. We undertook a records linkage study using the ISD Scottish Linked Congenital Anomalies Register to determine malformation rates in all singleton births (565731) in Scotland between 1992 and 2001, according to whether mothers had epilepsy, bipolar disorder (BPD) or neither of these. 2001 was chosen as the latest year of birth in the study, so that at least 5 years follow-up data would be available for the children. Disease coding used ICD9 or ICD10 definitions. Malformations were diagnosed in 12.3% of all deliveries (6.6% by 28 days of age), in 14.6%; of children of mothers with epilepsy (7.6% by 28 days) and 12.2%; of children of mothers with BPD (6.6% by 28 days). When Eurocat definitions were used, the background rate was 5.9% (4.3% by 28 days), the rate for children of mothers with epilepsy was 7.2% (5.1% by 28 days) and 6.6% (4.9% by 28 days) for children of mothers with BPD. These data show that the background malformation rate is higher than expected, Eurocat definitions underestimate malformation rate, many malformations are diagnosed after 28 days of age, and that maternal epilepsy is associated with significantly increased malformation rates compared with background and with maternal BPD. Part of this additional risk may be due to teratogenic effects of AEDs.

A second MHC susceptibility locus for multiple sclerosis. *S.J. Sawcer for the International Multiple Sclerosis Genetics Consortium (IMSGC)* Clinical Neurosciences, University of Cambridge, Cambridge, United Kingdom.

Variation in the Major Histocompatibility Complex (MHC) on chromosome 6p21 influences susceptibility to multiple sclerosis, with the DR15 haplotype (HLA-A3-B7-Cw7-DR15) being the most consistently identified risk factor. The high gene content, extreme polymorphism and extensive linkage disequilibrium (LD) that characterise the MHC have confounded efforts to resolve the nature of this association. The strongest effect originates in the class II region, with the DRB1 gene identified as the primary susceptibility locus. The possibility that other genes in the MHC independently influence susceptibility to multiple sclerosis has been suggested but remains unconfirmed. Here we show that the class I Human Leukocyte Antigen (HLA) gene, HLA-C, exerts an independent effect on susceptibility to multiple sclerosis. After excluding effects attributable to the DR15 haplotype we found residual evidence for association, maximal in the region of HLA-C, in independent simple nuclear family cohorts from the US (n=450) and UK (n=480). By extending analysis of the classical loci into 721 additional sporadic cases, and utilizing data from 3660 controls, we refined this secondary signal and show that it is partly due to allelic heterogeneity at the HLA-DRB1 locus, and partly due to an independent effect from the HLA-C locus ($p=5.9x10^{-5}$). Our results enhance understanding of the established DRB1 association in multiple sclerosis and identify a novel second susceptibility locus for this disease. The identification of HLA-C as a risk factor in multiple sclerosis implicates innate immune mechanism in particular the killer cell immunoglobulin-like receptors (KIRs). These results open up new opportunities for future research activities.

Association Study of Reading Disabilities and Genes in the Chromosome 15q21.3 region. *K. Wigg[1], J. Couto[1], Y. Feng[1], B. Anderson[2], T. Cate-Carter[2], R. Tannock[2], M. Lovett[2], T. Humphries[2], C.L. Barr[1,2]* 1) Cell & Molecular Div, Toronto Western Hosp, Toronto, ON, Canada; 2) Brain and Behaviour Programme, The Hospital for Sick Children, Toronto, ON, Canada.

Reading disabilities (RD) have been linked to a number of chromosomal regions including 15q. Recently a gene in the 15q region, EKN1, was identified via a translocation breakpoint in a family cosegregating with RD (Taipale et al, 2003). Several single nucleotide polymorphisms (SNPs) in this gene were found to be associated with reading disabilities in a small sample of families from Finland. In our sample of 148 families identified through a proband with reading difficulties, we found evidence for allelic association for one of these SNPS in EKN1 to the phenotype of RD identified as a categorical trait marker (chi-squared=5.586, 1 d.f., p=0.018) and to the reading component processes using quantitative analysis (Wigg et al., 2004). However, association was observed with different alleles and haplotypes than those reported to be associated in the Finnish sample. Several other follow up studies have not replicated the original findings (Meng et al, 2005, Marino et al, 2005) This indicates that the SNPs identified as associated are unlikely to be the functional DNA change contributing to reading disabilities. It may be in linkage disequilibrium with another variation, possibly in the regulatory region of EKN1 or in another gene in the region. We have expanded our study of the 15q region to include other possible candidate genes: Phosphatidylinositol glycan (PIGB), cell cycle progression 1 isoform 1 (CCPG1), pygopus homolog 1 (PYGO1), protogenin (PRTG) and neural precursor cell expressed (NEDD4). SNPs across these genes are being genotyped in our RD sample, and preliminary results show suggestive evidence of linkage in three of the SNPs genotyped ($p<0.09$). These results suggest that further studies of the genes in this region is warranted.

Noncompaction of the ventricular myocardium and hydrops fetalis in cobalamin C deficiency. *P. Tanpaiboon[1], P.F. Callahan[2], J. Sloan[1], D. Zand[3], U. Lichter-Konecki[3], C.P. Venditti[1]* 1) National Genome Research Institute, NIH, Bethesda, MD; 2) Child Cardiology Associates, Fairfax,VA; 3) Division of Genetics and Metabolism, Childrens National Medical Center, DC.

Noncompaction of the ventricular myocardium (NCV) is a rare congenital cardiomyopathy, believed to be caused by arrest of normal compaction process of endomyocardium. The phenotypes observed in affected individuals are highly variable ranging from asymptomatic to hydrops fetalis. Mutations in genes involving muscle structures and functions have been reported. Other than Barth syndrome, no inborn errors of metabolism associated with this condition have been described. We report a 2-year-old girl who presented with hydrops fetalis at gestational age 22 weeks. Fetal echocardiography revealed possible tricuspid atresia and poor biventricular function. The patient was born at 37 weeks. Neonatal echocardiography performed shortly after birth demonstrated noncompaction of the left ventricle and mild to moderate left ventricular dysfunction. At 3 days of age, metabolic evaluations revealed homocysteinemia and methylmalonic aciduria. Complementation studies assigned the patient to the cblC group and mutation analysis revealed a homozygous c.271dupA in the *MMACHC* gene. A repeat echocardiogram at 6 months of life showed improved left ventricular function with a low normal range ejection fraction. Ejection fraction at 30-month-old was sixty percent and fractional shortening was twenty seven percent. Cardiac function continued to stabilize and digoxin initiated in the first few days of life was discontinued at 18 months. This is the first report of cobalamin C deficiency associated with noncompaction of the ventricular myocardium. The findings seen in this patient expand the spectrum of prenatal and cardiac manifestations seen in this disorder, and raise the question of whether noncompaction of the ventricular myocardium will be seen in other cblC patients, especially those who have been described as having cardiomyopathy.

A simplified medium-throughput 48-plex SNP genotyping method. *L. Pawlikowska[1], C. Chu[1], Z. Jiang[2], P.-Y. Kwok[1]* 1) Ctr for Human Genetics and Cardiovascular Research Institute, University of California - San Francisco, San Francisco, CA; 2) Beckman Coulter, Fullerton, CA.

Current genotyping methods based on primer extension typically employ 6 sets of dye-labeled terminators to cover the 6 possible SNP allele combinations. For multiplex genotyping, the requirement that all SNPs in a panel have the same allele combination poses a design challenge for smaller projects with fewer than 400 SNPs, resulting in multiple incompletely filled panels and reduced efficiency. To overcome this limitation, we have explored the use of 2 fluorescent labels in a reagent set containing all 4 terminators (labeling 2 terminators with each dye). We have applied this strategy to the SNPstream 48plex genotyping system (Beckman Coulter), which uses multiplex PCR and single base primer extension chemistry on 384-well tag-array plates to genotype 48 SNPs simultaneously. The platform thus occupies a useful experimental space for mid-size (40-400 SNPs) genotyping projects, such as candidate gene studies and follow-up studies to larger scans. We have adapted the SNPstream 48plex to genotype mixed panels containing 4 SNP extension types using existing terminators labeled with two fluorescent dyes (TAMRA and Bodipy). Combining Bodipy-labeled A and T with TAMRA-labeled C and G allows for genotyping of CT, AG, GT and AC, i.e. all but the rarest (AT and CG), SNP allele combinations together. Alternatively, combining Bodipy-labeled C and T with TAMRA-labeled A and G permits genotyping of TG, CA, TA and CG SNPs.

We have genotyped 3 different mixed 48-plex SNP panels on a cohort of 95 human DNA samples with 81.3%3.6% average conversion rates and 96.4%1.3% average call rates. Genotyping accuracy was 100% using 5 duplicates included in the DNA panel, and 99.7%0.13% as compared to HapMap genotypes genotyped by singleplex primer extension. The mixed panels thus performed comparably to standard single-allele combination 48plex panels. We are implementing this streamlined medium-throughput genotyping method in several human candidate gene association and mouse mapping studies.

Detection of copy number changes in patients with mental retardation using high density SNP microarrays. *J. Wagenstaller[1], S. Spranger[2], B. Heye[5], B. Kazmierczak[2], M. Cohen[3], P. Freisinger[4], T. Meitinger[1,5], M. Speicher[1,5], T.M. Strom[1,5]* 1) Institute of Human Genetics, GSF National Research Center, Munich, Germany; 2) Praxis für Humangenetik, Bremen, Germany; 3) Kinderzentrum, Munich, Germany; 4) Children's Hospital, Technical University; Munich, Germany; 5) Institute of Human Genetics, Technical University; Munich, Germany.

Whole genome analysis using high-density SNP oligonucleotide arrays allows identification of yet unknown microdeletions, microduplications and uniparental disomies. We collected a cohort of 70 children and, when available, their parents with unexplained mental retardation with and without additional symptoms. High resolution banding analysis and metabolic investigations were inconspicuous. The genomic DNAs were analyzed using the Affymetrix GeneChip 100K array. Data analysis was performed with median normalization and genotype-specific dosage calculation using R-scripts and revealed 11 de novo copy number changes (CNCs), 8 deletions and 3 duplications. These CNCs varied in size from 500 kb to 10 Mb. Four of the CNCs were flanked by low-copy number repeats. A 1 Mb deletion in 17q21.3 has also been found deleted in other studies and encompasses a known inversion polymorphism of 900 kb. These deletions may define a new microdeletion syndrome. We also looked for known and new copy number variations (CNVs) in 100 healthy parents. Our data revealed 7 known and 68 new CNVs, most of them were unique. This supports the previous notion that at least the larger CNVs have a low population frequency. We compared the 100K Affymetrix platform with platforms that promise a higher resolution. The signal-to-noise ration (SNR) of the 500K Affymetrix array was considerable lower than the SNR of the 100K Affymetrix arrays and did not significantly increase the overall resolution. The SNR of the 300K Illumina arrays was somewhere in between. In summary, the resolution of copy number variation detection with 100K Affymetrix arrays is currently comparable with the resolution of BAC-array CGH. The increase of the number of features and the new design of feature localization should allow detection of single-gene deletions and known microdeletion syndromes.

A rapid and sensitive method for RNA integrity determination on capillary electrophoresis systems. *A.B. Shah[1], S. Karudapuram[1], L.K. Joe[1], M. Rhodes[1], Y. Lou[1], J. Keefe[1], J. Briggs[1], M. Wenz[1], C. Waldron[1], C. Carver[2], S. Bass[2]*
1) Applied Biosystems, Foster City, CA; 2) Gene Logic Inc., Gaithersburg, MD.

RNA quality is directly correlated to the success of various applications, such as microarray or real time qPCR-based gene expression analyses, cDNA library construction, Northern analyses, and RNAse protection assays, which utilize RNA samples from various organisms, tissues, cell lines, and precious biological samples. We present a novel method for examining RNA integrity using capillary electrophoresis that is more cost-effective and scalable than current standard methods. In addition, the sensitivity of the technique allows for use of less material and for the detection of impurities following RNA purification and degradation from nuclease contamination. Total RNA, derived from various tissues and cell lines, were stained with the dye SYBR-Green II and run through a custom polymer formulation on a capillary electrophoresis platform. Using downstream analysis software, we resolved RNA species and their relative quality based on parameters such as sizing, profile, peak area, and peak height. Our results highlight the potential for high-throughput capillary electrophoresis as a much more discriminatory and cost-saving method in evaluating RNA purity.

Discovery and association of gamma-glutyml carboxylase (GGCX) polymorphism with warfarin dosing. *M.J. Rieder* Genome Sciences, University of Washington, Seattle, WA.

Gamma-glutyml carboxylase (GGCX) is a component of the vitamin K cycle and carries out the carboxylation of protein glutamic acid (Glu) residues to gamma-carboxyglutamic acid (Gla), and results in the activation of several vitamin K dependent clotting factors (e.g. F2, F7, F9, F10). Given the critical role of GGCX in mediating this reaction, we studied the effect of GGCX polymorphisms that may influence the dosing requirements of patients stabilized on the anticoagulant warfarin. We performed complete resequencing in 16 kb encompassing GGCX in a discovery population of European-Americans (n=23), identifying 29 single nucleotide polymorphisms (SNPs) and indel polymorphisms. LD-Select was used to cluster these polymorphisms into six tagSNP bins ($r^2 = 0.65$). TagSNPs for GGCX were tested for an association with warfarin dosing in a well-studied clinical population (n = 186), using univariate, multivariate, and haplotype-based linear regressions. After adjusting for covariates such as other genetic (i.e. CYP2C9 and VKORC1) and patient factors (i.e. age, sex, amiodarone, losartan), all models revealed a single, noncoding tagSNP (GGCX-12970; C/G-0.11/0.89 allele frequency) associated with warfarin dose. No other polymorphisms in GGCX were found to be linkage disequilibrium with this tagSNP. Under the univariate, dominant effects model, homozygous carriers of the 12970-G allele had a higher warfarin dose requirement than 12970-C carriers (5.42.6 vs 4.62.3 mg/d). Full multivariate regression analysis showed that the GGCX-12970 polymorphism explained approximately 2% of the variance in warfarin dose (permutation p-value <0.02, dominant model). Haplotype analysis, used to infer and test for a warfarin dose association using a generalized linear model, revealed a single haplotype effect ($p < 0.03$, dominant model). This distinctive haplotype was the only carrier of the GGCX-12970/C allele. Both single SNP and haplotype associations suggest that GGCX-12970 contributes independently to the variability in warfarin dosing, and work is ongoing to understand the mechanism by which this SNP acts on this widely prescribed anticoagulant.

Variable functional impairment of RMRP mutations explain genotype - phenotype correlation in Cartilage hair hypoplasia and Anauxetic dysplasia. *C.T. Thiel[1], G. Mortier[2], I. Kaitila[3], A. Rauch[1]* 1) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany; 2) Department of Medical Genetics, Ghent University Hospital, Ghent, Belgium; 3) Clinical Genetics Research, University of Helsinki, Helsinki, Finland.

Mutations in the RMRP gene have been demonstrated to cause a wide phenotypic spectrum from Anauxetic dysplasia (AD) and Cartilage hair hypoplasia (CHH) to Metaphyseal dysplasia without hypotrichosis (MDWH). The RMRP gene encodes the RNA subunit of the ribonucleoprotein endoribonuclease, RNase MRP. So far, 5 mutations causing Anauxetic dysplasia, at least 62 mutations causing CCH and MDWH, and 8 SNPs have been identified. We recently demonstrated that RMRP gene mutations affect growth regulation by altering cyclin dependent cell cycle regulation and impaired ribosomal assembly (Thiel et al. 2005 Am J Hum Genet). Mutations located between the TATA box and the transcription starting site are reducing the transcription level of the RNA subunit. To clarify the influence of different base substitutions within the transcript on the clinical phenotype, 13 CHH/MDWH and 2 novel AD mutations each in different functional domains of the RMRP gene were tested for rRNA and mRNA cleavage activity. Whereas the AD mutations g.14GA and c.256_265delCAGCGCGGCT revealed a lack of expression, all remaining mutations demonstrated a variable decrease in cleavage activity. The degree of short stature and skeletal dysplasia correlated with the overall functional impairment, but mainly of rRNA cleavage activity (ribosomal assembly). Whereas significantly diminished mRNA cleavage activity (cyclin dependent cell cycle regulation) was a prerequisite for immunodeficiency. Thus, the clinical phenotype emerges in most cases of the combined effect of either a hypomorphic allel, hyploinsufficiency, or the respective effect on the cleavage activity.

Linkage analysis identifies a novel locus for Restless Legs Syndrome on chromosome 2q in a South Tyrolean population isolate. *I. Pichler[1], F. Marroni[1], C. Beu Volpato[1], S. Pedrotti[1], J.F. Gusella[2], C. Klein[3], G. Casari[4], A. De Grandi[1], P.P. Pramstaller[1,3,5]* 1) Institute of Genetic Medicine, European Academy, Bolzano, Italy; 2) Molecular Neurogenetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Boston MA, USA; 3) Department of Neurology and Human Genetics, University of Lübeck, Germany; 4) Vita-Salute University and San Raffaele Scientific Institute, Milan, Italy; 5) Department of Neurology, General Regional Hospital, Bolzano, Italy.

Restless legs syndrome (RLS) is a common neurological condition with three loci (12q, 14q, 9p) described so far though none of these genes has yet been identified. Isolated populations provide a powerful approach for mapping genes associated with complex disease phenotypes due to reduced genetic heterogeneity and environmental noise. We systematically assessed a population isolate in South Tyrol (Italy) for the presence of RLS. A 4-cM genome-wide scan was performed, including all idiopathic RLS patients (n=37) who originated in a small isolated village. Using both nonparametric and parametric analyses, we initially obtained suggestive evidence for a novel RLS locus on chromosome 2q. Follow-up genotyping yielded significant evidence for linkage (NPL score = 5.5, P value = .0000033; HLOD score = 5.1; = 1.0). Model-based linkage analysis was performed under the assumption of an autosomal dominant mode of inheritance. Haplotype analysis revealed a shared disease-haplotype between two families (Fam.S01 and Fam.S05) defining a candidate region of 8.2 cM; in addition, the affected individual in Fam.S016 shared three linked alleles at neighboring markers, suggesting a reduced candidate interval of only 1.6 cM. The three families were shown to descend from a common founder couple living in the 18th century resulting in a ten-generation pedigree. Two-point linkage analysis of this pedigree further supported the novel RLS locus on chromosome 2q (LOD score = 4.1). These findings re-emphasize the genetic heterogeneity of the disorder and strongly support the identification of a novel locus for RLS on chromosome 2q. Sequence analysis of the region to identify the causative gene is in progress.

The proposed association of ovarian cancer with Birt-Hogg-Dube syndrome. *S. Randall Armel, A. Pintzov, M. Howe, B. Rosen* Familial Ovarian Cancer Clinic, Princess Margaret Hospital, Toronto, Ontario, Canada.

Birt-Hogg-Dube syndrome (BHD) is an autosomal dominant condition characterized by multiple neoplasms that exhibits variable expressivity both within and between families. To date, more than 60 affected families have been identified from various populations. The most common manifestations of BHD are skin abnormalities, specifically fibrofolliculomas, acrochordons and trichodiscomas, which first appear in the patients thirties or forties. Other common symptoms include the appearance of lung cysts, spontaneous pneumothorax, and renal tumors. Less common symptoms that have been reported include colonic polyps and hereditary medullary thyroid carcinoma (MTC). We present a case of a 46-year-old woman affected with BHD presenting with freckles, breast lumps beginning in her thirties, enlarged thyroid and ovarian cancer (malignant mixed mullerian tumor). Full genetic analysis of BRCA1/2 in this patient was negative; however, she was found to carry a 1285insC mutation in the FLCN gene, which codes for folliculin. This mutation occurs in a C8 tract in exon 11, where 44% of all BHD mutations occur. Family history was remarkable, with at least one confirmed diagnosis of BHD in the probands niece, who presented with a colon adenoma, multiple (>80) trichodiscomas, breast lumps and a spontaneously resolving ovarian cyst. Several first and second-degree relatives presented with various cancers, including thyroid, colon and melanoma. In the literature, there has been one additional report of an ovarian cyst that was considered unrelated to the diagnosis of BHD at the time. To date, there are no other reported associations of ovarian cancer with a mutation in the FLCN gene. These findings suggest that a patient with BHD may be at an increased risk for developing ovarian cancer above that of the general population. We propose that women diagnosed with BHD should be offered ovarian cancer screening, consisting of annual transvaginal ultrasounds and CA125 blood tests.

Absence of ataxin-3 causes transcriptomic de-regulation of the ubiquitin-proteasome pathway, signal transduction, transcription regulation, and cell-structure/motility genes in *C. elegans*. *A.J. Rodrigues[1], G. Coppola[2], C. Santos[3], M.C. Costa[1], M. Aillion[4], J. Sequeiros[3], D. Geschwind[2], P. Maciel[1]* 1) ICVS/ECS,Univ. of Minho,Braga,Portugal; 2) Neurogenetics,Dept of Neurology,UCLA,Los Angeles,USA; 3) UnIGENe,IBMC,Porto,Portugal; 4) Dept of Biology,Univ. of Utah,Salt Lake city,USA.

Machado-Joseph disease is the most common dominant spinocerebellar ataxia and is caused by a CAG expansion in the *ATXN3* gene which encodes for ataxin-3. Ataxin-3 has been proposed to i) act as a deubiquitinating (DUB) enzyme in the ubiquitin-proteasome pathway, ii) be involved in transcriptional repression and iii) be related to structural and motility-related proteins.

To gain further insight into the function of ataxin-3, we have identified the *Caenorhabditis elegans* orthologue of the *ATXN3* gene and characterized its pattern of expression, developmental regulation and subcellular localization of the respective protein. We also demonstrate that, analogous to its human orthologue, *C. elegans* ataxin-3 has DUB activity *in vitro* against polyubiquitin chains. Mutations in the putative catalytic cystein C20 inhibit DUB activity and the josephin domain alone was capable of cleaving the polyubiquitin chains. Mutations in the two ubiquitin-interacting motifs did not interfere with ataxin-3 DUB activity.

We also characterized the first known ko animal models for ataxin-3 and found that the two strains were viable and displayed no gross phenotype. However, a microarray analysis of gene expression in both ko strains revealed a significant de-regulation of core sets of genes involved in the ubiquitin-proteasome pathway (7.5%), structural/motility components (50%), signal transduction (20.4%) and transcription regulation (4%). Interestingly, of these 290 differentially expressed genes, 253 were upregulated and 37 were downregulated. This gene identification provides important clues that can help elucidate the specific biological role of ataxin-3 and unveils some of the physiological effects caused by its absence or diminished function.

Performance of putatively functional variant assays in drug metabolism genes across multiple control populations using the Applied Biosystems TaqMan DME panel. *R. Welch[1], K. Haque[1], T. Harkins[2], F. Hyland[2], K. Lazaruk[2], F.M. De La Vega[2], M. Yeager[1]* 1) Core Genotyping Facility, DCEG, NCI. SAIC-Frederick, Inc., NCI-Frederick, Frederick, Maryland; 2) Applied Biosystems, Foster City, CA, USA.

A number of candidate genes encode enzymes responsible for the metabolism of drugs and other xenobiotics. Genetic variation in these Drug Metabolism Enzyme (DME) genes accounts for some of the variability in the effect of drugs in humans, and may contribute to complex disease. The CGF has genotyped N=2394 individual TaqMan assays in 220 DME genes, and has examined genetic variation among two groups of populations, 1) the International HapMap populations; and 2) the SNP500Cancer populations (http://snp500cancer.nci.nih.gov). In addition, the CGF has sequenced / genotyped, by alternative methodologies, 500 of the same SNPs in overlapping sets of individuals. We present an analysis of the DME variants typed and assay performance among various populations. 62% of these putative functional variants were polymorphic in at least one population. In/dels, splice site, missense, and nonsense SNPs were more likely to appear monomorphic (or have lower MAF than this study can detect) than the other types of variants. MAF in these variants were low (e.g. mean MAF of 0.16 in Europeans when polymorphic) as expected, since alleles likely to be under strong purifying or directional selection. Completion and concordance rates (internal duplication) for all assays were 99%. Further, genotype comparisons examining data generated at the CGF and previously published genotype / sequencing data for the same SNPs shows high concordance. However, interesting differences exist between CGF-generated data and the HapMap published data. Mendelian transmission analysis for the trios and relateds shows little inconsistency. Ongoing analyses include relative coverage of the data generated by the HapMap and studies in population genetics. In summary, this panel of assays performed extremely well on controls, and the CGF continues to investigate these SNPs in pharmacogenetic studies relevant to cancer. Funded by NCI Contract N01-CO-12400.

A Novel Glutamic Acid-358 to Glutamine Substitution Mutation in Ectodysplasin A causes X-linked Dominant Incisor Hypodontia Not X-linked Hypohidrotic Ectodermal Dysplasia. *P.S. Tarpey[1], T.J. Pemberton[2], D.W. Stockton[3], P. Das[4], V. Ninis[4], S. Edkins[1], P.A. Futreal[1], R. Wooster[1], S. Kamath[5], R. Nayak[6], M.R. Stratton[1], P.I. Patel[2]*
1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, Cambridgeshire, United Kingdom; 2) Institute for Genetic Medicine and the Center for Craniofacial Molecular Biology, University of Southern California, Los Angeles, CA; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Department of Neurology, Baylor College of Medicine, Houston, TX; 5) Kasturba Medical College, Mangalore, India; 6) Ambedkar Medical College, Bangalore, India.

The congenital absence of one or more teeth, or hypodontia, is classified as syndromic when it is associated with anomalies in other organs and non-syndromic when the anomaly is confined to teeth. We ascertained a large Asian Indian family that presented with a unique and rare apparently non-syndromic X-linked dominant hypodontia of their incisor teeth. Linkage analysis using 45 markers on the X-chromosome identified a 22.7 Mb interval on Xp11.22-Xq13.2 that contains 175 known and predicted genes. DNA from two affected males was included in an automated high-throughput mutation detection screen to systematically search for mutations within these genes. A c.1072C>G missense mutation in exon 8 of the ectodysplasin A (EDA) gene, mutations within which have been previously implicated in X-linked hypohidrotic ectodermal dysplasia (XLHED), was identified as the causative mutation in this family. This mutation predicts a substitution of glutamic acid for glutamine at amino acid residue position 358 (Q358E) in the TNF domain of the encoded EDA protein. Based on reported structural and functional observations for EDA, we hypothesize that the relatively conservative Q358E substitution only partially disrupts the interaction of the EDA homotrimers and their target receptors, affecting their function significantly only in the dental tissues, resulting in the observed unique hypodontia phenotype rather than the full XLHED phenotype associated with other mutations in the EDA gene. (Supported by NIH grant DE01412).

Sensitivity and specificity of detecting minor allele fractions through High-Resolution melting analysis. *G.H. Reed, Y. Wang, C.T. Wittwer* Pathology, University of Utah, Salt Lake City, UT.

Background: Detection of minor allele fractions is important in cancer diagnosis, detection of recurrence, detection of fetal DNA in the maternal circulation, and population studies of low frequency genes. The sensitivity of sequencing is limited to an allele fraction of around 20%. Methods: Detection of allele fractions ranging from 0.25% to 50% were evaluated using a double stranded DNA dye (LCGreen Plus), real-time PCR (LightCycler) and high resolution melting analysis (LightScanner and HR-1). For PCR templates we used mixtures of genomic DNA for HFE H63D, paroxysmal nocturnal hemoglobinuria, RhD, and the 2 bp deletion in the NCF-1 gene associated with chronic granulomatous disease. In addition, three different plasmids differing in their average GC content (40, 50, 60%) were used. Homozygous fractions were mixed to achieve various allele fractions. The presence or absence of variation was assessed by a blinded investigator using melting curve shape after fluorescence normalization and temperature overlay. Two unknown melting curves were always compared to two known homozygous melting curves for assessment of sensitivity and specificity. Results: Over 2,500 different blinded calls on various targets indicate that we can identify allele fractions as small as 0.25% with a sensitivity of 95-100% and a specificity of 83-97%. Accuracy depended on the allele fraction, with lower allele fractions more difficult to call correctly. The position of the mutation, the GC content of the PCR product and the choice of instrument did not appear to affect the results. Conclusion: Allele fractions down to 0.25% can be distinguished from the wild type through high resolution melting analysis. In addition to being superior to sequencing and most existing methods in detecting minor allele fractions, our method has the added advantage that it is a simple, rapid and inexpensive closed-tube alternative, which makes sample separation unnecessary.

Barriers and Motivators to Family-Based Screening for Hereditary Hemochromatosis (HH). *D.K. Wagener[1], K. Bandel[1], M. Reyes[2], D. Dunet[2], M. Trisolini[1]* 1) RTI International, Rockville, MD; 2) Centers for Disease Control and Prevention, Atlanta, GA.

Health care providers can facilitate detection of hereditary hemochromatosis (HH) and associated iron overloading in the body by counseling patients about the need for their family members to have a diagnostic test for iron overload. This qualitative research study used interviews and focus groups with HH patients (n=60), siblings of patients (n=25), and health care providers who treat patients with HH (n=10) to understand barriers and motivators to: (a) communication about HH and the need for diagnostic testing; and (b) the actions taken by siblings in response to being told they are at risk for HH. This report focuses on patients and siblings. Most HH patients recalled being told by their physician that family members should be advised to have diagnostic testing. HH patients passed this information to their siblings. HH patients identified factors which motivated communication with their siblings including: a high perceived seriousness of HH; perceived benefit of a diagnostic test; and a doctor's recommendation or Internet health information suggesting that siblings be tested. Barriers included estranged relationships with siblings; and, in one case, the perception that diagnostic testing was of little benefit to a sibling who was already ill and disabled. Our analyses indicate that the following factors motivated siblings of HH patients to seek diagnostic testing: perception that HH is serious; perceived benefit of screening; and knowing someone--especially a family member--who had a related complication or died of HH. Siblings who did not seek diagnostic testing identified these barriers: perception that personal risk of HH is low; belief that doctor would have mentioned HH if it was serious; perception that personal risk is low due to lack of symptoms; lack of understanding that HH is hereditary; costs of testing; worries about future insurability; and lack of routine doctor visits.

Overexpression of CUGBP suppresses the Fragile X CGG premutation repeat induced neurodegeneration in Drosophila melanogaster. *O. Sofola[1], R. Duan[2], P. Jing[2], D. Nelson[1], J. Botas[1]* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept Molec & Human Genetics, Emory University, Atlanta, GA.

Fragile X Syndrome is the most common form of hereditary mental retardation. It is caused by a large expansion of the CGG trinucleotide repeat (>200 repeats) in the 5 untranslated region of FMR1 that leads to transcriptional silencing of the gene. Individuals with CGG repeat expansions between 60 and 200 are referred to as premutation carriers. These premutation carriers are able to transcribe FMR1 and hence are phenotypically normal with respect to the features of Fragile X syndrome. However, a neurodegenerative disorder has recently been described in premutation carriers. A transgenic fly model expressing the 5 UTR of the human FMR1 gene with 90 CGG repeats was designed by Jin and colleagues to examine whether the premutation length repeat could cause neurodegeneration. The repeats are transcribed into RNA but are not translated into protein; flies expressing these CGG repeats in the eye display a disorganized eye phenotype. Furthermore, the eye phenotype could be suppressed by over expressing hsp70, a chaperone involved in protein folding. These results suggested that transcription of the CGG90 repeats lead to an RNA mediated neurodegenerative disease, possibly via influencing RNA binding proteins. We set out to identify these RNA binding proteins by carrying out a genetic screen on the CGG90 eye phenotype. The screen involved mating the CGG90 transgenic flies with other candidate mutant flies that expressed either a reduced or an increased level of different proteins. The progeny were examined for potential suppression or enhancement of the disorganized eye phenotype seen in control CGG90 transgenic flies. We show that overexpression of human CUGBP1, an RNA binding protein is able to suppress the neurodegenerative phenotype of the CGG90 transgenic fly. Furthermore, we show that the CUGBP1 protein is able to interact with the CGG repeats via hnRNPA2/B1, another RNA binding protein. These findings suggest potential pathways that are disturbed by expression of expanded CGGs that may contribute to neuronal degeneration.

Identification of Novel Asthma Susceptibility Loci Using a Family-Based Screening Approach. *K.G. Tantisira[1], A. Murphy[2], A.A. Litonjua[1], J. Lasky-Su[1], B.A. Raby[1], R. Lazarus[1], B. Klanderman[1], E.K. Silverman[1], C. Lange[2], S.T. Weiss[1]* 1) Channing Laboratory, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 2) Harvard School of Public Health, Boston, MA.

Introduction: The evaluation of genetic datasets to identify asthma susceptibility loci has been limited by multiple comparisons and failure to replicate. We hypothesized that a screening algorithm in the program FBAT would help to overcome these problems. The algorithm screens using the between family-component in order to identify candidates with the greatest power for association within the informative families, limiting the number of tests performed within the families. **Methods:** We tested the association of 861 single nucleotide polymorphisms (SNPs) in 116 candidate genes with asthma affection status in 400 Caucasian trios consisting of parents and Childhood Asthma Management Program probands. The screening algorithm identified and ranked SNPs in order of statistical power. Only the most powerful SNPs were formally evaluated by FBAT testing. **Results:** 570 SNPs in 62 genes had never previously been analyzed. Of SNPs ranked in the highest quintile of statistical power, SNPs in 20 genes were significantly associated with asthma affection status within the trios (p-values 0.0007-0.047). Among these were four genes that we have previously identified as asthma susceptibility genes (IL10, TBX21, TLR10, and VDR), supporting the validity of this approach. Three additional genes (NOS3, PLN, and BDKRB2) have been associated with asthma by others. Of the remaining genes, PTGIR, ITPR2, NDFIP1, ADCYAP1, CREB5, and RGS12 were both associated with asthma and within the top 5% of power, suggesting the greatest potential for replication. **Conclusions:** Novel asthma susceptibility genes have been identified using the FBAT screening approach, which may help address problems of multiple comparisions and poor likelihood of replication. Formal replication studies are planned.

Investigation of the *TNF receptor-associated factor (TRAF)* genes with rheumatoid arthritis. *C. Potter, J. Worthington, A. Barton* ARC-EU, Univ Manchester, Manchester, United Kingdom.

Background: The TNF receptor-associated factor (TRAF) family is an important group of intracellular adapter proteins for a wide variety of receptors including the TNF and IL-1 receptor superfamilies. Collectively, these molecules are essential for transducing extracellular cytokine signals which culminate in a variety of TNF- and IL1-induced disease-relevant processes. Thus, these genes represent strong candidate susceptibility factors for inflammatory diseases such as rheumatoid arthritis (RA).

Aim: To investigate association of RA with single nucleotide polymorphisms (SNPs) spanning the *TRAF1-6* genes.

Methods: Twenty three haplotype-tagging (ht) and 26 random SNPs were identified from phase 1 of the Hapmap dataset (www.hapmap.org). Genotyping was preferentially performed using MassARRAY as recommended by the manufacturer (www.sequenom.com/). Single point and haplotype analyses were performed in STATA and Helixtree software (Golden Helix, Inc), respectively. Samples were genotyped in three stages, only those SNPs showing association ($p<0.05$), either singly or by haplotype were carried forward.

Results: Forty-three SNPs were successfully genotyped and conformed to Hardy Weinberg expectations. Eight SNPs across the *TRAF2* and *5* genes were associated at single and/or haplotype analysis in the first subset of 351 cases and 368 controls. Following genotyping in an additional 594 cases and 368 controls, only one SNP, rs7514863, remained associated. This SNP was genotyped in the remaining samples and demonstrated a significant association across the entire cohort (1469 cases and 2760 controls; OR for minor allele = 1.2 (1.06-1.37), $p= 0.004$).

Conclusion: We have found evidence for association of a SNP upstream of a strong candidate RA susceptibility gene, *TRAF5*, in a large cohort of patients and controls. Further association and functional studies are required to investigate the role of this SNP in RA disease causation.

Association Analysis of CTLA4 Polymorphisms in Mexican Population with Childhood-Onset Systemic Lupus Erythematosus. *G. Salas[1], V. Baca[2], R. Velazquez[1], F. Espinoza[3], S. Jimenez[1], G. Jimenez[1], L. Orozco[1]* 1) Laboratory of Research, National Institute of Genomic Medicine, Mexico City, Mexico; 2) Department of Pediatric Rheumatology, CMN-Siglo XXI, IMSS. Mexico City, Mexico; 3) Department of Immunology, INP,SS. Mexico City, Mexico.

Introduction. Susceptibility to systemic lupus erythematosus (SLE) has been attributed to complex interaction between genetic and environmental factors. The gene region 2q33 has been identified as a susceptibility region for SLE in genome-wide scans. This region harbors the Cytotoxic T Lymphocyte Antigen 4 (CTLA4) gene that encodes an immunoinhibitory receptor expressed on activated T cells, acting as a negative feedback regulator of T-cell activation. Polymorphisms in CTLA4 gene have been implicated in the development of several autoimmune disorders, including SLE. However, results obtained in different studies on the association of SLE with CTLA4 polymorphisms have been inconsistent. Objective. The aim of this study was to investigate the possible association of the -318C/T, +49A/G and the CT60A/G polymorphisms in the CTLA4 gene with childhood-onset SLE in Mexican population. Methods. We performed a case-control association study in 245 pediatric patients with SLE and 360 unrelated, healthy Mexican controls. Genotyping of these polymorphisms was carried out by the 5 nuclease assay (TaqMan). The genotypes and allele frequencies were compared between cases and controls by X2 test. Results. There were no significant differences in the distribution of genotypes and allele frequencies in the -318C/T and +49A/G polymorphisms between SLE patients and controls. SLE patients had a higher frequency of the CT60A allele with a marginal statistical significance (47.35%; versus 41.67%;, P = 0.051; OR 1.26, 95%; CI = 0.99-1.59), which was no longer statistically significant after correcting the P value (P = 0.10). Conclusion. Our results suggest that these polymorphisms in CTLA4 gene do not confer a relevant role in the susceptibility of childhood-onset SLE in Mexican population. Genotyping of the polymorphism in the CTLA4 gene promoter region (-1722T/C) is underway, as well as the haplotype analysis.

Molecular analysis of a large FMR1 gene deletion. *R. Polli, A. Casarin, L. Anesi, E. Leonardi, M. Martella, A. Murgia* Dept Pediatrics, Univ Padua, Padua, Italy.

Most of the cases of fragile X syndrome result from expansion and hyper-methylation of the CGG tract in the FMR1 gene. Deletions and point mutations of FMR1 are much less common. We report the case of a female, member of a fragile X syndrome pedigree, in whom the molecular analysis allowed the identification of a large deletion involving the 5UTR region and part of the coding sequence of FMR1. Her brother, previously tested, was found to carry a reverse-mutation with presence of fully mutated fragments together with a deletion within the repeat tract. Southern blot, performed with the use of StB 12.3 as a probe and EcoRI/EagI double digestion, showed in the female two fragments, of 5.2 and 2.8 Kb, nevertheless the relative intensity of the bands appeared slightly unbalanced and the amount of DNA loaded on the lane suggested a reduced FMR1 gene dosage. PCR analysis of the FMR1 CGG repeats allowed the identification of a normal allele with 31(CGG)s and of a premutation with approximately 70 repeats in the mother, while the father carried a 30 repeats allele. The daughter presented only the paternal 30 (CGG)s. In order to confirm the loss of the mutated maternal allele and to map the deletion breakpoints, we performed a haplotype analysis with the use of polymorphic markers FraxaC1, FraxaC2, DXS548 and several SNPs located within the FMR1 coding sequence, and a Real Time quantitative PCR analysis. We have located the 3breakpoint within intron 9 of the FMR1 gene while the position of the 5 breakpoint is currently under investigation. The extreme conditions of mosaicism seen in Fragile X affected individuals are due to expansions and deletions commonly contained within the unstable trinucleotide CGG repeats or including immediately flanking sequences. The occurrence of deletions extending beyond the region of repeats must be due to the presence of other rearrangement-prone sequences that might be somehow influenced by the FMR1 expansion/methylation.

Improving Power in Genome-Wide Association Studies: Weights Tip the Scale. *K. Roeder[1], L. Wasserman[1], B. Devlin[2]* 1) Dept. Statistics, Carnegie Mellon Univ., Pittsburgh, PA; 2) Dept. of Psychiatry, Univ. of Pittsburgh SOM, Pittsburgh, PA.

Genome-wide association is considered a promising approach for identifying genetic variants that are associated with human disease. Scanning the genome for association between markers and complex disease typically requires testing hundreds of thousands of genetic polymorphisms. When testing such a large number of hypotheses, various strategies are available for balancing the trade-off between power to detect meaningful associations and the chance of making false discoveries. One recent suggestion is to apply differential weights to the hypotheses so as to increase the power to detect likely signals. Weights can be incorporated into any multiple testing proceedure that relies on P-values, such as false discovery or Bonferroni. Roeder et al. (2006;78:243-252) investigated the potential for using weights based on an externally derived source, such as a linkage trace. Their results suggest that if the weights are informative, the weighted procedure improves power considerably; remarkably, the loss in power is small even when the weights were uninformative. This result holds provided the tests that are up-weighted are relatively sparse. We investigate this premise further and quantify the gain function for a binary system of weights. We find that, if a given fraction of tests are up-weighted, then a unique choice of weights exists to optimize the gain function. For a 2-stage design, internally derived weights are also an appealing choice. For instance, suppose that a fraction of the samples is genotyped on a large number of markers in stage 1, and then only the most promising subset of the markers is genotyped on the remaining samples in stage 2. With this 2-stage design, stage 1 can be used to formulate the weights, and both stages can be used in the analysis. This strategy yields weights that are nearly optimal. We compare this approach to the one proposed by Skol et al. (Nat Genet 2006;38:209-213).

Biotin changes multiple proteins expression in Saccharomyces cerevisiae grown under fermentative and aerobic conditions. *A. Velázquez-Arellano[1], V. Pérez-Vázquez[1], A. Hernández-Mendoza[1], M. Hernández[2], G. Martínez-Batallar[2], S. Encarnación[2], S. Uribe[3], D. Ortega-Cuéllar[1]* 1) Nutritional Genetics, Instituto de Investigaciones Biomédicas, UNAM & Instituto Nacional de Pediatría, Mexico City, D.F., Mexico; 2) Centro de Ciencias Genómicas UNAM, Cuernavaca, Mor., Mexico; 3) Instituto de Fisiología Celular UNAM, Mexico City, Mexico.

In rat and human cells, the vitamin biotin acts as regulator of reportedly over 1000 diverse proteins, this role being different from prosthetic group of carboxyl transferring enzymes. The regulatory functions are enigmatic, without apparent relation with its structure. To find clues for these effects, we have turned to yeast Saccharomyces cerevisiae and chose a proteomic approach, using low (2 nM), intermediate (200) and high (20,000) media concentrations, with glucose or lactate as carbon sources. Proteins were separated by 2D electrophoresis, stained by Coomassie and identified by MALDI-TOFF MS. We observed approximately 650 proteins (11% of total yeast proteins) in cultures containing glucose (fermentative); 42 of them changed their expression: 22 diminished when biotin was intermediate or high, whereas 11 were increased. Some others did not change their amount but their position in the 2D gel, suggestive of a post-translational change such as phosphorylation. On cultures grown on lactate (aerobic), approximately 590 proteins were observed (10.6 % of the total yeast); 48 of them changed their expression: 33 diminishing and 2 increasing their amounts when biotin was present. Those proteins were classified according to their function: 4 were associated with carbohydrate metabolism, 2 were DNA binding proteins, 4 were stress-responsive proteins, 3 were associated with purine and pyrimidine synthesis, 1 with DNA replication, 3 with protein synthesis, 1 was structural and 3 others were of miscellaneous or unknown functions. Therefore, the pleoitropic regulatory effects of biotin seem to extend along the eukaryotes, and the easily manipulable yeast may serve as a model organism to study these effects and their regulation. (Supported by PAPIIT IN228605 from DGAPA-UNAM).

Fmr1 gene family regulates circadian clock in mammals. *J. Zhang[1], Z. Fang[1], K. Kaasik[2], C.C. Lee[2], B.A. Oostra[3], D.L. Nelson[1]* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Dept of Biochemistry, UT-Houston Medical School, TX; 3) Dept of Clinical Genetics, Erasmus University, Rotterdam, The Netherlands.

Fragile X syndrome, the most common heritable cause of mental retardation, results from loss-of-function mutations in the fragile X mental retardation (FMR1) gene that lead to absence of its gene product (FMRP). FMRP belongs to a family of proteins that includes the Fragile X related proteins 1 and 2 (FXRP1 & FXRP2). FXRPs share high similarity in their functional domains with FMRP. It is likely that FXRPs play redundant roles with FMRP. Fruit fly *Drosophila* models carrying loss-of-function alleles of *dfxr* have shown defects in circadian activity. We therefore study circadian rhythm in mice with knockout mutations in the *Fmr1* and *Fxr2* genes. We examined circadian wheel running activity in *Fmr1* knockout, *Fxr2* knockout and *Fmr1*/*Fxr2* double knockout animals using a circadian controlled locomotor activity assay. We observed that *Fmr1* and *Fxr2* single knockout mice showed shorter period lengths than wildtype littermates in the absence of light cues, while double knockout mice displayed a total loss of rhythmicity even in the presence of light input. This arrhythmic phenotype is unique among mouse models with circadian defects studied to date. We have examined the circadian mRNA expression of 6 known central clock component genes in liver. We found that the patterns of cyclical behavior for the *Per1*, *Per2*, *Cry1* and *Npas2* genes were altered and that the peak of *Per2* mRNA expression is abnormally low in both *Fxr2* and double knockout mice. Using an *in vitro* transfection assay to measure luciferase output from Per promoter constructs, we observed that *Fxr2* alone or *Fmr1* and *Fxr2* together can increase *Per1* or *Per2* induced *Bmal1-Npas2* dependent activation of both the *Per1* and *Per2* promoters, and that the effects are dependent on the dose of FXRP2. Together, our data suggest a role for the *FMR1* gene family in regulation of the mammalian central circadian clock, which could be significant to further understand the learning and memory related deficiencies observed in fragile X patients.

Identification of a cryptic 11;17 translocation resulting in a novel *NUP98-PHF23* fusion in acute myeloid leukemia. *J.C. Reader[1], J.S. Meekins[2], I. Gojo[3,4], Y. Ning[1,2]* 1) Program in Human Genetics; 2) Dept Pathology; 3) Dept Hematology Oncology, University of Maryland School of Medicine, Baltimore, MD; 4) Marlene and Stewart Greenebaum Cancer Center, Baltimore, MD.

Chromosomal abnormalities on 17p are associated with a variety of leukemias. We recently identified a patient with acute myeloid leukemia (AML) that presented with a possible abnormality on 17p by standard karyotype analysis. Fluorescence *in situ* hybridization (FISH) was performed using a *p53* probe to confirm the involvement of 17p, but a normal signal pattern was observed. Further FISH analysis with a *LIS1* probe distal to *p53* revealed a cryptic balanced 11;17 translocation. We attempted to identify the translocation breakpoints. Considering the *NUP98* gene located at 11p15 is commonly involved in translocations associated with AML, we constructed a breakapart probe set using bacteria artificial chromosome (BAC) clones containing the telomeric and centromeric ends of *NUP98*. With this probe we demonstrated the involvement of *NUP98* in our patient. The breakpoint on 17p occurred in the region between *p53* and *LIS1*. After constructing and testing a series of BAC clone probes between the two genes we narrowed down the breakpoint to within 100 Kb. Using a candidate gene approach we were able to amplify a fusion transcript by RT-PCR. Sequence analysis revealed a novel in-frame fusion of *NUP98* exon 13 with *PHF23* exon 4. *PHF23* is a novel gene encoding a hypothetical protein containing a plant homeodomain (PHD) type zinc finger which is thought to play a role in transcriptional regulation. *NUP98* is one of the most promiscuous fusion partner genes in hematological malignancies with more than 20 different fusion partners on various chromosomes; however, the 11;17 translocation and the resultant *NUP98-PHF23* fusion is a novel finding in AML. The FISH probes developed in this study have not only provided accurate cytogenetic diagnosis, but also made it possible to monitor therapy and disease progression. In addition, further characterization of the new fusion gene will aid in understanding the mechanism of leukemic transformation.

Megalencephaly, thick corpus callosum, dysmorphic facial features, seizures, enamel defect and mental retardation in two unrelated patients: a new syndrome? *M. Rio[1], I. Desguerre[2], N. Boddaert[3], M. Le Merrer[1], A. Munnich[1], V. Cormier-Daire[1]* 1) Medical Genetics, Necker Hospital, Paris, France; 2) Pediatric Neurology, Necker Hospital; 3) Pediatric Radiology, Necker Hospital.

Macrocephaly associated with mental retardation is a part of various syndromes including overgrowth conditions, cutis marmorata telangiectatica, Cowden disease, and neuro-metabolic disorders. We report here a new association characterized by megalencephaly, thick corpus callosum, mental retardation, seizures, specific facial features, and enamel defect in two unrelated boys. Case 1 is the second child of unrelated parents. He was able to walk alone at 3 years of age, developed seizures at the age of 5 and had limited speech. The physical examination at the age of 9 revealed normal weight and length but a large head circumference (+3SD) and dysmorphic features including downslanting palpebral fissures, long and expressionless face, small mouth, enamel defect, and strabismus. He also had distal mucle atrophy. Case 2 is the first child of first cousin parents. Parameters at birth were above the normal range. Head circumference curve was above + 4 SD whereas length and weight were in the normal range at 3 years of age. Seizures appeared at the age of 3. He was able to walk at 8 and had only a few words. He had the same dysmorphic features (long expressionless face, downslanting palpebral fissures, small mouth,enamel defect, and distal amyotrophy). Extensive metabolic and cytogenetic studies were normal in the two boys. Myotonic dystrophy and fragile X were excluded in case 1. In addition, molecular screening of NSD1, GPC3 and the 11p15 region was negative in case 2.In the two children, brain MRI detected bilateral megalencephaly, a thick corpus callosum, an enlarged white matter and normal ventricles.This association of megalencephaly and thick corpus callosum has been previously reported by G. Göhlich-Ratmann in 1998 in 3 children who had in addition pachygyria and complete lack of motor development, features not observed in our cases. We hope that ongoing cytogenetic and molecular studies will further define this new entity.

FINLAY-MARKS Syndrome: Thirty Year Follow-up in the affected one of two Dyzigotic Twins. *A. Zeffiri[1], M. Ottaviani[1], M. Isoldi[1], S. Stagi[1], L. Di Medio[1], M. Levi[1], L. Carosi[1], L. Giunti[2], U. Ricci[2], M.L. Giovannucci Uzielli[1]* 1) Dept. Paediatrics, Genetics, University of Florence, Florence, Italy; 2) Childrens Hospital A. Meyer, Florence, Italy.

Finlay-Marks syndrome, or Scalp-Ear-Nipple syndrome (SEN, OMIIM 181270) is a very rare Autosomal Dominant disorder, first described in 1978 by Finlay and Marks in a family with 10 affected individuals over five generations. The clinical diagnosis is especially based on the occurrence of scalp defect, dysplastic external ears, and absent or rudimentary nipples and breasts. Other clinical features were reported in the few additional cases described in the literature: in particular, urinary tract malformations and/or disfunctions, and diabetes. We report the follow-up study performed in our Genetics Unit, in the affected one of two dyzygotic female twins, since the age of 2 years and during 30 years. The periodical clinical evaluation, with the diagnostic laboratory and instrumental tests, performed in order to follow the natural history of the phenotype, revealed a progressive number of additional abnormal features. In the same time, we were able to exclude other features reported in this disorder: in particular, no hydrocephaly or large ventricle, no cataract nor hearing impairment. Normal intelligence and behaviour. The stature is reduced if compared with the twin sister, the brother, and both parents. The patient was submitted to surgery correction of the congenital bald nodules over the scalp, reduction of the abnormal eye spacing, correction of the prominent and dysplastic ears, correction of the bilateral athelia and amastia by reconstruction of nipples and breasts. Unilateral renal hypoplasia was revealed by ultrasounds at age 5 years. Only recently the patient developed severe renal hypertension. Normal 46,XX karyotype. By using a battery of polymorphic DNA markers we confirmed the DZ twinning.

Variation in the Human Matrix Metalloproteinase-9 (MMP-9) Gene is Associated with Arterial Stiffness in Healthy Individuals. *Y. Yasmin[1], C.M. McEniery[1], K.M. O'Shaughnessy[1], P. Harnett[1], A. Arshad[1], S. Wallace[1], K. Maki-Petaja[1], B. McDonnell[2], M.J. Ashby[1], J. Brown[3], J.R. Cockcroft[1], I.B. Wilkinson[1]* 1) Clinical Pharmacology Unit, University of Cambridge, Cambridge, UK; 2) Department of Cardiology, University of Wales College of Medicine, Cardiff, UK; 3) Trinity College, Cambridge, UK.

Background Arterial stiffness is an important determinant of cardiovascular risk. Elastin, is the main elastic component of the arterial wall, and can be degraded by a number of enzymes including serine proteases and matrix metalloproteinases (MMPs). Serum MMP-9 levels correlate with arterial stiffness and predict cardiovascular risk. Polymorphisms in the MMP-9 gene are also associated with large artery function in subjects with coronary artery disease. Therefore, we investigated the influence of known MMP-9 (-1562C>T, R279Q) polymorphisms on arterial stiffness in a large cohort of healthy individuals (n=865). Methods Aortic pulse wave velocity (PWV) and augmentation index were assessed using SphygmoCor. Supine blood pressure, biochemical markers, serum MMP-9 levels and serum elastase activity (SEA) were determined by standard methods. Genomic DNA was extracted and genotyping performed using PCR-RFLP and a validated Taqman assay respectively. Results Aortic PWV, serum MMP-9 and SEA were higher in carriers of the rare alleles for the -1562C>T and R279Q polymorphisms. These polymorphisms were also associated with aortic PWV after correction for other confounding factors. Stepwise regression models with known or likely determinants of arterial stiffness revealed that ~60 percent of the variability in aortic PWV was attributable to age, mean arterial pressure and genetic variants ($P<0.001$). MMP-9 whole genotypes also had a significant dose-dependent effect on aortic PWV and serum MMP-9 levels. Conclusions We have demonstrated for the first time that aortic stiffness and elastase activity are influenced by MMP-9 gene polymorphisms. This suggests that the genetic variation in this protein may be involved in the process of large artery stiffening presumably through effects on turnover of matrix proteins in the vessel wall.

Distal arthrogryposis type 5 is caused by defects of myosin. *R. Toydemir[1], L.B. Jorde[1], M. Bamshad[2,3]* 1) Department of Human Genetics, Univ Utah, Salt Lake City, UT; 2) Departments of Pediatrics and Genome Science, Univ Washington, Seattle, WA; 3) Childrens Hospital and Regional Medical Center, Seattle, WA.

The distal arthrogryposes (DA) are a group of syndromes characterized by congenital contractures of the hands and feet, limited proximal joint involvement, autosomal dominant inheritance, reduced penetrance, and variable expressivity. To date, 10 different DA syndromes have been characterized. Among the DAs, DA5 is unique since in addition to contractures of the skeletal muscles, affected individuals have ocular abnormalities such as ptosis, ophthalmoplegia, and strabismus. Based on our previous findings, which showed DAs are caused by mutations that encode proteins of contractile apparatus of myofibers, we hypothesized that DA5 might be caused by contractile proteins that are expressed in both skeletal and extraocular muscles. Two such proteins are myosin heavy chain IIa and myosin heavy chain 13 that are encoded by *MYH2* and *MYH13*, respectively. We screened the entire coding region of these genes in 8 independent cases of DA5. In two cases, we found missense mutations in *MYH2* that caused substitutions of highly conserved amino acid residues. Neither of these mutations was found in more than 200 chromosomes from controls matched for geographic ancestry. Additionally, one of the two DA5 cases with a *MYH2* mutation also had a mutation in *MYH13*. This mutation also alters a highly conserved amino acid residue and it is not found in the healthy population. Our results suggest that DA5 is genetically heterogeneous, and mutations in *MYH2* cause a subset of DA5 cases. In addition, mutations in other contractile proteins might modify the phenotype associated with *MYH2* mutations or, alternatively, *MYH2* might in some cases modify a phenotype caused by mutations in genes that encode other contractile proteins.

HNF4A variants predispose to high serum lipid levels and the metabolic syndrome. *D. Weissglas[1], A. Huertas-Vazquez[1], T. Tusie-Luna[2], C. Aguilar-Salinas[2], M-R. Taskinen[3], TW. de Bruin[4], CJ. van der Kallen[5], P. Pajukanta[1]* 1) Dept. of Human Genetics, UCLA, Los Angeles, USA; 2) INCMNSZ, Mexico City, Mexico; 3) Dept. of Medicine, University of Helsinki, Finland; 4) GlaxoSmithKline, Translational Medicine and Genetics, Research Triangle Park, USA; 5) Dept. of Medicine, CARIM, Academic Hospital, Maastricht, The Netherlands.

Hepatic nuclear factor 4, alpha (HNF4A) has been associated with type 2 diabetes mellitus (T2DM) in several populations. Considering the phenotypic overlap between T2DM and familial combined hyperlipidemia (FCHL), the most common dyslipidemia predisposing to coronary heart disease (CHD), we previously investigated HNF4A in FCHL families from two distinct populations, Finnish and Mexicans. We observed that common HNF4A variants are associated with high serum lipid levels and the metabolic syndrome (MS). Importantly, we found two common HNF4A haplotypes (rs6031558-rs745975-rs3212198) that were associated with elevated serum triglycerides (TGs) (P=.006) and total cholesterol (P=.005) in both Finnish and Mexican FCHL families. In the present study we sequenced subjects with the risk or protective haplotypes for the coding region of HNF4A to identify the functional variant(s). Although no coding variants differ between the haplotype groups, a variant adjacent to exon 5, was found in 10 of the risk-haplotype carriers and was absent in the protective-haplotype group (P=.03). We are currently analyzing this variant for a possible role in FCHL. We also examined the HNF4A variants implicated in the Finnish and Mexican families, in an independent study sample comprising of 557 individuals from 33 Dutch FCHL Families. In the Dutch FCHL families, rs745975 was individually associated with both TGs and the MS (P=.04, .01). Haplotype analyses in the Dutch FCHL families also showed significant associations with FCHL, high TGs and with the MS for several HNF4A haplotypes (P=.01-.05). We are currently investigating the potential effect of all implicated HNF4A variants on the expression of the downstream genes. Taken together, these data imply that common HNF4A variants confer the susceptibility to high serum lipid levels and the MS.

Phactr2, Genomewide association and Parkinsons disease. *O.A. Ross[1], J.T. Stone[1], J. Aasly[2], T. Lynch[3], M.J. Farrer[1]* 1) Dept of Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Department of Neurology, St. Olav's Hospital, Trondheim, Norway; 3) Department of Neurology, Mater Misericordiae Hospital & The Conway Institute, University College, Dublin, Ireland.

The first genomewide association study has been reported in Parkinsons disease (PD). Although the study nominated eleven chromosomal loci follow-up independent replication studies have not been able confirm the role of these in disease. The study involved two tiers with the second a case-control series design. Interestingly the SNP with the lowest p-value in Tier 2 was not one of the nominated loci. This SNP, rs11155313 ($P<0.000016$) is located in the Phactr2 gene on chromosome 6. The Phactr2 protein belongs to the Phactr protein family which are reported to regulate protein phosphatase 1 activity. Our study identified a significant association between this SNP and a case-control series from the Irish population. This association could not be replicated in a case-control series from Norway. Given the importance of phosphorylation and kinase genes in PD the role of the Phactr family of proteins in neurodegeneration deserves further investigation.

Clinical and radiographic delineation of Odontochondrodysplasia. *J. Spranger[1], F. Antoniazzi[2], M. Brugnara[2], Y. Alanay[3], K. Lachlan[4], S. Ikegawa[5], G. Nishimura[6], S. Unger[7,1], A. Superti-Furga[1]* 1) Dept of Pediatrics, Univ of Freiburg, Germany; 2) Dept of Pediatrics, Univ of Verona, Italy; 3) Div Clin Genet, Dept of Pediatrics, Hacettepe Univ, Ankara, Turkey; 4) Wessex Reg Genet Serv, Southampton, UK; 5) Lab Bone and Joint Dis, SRC, RIKEN, Tokyo, Japan; 6) Dept of Radiol, Tokyo Metrop Kiyose Childrens Hosp, Kiyose, Japan; 7) Inst Human Genet, Univ of Freiburg, Germany.

The association of dentinogenesis imperfecta with chondrodysplasia (odontochondrodysplasia; ODCD) has been reported in 5 individuals so far. We diagnosed ODCD in four unreported children and retrospectively in two brothers reported previously as metatropic dysplasia variant, bringing the total number of subjects with ODCD to eleven. ODCD manifests at birth with short stature, narrow thorax, and severe spondylometaphyseal dysplasia; three of the eleven individuals died in the first two years of life with respiratory insufficiency. In childhood, high forehead, flat nose, mesomelic limb shortening, joint laxity, scoliosis, and dentinogenesis imperfecta with small, brownish, and fragile primary teeth become apparent. Mental development is normal and eye or ear complications have not been seen so far. Radiographic features are marked spondylar dysplasia with coronal clefts in infancy; square iliac wings with wide lacy borders, horizontal acetabular roofs, and coxa valga; progressive metaphyseal splaying with enchondromatous changes; mesomelic shortening; short metacarpals and phalanges with round cone-shaped epiphyses; and osteopenia with expanded diaphyses and thin cortex. The differential diagnosis in the newborn is with SMD Sedaghatian (platyspondyly with spiked metaphyses) and with collagen 2 disorders (platyspondyly with coronal clefts); later, ODCD resembles metatropic dysplasia (narrow thorax and spondylar changes), Dyggve-Melchior-Clausen syndrome (SEMD with lacy iliac crests), or severe Shwachman-Diamond syndrome (narrow thorax and metaphyseal changes; the SBDS gene was normal in one case). The consistency of findings in 11 individuals confirms that ODCD is a distinct entity. Three pairs of affected sibs born to unaffected parents suggest AR inheritance.

A Novel Missense Mutation, p.R808W, in the *HOPA* Gene is Present in 10% of a Cohort of FG Syndrome Families. *H. Risheg[1], M.J. Friez[1], J.M. Graham Jr.[2], J.B. Moeschler[3], R.C. Rogers[1], J.M. Opitz[4], R.E. Stevenson[1], C.E. Schwartz[1]* 1) Greenwood Genetic Center, Greenwood , SC; 2) Cedars-Sinai Medical Center, Los Angeles, CA; 3) Dartmouth Medical School, Lebanon, NH; 4) University of Utah School of Medicine, Salt Lake City, UT.

FG Syndrome (MIM 305450) is an X-linked recessive form of mental retardation (XLMR) associated with hypotonia, macrocephaly, dysgenesis of the corpus callosum, and other anomalies. This syndrome is heterogeneous with 5 possible loci on the X chromosome. One locus (FGS1) is in Xq12-q22. The *HOPA* gene, located at Xq13, is a human opposite-paired gene involved in thyroid hormone signal transduction, making it a good candidate gene for XLMR given our understanding of the *MCT8* gene. Our initial study consisted of sequencing the 45 exons of *HOPA* in 24 probands from XLMR families with linkage covering the Xq13 interval. Sequence analysis identified a missense change in 2/24 XLMR male probands (one Caucasian/ one African American), both of which have similar clinical features of FG syndrome. This missense change (c.2422 C>T) in exon 21 results in an arginine to tryptophan change at amino acid 808 (p.R808W). Affected males and obligate carrier females were concordant for the alteration in the families of both FG males. The alteration was not found in 451 normal adult male controls, 343 consecutive male newborns and 64 normal adult female controls, making it unlikely that it represents a rare polymorphism. Simulated protein modeling indicates the alteration has a pathogenic effect on the structure of the *HOPA* protein. Subsequently, a panel of 48 samples from either males diagnosed with FG syndrome or mothers of boys diagnosed with FG syndrome, were tested for the c.2422 C>T alteration. Analysis revealed 3 additional individuals with the same change (1 male from a large family with 3 other deceased affected males, and 2 unrelated obligate female carriers). To date, a total of 3 hemizygous males affected with FG syndrome and 2 heterozygous females, from 5 apparently unrelated FG syndrome families, have been identified. Thus, the novel p.R808W missense mutation of *HOPA* has been found in 10% of the FG syndrome families tested.

Exon resequencing - the search for sequence variation in the human genome. *J. Rogers, J. Allen, H. Arbery, G. Bethel, R. Bennett, S. Bhaskar, A. Dunham, M. Bush, J. Burton, J. Durham, T. Eades, M. Earthrowl, S. Hunt, S. Leonard, K. McLay, D. Niblett, R. Norris, A. Sanderson, Y. Umrania, A. Coffey* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

The primary aim of the ExoSeq programme is to obtain a near-complete catalogue of common variation in human genes. Initially, we are re-sequencing exons in 48 Caucasian individuals using high-throughput sequencing of PCR products. For all known protein-coding genes, novel coding sequences and transcripts, exons and their flanking sequence are extracted from the Vega database, which contains high-quality manually curated annotation to allow us to identify all exons for each gene. Primers are designed to encompass the exon and splice sites and are checked for uniqueness prior to synthesis. Primers are pre-screened with successful primer pairs being re-arrayed and grouped together for amplification. Bi-directional sequencing of amplicons is carried out using Big Dye chemistry with a success rate of over 95%. We are currently processing 3,000 STSs per week (1 million sequencing reads per month).

SNPs are called using a novel algorithm developed in-house, ExoTrace. All high confidence variants detected automatically or those passing manual review are deposited in dbSNP on a monthly basis. To date we have identified over 75,000 SNPs, approximately 41% of which are novel (66% of which are rare), and 10% of which represent non-synonymous changes.

We are developing methods for analysing variation in other regions of the genome of potential functional importance, including promoters and other regulatory elements identified as those showing varied levels of conservation between species.

Variations in disease studies and medical sequencing projects are also underway in areas including epilepsy, cardiovascular disease, platelet biology, deafness, diabetes and cognition. Exons are sequenced in both the Caucasian samples and patient samples to identify additional SNPs for association studies or direct detection of mutations.

Adenoviral-mediated correction of methylmalonyl-CoA mutase deficiency in mut human hepatocytes. *M.S. Tsai[1], R.J. Chandler[1], K. Dorko[2], J.L. Sloan[1], M. Korson[3], R. Freeman[4], S. Strom[2], C.P. Venditti[1]* 1) GDRB,NHGRI,NIH, Bethesda, MD; 2) Department of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, PA; 3) Metabolism Service,Tufts University, Boston, MA; 4) Department of Surgery, Tufts University, Boston, MA.

Mut class methylmalonic acidemia (MMA) is a metabolic disorder caused by deficiency of the mitochondrial-localized, adenosylcobalamin-dependent enzyme, methylmalonyl-CoA mutase. Liver transplantation in the absence of severe hepatic dysfunction has been used as a supportive therapy in severely affected patients, and provides significant increase in metabolic stability. As a first step to examine the effectiveness of gene and cell therapy in this disorder, viral correction experiments were performed on primary human hepatocytes derived from a mut MMA patient. The affected patient exhibited a severe clinical phenotype and harbored two early premature truncating mutations, E224X and R228X, in the methylmalonyl-CoA mutase gene. He underwent a combined liver-kidney transplant at the age of 5 years. Primary hepatocytes were isolated from the native liver by a three-step collagenase digestion method and used to test the efficacy of gene delivery using a bi-functional adenoviral vector that expressed the methylmalonyl-CoA mutase gene as well as EGFP. Viral infection and delivery were monitored by fluorescence. Measuring C-14 propionate incorporation into macromolecules assessed enzymatic correction, and Western analysis was used to demonstrate protein expression. Functional correction of the mut hepatocytes was comparable to the degree of correction achieved using MEF cell lines derived from Mut knock-out mice, and showed a restoration of propionate flux and prominent expression of the enzyme on Western analysis. The protein expression levels from the corrected cells were equal to or greater than that seen in extracts derived from a control human liver. These studies provide proof of principle for hepatocyte-mediated gene delivery in methylmalonic acidemia. In the future, MMA may be amenable to liver-specific gene and cell-based therapies as an alternative to liver transplantation, which consumes an already scarce resource.

Microdissection-based genomic array analysis: what you see is what you get. *J. Yu[1], Z. Qi[1], G.M. Rice[2], R. Selzer[3], T. Richmond[3], K. Thompson[2], S. Liao[4], R.M. Pauli[2], D. Albertson[1], D. Pinkel[1], J.E. Hearst[4]* 1) University of California San Francisco, San Francisco, CA; 2) University of Wisconsin - Madison, Madison, WI; 3) NimbleGen Systems, Inc., Madison, WI; 4) University of California Berkeley, Berkeley, CA.

Chromosome microdissection is a unique technique for in situ chromosome cloning - direct isolation and cloning of any chromosome or chromosome region of interest from a single cell or a few cells for genomic analysis. We show here that dissected DNA samples from marker chromosomes and abnormal chromosome regions that carry a deletion and a balanced translocation, respectively, can be readily amplified and analyzed with either oligo- or BAC-based genomic arrays. It demonstrates that virtually any chromosomal abnormality can be comprehensively characterized with microdissection-based DNA array analysis for chromosome origin, breakpoints, gene content and other genomic features. The analysis is straightforward, quick and reliable. In particular, the analysis is especially powerful for characterization of abnormalities that cannot be easily analyzed with Array-based comparative genomic hybridization (array CGH), such as balanced rearrangements and low-level mosaicism or mixed normal/abnormal cell populations that are frequently seen in cancer specimens.

The CHD7 protein, mutated in CHARGE syndrome, binds to specific sites on chromatin. *P.C. Scacheri[1], F. Tie[1], S.R. Lalani[2], J.W. Belmont[2], F.S. Collins[3]* 1) Genetics, Case Western Reserve University, Cleveland, OH; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) National Human Genome Research Institute, NIH, Bethesda, MD.

Babies born with CHARGE syndrome have multiple birth defects including coloboma of the eye, heart malformations, choanal atresia, cleft lip and palate, retardation of growth, genital abnormalities, and ear abnormalities. In 2004 it was shown that de novo mutations in the CHD7 gene (coding for chromodomain helicase DNA-binding protein 7) cause most cases of CHARGE syndrome, but little information has been available about the normal function of the protein. Based on homology to other proteins in the CHD family, we hypothesized that CHD7 is located in the nucleus and is associated with chromatin. To address these hypotheses we made antibodies to CHD7 and tested them by subcellular fractionation and Western blot analysis as well as by chromatin immunoprecipitation on tiled microarrays (ChIP-chip). Our results reveal for the first time that: 1) CHD7 is a nuclear protein; 2) CHD7 is physically associated with chromatin; and 3) CHD7 binds to promoters, at or near transcriptional start sites. The ChIP-chip data also indicate that CHD7 does not bind globally to all promoters, but rather co-localizes to a subset of those specifically marked with methylation of lysine 4 on histone H3 (H3K4me), suggesting that CHD7 targets a specific subset of transcriptionally active genes. Some of the CHD7 target genes, including several genes within the HOXA cluster, suggest clues to mechanisms underlying the complex phenotype of CHARGE syndrome. We hypothesize that CHD7 is involved in transcription regulation, and that haploinsufficiency of CHD7 affects expression of multiple CHD7 target genes during development, leading to birth defects in several organ systems.

Coupling of UPR Induction with Aminoglycosides: A Potential Therapeutic Strategy for Genetic Disorders Caused by Nonsense Mutations. *N.A. Sharifi, H.C. Dietz* Inst of Genet Med, Johns Hopkins Univ Sch of Med and HHMI, Baltimore, MD.

It is estimated that nonsense mutations are seen in up to 20% of all human disease alleles. The presence of a PTC does not usually lead to production of truncated peptides since the majority of nonsense transcripts are recognized and degraded by a translation-coupled and highly efficient process known as nonsense-mediated mRNA decay (NMD). Recent attempts to treat diseases caused by nonsense mutations with readthrough-promoting agents (e.g. aminoglycosides) have shown limited and highly variable success in model systems and in people. A near uniform finding is that these agents do not increase the amount of nonsense transcripts. Thus, despite high readthrough potency for selected drugs, the opportunity is simply lacking in the face of ongoing NMD. While simultaneous inhibition of NMD and promotion of readthrough represents a potentially potent strategy, the toxicity of known drugs that inhibit NMD precludes their use in both animal models and people. Our microarray analysis of physiologic mRNA substrates for mammalian NMD revealed significant overlap with transcripts that are upregulated by the unfolded protein response (UPR). Initiation of the UPR in response to diverse forms of cellular stress induces phosporylation of eIF2 and the subsequent inhibition of bulk translation, while maintaining selective translation of proteins that would promote cellular survival (e.g. ATF3). It seemed possible that either inhibition of NMD leads to the production of truncated proteins that then initiate the UPR, or that the induction of UPR and subsequent relative inhibition of translation inhibits NMD. We provide definitive experimental evidence that only the latter is true. Furthermore, the inhibition of NMD was both potent and observed in all tested nonsense transcripts. Furthermore, we show that geldanamycin and its less toxic derivative 17AAG, which are in phase II clinical trials for anti-tumor activity in people, both induce the UPR and inhibit NMD. These agents maintain sufficient residual translation to support readthrough protein production in the presence of aminoglycoside, constituting a complete strategy for the treatment of diseases caused by PTCs.

Genetic vs. environmental hypotheses of disease causation: the case of autism. *H.K. Tabor, M. Mohindra, A. Boyce, M. Cho* Stanford Ctr for Biomedical Ethics, Stanford University, Palo Alto, CA.

The completion of the Human Genome Project has led to an increase in association studies of complex traits, or traits with both genetic and environmental components. The proliferation of these studies has led to conflict around how causation is determined and what it means if a disease is environmental or genetic in origin. To examine how causation is framed for complex traits, we examined a disease with a history of such discussions: autism. While the genetic component of autism is well established, no single genes have been conclusively identified that account for the majority of cases. Furthermore, potential environmental causes of autism have received a great deal of media attention, leading to public debate about disease causation. We are analyzing the report Immunization Safety Review: Vaccines and Autism published by the National Academy of Sciences in 2004. This report examined the hypothesis that vaccines are causally associated with autism. We analyzed the text of the report itself and of the public submissions to the committee, evaluating the evidence and language used to support causation models using the causal criteria originally proposed by the epidemiologist Austin Bradford Hill. Our preliminary analyses suggest that groups supporting environmental causes emphasize different causal criteria and evidence than those arguing against environmental causes. Environmental cause advocates tend to emphasize criteria of temporal sequence, biological gradient, and experimental evidence, while environmental cause opponents tend to cite strength of association and consistency of evidence. Both perspectives cited specificity, biologic rationale, coherence, and analogous evidence. Our preliminary analysis suggests that consensus in the scientific and public arenas may be less dependent on the strength or quantity of certain kinds of evidence and more on the ability to reconcile differing priorities for causal criteria. These differing priorities may reflect the social implications of different causal pathways and of the agendas of the groups that advocate for them.

Identifying schizophrenia-associated non-coding variants in the NOS1AP gene. *N. Wratten[1], H. Memoli[1], M. Azaro[1], J. Messenger[1], J. Hayter[1], S. Buyske[2], A. Bassett[4,5], E. Chow[4,5], L. Brzustowicz[1,3]* 1) Dept Genetics, Rutgers University, Piscataway, NJ; 2) Dept Statistics, Rutgers, NJ; 3) Dept Psychiatry, UMDNJ-NJMS, Newark, NJ; 4) Clinical Genetics Research Program, University of Toronto, ON, Canada; 5) Dept Psychiatry, University of Toronto.

The *NOS1AP* locus has been implicated by both linkage and association studies in pedigrees of European descendents as a schizophrenia susceptibility gene. Studies in the rat indicate that the NOS1AP protein functions in the NMDA receptor pathway and is therefore a good candidate gene for schizophrenia. Furthermore, genotype data from different populations suggest that multiple independent regions within the 300 kb *NOS1AP* genomic locus are associated with schizophrenia. In our pedigrees none of the identified coding SNPs are associated with disease, indicating that the mutations(s) are located in regulatory sequences. Evidence from expression studies of the various *NOS1AP* transcripts suggests that this gene contains multiple regulatory modules. We performed a comprehensive screen of the *NOS1AP* gene for schizophrenia-associated regions by genotyping almost 70 markers selected using a tag-SNP approach to minimize LD between markers. Genotype data was generated using a multiplex PCR-LDR assay and analyzed for association with schizophrenia. Approximately 40% of markers in the large second intron showed association with schizophrenia including a SNP within a 1 kb region that is highly conserved within mammals. This sequence was tested for regulatory function using a luciferase reporter assay and found to act as a repressor of the *NOS1AP* promoter in neuronal cell culture. Comparison of the two allelic variants of this regulatory sequence indicated some difference in the level of repression between alleles. However, the difference in repression conferred by the alleles was dependent on the neuronal cell line used and could reflect differences in transcription factor composition between cell lines. Future experiments will test whether this region and other schizophrenia associated regions from *NOS1AP* function in rat primary neuronal cell culture.

Successful bone marrow transplant in a child with mevalonic aciduria. *V. Valayannopoulos[1], B. Neven[2], P. Quartier[2], S. Romano[1], D. Rabier[3], MO. Rolland[4], L. Cuisset[5], AM. Prieur[2], A. Fischer[2], P. Delonlay[1]* 1) Metabolic Ped, Necker-Enfants Malades Hosp, Paris, France; 2) Ped ImmunoHematology; 3) Biochemistry Lab, Necker-Enfants Malades Hosp, Paris, France; 4) Biochemistry Lab, Debrousse Hosp, Lyon, France; 5) Genetics Lab, Cochin Hosp, Paris, France.

Mevalonic aciduria (MA) (OMIM +251170) is a rare inborn error of isoprene biosynthesis caused by a deficient activity of mevalonate kinase (MVK) resulting from mutations in the MVK gene. The neonatal phenotype is characterised by severe periodic fever attacks, ataxia, failure to thrive and cataracts. The prognosis is usually poor and children die in early infancy. The mechanism of recurrent inflammatory disease is unclear. Serum levels of pro-inflammatory cytokines are increased during attacks. We hypothesized that replacement of the haematopoietic system by a bone marrow transplant (BMT) from a healthy geno-identical donor may improve inflammatory symptoms. We report a 2.5 years old boy with mevalonic aciduria diagnosed at the age of 3 months upon elevated mevalonic acid in urine, confirmed by severely impaired activity of mevalonate kinase in lymphocytes and a homozygous mutation in the MVK gene. He presented at birth with low birth weight, severe anemia, hepatosplenomegaly and liver disease. Recurrent episodes of fever were noted every two weeks, with transient rash and abdominal pain. He had failure to thrive and mild cerebellar ataxia. The effect of several anti-inflammatory drugs on febrile attacks was very transient. Because of the very severe condition of the child, we proposed a BMT from a geno-identical heterozygous sister. Hematological recovery was achieved on day 21 post BMT with a 96% donor chimerism. We are now 5 months since the BMT and the child has presented no new fever attack and no complication. The volumes of liver and spleen have significantly decreased. Body growth is good and psychomotor development improved. Mevalonate aciduria has decreased significantly. Mevalonate kinase activity has not been tested yet due to lymphopenia. In conclusion, BMT is a feasible procedure in MA patients and may be efficient to prevent inflammatory attacks. However, these encouraging data are still preliminary.

Association Study of RANTES Polymorphisms in Childhood-Onset Systemic Lupus Erythematosus and Juvenile Rheumatoid Arthritis in Mexican Population. *J. Ramirez[1], V. Baca[2], R. Velazquez[1], M. Morales[1], F. Espinosa[3], L. Orozco[1]* 1) Laboratory of Research,National Institute of Genomic Medicine,Mexico City,Mexico; 2) Department of Pediatric Rheumatology, CMN-Siglo XXI,IMSS.Mexico City, Mexico; 3) Department of Immunology,INP,SS.Mexico City,Mexico.

Introduction. Recent studies in Asian populations have found two single nucleotide polymorphisms (SNPs) in the promoter region of RANTES gene (-403 G/A and -28C/G), to be associated with increased risk of developing systemic lupus erythematosus (SLE) and rheumatoid arthritis. RANTES -28C/G SNP was associated with childhood-onset SLE, while in adult SLE patients the two SNPs did not correlate with SLE as individual polymorphisms. However, a compound genotype (-403 G/G and -28C/C) was significantly more frequent in SLE than controls, and the -403 G/A SNP was associated with lupus nephritis. Otherwise, the -403A allele was associated with RA susceptibility. Objective. To asses the possible association between RANTES -403 G/A and -28C/G polymorphisms and childhood-onset SLE and juvenile rheumatoid arthritis (JRA) in Mexican population. Methods. We performed a case-control association study in 250 pediatric patients with SLE, 115 patients with JRA and 265 healthy Mexican controls. Genotyping was carried out by TaqMan. The genotypes and allele frequencies were compared between cases and controls by x^2 test. Results. There were no significant differences in the distribution of genotypes and allele frequencies in the RANTES promoter polymorphisms between SLE patients and controls. Neither association with lupus nephritis or SLE with compund genotypes was observed. Otherwise, there was a significant difference in the -403A allele frequency between JRA patients and controls (35% versus 27%, P = 0.03; OR = 1.4, 95% CI = 1.04-2.01), however the association was no longer statistically significant after correcting the P value (P = 0.06). Conclusion. Our results suggest that -403 G/A and -28C/G SNPs in RANTES gene are not associated with childhood-onset SLE susceptibility or lupus nephritis in Mexican population. However, we could not rule out completely the relationship of the -403A allele with JRA due to the small sample size.

Methyl Primer Express Software and influence of amplicon characteristics to success rate in sequencing of bisulfite treated DNA. *E.S. Vennemeyer[1], A.A. Pradhan[1], A. Rico[2], B. Finkelnburg[3], M.F. Fraga[4], C. Ferrero[4], M. Esteller[4]* 1) Applied Biosystems, Foster City, CA; 2) Applera France S.A; 3) Applera Deutschland, GmbH; 4) 4Cancer Epigenetics Laboratory, Spanish National Cancer Centre (CNIO), Madrid, Spain.

A well known method to study methylation patterns is to treat gDNA by sodium bisulfite to distinguish methylated cytosine (5mC) from unmethylated C, which is deaminated to uracil (U) and replaced by thymine (T) in subsequent amplification. 5mC still remains as C. Subsequent amplification can focus on selective amplification of methylation patterns in CpG islands (methyation specific PCR, MSP) or on amplification of bisulfite treated (converted) gDNA (Bisulfite treatment specific PCR, BIS). Selection of PCR focus is done by primer design. After PCR, sequencing can clarify the methylation pattern but several factors must be taken into account to ensure reliable data. During the bisulfite treatment base composition will undergo dramatical changes. This must be taken under consideration during primer and amplicon design for the initial amplification. Dependend on the base composition of the target region the design may change the originally focused strategy for sequencing. In first instance, strategy is depending on preferred outcome: 1. More or less methylated? Which CpG in target region is differentially methylated? Direct sequencing of PCR products. 2. Semi-quantitative results Cloning of PCR products and sequencing of multiple clones. In a second instance, the base composition of the amplicon itself will lead to the conclusion, whether direct sequencing of PCR products can be done or not. Here we use a new PC Software called Methyl Primer Express to design BIS oligos on different promotor-target regions to show examples for critical amplicons and recommendations for successful amplification and sequencing.

A QTL influencing both serum PAF-AH activity and LDL cholesterol concentration maps to the baboon ortholog of human chromosome 2p. *A. Vinson[1], M.C. Mahaney[1,2], L.A. Cox[1,2], J. Rogers[1,2], J.L. VandeBerg[2], D.L. Rainwater[1]*
1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Southwest National Primate Research Center, San Antonio, TX.

Given their correlated contributions to cardiovascular disease (CVD) risk, biomarkers of inflammation and lipoprotein metabolism may share genes that influence risk of CVD. In this study, we analyzed variation in the activity of serum platelet-activating factor acetylhydrolase (PAF-AH, an enzyme associated with inflammation) and low-density lipoprotein cholesterol concentration (LDL-C, a risk factor for CVD), from 650 pedigreed baboons (*Papio hamadryas*) fed a low-cholesterol, low-fat basal diet. We estimated the genetic correlation between PAF-AH and LDL-C at 0.51 (p0.00001), indicating that approximately 26% of the additive genetic variance in each trait was attributable to the effects of the same gene(s). To locate genes with common effects on variation in serum PAF-AH activity and LDL-C concentration, we performed both univariate and multivariate multipoint linkage scans of the baboon genome. Our univariate analyses found significant evidence for a QTL affecting serum PAF-AH (LOD=2.79, genome-wide p=0.0395) and suggestive evidence for a QTL affecting LDL-C (LOD=2.16). Both QTLs were located at the same point on the baboon ortholog of human chromosome 2p, in a region corresponding to 2p24.2-23.3. We used bivariate linkage analysis to test the hypothesis that a single QTL explains some or all of the additive genetic correlation between serum PAF-AH activity and LDL-C concentration. This bivariate analysis improved evidence for the QTL (LOD=3.19, genome-wide p=0.0148) over that obtained in the univariate screens for each trait. Likelihood ratio tests of the QTL-specific genetic correlation between the traits ($_Q$=0.62) rejected hypotheses of co-incident linkage (P[$_Q$=0]=0.0465) and complete pleiotropy (P[$_Q$=1]=0.0217). We interpret this partial QTL pleiotropy to be consistent with sharing by PAF-AH and LDL-C of the effects of some, but not all, QTL polymorphisms. We conclude that a QTL mapping to human chromosome 2p24.2-23.3 affects variation in both serum PAF-AH activity and LDL-C concentration.

Single-exon deletion or a large deletion of 42 exons in dystrophin gene can be detected with multiplex ligation-dependent probe amplification (MLPA) in Chinese DMD patients. *X.Z. Wang[1], F. Yao[2], N. Zhong[1,3]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) Peking Union Medical University, Beijing, China; 3) New York State Institute for Basic Research, Staten Island, NY.

Duchenne muscular dystrophy (DMD) is one of the most common X-linked recessive neuromuscular diseases. It is caused by genetic defects of dystropin gene with deletion, duplication, or point mutation that results in muscle fatigue and dystrophy. Usually, gene deletion of one or more exons of dystrophin accounts for about 55-65% of DMD/BMD patients, duplication for about 5-10% patients, and point mutation for 25% patients. Most of hotspot deletion of dystrophin can be detected by a classical multiplex PCR and the point mutation can be detected by PCR/sequencing analysis, however, it remains a challenge to detect duplication. The multiplex ligation-dependent probe amplification (MLPA) is an efficient procedure that can accurately analyze the copy number and deletion mutation of whole dystropin gene. We have developed a protocol with two reactions for simultaneous detection of entire dystropin gene. Each reaction may analyze 39.5 exons of dystrophin gene. The MLPA was applied to study 16 DMD/BMD patients who were collected in Beijing area. Deletion can be detected among 10 patients with MLPA. Seven patients were found to have deletion at previously reported hotspot regions from exon 45 to exon 55, which can be detected with a classical multiplex PCR. Two patients who had not been found deletion by the classical multiplex PCR could be detected with MLPA to have rare deletions of a single exon 18 or exon 43. A large fragment deletion spanning 42 exons from exon 3 to exon 44 was detected in one patient. Compared to the classical complex PCR, our MLPA protocol may increase the detecting rate and provide a simple, rapid and accurate method for both hotspot and non-hotspot regions.

When Autism Meets Neoplasia? - the *PTEN* Hamartoma Tumor Syndrome. *J. Stein[1], K. Holland[2], C. Eng[1], M.R. Natowicz[1]* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 2) Division of Pediatric Neurology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Autism is an etiologically heterogeneous disorder; different chromosomal and monogenic causes are typically noted in <10% of cases and in most cases a specific etiology is not established. *PTEN* hamartoma tumor syndrome (PHTS) is an autosomal dominant disorder encompassing a variety of clinical syndromes including Bannayan-Riley-Ruvalcaba syndrome (BRRS). Clinically, BRRS is characterized by macrocephaly, lipomas, hemangiomas, hamartomatous intestinal polyposis, and pigmented macules of the penis. Neurological manifestations of BRRS include developmental delay and myopathy. We report a boy with macrocephaly, seizures, hypotonia, markedly delayed speech and cognitive development, lipomas, multiple intestinal polyps, pigmented macules of the penis, hemangiomas, scrotal tongue and autism associated with a de novo germline mutation in the *PTEN* (831-833insT). This case adds to the few published reports regarding a possible association of autism spectrum disorders in those with *PTEN* mutations. The only other published report of a family with classic Cowden syndrome with autistic features also had a germline *PTEN* truncating mutation. While our patient has classic features of BRRS, we have (Butler *et al.*, J Med Genet 2005) identified germline *PTEN* mutations in 3 of 18 children ascertained by macrocephaly and autism alone. In contrast to patients presenting with BRRS and autism, these germline *PTEN* mutations are all missense. Autism spectrum disorders as a true component of PHTS, is supported not only by of our patient-based observations, but by a neuron-specific *pten* knock-out murine model that appears to display features of autism (Kwon *et al.*, Neuron 2006). Therefore, PHTS needs to be seriously considered in individuals with autism who have even only a few major features associated with BRRS or with extreme macrocephaly, particularly in view of the genetic ramifications and medical surveillance implications of this diagnosis.

Copy number analysis and allele quantitation by 60,000 plex Molecular Inversion Probes (MIPs) on GeneChip arrays using 75ng genomic DNA. *Y.K. Wang, M. Moorhead, S. Lin, C. Chen, T.D. Willis, G. Karlin-Neumann, M. Faham* Affy Lab, Affymetrix, South San Francisco, CA.

Copy number polymorphism (CNP) has been identified in recent years as one of the many sequence variations occurring to the human genome. CNP could underlie mechanisms of segmental duplication, fragile sites and regulation of gene expression. Copy number change is also a hallmark of tumor cells. Distinguished patterns of amplification / deletion are associated with various tumor types at specific stages of tumorgenesis. Many chip based technologies, including Bacterial Artificial Chromosome (BAC) CGH, cDNA CGH, and oligonucleotide arrays have been used to address the issues. We are developing technology for copy number analysis based on Molecular Inversion Probes (MIPs). Advantages of this technology include: 1. Sensitivity: Detection of single copy changes. Our performance evaluation is based on false positive and false negative rates using 1X & 3X samples as known single copy changes evaluated against known diploid samples. 2. Customization: Ability to focus on the most relevant genomic segments. 3. Preservation of allele information: loss-of-heterozygosity (LOH) and other disturbances in the allele ratio can be detected. 4. Ability to work with FFPE (formalin fixed paraffin embedded) samples: Given the small probe footprint, degraded samples can work successfully with MIP. We have further developed the protocol in order to use a small amount of DNA (75ng total) and to have 60,000 plex reactions in a single tube. Algorithms have also been developed to 1) correctly assess the data quality of every sample that has been assayed, including highly disintegrated tumor genomes; 2) correct for non-linear effects in signal response (such as saturation at very high copy numbers) so that the inferred copy number measurements are accurate over a wide dynamic range. Examples will be given in the presentation to highlight all the above.

Linkage and association of the CHD7 gene with susceptibility to adolescent idiopathic scoliosis. *C. Wise[1], X. Gao[1], D. Gordon[2], J. Gillum[1], R. Browne[1], C. Helms[3], D. Zhang[1], S. Shoemaker[4], M. Lovett[3], A. Bowcock[3], J. Herring[4]* 1) Seay Center for Musculoskeletal Research, Scottish Rite Hospital, Dallas, TX; 2) Department of Genetics, Rutgers, The State University of New Jersey; 3) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 4) Dept. Orthopaedics, Texas Scottish Rite Hospital, Dallas, TX.

Idiopathic scoliosis (IS) (OMIM 181800) is the most common spinal deformity in children, with a prevalence of 1-2%. The underlying etiology of IS is unknown, although inheritance is complex and linkages to chromosomes 6p, 8q, 9q, 10q, 15q, 16q, 17p, 18q, 19p, and Xq have been described by us and others. A family harboring a co-segregating pericentric inversion of chromosome 8 (inv(8)(p23q11.21) has also been described, where one of the breakpoints resides near a previously detected linkage peak. When a new cohort of 52 IS families was evaluated for linkage to candidate regions as part of a linkage follow-up study, strongest evidence for linkage was obtained with 8q loci (multipoint LOD = 2.77; NPL P = 0.001). Two linked loci also displayed association with IS susceptibility (TDTae < .02). The gene encoding the chromodomain helicase DNA binding protein 7 (CHD7) lies within the interval defined by these loci and approximately 11 Mb distal to the previously reported 8q break. Coding and splice site mutations in CHD7 have been described in the CHARGE syndrome of multiple developmental anomalies. Moreover, a high prevalence (>60%) of later-onset scoliosis has been reported in surviving CHARGE syndrome patients. Linkage and association studies of SNPs within CHD7 in the 52 families revealed overlapping peaks of linkage (two-point ASP LOD = 2.08, P = 9.8x10-4) and association with TDTae P < .005 for multiple loci in a 57 kb block of relatively high linkage disequilibrium encompassing exons 2-4 within CHD7. Our results identify CHD7 as the first candidate gene for IS susceptibility mapped by linkage, and provide insight into its underlying pathogenesis. These findings also suggest possible etiological overlap between more rare, early-onset (CHARGE) and common, later-onset (IS) developmental diseases.

The NCBI RefSeq Project: maintaining annotated genomes. *K. Pruitt* National Center for Biotechnology Information, DHHS/NIH/NLM, Bethesda, MD.

Deriving benefits from genomic sequencing, especially in the area of health care applications, depends on the availability of high-quality sequence and annotation. The National Center for Biotechnology Information (NCBI) supports the maintenance of, effective use of, and access to annotated genomes in several ways including: (a) calculating periodic updates to the annotation; (b) supporting updates of the assembled genome sequence (human and mouse); (c) providing numerous cross-linked resources that are critical to integrating sequence data with biological knowledge; (d) providing the RefSeq collection.

The Reference Sequence (RefSeq) project provides curated sequence standards for proteins, transcripts, and genomes and is used internationally as a reagent for annotating several genomes. Since sequence annotation is provided by more than public resource using different methods, the resulting information is not always identical; the inconsistency in both annotation results and the data presentation style among public annotation resources hampers use of the human genome data and may confound interpretation. The Consensus CDS (CCDS) project was established as a collaboration to identify validated protein coding sequences that have been annotated identically on the human genome by both major providers of annotation data: (a) NCBI (as displayed in the Map Viewer), and (b) WTSI and EBI (as displayed in the Ensembl and UCSC genome browsers). The CCDS collaboration includes ongoing curation of protein coding genes by the collaboration members (NCBI, EBI, WTSI, UCSC). The RefSeq collection is an integral component of the CCDS project; CCDS curation decisions are first reflected in updates to the RefSeq collection, and then in updates to the displayed genome annotation.

The presentation will include the current status of the RefSeq collection, with a focus on the human collection, and including aspects of: a) quality assessment; b) curation; and c) their use in maintaining and updating genome annotation including identification of consistent annotations via the CCDS project.

.

Coexistence in the same family of both focal and diffuse forms of hyperinsulinism. *F. Sauvat[1], V. Valayannopoulos[2], M. Vaxillaire[3], F. Jaubert[4], J. Rahier[5], M. Ribeiro[6], M. Polak[7], C. Nihoul-Fekété[1], P. de Lonlay[2]* 1) Pediatric Surgery; 2) Metabolic Pediatrics, Necker-Enfants Malades Hosp, Paris, France; 3) CNRS UMR 8090, Lille, France; 4) Pathology Department, Necker-Enfants Malades Hosp, Paris, France; 5) Pathology Department, St-Luc Hosp, Brussels, Belgium; 6) CEA, Orsay, France; 7) Ped Endocrinology.

Neonatal hyperinsulinism (HI) is the most important cause of hypoglycemia in early infancy. The inappropriate oversecretion of insulin is responsible for profound hypoglycemia. The histopathological lesions associated with neonatal HI are diffuse or focal. Focal islet cell hyperplasia is sporadic and associated to a loss of maternal alleles from the 11p15 region in the hyperplasic lesion associated to a somatic reduction to hemi- or homozygosity of a paternally inherited mutation of the sulfonylurea-receptor (SUR1) gene. Diffuse HI may be familial and involves SUR1 or the inward-rectifying K+ channel (Kir6.2) in recessively inherited HI. We present here the first case of coexistence of both focal and diffuse neonatal HI in the same consanguineous family. The first child presented at birth with severe neonatal HI. A transhepatic selective pancreatic catheterization revealed a local insulin hypersecretion in the body of the pancreas and a limited pancreatectomy permitted to fully cure the child. A paternally inherited heterozygous mutation of the SUR1 gene has been identified along with a loss of 11p15 heterozygosity (LOH) of maternal origin in the lesion. The second child, a girl, suffered from severe neonatal HI. An 18F-fluoro-L-DOPA PET scan revealed a diffuse uptake of the radiotracer compatible with a diffuse form of HI. Molecular analysis of the SUR1 gene displayed a homozygous SUR1 mutation identical to the one found in the first child at the heterozygous form. Both parents are heterozygous for this mutation. A subtotal pancratectomy has been performed. In conclusion, genetic counseling for couples that had a child with a focal form of HI should be prudent in the case of a consanguineous couple as a heterozygous mutation can be carried by both parents that can lead to a diffuse form of HI in the following pregnancies.

Association of LRRK2 gene tSNPs with early onset Parkinsons disease. *B. Patra[1], A.J. Parsian[1], B. Racette[2], J. Zhao[3], J.S. Perlmutter[2], A. Parsian[1]* 1) University of Arkansas for Medical Sciences, Little Rock,AR; 2) Department of Neurology, Washington University School of Medicine, St. Louis, MO; 3) MRC Epidemiology Unit, Strangeways Research Laboratory, Cambridge, UK.

Pathogenic mutations within the leucine-rich repeat kinase 2 (LRRK2) gene is reported to be responsible for autosomal dominant and late-onset Parkinson disease (PD) along with other six genes that have been identified in PD families (SNCA, PRKN, PINK1, DJ-1, MAPT and UCH-L1). LRRK2 has been described recently as the most common candidate gene for familial and sporadic form of PD (SPD). Mutations in LRRK2 gene have been reported from the PD patients of all ages. Six tagging SNPs (tSNP, Skipper et al., 2005) have been found in LRRK2 that capture the variations within the gene and associated with sporadic PD. In present investigation we screened a sample of 225 familial PD (FPD), 349 SPD, and 187 matched normal controls with the six tSNPs. For tSNP rs10784486, the genotype frequency for CC was significantly (2 = 6.32, p = 0.043 0.0016 SE) higher in SPD than controls. Allele frequency of tSNP rs1388598 C was significantly higher in SPD than FPD (2 =5.48, p=0.0220.0011) and controls (2 =4.48, p=0.0340.0014 SE). The PD affected individuals were categorized into two groups based on age of onset (AON) of 50 and 51 years. Early onset PD (AON <50) showed higher significant association with tSNPs rs10784486 and rs1388598. For tSNP rs10784486 the genotypes CC and AC frequencies were significantly higher in SPD than FPD (AON < 50, 2 = 7.55, p = 0.024 0.0012 SE) and controls (2 = 6.86, p = 0.03 0.0014 SE). Similarly, the rs1388598 CC and CT genotypes frequencies were significantly higher in SPD individuals than FPD (AON < 50, 2 = 6.65, p = 0.026 0.0012 SE) and controls (2 = 9.54, p = 0.008 0.0007 SE). The allele frequency of rs1388598 C allele was significantly higher in SPD (AON <50 years) than controls (2 = 9.60, p = 0.003 0.0004 SE) and FPD (AON < 50, 2 =7.15, p=0.010.0008 SE). We can conclude from our study that variations within LRRK2 gene have strong association with SPD than familial form and may also contribute to onset of SPD.

Investigation of variants within dopamine pathway genes on risk of Parkinsons disease. *J.M. van der Walt, W.K. Scott, G. Mayhew, M.A. Hauser, Y.J. Li, K. Fujiwara, J.M. Vance, E.R. Martin* Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC.

Dopamine is a vital neurotransmitter responsible for controlling both mental and physical health. Dopaminergic neurons degenerate in Parkinson's disease (PD) leading to motor defects observed in patients. We examined polymorphisms within the dopamine beta-hydroxylase (DBH) gene and the aldehyde dehydrogenase 1 family member A1 (ALDH1A1) gene for association with PD risk. These genes were chosen based upon their biological function and location in an area of linkage on chromosome 9q. DBH catalyzes the conversion of dopamine to noradrenaline and has been previously implicated as a protective genetic factor for PD. ALDH1A1 acts in the detoxification of aldehydes that result from the metabolism of dopamine by monoamine oxidase. We investigated the effect of the protective polymorphism located within the promoter region of DBH plus six SNPs including both tagging and supplementary SNPs located throughout the gene for association with PD in a large family-based study (N=760). No significant association was observed between PD and any SNP by the pedigree disequilibrium tests (PDT) or genotype-PDT tests in our overall dataset. We also analyzed 11 SNPs throughout ALDH1A1 and demonstrated significant association in the early onset PD families (age at onset 40 years; N=110) with four markers: rs918836 (5 UTR;p=0.01), rs595958 (intronic; p=0.02), rs8187915 (exon 3, synonymous; p=0.006) and rs2017362 (intron; p=0.01). All associated SNPs are in moderate linkage disequilibrium (r2 range=0.4 - 0.6). Since ALDH1A1 also contributes to the metabolism of ethanol, we examined the interaction of SNPs with alcohol consumption of PD patients using GEE models. A significant interaction was detected with exonic SNP rs81879125 and ever consuming of beer, wine, or liquor (p=0.019). Our findings do not confirm the protective effect of the previously associated polymorphism in DBH; however, these results suggest that variants within ALDH1A1 might influence risk of early onset PD. Defects in ALDH1A1 may lead to impairment in dopamine turnover and cause subsequent oxidative damage within neurons.

Examination of chromosome 1q43 in multiple sclerosis. *N. Schnetz-Boutaud[1], J.L. McCauley[1], Y. Bradford[1], S.G. Gregory[2], D.M. Mortlock[1], S. Schmidt[2], J.R. Oksenberg[3], S.L. Hauser[3], L.F. Barcellos[4], M.A. Pericak-Vance[2], J.L. Haines[1]* 1) Center for Human Genetics Research and Dept of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Center for Human Genetics and Dept of Medicine, Duke University Medical Center, Durham, NC; 3) University of California at San Francisco, San Francisco, CA; 4) University of California at Berkeley, Berkeley, CA.

Although the genetic influence in MS is overwhelming, studies have failed to consistently identify genes specific to MS susceptibility outside of the major histocompatibility complex (MHC). Genomic screens have identified numerous regions of interest for MS loci but, with the exception of the MHC, these studies have largely failed to replicate significant results. We previously performed a genome-wide linkage screen using a panel of 390 microsatellite markers and detected significant evidence of linkage to a region spanning approximately 7Mb within chr1q43 in a dataset of 245 multiplex families. This region is also supported by results from other MS linkage screens and linkage seen in additional autoimmune disorders such as rheumatoid arthritis and systemic lupus erythematosus.

For our follow-up of this region, we selected and tested association to MS for 768 SNPs prioritized based on multi-species conservation. This approach sought to increase the likelihood of successfully identifying an associated SNP given the hypothesis that nucleotides strongly conserved across species are of greater biological importance than those which are less conserved. Association analyses of these follow-up markers revealed multiple (>60) nominally significant (p 0.05) results in an expanded dataset of multiplex and singleton MS families. While none of these markers alone demonstrate overwhelming significance, several of the significant SNPs are clustered within small genomic regions. Furthermore, multiple markers within the *RYR2*, *FMN2*, and *RGS7* genes were significant. Thus these genes are the strongest candidates for involvement in the etiology of MS and are being examined in further detail.

Analysis of nine autosomic STR loci on recent human phylogenies of southeast of Brazil. *R. Silva[1], A. Debes-Bravo[2], L. Morganti[2], S. Bydlowski[2,3], R. Moura-Neto[4]* 1) Instituto de Biofisica Carlos Chagas Filho, Universidade Federal do Rio de Janeiro, Brazil; 2) Divisão de Pesquisa e Biologia Molecular, Fundação Pró-Sangue Hemocentro de São Paulo, Brazil; 3) Departamento de Hematologia, LIM-31, Faculdade de Medicina da Universidade de São Paulo,Brazil; 4) Instituto de Biologia, Universidade Federal do Rio de Janeiro,Brazil.

We have investigated the use of nine STR loci (CSF1PO, TPOX, TH01, vWA, F13A01, FESFPS, F13B, D16S539, D7S820, and D13S317), routinely applied in forensic analysis, for delineating phylogenetic relationships among 5 different geographic groups in Southeast of Brazil, comprising the three major ethnic groups (European-, African-, and Asian-descents). The resulting tree topology was consistent with the ethno-history and ethno-partitioning, corroborating data obtained using classical genetic polymorphisms. The results showed a low coancestry coefficient value across our population. The highest value obtained was 0.0159, taking the São Paulo Asian-descendants and Rio de Janeiro European-descendants. The Brazilian sample data corroborate the notion of human phylogenies in well-defined clusters of ethno geographic origins: African, Caucasian, Greater Asians and Amerindians. It seems reasonable to assume the absence of any population substructure in the São Paulo and Rio de Janeiro databases. Our data on coancestry coefficient (= 0.0045) do not support any calculations that may infer ethnic background and the UPGMA tree analysis has shown no significant genetic distance among the studied groups. Therefore, the profiles of nine STRs on both analyses, PCA and Genetic Distance Analysis were essentially similar and agreed to those data described for other genetic systems already described. Supported by: CNPq, FAPERJ,

.

MAPK Pathway Mutations in CFC Syndrome: Delineation of Molecular Heterogeneity and Genotype-phenotype Correlation. *K.A. Rauen, P. Rodriguez-Viciana, A.L. Estep, W.E. Tidyman* University of California, San Francisco, CA.

Cardio-facio-cutaneous (CFC) syndrome is a multiple congenital anomaly disorder in which individuals have characteristic dysmorphic craniofacial features, cardiac defects, ectodermal anomalies, developmental delay and hypotonia. We recently reported that CFC is caused by alteration of activity through the mitogen-activated protein kinase (MAPK) pathway due to heterogeneous de novo mutations in dual specificity protein kinases B-Raf, MEK1 and MEK2 (Rodriguez, et al., Science. 2006. 311:1287-90.). In this study, we sequenced 13 additional individuals with the clinical phenotype of CFC including two HRAS-mutation negative individuals who phenotypically meet criteria for the clinical diagnosis of Costello syndrome (Estep, et al., Am J Med Genet A 140:8-16.2006). Novel missense BRAF mutations in exons 13 and 16 (the protein kinase domain) were identified that have not been previously described in CFC individuals (Rauen, Am J Med Genet. In Press. 2006). In addition, heterogeneous missense BRAF mutations in exon 11 and 12, novel small in-frame deletions in BRAF exon 11, and a novel MEK2 missense mutation in exon 3 were identified. As more heterogeneous mutations are identified, a genotype-phenotype correlation is emerging. CFC individuals with Q257R B-Raf mutations have many phenotypic features in common including characteristic facies, cardiac defects, short stature, failure to thrive, abnormal brain imaging, musculoskeletal and ocular abnormalities and relatively mild developmental delay. In contrast, individuals with the kinase impaired G596V B-Raf substitution have a milder phenotype as indicated by normal growth and development, and no cardiac, GI or brain abnormalities. Individuals with missense amino acid substitutions reported altered in cancer appear to have more severe phenotypes. CFC syndrome is genetically heterogeneous with several genes within a defined pathway being causative including BRAF, MEK1 and MEK2. As larger cohorts of patients are studied, genotype-phenotype correlations are emerging. In addition, molecular testing will assist in clarifying the correct diagnosis and subsequently will lead to the appropriate management for these patients.

Identifying candidate genes associated with Autism by whole genome tilepath microarray analysis. *J. Virgadamo[1], J.J. Connelly[1], R. Abramson[2], M. Cuccaro[1], J.P. Hussman[3], J.M. Vance[1], M.A. Pericak-Vance[1], S.G. Gregory[1]* 1) Duke Center for Human Genetics, DUMC, Durham, NC; 2) Dept of Neuropsychiatry, SOM-USC, Columbia, SC; 3) Hussman Foundation, Ellicott City, MD.

Autistic disorder (AutD) is a neurodevelopmental disorder characterized by disturbances in social, communicative, and behavioral functioning. Several linkage screens and numerous association studies have been carried out, however a consensus gene implicated in the etiology of AutD has yet to be identified. It has been established that at least 5% of individuals with idiopathic autism contain chromosomal rearrangements, suggesting that genomic loss or gain could underlie the development of AutD. Here we describe use of whole genome BAC tilepath microarrays, at 100kb resolution, to identify regions of chromosomal rearrangement within 121 probands from our unique multiplex AutD families. We have identified 85 regions of large genomic gain or loss (average size 0.8 Mb) contained within at least one or more of the 121 individuals within our dataset. Rearranged regions were defined as those containing a minimum of 3 BAC clones with the same trend of loss or gain within a sliding window of 6 clones. Twenty-eight of these regions contain known copy number polymorphisms (CNPs); 10 contain known segmental duplications; 1 was a novel region of CNP from our control experiments using 54 phenotypically normal individuals; and 46 contained no known duplication or CNP. A total of 15 regions localized to previous linkage data, while 12 of the regions did not contain any known genes. We also identified small regions of loss or gain (individual BAC clones, ~0.1Mb) within at least 10 of the 121 probands in our analysis. Clones needed to show loss or gain across multiple print runs and control individuals, not contain known CNPs and needed to be correctly localized by BAC end sequence. Twenty-seven clones showed genomic loss or gain, including 17 which contained genes and four which localized to known regions of genetic linkage. We are currently following-up these regions by dye-swap arrayCGH experiments and real-time quantitative PCR verification.

Common SNPs in *TCF7L2* are reproducibly associated with type 2 diabetes and reduce the insulin response to glucose in non-diabetic individuals. *R. Saxena[1,2], L. Gianniny[2], N. Burtt[2], V. Lyssenko[3], C. Giuducci[2], M. Sjögren[3], J. Florez[1,2], P. Almgren[3], B. Isomaa[4], M. Orho-Melander[3], U. Lindblad[3,5], M. Daly[1,2], T. Tuomi[4], J.N. Hirschhorn[2,6,7], K. Ardlie[2,8], L. Groop[4], D. Altshuler[1,2,7]* 1) Massachusetts General Hospital, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Lund University, Malmö, Sweden; 4) University of Helsinki, Helsinki, Finland; 5) Skaraborg Institute, Skövde, Sweden; 6) Childrens Hospital, Boston, MA; 7) Harvard Medical School, Boston, MA; 8) Genomics Collaborative Inc., Cambridge, MA.

Recently, common non-coding variants in the *TCF7L2* gene were strongly associated with increased risk of type 2 diabetes in samples from Iceland, Denmark and the US. We genotyped 13 SNPs across *TCF7L2* in 8,310 individuals in family based and case-control designs from Scandinavia, Poland and the US. We convincingly confirmed the previous association of *TCF7L2* SNPs with risk of type 2 diabetes (rs7903146T OR 1.40 (95% CI 1.30 - 1.50); $P = 6.74 \times 10^{-20}$). In non-diabetic individuals, the risk genotypes were associated with a substantial reduction in the insulinogenic index derived from an oral glucose tolerance test (risk allele homozygotes have half the insulin response to glucose of non-carriers; $P = 0.003$), but not with increased insulin resistance. These results suggest that *TCF7L2* variants may act through insulin secretion to increase risk of type 2 diabetes.

Case Report: short rib-polydactyly and macrocephaly, a novel syndrome? *H.Y.C. Wanderley, L.O. Dewes, O.A.P. Artigalas, C. Deutschendorf, R. Giugliani, J.C.L. Leite* Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Porto Alegre, Rio Grande do Sul, Brazil.

The proband is the third child of his parents. He has 2 older sibs. Maternal age at the time of his birth was 31 years old and the paternal age was 37 years old. There was history of a previous miscarriage. Family history was negative for malformations or consanguinity. During pregnancy was detected rib shortening and polydactyly and he was delivered at 38 weeks gestation. Birth weight was 3185 gr. (p25), length 46,5 cm (p5), OFC: 41 cm (p97) . The Apgar scores were 1/4/8. At the first day of life he developed respiratory distress and was transferred for the Neonatal Intensive Unit Care, needing mechanical ventilation. On clinical examination he has a macrocephaly, wide anterior fontanels, small nose, epicantus, lobulated gums, multiple oral frenula, short and narrow thorax, polydactily in hands and feet. X-rays showed narrow thorax with short ribs, shortening of long bones, hands and feet with postaxial polydactily, hypoplasic iliac bones and acetabular dysplasia hook-like downward protusion. These findings suggest Ellis-van Creveld Syndrome (polydactyly, narrow thorax, oral frenula) but macrocephaly is not found in the syndrome. The groups of the short rib-polydactyly syndromes is formed by many entities with little variation among them. The one closest to our case is the Beemer-Langer Type, with findings like craniofacial anomalies, hydrocephaly, small thorax, short limbs, polydactyly, oral frenula, flat face, hipertelorism. The clinical-radiographic features do not allow a definite distinction between the two syndromes, neither others short-ribs syndromes, leading to an overlaping phenotype or a novel syndrome.

Microarray expression profiling identifies genes with altered expression in the developing brain of an AGTR2-deficient mouse. *T. Pawlowski[1,2], S. Heringer-Walther[3], C-H. Cheng[2], J. Archie[1], C-F. Chen[2], T. Walther[3], A.K. Srivastava[1,2]* 1) Greenwood Genetic Center, Greenwood,SC; 2) Department of Genetics & Biochemistry, Clemson University, Clemson, SC; 3) Department of Cardiology, Charité,Campus Benjamin Franklin, Berlin, Germany.

Mental retardation (MR) is the most common developmental disability, affecting cognitive function in about 1-3% of the human population. Studies in humans and mice indicated a possible role for angiotensin II type 2 receptor (AGTR2) in learning, memory, and behavior. Mutant mice lacking AGTR2 ($Agtr2^{-/y}$) were found to be significantly impaired in their learning performance and exhibited abnormal dendritic spine morphology (T. Walther, unpublished), a feature consistently found to be associated with MR. However, AGTR2 gene function in brain and the molecular mechanism by which AGTR2 exerts its physiological action remains elusive. In order to identify transcripts in the developing brain that depend on AGTR2 function, we analyzed RNA isolated from brains of $Agtr2^{-/y}$ and control mice at developmental stage E15 and at birth using Agilent whole mouse genome 44K arrays. Gene expression profiles of the $Agtr2^{-/y}$ brain samples were compared to profiles of the control brains. A Q-test followed by a t-test (FDR0.1) produced a list of 39 differentially expressed genes at E15 in $Agtr2^{-/y}$ mouse brain. Data analysis using GeneSpring GX (FDR0.3 and p.001) produced a list of 133 genes (88 up-regulated, 45 down-regulated) differentially expressed at E15. A similar analysis (FDR 0.3 and p.005) in newborn brains identified a list of 397 differentially expressed genes (270 up-regulated, 127 down-regulated) in $Agtr2^{-/y}$ mouse brain. Validity of expression differences at E15 was verified by real time RT-PCR quantitation for 7 genes: Ahcy, Ube2m, Bmp2k, Syn2, Prosc, Prdm16, and Nfia. These differentially expressed genes encode molecules that are involved in multiple cellular functions. Further analysis might reveal if some of the genes influenced by AGTR2 may also contribute to the pathophysiology of mental retardation.

Detection of a de novo interstitial 2q microdeletion by CGH microarray analysis in a patient with limb malformations, microcephaly and mental retardation. *A.M. Svensson[1, 2], C.J. Curry[4], S.T. South[1], H. Whitby[1], J. Fisher[4], A.J. Brothman[1,3]* 1) Department of Pediatrics, Univ of Utah, Salt Lake City, UT; 2) Department of Pathology, Univ of Utah, Salt Lake City, UT; 3) Department of Human Genetics, Univ of Utah, Salt Lake City, UT; 4) Genetic Medicine Central California/UCSF, Fresno, CA.

We report on a 16 year old Laotian-American female, who first presented at age 2 ½ with microcephaly, developmental retardation, and skeletal abnormalities of the upper limb including mild, simple, incomplete syndactyly involving the web spaces between the second and third and the third and fourth fingers, short middle phalanges and significant clinodactyly of the fifth digit at the distal IP joint on both hands, as well as symphalangism involving the metacarpal joints of the second and fifth digits bilaterally and mildly anomalous palmar dermatoglyphics. Her lower limbs displayed symphalangism of the phalangeal-metatarsal junction of the second, third and fourth digits on both feet, with fusion of the middle and distal phalanges of the second and fifth digits and hallux valgus bilaterally. The patient is the daughter of healthy, non-consanguineous parents and has a 21-year old sister in good health. Family history is unremarkable. A G-banded chromosomal study performed at age 4 showed normal results. Following re-examination at age 15 ½, a comparative genomic hybridization analysis was performed. Genomic microarray analysis by the Spectral Genomics Constitutional Chip did not reveal any abnormalities. However, analysis using the Spectral Genomics 1 Mb Hu BAC array platform indicated a microdeletion involving two BAC clones mapping to chromosome 2 at band q31.1, suggesting partial monosomy for this region. FISH using a probe corresponding to one of the deleted BAC clones confirmed deletion of this region in the patient, but showed no deletion in either parent. The minimal size of the deletion is 1.207 Mb and the maximal size is 3.334 Mb. This small deletion is likely responsible for the patient's phenotype. The candidate genes involved in limb development in the implicated region will be discussed.

Nearly identical haploid karyotype in two tumors, masked by the larger pseudo-diploid subclone. *D.L. Van Dyke[1], S. Wei[2], K.G. Monaghan[2], P. Blunden[3], P. Mazzara[3], R. Raghavan[4], A.M. Oliveira[1], A.E. Wiktor[1], G. Keeney[1], R.P. Ketterling[1]* 1) Mayo Clinic, Rochester, MN; 2) Henry Ford Hospital, Detroit, MI; 3) St John Medical Center, Detroit, MI; 4) Loma Linda University Medical Center, CA.

Near-haploid karyotypes in cancer are very uncommon, except in acute lymphoblastic leukemia. They are observed sporadically in sarcoma and carcinoma, but are recurrent findings in inflammatory leiomyosarcoma. We describe the karyotype and genotype of two distinct tumors with strikingly similar nearly identical near-haploid karyotypes - a peritoneal mesothelioma and a retroperitoneal malignant peripheral nerve sheath tumor. The findings suggest that they share some of the same mechanisms of clonal evolution despite their distinct biology. Tumor diagnoses were confirmed by histopathology and immunohistochemistry. Cell cultures were established from tumor adjacent to the ovary (Case 1) or pelvic mass (Case 2). The karyotype of Case 1 (biphasic mesothelioma) was 27,XX,i(5)(p10),+7,der(15)t(8;15)(q24.1;p11.2),+dic(1;20)(p13;p13)[2]/54,idemx2[90]/101-108,idemx4[19]. The chromosome result of Case 2 (malignant peripheral nerve sheath tumor) was 26,X,+i(5)(p10),+7,der(15)t(1;15)(q12;p12),+20[5]/52,idemx2[20]. In both cases, reverse transcriptase polymerase chain reaction analyses were negative for the synovial sarcoma fusion genes. The karyotypes were near-haploid but diploid for 1q, 5p, 7, and 20. Chromosome 7 remains diploid in most near-haploid tumors, suggesting that monosomy or partial loss of chromosome 7 is lethal to these cells. A potential effect of near-haploidy is loss of tumor suppressor gene expression, with the remaining gene inactivated by another mechanism. For mesothelioma, other than p16, p14 and NF2, the importance of tumor suppressor genes is unknown. These cases illustrate an under-appreciated mechanism of global loss of heterozygosity by extensive chromosome loss from a diploid cell population. Near-haploid tumors may be more common than generally recognized because most exhibit a predominant near-diploid subclone masking its near-haploid origin (only two near haploid metaphase cells were found in Case 1).

Performance and data quality comparison for two genome wide association products: Illumina Sentrix Human-1 Genotyping Beadchip and Affymetrix GeneChip Human Mapping 100K Set using AREDS study samples. *Y. Tsai[1], C. Bark[1], K. Hetrick[1], H. Hobbs[1], J. Strand[1], E. Kwasnik[1], M. Barnhart[1], J. Gearhart[1], H. Chin[2], P. Dudley[2], K. Doheny[1], E. Pugh[1]* 1) CIDR, IGM, JHUSOM, Baltimore, MD; 2) NEI, NIH, Bethesda, MD.

A total of 400 case and 200 control Age Related Eye Diseases samples were analyzed on both products. Affymetrix sample/data integrity was assured via custom informatics tools integrated with Affymetrix SDKs and PE Multiprobe II worklisting. Samples were injected into GeneChips using the Multiprobe and all sample/experiment information was uploaded into the GCOS database. Illumina's automation programs were used on a Tecan robot as well as custom applications developed for the Biomek 2000 and PE Multiprobe II. Illumina sample/data integrity was assured using a custom LIMS application. The DM and BRLMM algorithms were used to analyze Affymetrix data. BeadStudio software and standard cluster file was used to analyze Illumina data. There was no manual data editing. The Affymetrix BRLMM and Illumina datasets excluded samples with call rates less than 97.5% (7 Illumina, 87 Affymetrix). The reproducibility rates for Affymetrix DM, BRLMM, and Illumina were 99.82%, 99.85% and 99.995%. The Mendelian consistency rates were 99.83%, 99.54% and 99.995%. Concordance with HapMap data for control samples was 99.75%, 99.75% and 99.64%. Overall data quality of BRLMM analyzed data was verified through comparison of 4,242 shared SNPs and 533 shared samples between the two 100K platforms. The concordance rate was 99.90%. For final release, we excluded SNPs with replicate or inheritance errors or call rates in the lowest one percentile (1,693 Illumina, 3,728 Affymetrix BRLMM). There were 116,190, 112,467 and 107,672 called SNPs for Affymetrix DM, BLRMM and Illumina, respectively. Likewise the respective call rates were 97.7%, 99.5% and 99.8%. After recalling all Affymetrix data using BRLMM, the call rate and other data quality measures are similar between the two products. However, the redo rate for Affymetrix remains higher than that of Illumina (14% versus 5%) and there is substantial more labor required to produce the Affymetrix dataset.

New Communities Added to the International HapMap Project Resource: Analysis of Microsatellite Frequencies.
L.H. Toji, C.M. Beiswanger, B.A. Frederick, D.L. Coppock Coriell Institute for Medical Research, Camden, NJ.

In Phase I and II of the International HapMap Project, four communities were selected for inclusion, the CEPH samples from Utah (of European ancestry), the Yoruba from Ibadan, Nigeria, Han Chinese in Beijing, China and Japanese in Tokyo, Japan. In collaboration with the NHGRI, the NIGMS Human Genetic Cell Repository has prepared lymphoblastoid cell lines and DNA from each of the submitted samples. Extensive analysis of the first set of samples from these communities yielded over 3,900,000 SNPs for each cell line. A second set of samples from each of these communities is being distributed for additional study. Cell lines and DNA are being prepared from samples from seven additional communities. Samples from the Denver (Colorado) Metropolitan Han Chinese Community, Luhya from Webuye, Kenya, People of Mexican Origin in Los Angeles, California, and People with African Ancestry in the Southwestern United States are available. The samples from the Tuscan Community from Prato, Italy and the Gujarati Community from Houston, TX are currently being collected. As part of the routine quality control procedure to distinguish individual samples in the Repository, the identity of each DNA sample in these panels has been confirmed using a set of six highly polymorphic microsatellite markers. The cumulative profiles for each marker for the HapMap panels will be compared to each other and to previously collected profiles from the NIGMS Repository; the similarities and differences between all of the panels will be discussed. Additional information about the availability of these samples can be found at: http://ccr.coriell.org/nigms/ products/hapmap.html.

Polyglutamine-expanded peptides produce neurodegeneration through a JNK-dependent, Bax-dependent pathway of apoptotic activation. *J.E. Young[1], J.P. Taylor[3], R. Martinez[1], A.C. Smith[1], K.H. Fischbeck[4], G.A. Garden[2], A.R. La Spada[1]* 1) Lab Medicine, Univ. of Washington, Seattle, WA; 2) Neurology, Univ. of Washington, Seattle, WA; 3) Neurology, Univ. of Pennsylvania, Philadelphia, PA; 4) NINDS, NIH, Bethesda, MD.

Nine neurodegenerative diseases are caused by polyglutamine (polyQ) tract expansions in unrelated proteins. Studies suggest that the pathology in these diseases stems from the production of a misfolded polyQ-expanded protein which disrupts normal cellular pathways through a gain-of-function effect. Many polyQ proteins are cleaved, yielding a polyQ-containing peptide with enhanced toxicity. To understand the toxicity of truncated polyQ-expanded peptides, we expressed N-terminal fragments of polyQ-expanded androgen receptor (AR), huntingtin (htt), and ataxin-7 (atx7) in neuronal cell lines and primary neurons. Expression of these N-terminal peptides induced caspase-dependent apoptosis in primary cortical or cerebellar granule neurons. Using neurons derived from transgenic mice or mice deficient in apoptosis-related genes, we determined that apoptosis induced by polyQ-expanded AR, htt, and atx7 is dependent on the pro-apoptotic gene Bax and can be inhibited by the anti-apoptotic protein Bcl-2 ($p < .05$ by ANOVA). Because several pro-apoptotic BH3-only proteins are transcriptionally regulated by Jun NH2-terminal kinase (JNK), we tested the role of JNK in the apoptotic activation pathway. We observed that phosphorylation of c-Jun was an early event by immunostaining primary neurons for c-Jun-P shortly after expressing polyQ-expanded proteins ($p < .05$) and the presence of a JNK inhibitor prevented cell death and degeneration in these cells ($p < 05$). Interestingly, cytosolic localization of the truncated polyQ-expanded proteins was required for toxicity and cell death. Therefore, our studies suggest that truncated polyQ-expanded peptides in the cytosol result in JNK-mediated cell stress, culminating in Bax-dependent activation of caspases in primary neurons. These findings provide impetus for the development of therapeutic agents aimed at the inhibition of proteolytic cleavage of polyQ proteins.

Symptomatic monoallelic dimorphic mosaicism resulting from early embryonic mitotic mutations. *U. Schwarze*[1], *D.L. Riegert-Johnson*[2], *H.C. Dietz*[2], *P.H. Byers*[1] 1) University of Washington, Seattle, WA; 2) Johns Hopkins University, Baltimore, MD.

We recently identified two individuals who were mosaic for two reciprocal mutations such that they had cells with one normal allele and one of each of two mutant alleles, but no cells with only normal alleles. The first individual is a 3 year old boy with bilateral congenital hip dislocation and significant joint hypermobility. Cultured fibroblasts made some normal and some abnormal type I procollagen molecules with the abnormal molecules resembling those seen in Ehlers Danlos syndrome (EDS) type VIIB, but with less than the expected amount of the abnormal pro2(I) chain. The cDNA contained normal *COL1A2* transcripts and two abnormal transcriptsone in which exon 6 was missing and another that lacked exons 4-10. The first mutation deleted the 3end of exon 6, and a portion of intron 6. The second mutation had breakpoints in introns 3 and 10 with the ends joined by a reverse complementary portion of intron 6. Single cells contained one normal allele and either mutant allele. The normal allele was the same in all cells and the two mutations had each occurred on the other chromatid. No cells had only normal alleles. The second individual had symptomatic vascular EDS and was mosaic for two mutations in the *COL3A1* gene that were in equal abundance and, combined, were equal in amount to the normal allele. Both mutations deleted 27bp from exon 48 of the gene. That exon has a repeat element of 14nt separated by a 13nt spacer; the repeat differs by one nucleotide. The deletions removed either the first repeat and the 13nt spacer or the spacer and the second 14nt repeat. The mutations occurred by mitotic rearrangement during division of the first cell that gave rise to the lineage from which the embryo developed. Other individuals in whom deletions or duplications are present could also have reciprocal or related mutations that have not been identified. Finally, such findings could explain the unexpected birth of children with different but related phenotypes to individuals with an identified mutation who is unknown to be mosaic for different mutations in the same gene.

A zebrafish model of cobalamin C deficiency displays development defects of the central nervous system. *J. Sloan[1], T. Blake[2], R.J. Chandler[1], M.S. Tsai[1], B.P. Brooks[3], C.P. Venditti[1]* 1) GDRB/NHGRI/NIH, Bethesda, MD; 2) Zebrafish Core Facility/NHGRI/NIH, Bethesda, MD; 3) OSD/NEI/NIH,Bethesda, MD.

Cobalamin C deficiency (cblC) features a combined impairment of the cobalamin dependent enzymes, methionine synthase and methylmalonyl-CoA mutase. It is caused by mutations in MMACHC, a gene of unknown function that is suspected to participate in intracellular cobalamin trafficking. The clinical spectrum of cblC is wide and can feature prenatal manifestations, such as congenital microcephaly and intrauterine growth retardation (IUGR). To examine the phenotype caused by loss of function of this gene, we have created and studied a zebrafish model of cobalamin C deficiency. The zebrafish MMACHC gene was identified using informatics and cDNA cloning. FITC-tagged morpholinos targeting the cognate ATG and an exonic junction were designed and used to knock-down the zebrafish homologue. Both morpholinos produced a similar phenotype and displayed a dose-dependent response. Injected fish began to display defects at 24 hours, including brain necrosis and diminished movement when compared to injected controls. The morphants had delayed hatching and by 48 hours, were significantly smaller in size, had less blood, smaller heads and eyes, and grossly abnormal swimming and behavior compared to controls. By 96 hours, some animals displayed pericardial edema. Additionally, histologic examination revealed a fatty liver. RT-PCR studies using total RNA from the exonic morphants harvested on day 6 showed a knock-down of the cognate message. Metabolic analysis using extracts derived from the morphants showed increased homocysteine, methylmalonic acid and cystathionine, a pattern similar to that seen in affected patients. The model presented here is the first animal model of cblC and faithfully replicates some of the more severe findings seen in humans. Furthermore, it demonstrates the utility of zebrafish to easily examine aspects of metabolic diseases that will be difficult to study in other organisms, such as embryonic manifestations, and should facilitate the testing of new therapies for cobalamin C as well as allow developmental mechanisms affected in this disorder to be explored.

Association of VEGFR-1, 2, and 3 htSNPs with susceptibility to preeclampsia. *S.M. Zeng[1], J. Yankowitz[1], J. Murray[2], D. Merrill[3]* 1) Dept OB/GYN, Univ Iowa Col Med, Iowa City, IA; 2) Dept Ped, Univ Iowa Col Med, Iowa City, IA; 3) Dept OB/GYN, Wake Forest College of Medicine, Winston-Salem, NC.

Preeclampsia (PE) is a multiorgan, pregnancy-specific disorder, characterized by hypertension and proteinuria. PE is a major cause of maternal and neonatal mortality and morbidity worldwide. The etiology of PE remains unclear. Placental angiogenesis-related factors such as sFLT-1 (soluble fms-like tyrosine kinase 1), vascular endothelial growth factor (VEGF), placental growth factor (PlGF) and their receptors including VEGFR-1 (FLT-1), VEGFR-2 (Flk or KDR) and VEGFR-3 (Flt-4) may be involved in PE pathogenesis. We previously performed a haplotype-based association study on VEGFR-1 and showed one SNP at intron 17 linked to PE risk. We hypothesize that some SNPs of VEGFR genes contribute to PE susceptibility.We investigated the association of VEGFR-1, -2 and -3 htSNPs with PE susceptibility. A haplotype-based association study was carried on in a Caucasian population including 564 patients with PE and 564 normal pregnant women. Diagnosis of PE was according to the standard criteria. The htSNPs were selected from HapMap (www.hapmap.org). We genotyped 3 htSNPs for upstream and 3 for downstream of VEGFR-1, 2 neighboring the htSNP previously linked to PE-risk, 6 htSNPs for VEGFR-2 and 4 htSNPs for VEGFR-3. Genotyping was performed using TaqMan-PCR assay. Over 400 patients and over 400 controls yielded clear genotype data for each htSNP.

One htSNP upstream to VEGFR-1 and 1 in VEGFR-2 had a significant difference in genotype and allele frequencies between patients and controls. Both were in Hardy-Weinberg equilibrium (P0.05). The other 16 htSNPs had no significant difference in their allele and genotype frequencies between controls and patients (P0.05). The upstream htSNP is between VEGFR-1 and C13orf12, 27 kb upstream from VEGFR-1. The frequency of its minor allele C was significantly higher in the patients (472/890=0.530) than in the normal women (443/930=0.476) (P0.025). The VEGFR-2 htSNP is in intron 12. Its minor allele T had a significantly lower frequency in patients (270/826=0.327) than in controls (354/930=0.381) (P0.025).

Mechanisms and clinical outcomes associated with placental mesenchymal dysplasia. *W. Robinson[1], J.L. Lauzon[2], A.M. Innes[2], J. Slee[3], K. Lim[1], S. Arsovska[1], N. Smith[4], A. Murch[4], D.E. McFadden[1]* 1) U. British Columbia, Vancouver, BC, Canada; 2) U. of Calgary, Alberta Children's Hosp., Calgary, AB, Canada; 3) Genetic Services of West. Australia, Princess Margaret Hosp. for Children, Perth, Australia; 4) King Edward Memorial Hospital Subiaco, Australia.

Placentae with mesenchymal dysplasia (PMD) are typically larger than average and show cystic areas on ultrasound. Diagnosis is confirmed by the observation of enlarged hydropic villi, abnormal placental blood vessels, and absence of trophoblast hyperplasia on pathological examination. Fetal outcomes are variable and are often associated with growth restriction. However, enigmatically, some fetuses show features of Beckwith-Wiedemann syndrome (BWS). PMD has recently been associated with androgenetic (complete paternal uniparental disomy) mosaicism in the placenta. To understand the origin and outcomes of PMD, we preformed detailed molecular testing of placental, fetal and parental samples from three new cases of PMD. Including two previous cases (Kaiser-Rogers et al. J Med Genet 43:187), four of five PMD cases showed a placental karyotype of 46,XX but had a mixed population of androgenetic and normal cells that appeared to be derived from fertilization of a single egg with either one or two sperm. All four cases showed some fetal growth restriction and two presented with liver cysts and/or liver hemangiomas. Three of these four cases survived to term and showed normal post-natal development, but all three had multiple capillary skin hemangiomas. In contrast, the fifth case was a male fetus showing overgrowth with an enlarged heart, marked fetal ascites and intrauterine fetal death at 34 weeks, but no other BWS features. Mosaicism for an unbalanced translocation leading to deletion of the maternal copy of the BWS region on 11p15.5 was observed in placental, but not fetal samples. Thus, PMD can be caused by mosaic loss of maternally expressed genes in 11p15.5 alone, though is more often associated with whole-genome androgenetic mosaicism or chimerism. Variation in fetal outcomes appear to result from differences in both the underlying mechanism and the level and distribution of abnormal cells.

Heterozygosity of A91V-PRF1 in patients with Familial Hemophagocytic Lymphohistiocytosis. *K. Zhang[1], J.A. Johnson[1], J. Biroschak[1], J. Villanueva[2], S.M. Lee[2], J. Bleesing[2], R.J. Wenstrup[1], A.H. Filipovich[2]* 1) Division of Human Genetics, Cinncinnati Children's Hosp, Cincinnati, OH; 2) Division of Hematology/Oncology, Cinncinnati Children's Hosp,.

Familial hemophagocytic lymphohistiocytosis (FHL) is a genetically heterogeneous disorder of immune regulation characterized by defects in cell-mediated cytotoxicity that results in fever, hepatosplenomegaly and cytopenias, typically in early childhood. FHL is inherited in an autosomal recessive manner. Mutations in either PRF1 or Munc13-4 are identified in about 50% of North American patients with FHL. The A91V-PRF1 genotype has been variously reported as a nonpathogenic variant, a genetic modifier, and as a disease-causing mutation. To further illustrate the relationship of A91V-PRF1 with FHL, we investigated the A91V-PRF1 allele in 150 unrelated patients with the clinical diagnosis of FHL in North America. The heterozygous A91V-PRF1 genotype was observed in 24 unrelated FHL families, significantly more frequent than observed in our race-matched control population (16% vs. 3%, $P<0.01$). This suggests that A91V-PRF1 is an important genetic susceptibility factor for developing of FHL. Four of the A91V-PRF1 patients had other bi-allelic PRF1 mutations. Mutational analysis of Munc13-4 was performed in 14 of the remaining A91V-PRF patients. Three patients with heterozygous A91V-PRF1 had bi-allelic Munc13-4 mutations, three were heterozygous for Munc13-4 mutations and eight did not have identified mutations in Munc13-4. The finding of A91V-PRF1 in combination with homozygous and heterozygous mutations in Munc13-4 and PRF1 suggests that A91V-PRF1 acts as a genetic modifier in individuals with underlying disease-causing mutations in PRF1 or Munc13-4 and may influence disease-expression. Additional studies need to be done to illustrate the exact functional effect of A91V-PRF1 in the cytotoxic pathway. In summary, A91V-PRF1 appears to be an important genetic susceptibility factor, but is not disease-causing per se. Mutational analysis of Munc13-4 and other HLH causing genes is recommended for HLH patients with A91V-PRF1 genotype.

Natural History of MPS II: Clinical Aspects. *L.L.C Pinto, I.V.D Schwartz, M.V.R Muñoz, T. A. Vieira, R. Giugliani*
Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Porto Alegre, RS, Brazil.

Purpose: MPS II is an X linked disorder caused by a deficiency of iduronate sulphatase. The incidence of MPS II is 1:400.000 live births. Clinical findings are very heterogeneous. Phenotypes of MPS II can be classified as mild or severe due to absence/presence of neurological impairment. This is the first study performed in Brazilian MPS II patients about the natural history of this disease. The aim of this study was to characterize the natural history of this disease. Methods: An observational study was conducted in 20 Brazilian MPS II male patients. W e collected the data including asked to present age clinical course, age of onset, symptoms, history of neurological regression. A physical examination of all patients was performed. Results: 1) Regional distribution in Brazil: Southeast (10/20), Northeast (6/20) and South (4/20; 2) current age ranging between 3 and 26 yrs (average: 9.4 yrs); 3) Average age at symptoms onset: 2.3 yrs; 4) Average age at biochemical diagnosis: 5.9 yrs; 5) Major initial symptoms: increased abdominal volume and upper airway infection; 6) Sixteen (16/20) patients underwent surgical procedures, mainly hernioraphy; 7) Six (6/20) patients present mild MPS II; 8) Ten patients (10/20) presented neurological regression (5.1 yrs average); 9).Six (6/20) patients had history of epilepsy; 10).Two (2/20) patients were whealchair dependent; 11) Twelve (12/20) patients reported respiratory symptoms; 12) Seven (7/20) reported ear tubes usage and three (3/20) were using hearing aids; 13) The heigth was below 2 SD in 10/19 patients; 14) Macrocephaly was present in 18/20 patients; 15) Weight was above 2 SD in 7/20 patients; 16).Plebby ivory skin was observed in 3/20 patients. Conclusion: These data may contribute to a better understanding of the progressive nature of this disease, which should be taken into account on the assessment of efficacy of treatment protocols.

Association of vitamin D receptor haplotypes with early onset type 1 diabetes in Newfoundland. *K.S. Wang[1], M. Liu[1], B. Bharaj[1], H.T. Chen[1], J.A. Curtis[2], L.A. Newhook[2], A.D. Paterson[1,3]* 1) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Canada; 2) Department of Pediatrics, Memorial University of Newfoundland, St. John's, Canada; 3) Department of Public Health Sciences, University of Toronto, Toronto, Canada.

Background: Type 1 diabetes (T1D) is a T-cell mediated autoimmune disease. Several epidemiological studies in humans provide evidence that vitamin D supplementation can decrease the risk of T1D while in animal models vitamin D can prevent or suppress the development of various autoimmune diseases. Vitamin D compounds are known to suppress T-cell activation by binding to the vitamin D receptor (VDR) on chromosome 12q12-14. Some VDR polymorphisms have been implicated in susceptibility to T1D, but reports have been inconsistent. Therefore, it is crucial to investigate the association of more VDR polymorphisms and their haplotypes with T1D and age at onset (AAO). **Methods:**Six SNPs in the VDR gene, one commonly studied SNP rs10735810 (FokI) and five newly identified SNPs covering three haplotype blocks (A, B and C), were genotyped in 512 families from a relatively isolated population in Newfoundland (NF) which has a high incidence of T1D. PBAT-GEE was used to asses the association. For haplotype analysis, we used a sliding window of 3 adjacent SNPs. We also stratified T1D according to their AAO (16 years) (420 early and 92 late onset probands) to reduce the possible heterogeneity. **Results:** An association was observed between rs2408876 and T1D in the early onset families (p=0.027). Particularly, a three-SNP haplotpye defined by rs10735810-rs2408876-rs6823 showed the most significant association with T1D (p=0.000035) in the early onset families. Furthermore, the same three-SNP haplotype revealed the most significant association with AAO in the early onset families (p=0.00026). **Conclusions:**Our findings strongly support a role of VDR haplotypes in the etiology of early onset T1D in NF population but the causative variant remains to be determined. In future research it is necessary to identify more variants and perform haplotype analysis combined with functional studies in order to elucidate the role of the VDR gene in T1D.

Generalized Genomic Distance-Based Regression Methodology for Multilocus Association Analysis. *J. Wessel*[1, 2, 3], *N.J. Schork*[1, 2] 1) Dept Psychiatry, Univ California, San Diego, La Jolla, CA; 2) Dept Family and Preventive Medicine, Univ California, San Diego, La Jolla, CA; 3) Graduate School of Public Health, San Diego State University, San Diego, CA.

Large-scale, multilocus genetic association studies that either focus on candidate genes or the whole genome require powerful and appropriate statistical analysis tools that are designed to relate genotype and haplotype information to phenotypes of interest. Many analysis approaches consider relating allelic, haplotypic, or genotypic information to a trait using extensions of traditional analysis techniques such as contingency table analysis, regression methods, and analysis-of-variance techniques. We consider a complementary approach that involves the characterization and measurement of the similarity of the allelic composition of a set of individuals diploid genomes at multiple loci in the regions of interest or across the entire genome. We describe a regression method that can be used to relate variation in the measure of genomic dissimilarity (or distance) among a set of individuals to variation in their trait values. Weighting factors associated with functional or evolutionary conservation information of the loci can be used in the assessment of dissimilarity. The proposed method is very flexible and easily extended to complex multilocus analysis settings involving covariates. In addition, the proposed method actually encompasses both single locus and haplotype-phylogeny analysis methods, which are two of the most widely used approaches to genetic association analysis. We showcase the method with data described in the literature taking both a candidate gene approach and whole genome association. Ultimately, our method is appropriate for high-dimensional genomic data and anticipates an era when cost-effective exhaustive DNA sequence data can be obtained on a large number of individuals over-and-above genotype information focused on a few well-chosen loci.

Low expression of *GJB2* and *GJB6* segregates with DFNB1 deafness and with a distant 131 kb deletion in an extended Michigan family. *E. Wilch[1], M. Zhu[2,3], K.B. Burkhart[3,4], M. Regier[5], J.L. Elfenbein[6], R.A. Fisher[7], K.H. Friderici[1,2,3,7]* 1) Genetics Program, Michigan State Univ, East Lansing, MI; 2) Cell & Molecular Biology Program, Michigan State Univ, East Lansing, MI; 3) Department of Microbiology & Molecular Genetics, Michigan State Univ, East Lansing, MI; 4) Life Sciences Institute, Univ of Michigan, Ann Arbor, MI; 5) Department of Epidemiology, Michigan State Univ, East Lansing, MI; 6) Department of Communicative Science & Disorders, Michigan State Univ, East Lansing, MI; 7) Department of Pediatrics & Human Development, Michigan State Univ, East Lansing, MI.

In a large kindred of German descent, we have identified a novel allele that segregates with profound deafness when present in *trans* with the 35delG allele of *GJB2*. Qualitative PCR-based allele-specific expression assays show that expression of both *GJB2* and *GJB6* from the novel allele is dramatically reduced. Individuals carrying this allele also have on the same chromosome a 131 kb deletion whose proximal breakpoint is about 148 kb upstream of the transcriptional start site of *GJB6*. This deletion overlaps two previously identified deletions of 309 kb and 232 kb that truncate *GJB6* and that segregate as recessive DFNB1 mutations. The three deletions share a common interval of 96 kb. Taken together, these data suggest that disruption of a relatively distant regulatory element of *GJB2* and *GJB6*, such as a locus control region, explains the low-expression phenotype that we have observed, and is responsible for the deafness in individuals bearing these deletions in *trans* with identified *GJB2* mutations. Characterization of *GJB2/GJB6* regulatory elements may provide the means to identify many more *GJB2* mutations that are believed to exist, but that have so far remained elusive.

Array CGH is superior to other methodologies at detecting somatic mosaicism. *V.R. Sutton, C. Shaw, D.A. Scott, A. Patel, S. Trilochan, A. Pursley, J. Li, P. Stankiewicz, A.C. Chinault, J.R. Lupski, A.L. Beaudet, S.W. Cheung* Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

We have developed a targeted aCGH platform known as chromosome microarray analysis (CMA) for clinical use in our diagnostic laboratory. This platform contains bacterial artificial chromosome (BAC) clones that encompass telomeric and pericentromeric regions as well as regions of the genome involved in common microdeletion/microduplication (genomic) disorders. Therefore in a single assay, hundreds of genomic regions can be interrogated for gains or losses in copy number. We have performed CMA using the latest version of our array on 2585 samples and identified 12 cases in which the results were indicative of mosaicism. Ten had an aneuploidy, one had a ring chromosome and one had segmental aneusomy. In 11/12 cases, prior routine chromosome analysis had been normal. We therefore hypothesized that CMA may be a more sensitive method for detecting mosaicism. The presence of mosaicism in all cases was confirmed by one or more of the following methodologies: G banded chromosome analysis of stimulated T-cells or B-cells from peripheral blood or cultured skin fibroblasts; FISH analysis on stimulated T-cells or whole blood smear. Estimates of the level of mosaicism were higher for CMA compared with methodologies that use T-cells in all cases. We believe that this is due to the selection bias against aneuploid T-cells both *in vivo* during VDJ recombination and cellular division, and *in vitro* during T-cell stimulation for routine chromosome analysis and FISH. The estimates of the level of mosaicism were also higher for CMA compared with FISH of unstimulated nucleated cells from whole blood in almost all cases, likely because FISH requires that the cells are alive and aneuploid cells likely die at a faster rate than euploid cells. Thus, we assert that CMA is superior to other standard methodologies in detecting mosaicism and estimating the level of mosaicsm for both aneuploidies and other cytogenetic aberrations.

Gene-Gene Interaction in Nicotinic Receptor Genes: Association Study of Smoking in Adult ADHD. *S. Voineskos, V. De Luca, J. Umesh, J. Kennedy* Dept Psychiatry, CAMH, Clarke, Toronto, ON, Canada.

A number of studies have suggested that the alpha-7-nicotinic receptor subunit gene D15S1360 polymorphism is associated with schizophrenia, and a deficiency in the normal inhibition of the P50 auditory-evoked response. Schizophrenia patients and some patients with ADHD show a failure of inhibition in their 50 ms response to the second of a pair of tones. Furthermore, high-dose nicotine transiently normalizes the abnormality in P50 inhibition in schizophrenia patients and in their relatives. Psychiatric patients are heavy smokers. This rate is higher than the general population. In this study we hypothesized that the D15S1360 marker and other nicotinic receptor genes are associated with increased smoking in patients with Adult ADHD. Our sample consisted of 200 DSM-IV patients affected by Adult ADHD from the Toronto area. Current smoking status was assessed by medical history questionnaire, and there were 56% of smokers and 44% non-smokers. There was no difference in age or ethnicity between the two groups. We found no association between the D15S1360 alleles and smoking risk (chi-sq=4.45, 3df, p=0.21). Although these findings are negative, further study into the relationship between smoking and nicotine system genes is warranted in psychiatric population.

Replication of the association between NOS1AP (CAPON) and cardiac repolarization in the Old Order Amish.

W. Post[1], H. Shen[2], C. Damcott[2], A. Chakravarti[1], D.E. Arking[1], W.H.L. Kao[1], J. OConnell[2], B.D. Mitchell[2], A.R. Shuldiner[2] 1) D.W. Reynolds Center, Johns Hopkins University, Baltimore, MD; 2) Division of Endocrinology, Diabetes and Nutrition, University of Maryland, Baltimore, MD.

The electrocardiographic QT interval is a measure of cardiac repolarization that predicts risk for cardiovascular events in the general population. Through a genome-wide association study in the German KORA Study, we recently reported variation in QT interval to be associated with a SNP in NOS1AP (rs10494366), the gene encoding the PDZ ligand of neuronal nitric oxide synthase. These results were subsequently replicated in two other independent Caucasian populations from Germany and the U.S. Since genetic heterogeneity between populations may exist, we assessed the association between NOS1AP and the QT interval in the Old Order Amish using single SNP and haplotype analyses. Based on fine mapping in the KORA study, 4 SNPs in the 5 end of NOS1AP were selected using the Tagger tool in Haploview, that captured all major haplotypes (>1% frequency) in the region of interest (~120 kb segment). Genotyping in 439 subjects from the Amish Heredity and Phenotype Intervention (HAPI) Heart Study was performed using TaqMan. Association analyses were performed using a variance components methodology implemented in SOLAR which accounts for the relatedness of individuals. Variation in QT interval was modeled as a function of age, gender, and heart rate, additive genetic effects (or heritability) and a residual error component. Adjusted QT interval heritability was 0.42 (p= 0.003). The SNPs were highly correlated (D 0.97- 0.99) and common (MAF 34- 45%). Genotype frequencies satisfied Hardy Weinberg equilibrium. There were significant associations between 2 of the 4 SNPs (rs1415262, p=0.03 and rs10494366, p=0.009) and the adjusted QT interval. SNP rs10494366 explains 1.6% of the variability in adjusted QT interval. One of the 2 major haplotypes, comprising all the major alleles (frequency 53%), was associated with shorter QT interval (P=0.01). In summary, we have demonstrated association between NOS1AP and QT interval in the Amish, consistent with findings across other Caucasian populations studied to date.

Outcome analysis of pregnancies screening positive for Smith-Lemli-Optiz syndrome. *M. Steinraths[1], A. Mattman[2], S. Langlois[1,2]* 1) Dept of Medical Genetics; 2) Dept of Pathology, University of British Columbia, Vancouver, BC, Canada.

Smith-Lemli-Opitz syndrome (SLOS) is characterized by growth retardation, developmental delay, and minor/major malformations. Due to low fetal cholesterol, SLOS presents with low maternal serum unconjugated estriol (uE3). Other conditions presenting with low uE3 on triple marker screen (TMS) include trisomy 18, triploidy, anencephaly, steroid sulfatase (STS) deficiency, fetal adrenal abnormalities and intrauterine fetal demise (IUFD). Our study aims to define the risk for an abnormal outcome in pregnancies screening positive for SLOS when all known causes have been excluded. We applied a SLOS screening algorithm to 100,000 TMS collected between 1995-2005, identifying 260 as screen-positive. Outcome information was obtained for screen-positive pregnancies through chart review and physician questionnaires. To date, outcome is known for 204/260 (78%) pregnancies. Outcomes include IUFD in 87/204 (43%), aneuploidy or triploidy in 45/204 (22%), anencephaly in 12/204 (6%), STS deficiency in 11/204 (5%) and adrenal hypoplasia in 1/204 (0.4%). Maternal steroid treatment was noted in 3/204 (1%). There have been no pregnancies with SLOS identified to date. 45/204 (22%) pregnancies had no recognized cause of low uE3. Outcomes were obtained for these (group 1) and 69 age-matched control pregnancies with normal uE3 (group 2). In group 1, pregnancy and long-term outcome was normal in 25/45 (56%). Intrauterine growth restriction (IUGR) was seen in 6/45 (13%) and pregnancy-induced hypertension (PIH) in 4/45 (9%). Multiple congenital anomalies were present in 10/45 (22%). In group 2, outcome was normal in 63/69 (91%), IUGR was seen in 1/69 (1%) and PIH in 3/69 (4%). Developmental delay and congenital anomalies were seen in 2/69 (3%). Proposed etiologies for an increased rate of abnormal outcome in pregnancies with low uE3 on TMS include multiple congenital anomaly syndromes affecting the pituitary/adrenal axis or cholesterol biosynthesis disorders other than SLOS. This outcome information will allow comprehensive genetic counseling of pregnancies screening positive for SLOS and improve assessment of newborns with low uE3 identified prenatally.

Genotype to Biochemical Phenotype correlation in Tay-Sach's disease. *R. Zimmer[1], L. Mays[1], S. Bhatt[1], S. Marenberg[2]* 1) Genzyme Genetics, Orange, CA; 2) Genzyme genetics, Santa Fe, NM.

Tay-Sachs disease is an autosomal-recessive, lysosomal storage disorder caused by mutations of the HEX A gene that codes for enzyme beta-hexasaminidase A. The disease has variable age of onset, and variable clinical manifestations, with three main subtypes of infantile-onset, juvenile-onset, and adult-onset. Tay-Sachs disease has been reported in all ethnic groups, but it is most prevalent among Ashkenazi Jewish, Cajun, and French-Canadians individuals. Although carrier screening is often performed via an assay of total and percent HEX A enzyme activity, direct mutation improves Tay-Sachs disease detection, aids in identification of associated mutations, and helps differentiate between disease causing, and non-disease causing mutations. Certain mutations are more common within specific ethnic groups, and may be associated with a particular subtype of Tay-Sachs disease. We reviewed our data of over 700 Tay-Sachs carriers, to evaluate the relationship of the biochemical phenotype in terms of HEX A percentage, with a specific Tay-Sachs DNA mutation. The results showed that the HEX A percentage varied with the type of mutation. The HEX A percentage was observed to be relatively higher with an average value of 47.5 % (non carrier reference range more than 55%), for the pseudodeficiency alleles (R247W and R249W) and also for the late onset mutation (G269S). Whereas, the average values of HEX A percentage was 44.2% for 1421 +1 G C mutation, 42.6 % for 7.6 kb deletion mutation, 44.5 % for +TATC1278 mutation, and 45.6 % for IVS 7 +1 G A and IVS 9 +1 G A mutations. Our study indicates that the HEX A percentage varies with the type of mutation. The HEX A percentage is relatively higher with the less severe mutations or with non-disease causing mutation as compared to the infantile onset mutations.

Pharmacokinetic gene variants do not influence response or tolerance to citalopram in a STAR*D sample. *E. Peters[1], S. Slager[2], J. Kraft[1], G. Jenkins[2], M. Reinalda[2], P. McGrath[3], S. Hamilton[1]* 1) Psychiatry/Biopharm Sci, Univ of California, San Francisco, San Francisco, CA; 2) Division of Biostatistics, Mayo Clinic College of Medicine, Rochester, MN; 3) New York State Psychiatric Institute and Columbia University.

Clinical outcome of antidepressant treatment is variable, in terms of both efficacy and side effect burden. This study investigated the potential role of pharmacokinetic gene polymorphisms in determining patient response and tolerance to the selective serotonin reuptake inhibitor (SSRI) citalopram. Using 1,914 depressed subjects from the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study, we examined several known and putatively non-functional alleles in the CYP2D6 (*3-*9) and ABCB1 genes, as well as the CYP2C19*2, CYP3A4*1B, and CYP3A5*3C polymorphisms for association to citalopram response and tolerance. In order to limit type I error, we used a split-sample study design, and required a p-value of less than 0.05 in both the discovery and validation sample sets. None of the variants met this criteria for study-wide significance. Our most significant association in the discovery set was between the medication tolerance phenotype and the CYP2C19*2 variant ($p<0.01$; recessive odds ratio, 95% CI: 0.25, 0.06 - 0.96). This association was not replicated in our validation sample set ($p=0.57$), which had adequate power to detect an effect of this magnitude. CYP2D6 and CYP2C19 poor metabolizer (PM) status, inferred from genotype data, was also not significantly associated with response or medication tolerance. Furthermore, we investigated pairwise interactions using all variants genotyped and found no significant results. Thus, for pharmacological treatment with citalopram, routine screening of common pharmacokinetic DNA variants may be of limited clinical utility.

An automated method for extracting normalized mentions of human genes and proteins in biomedical text. *P.S. White[1,2], K. Murphy[2], R. O'Hara[2], M. D'arcy[2], S. Carroll[2], Y. Jin[2], H-R. Fang[2], J. Kim[2], M. Mandel[3], M. Liberman[3,4,5], R. McDonald[5], F. Pereira[5]* 1) Division of Oncology, Children's Hospital of Philadelphia; 2) Department of Pediatrics, University of Pennsylvania; 3) Linguistic Data Consortium, University of Pennsylvania; 4) Department of Linguistics, University of Pennsylvania; 5) Department of Computer and Information Science, University of Pennsylvania.

We developed an automated text mining process to identify and normalize references to human genes in biomedical text. Gene named entity recognition (NER) was performed using a machine-learning algorithm that considers semantic and syntactic features in text. Identified mentions were then normalized to standard gene names using vocabulary and approximate string matching. The combined gene NER and normalization process performed document retrieval with 95.7% precision and 85.7% recall at the document level. When applied to MEDLINE, the process identified 36,953,389 gene mentions, 17,897,933 of which normalized to 14,501 human genes. We built a web interface (FABLE) to retrieve MEDLINE articles mentioning human genes, and to compile lists of keyword-defined concepts and articles. FABLE supports searches for gene names and aliases and returns MEDLINE articles in which the query genes are mentioned, regardless of which gene alias(es) were used in the article. Results can be sorted in various ways, including by query relevance and journal impact factor. FABLE demonstrated 93.9% accuracy when comparing its ten most relevant articles with PubMed for 50 random genes. FABLE identified on average 33% more articles than PubMed. FABLE also allows users to generate lists of MEDLINE-mentioned genes implicated in any keyword-defined concept (e.g., schizophrenia NOT bipolar). A query of FABLE with a set of keywords results in a list of genes that co-occur in an article with the input keyword(s). Lists consist of normalized gene symbols, the number of articles in which each gene is mentioned, and the implicating articles. FABLE-generated gene list evaluation indicated comparable precision and higher recall than manually-established lists. Access FABLE at http://fable.chop.edu.

Variation in Liver Enzymes Share Genetic Factors with the Metabolic Syndrome. *D. Wang[1], X. Guo[1], H. Yang[1], M. Quiñones[2], W.A. Hsueh[2], J.I. Rotter[1]* 1) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Aspartate transaminase (AST or SGOT), alanine transaminase (ALT or SGPT), and alkaline phosphatase (ALP) are commonly used biomarkers in detecting liver damage. Clinical and epidemiological evidences suggest that components of the metabolic syndrome, such as obesity, diabetes, and elevated triglycerides, may be associated with nonalcoholic fatty liver (NAFL), which would manifest as elevated liver enzymes. To investigate genetic contributions to liver enzymes and their interrelationship with the metabolic syndrome, we estimated the heritability of liver enzymes and their co-heritability with components of metabolic syndrome in 101 two-generation Mexican-American families ascertained via a parent diagnosed with CAD (the MACAD study). Liver blood enzymes (AST, ALT, and ALP) and features of the metabolic syndrome (body mass index (BMI), systolic and diastolic blood pressures (SBP and DBP), high-density lipoprotein cholesterol (HDLC), low-density lipoprotein cholesterol (LDLC), triglyceride, fasting glucose and fasting insulin) were measured in 274 apparently healthy adult offspring. Heritability and co-heritability ($_G$) were estimated using the variance component methods implemented in SOLAR. The estimated heritability was 0.64 ($p=1x10^{-7}$) for AST, 0.44 (p=0.0002) for ALT, and 0.75 ($p=2x10^{-11}$) for ALP. AST shared significant genetic contributions with fasting glucose ($_G$=0.57, standard error (se) =0.19) and fasting insulin ($_G$=0.50, se=0.23). ALT shared significant genetic contributions with SBP ($_G$=0.38, se=0.17) and fasting insulin ($_G$=0.66, se=0.21). ALP shared significant genetic contributions with BMI ($_G$=0.50, se=0.14), SBP ($_G$=0.61, se=0.13), DBP ($_G$=0.59, se=0.15), and fasting insulin ($_G$=0.41, se=0.19). Our data suggest that a significant portion of the variability in liver enzymes is explained by genetic factors in healthy (but at risk) Mexican Americans and that variation in liver enzymes shares substantial genetic contributions with components of metabolic syndrome in this population.

Signatures of recent natural selection in drug-metabolism genes. *M. Yeager-Jeffery[1], F. Hyland[2], K. Lazaruk[2], K. Haque[1], R.A. Welch[1], F.M. De La Vega[2]* 1) SAIC-Frederick, Inc., CGF, DCEG, NCI-Frederick, MD 21702; 2) Biosystems, Foster City, CA.

Drug metabolizing enzymes (DME) participate in the biotransformation of various endogenous and exogenous compounds, including therapeutic drugs. Functional polymorphisms within DME genes have been shown to alter drug responses and their frequencies often vary between populations. Since the human xenobiotic environment varies with diet and lifestyle, these genes are prime candidates for finding signatures of recent natural selection. Previous studies have identified patterns of variation suggestive of selective pressure in members of the CYP3A gene family and a few other DME genes. We genotyped 2,394 non-synonymous SNPs in 217 DME genes (TaqMan Drug Metabolism Genotyping Assays) on the HapMap Project samples. We investigated if we could identify evidence of natural selection across these genes independently and in combination with the HapMap genotypes. We analyzed the distribution of population differentiation statistics (Fst, Pexcess, and d) and extended homozygosity for core gene haplotypes. Preliminary results have identified a number of genes as possibly having very different evolutionary histories in different human populations, including NAT2, ALDH2, ADH1B, and members of the ABC-transporter and cytochrome P450 gene families, some of which are consistent with previous reports. Genome-wide empirical scans for selective sweeps have been recently performed with the HapMap data. However, DME genes and their functional variants are underrepresented in such studies due to the difficulty in obtaining working genotyping assays across these highly homologous gene families; e.g. fewer than 30% of the SNPs in our collection were successfully typed by the HapMap. Therefore, combining our data with that of the HapMap allows for the first time comprehensive scan for signatures of natural selection across DME genes, important mediators of adaptation of human populations to their environments. Funded by NCI Contract N01-CO-12400.

MOLECULAR ANALYSIS OF A NOVEL FLN1 GENE MUTATION. *S. S. Tsuneda[1], F.R. Torres[1], M.A. Montenegro[2], M. Guerreiro[2], F. Cendes[2], I. Lopes-Cendes[1]* 1) Medical Genetics Department, Faculdade de Ciencias Medicas UNICAMP, Campinas, SP, Brazil; 2) Neurology Department, Faculdade de Ciencias Medicas, UNICAMP, Campinas, SP, Brazil.

Recent studies have demonstrated that mutations in FLN1 gene are responsible for bilateral periventricular nodular heterotopia (BPNH). We identified a novel mutation (1159G>C), in a family segregating BPNH. However, the exact molecular mechanism by which this mutation lead to abnormal FLN1 protein was unclear. The purpose of this study was to investigate the molecular mechanism of this new mutation. Total RNA was obtained from peripheral blood samples, from 2 BPNH patients (mother and daughter) and control individuals. RT-PCR was performed by standard techniques and the cDNA was amplified using specific primers spanning the region containing exon 6 and exon7. Amplicons were cloned into pGEM-T vector, gel-purified and subsequently sequenced, using SP6 and T7 primers. Analysis of the cDNA amplicon demonstrated a different pattern of electrophoretic migration between patients and controls. The sequencing of these fragments showed that amplicons from individuals with BPNH kept the intronic sequence between exons 6 and 7. Our data clearly showed that the molecular mechanism of the mutation 1159G>C is the abolishment of the exon 6 donor splicing, resulting in an alternative stop codon and, possibly, in a truncated protein. Thus an aminoacid substitution, as suggested previously, is not the mechanism involved in the etiology of BPNH sydrome in the patients analysed.

Self-collected buccal cell samples: DNA yield and participation rates. *V.J. Smith[1], M.M. Jenkins[2], C. Sturchio[2], M. Gallagher[3], C.A. Hobbs[1]* 1) University of Arkansas, Little Rock; 2) Battelle contractor to CDC, Columbus, OH; 3) Centers for Disease Control and Prevention (CDC), Atlanta, GA.

The National Birth Defects Prevention Study (NBDPS) is a population-based case-control study of environmental and genetic risk factors. Following a maternal interview, participants are instructed to collect buccal cells from mother, father, and child using 2 cytobrushes each and return them by mail to the study site. One brush per participant is shipped to CDC and the other is retained by the local site. Due to concerns regarding the amount of DNA extracted from 1 cytobrush, a pilot study was conducted to determine if doubling the number of brushes per participant would increase the quantity of DNA while maintaining the participation rate. 554 Arkansas (AR) families representing 404 case- and 150 control-parental triads were sent 4 cytobrushes per individual during a 16 month period. Two brushes per individual were shipped to CDC and two retained at the study site. DNA was extracted from the 2 pooled cytobrushes sent to CDC and quantified using RT-PCR. 341 case and 112 control families returned kits, resulting in an overall participation rate of 81.8%. Participation rates during the pilot study did not vary significantly from rates when AR participants were asked to collect 2 cytobrushes per individual. DNA yields for 2 pooled brushes from AR families were compared with yields for 1 brush from the other 8 NBDPS study sites for the same 16 month period. DNA extracted from 1 brush resulted in a mean DNA yield of 1.8 g, 1.5 g, and 1.6 g from mothers, fathers, and children, respectively. DNA extracted from 2 cytobrushes resulted in respective mean DNA yields of 2.3 g, 1.9 g, and 2.1 g. Thus, the respective percent increases in DNA were 27.6%, 25.6%, and 32.1%. The results of the pilot study did not warrant the additional expense needed to request four cytobrushes from each NBDPS participant and Arkansas reverted back to collecting two cytobrushes per participant. The effects of increasing the number of cytobrushes sent per NBDPS participant may be of value to others involved in large genetic epidemiology studies.

Analysis of the 3 UTR of the *MECP2* gene in patients with clinical diagnosis of Rett syndrome and mental retardation. *M. Santos[1,2], A.M. Coutinho[3], J. Yan[4], C. Yang[4], J. Feng[4], A. Vicente[3], T. Temudo[5], S. Sommer[4], P. Maciel[1]* 1) ICVS, School of Health Sciences, Univ. Minho, Braga, Portugal; 2) ICBAS, Univ. Porto, Portugal; 3) IGC, Oeiras, Portugal; 4) Centre for Molecular Diagnosis, City of Hope Medical Centre, Duarte, California, USA; 5) HGSA, Porto, Portugal.

Mutations in the methyl-CpG binding protein 2 (*MECP2*) gene are associated with Rett syndrome (RTT), a developmental disorder affecting mainly females with neurological manifestations including mental retardation and autistic features. Mutations in the coding region of *MECP2* are identified in around 80% of classic RTT patients and 30% of variant forms of the disease. It has been proposed that mutations in non-coding regions of the gene or in other genes may be the unidentified cause of the disorder in these cases. The role of the 3 untranslated region (UTR) of a gene might be in regulating the stability of the mRNA, its translatability or sub-cellular localization. Mutations in the 3 UTR of genes have been identified as the genetic cause of a number of neurological diseases. In this work we explored the role of the 3UTR of the *MECP2* in patients with clinical diagnosis of RTT and mental retardation who had no mutations in the coding region of the *MECP2* gene: focusing on regions of the 3UTR with almost 100% conservation at the nucleotide level among mouse and human, searching for pathogenic variants. A total of 67 affected females were studied,and compared to 143 caucasian blood donors of Portuguese origin. The 3UTR was scanned for mutations using DOVAM-S and the variants identified were automatically sequenced. Two 3UTR variants in the *MECP2* were found (2763GA and 10158CG) in our group of patients. However, the 10158CG variant was also present in the unaffected father of the patient, whereas variant 2763GA was identified in the control population. Our data indicate that mutations in this region must be rare and do not account for a significant proportion of classical RTT without genetic explanation. Nevertheless, in order to clarify this point a larger number of patients should be screened for mutations in these regions of high conservation.

Genetic Models for Li-Fraumeni Syndrome in the Presence of Germline p53 Mutations. *C.C. Wu[1], S. Shete[1], C.I. Amos[1], L.C. Strong[2]* 1) Dept Epidemiology, Univ Texas MD Anderson CA Ctr, Houston, TX; 2) Clinical Cancer Genetics, Dept Molecular Genetics, Univ Texas MD Anderson CA Ctr, Houston, TX.

Germline p53 mutations have been identified in some families with Li-Fraumeni syndrome (LFS). LFS is a rare familial cancer syndrome characterized by a high frequency of early-onset and diverse tumor types and an increased frequency of multiple primary tumors. In the presence of a stable germline p53 mutation segregating in a family, the age of cancer onset and multiplicity of tumors within a family is highly variable, suggesting the presence of additional genetic factor(s). Given these observations, we proposed to investigate the residual genetic effects accounting for the observed genetic and phenotypic heterogeneity. We analyzed 6 pedigrees with hereditary germline p53 mutations, which is a subset of 159 extended LFS pedigrees ascertained through 3-year survivors of childhood soft tissue sarcoma who were treated at M. D. Anderson Cancer Center from 1944 to 1975. In those kindreds, a total of 62 germline p53 mutation carriers have been identified. To determine the hypothetical genetic model for the unobserved non-p53 gene(s) or modifier(s) of cancer risk in the presence of germline p53 mutations, we included confirmed invasive cancers excluding nonmelanoma skin cancer and in situ carcinoma as a single combined phenotype. We applied a complex segregation analysis that allowed us to associate the simultaneous effects of germline p53 mutations and unobserved gene(s) underlying LFS with cancer incidence in these families, possibly accounting for genetic modification of cancer risk among or within these families. Our finding showed modest evidence of an interaction between germline p53 mutations and the unobserved gene, suggesting the presence of p53 modifier(s). However, the effects of the modifier were very small, and the genotype-dependent effects of p53 in terms of age-of-onset changes were all within 2 years.

Identification of novel small RNAs in adult neural stem cells. *K. Szulwach[1], X. Zhou[2], P. Jin[1]* 1) Department Human Genetics and Program in Genetics and Molecular Biology, Emory Univ, Atlanta, GA; 2) Department of Neuroscience, University of New Mexico, Albuquerque, NM.

Small RNAs (18-28nt), including microRNAs (miRNAs), have been increasingly recognized to play critical roles in many forms of gene regulation and diverse cellular pathways, including stem cell maintenance and differentiation. Defining the molecular events underlying stem cell self-renewal and differentiation are essential steps towards understanding stem cell biology. It has been hypothesized that small RNAs are key mediators of stem cell fate decisions and act in concert with transcriptional regulators to control adult neural stem cell (aNSC) self-renewal and differentiation. aNSCs continuously generate new neurons that are functionally integrated into neural circuits and so are thought to hold therapeutic potential in neurodevelopmental and neurodegenerative disease. In an effort to gain an understanding of how small RNAs may contribute to the maintenance and differentiation of aNSCs, we have created a cDNA library of 18-28nt small RNAs from mouse primary aNSC. Initial high-throughput sequencing of this library has produced 338,144 reads including 4,243 unique sequences that occurred a total of 13,138 times. While 178 known miRNAs were observed 7,925 times, an additional 2,889 unique sequences were seen a total of 5,876 times and represent potentially novel small RNAs specific to aNSC. The ~16-fold-increased observation of unique sequences compared to known miRNA sequences in primary aNSCs indicates the potentially large numbers of undiscovered small RNAs with important functions in aNSC. Interestingly, many of the potentially novel small RNAs have correlated with previously identified ESTs found specifically in stem cells and have mapped to evolutionarily conserved genomic loci. Some of the identified RNAs, along with flanking sequences, are predicted to form energetically stable stem-loop hairpins capable of processing by components of the RNAi pathway. Identification of this large group of small RNAs will lead to the discovery of adult neural stem cell specific small RNAs important for proper maintenance and differentiation of aNSCs.

CAG repeat instability and motor deficit in a transgenic mouse model of Machado-Joseph disease. *A. Silva-Fernandes[1], M.C. Costa[1], R. Franco-Duarte[1], P. Oliveira[1,2], P. Maciel[1]* 1) ICVS, School of Health Sciences, Univ. Minho, Braga, Portugal; 2) Dep. Production and Systems Engineering, School of Engineering, Univ. Minho, Braga, Portugal.

Machado-Joseph disease (MJD) is a late-onset autosomal dominant neurodegenerative disorder caused by a CAG repeat expansion in the *ATXN3* gene, encoding ataxin-3. Its main neurological features are progressive ataxia, ophthalmoplegia, pyramidal and/or extrapyramidal signs. We have generated a transgenic mouse model that expresses a human cDNA variant of the *ATXN3* gene under the regulation of a general expression promoter (PCMV). We have obtained two founders: founder A (94 CAGs, two transgene copies), and founder B (83 CAGs, ten transgene copies). Human ataxin-3 carrying an expanded polyQ tract was detected in both peripheral tissues and in the central nervous system (CNS) in both transgenic lineages. In order to study the intergenerational instability of the CAG repeat, we analyzed a total of 46 transmissions of lineage A and 26 transmissions of lineage B, for both maternal and paternal meioses. We observed intergenerational instability in both lineages. Additionally, somatic instability was observed in lineages A and B, in both peripheral tissues and in the CNS. In order to assess motor coordination, we have performed the Rotarod test using six constant speeds (5, 8, 15, 20, 24, 31 rpm) and an accelerating rod task (4-40 rpm). Until now, we tested the animals at 16, 24 and 36 weeks of age. Both heterozygous and homozygous transgenic mice of lineage A, presented a significant decrease in the latency to fall in both paradigms since 16 weeks of age. For lineage B no motor impairment was yet found, suggesting that repeat length may be more relevant than gene dosage for disease manifestation. In summary, this transgenic mouse model presents a progressive motor coordination impairment phenotype as well as intergenerational and somatic instability of the CAG repeat, as the human MJD patients, suggesting that it could be useful both in the study of MJD pathogenesis and therapy development, as for the analysis of the molecular basis of the CAG repeat instability in this disorder.

Uncovering the complex nature of an Apparently Balanced Translocation by High Density SNP Oligonucleotide Microarray Analysis (SOMA) and High Resolution Comparative Genomic Hybridization. *A. Sobrino[1], O. Nahum[2], V. Jobanputra[1,3], K. Anyane-Yeboa[3], Y. Sun[2], E. Bottinger[2], W. Zhang[2], D. Warburton[1,3], B. Levy[1,3]* 1) Genetics Lab, New York Presbyterian Hosp, New York, NY; 2) Depts Medicine & Pediatrics, Mount Sinai School of Medicine, New York, NY; 3) Depts Genetics and Development, Pathology & Pediatrics, Columbia University Medical Center.

We report the work-up of a patient with clinical abnormalities and an apparently balanced translocation. The patient, a 1 yr-old male, presented with mild developmental delays and dysmorphic features which included hypertelorism, large cupped ears, micrognathia, wide-spaced nipples, left simian crease, and hypotonia. His OFC was 47 cm (50%), weight 10.45kg (50%) and height 80cm (90%). His birth weight was 3900g. Cytogenetic analysis indicated a rearrangement between chromosomes 8 and 13 such that the entire long arm of chromosome 13 appeared to be translocated to the terminal region of the short arm of chromosome 8. The karyotype was initially performed by another lab and designated 45,XY,t(8;13). FISH using a subtelomeric 8p probe revealed a single signal on the normal chromosome 8 but no signal on the derivative chromosome 8, indicating a terminal deletion. In addition, FISH using a 13/21 alpha satellite probe showed no signal on the translocated chromosome 13. High resolution CGH indicated a loss of the most distal region of the short arm of chromosome 8 (8p23.3-8pter) and the most proximal region of the long arm of chromosome 13 (13q12.1-13q12.2). Interestingly, CGH also detected an interstitial gain on the short arm of chromosome 8 (8p12-8p23.1). Further characterization of these regions was achieved by means of high-density SNP oligonucleotide microarray analysis (SOMA) where copy number gains and losses were determined by the Circular Binary Segmentation method. SOMA confirmed the CGH results and improved the resolution of the size of the imbalances. The deletions on 8p and 13q are estimated to be approximately 6.7 and 2.0 Mb respectively, while the duplication on 8p21.2 is about 12.1 Mb. This case illustrates the utility of SOMA as well as conventional CGH to define more accurately the nature of an abnormal derivative chromosome.

CGH analysis of a rare case of squamous cell carcinoma of the urachus of the bladder. *W. Thelmo[1], M.J. Macera[2,3], J. Breshin[2,3], P. Chandra[3], A. Babu[2,3]* 1) Dept Pathology; 2) Div Molec Medicine & Genetics; 3) Dept Medicine, Wyckoff Heights Med Ctr, Brooklyn, NY.

A seventy two year old female was admitted for gross hematuria. She has a history of hypertension, asthma and urinary reflux. She denied dysuria or increase of urinary frequency. She had no weight loss, fever, chills, nausea or vomiting or a history of passing out stones in the urine. She is a non-smoker. She underwent cystoscopy and urinary bladder biopsy which showed high grade urotherlial carcinoma with necrosis. Three weeks later, this was followed by radical cystectomy and ileal conduit. There was a tumor in the dome of the bladder with ulceration demonstrating squamous cell carcinoma with invasion of the urachal remnant. The rest of the bladder showed chronic cystitis, diffuse without squamous metaplasia or any evidence of parasites (Schistosoma). Right and left pelvic lymph nodes were all negative for tumor. Comparative genomic hybridization (CGH) analysis was done on DNA extracted from formalin fixed tumor and identified loss of a chromosome 17 as well as the entire 16p arm. The UroVysion probe was then applied to sections of the tumor. Three abnormal clones were detected: one with a single 17 centromere and a single p16 gene (located at 9p21) (27.0%), the second with a single 17 centromere and two p16 genes (17.0%), and the third with two 17 centromeres and a single p16 gene (25.0%). The remaining cells (31.0%) showed normal signal numbers for all probes. No loss of 9p was seen by CGH, likely due to a small deletion below the detection level of the test. Deletions of part of or loss of the entire chromosome 9 are the most common findings in all bladder cancers. Loss of chromosome 17 has been associated with progression in this disease. Only approximately 7% of non schistosome related bladder cancer is squamous cell, and aberrations of chromosome 17 and loss of 16p are more frequently observed in transitional cell carcinoma than squamous cell carcinoma. This case represents an unusual presentation and further study may help to elucidate this complex disease.

A Single Nucleotide Polymorphism in the *COX2* gene is significantly associated with prostate cancer in men of European Ancestry. *P. Pal[1], H. Xi[1], R. Kaushal[1], G. Sun[1], J. Mallik[1], B.K. Suarez[2], W.J. Catalona[3], R. Deka[1]* 1) Center Genome Information, Univ Cincinnati, Cincinnati, OH; 2) Department of Psychiatry and Genetics, Washington University, St. Louis, MO; 3) Department of Urology, Northwestern University Feinberg School of Medicine, Chicago, IL.

We have tested for association of variants in *COX1* (9q32-33.3) and *COX2* (1q25.2-25.3) genes with prostate cancer in men of European origin. COX1 and COX2 are two isoforms of cyclooxygenase that are involved in the inflammatory pathway and have been implicated in the etiology of prostate cancer (PC). Using the SNPlex platform (ABI), thirty single nucleotide polymorphisms (SNPs) in *COX1* (15 SNPs) and *COX2* (15 SNPs) were genotyped in 347 histologically confirmed PC cases from 275 multiplex sibships and 346 unrelated controls; all cases and controls are of European ancestry. We did not find association with *COX1* variants. We observed a highly significant association with one SNP (rs2206593, GA) in the 3UTR of *COX2* (Minor Allele Frequency: 8% in cases and 2% in controls, $p<0.0001$). A haplotype defined by the minor allele of this SNP was found to be significantly over-represented in cases (7% versus 2%; OR: 4.74, 95% CI 2.4-9.4, multiple adjusted $p<0.0001$). Previous studies have shown that COX2 is consistently over-expressed in PC tumors. Our results suggest a plausible role of *COX2* in PC tumorigensis.

Reconstruction of the ancestral allele of the 8p23 inversion polymorphism. *E. Slaten[1], P.N. Rao[2], R.A. Ophoff[1,3]* 1) Cntr for Neurobehavioral Genet, Univ of California, Los Angeles, Los Angeles, CA; 2) Dept of Pathology, Univ of California, Los Angeles, CA; 3) Dept. of Human Genetics, Univ. of California, Los Angeles, CA.

Recent studies have shown a widespread distribution of genomic variations in the human genome. For some of them a functional consequence is known but for the vast majority it is not clear whether these variations have beneficial or negative effects on phenotype. While a large number of duplications and deletions have been reported while only a limited number of inversion variants have been described. Our study focuses on a common inversion polymorphism at chromosome 8p23 spanning nearly 4 megabases and flanked by large blocks of segmental duplications. The 8p23 inversion region is reported to be associated with severe bipolar, panic disorder and schizophrenia. However, there is no evidence of direct involvement of this inversion in these diseases. The observation that different haplotypes are linked to the inversion suggests recurrent inversion events in human history, possibly mediated by the flanking segmental duplications. Comparative syntenic analysis between human and mouse suggests the inverted order to be ancestral. To test this hypothesis we examined inversion status in three different ethnic groups of >25 individuals each: African American (AA), European American (EA), and Hispanic American (HA). We observed different inversion allele frequencies ranging from 65% in AA to 53% in HA. A previous study had reported an allele frequency of 27% in an Asian population. We further examined inversion status of some non-human primates including two chimpanzees, gorilla, rhesus monkey and bonobo. In these primate species, not only was the inverted allele was the most common but we also observed heterozygosity in the chimpanzees. Our data suggests that in human history the inverted allele is most likely to be ancestral, and shows that this inversion polymorphism extends into the other branches of the phylogenetic tree of primates.

Combined use of Cytogenetics, FISH and Array-CGH in Detection of Interstitial 7q Deletion. *M.L. Wiggins, D.L. Pickering, D.H. Zaleski, I.S. Kanev, S.D. Nielsen, G.B. Schaefer, B.J. Dave, W.G. Sanger* Human Genetics, University of Nebraska Medical Center, Omaha, NE.

We present a case of an 11 year old female with an interstitial deletion of 7q diagnosed by conventional cytogenetic methods combined with high resolution array-CGH (aCGH). She presented with marked growth and developmental delays, microcephaly, moderate to severe scoliosis, absence of the distal sacrum and coccyx with residual ossification center and prominence of the posterior bony elements, right renal atrophy, status post repair of severe bilateral ureteral vesicle junction obstruction, syrinx, with concerns for her vision. Upon additional examination, her physician also noted a hypoplastic uvula, normal extremities and digits, normal genitalia and normal chest with early breast budding. Neurologically, she had an unusual gait with stereotypic repetitive hand movements. Cytogenetics, FISH, aCGH and MECP2 studies were requested on peripheral blood from this patient who was referred for possible Rett syndrome. Cytogenetic analysis, at a 750 band level, revealed a deletion within the 7q terminal region. Subsequent FISH studies using a telomere probe for 7q were normal as were aCGH studies using the Spectral Genomics Constitutional Array 400. We then used the Spectral Chip 2600 and the deletion of 7q was confirmed and further characterized as an interstitial deletion of 4 clones encompassing an approximate 6MB region from chromosomal region 7q36.2-7q36.3 as follows: arr cgh (RP11-43L9 - RP11-58F7)x1. The findings in the case demonstrate the importance of continuing to perform cytogenetic studies in addition to FISH and in depth aCGH in the diagnosis of congenital abnormalities. This combination of tests enhances accurate delineation of chromosomal regions and the DNA segments deleted or duplicated and assists with genotype/phenotype correlations.

A novel COL1A2 mutation leading to osteogenesis imperfecta type 1 in identical twins. *T.P. Ponnapakkam, D. Sledge, R. Gensure* Pediatrics, Ochsner Clinic Foundation, New Orleans, LA.

Osteogenesis imperfecta (OI) is an autosomal dominant disorder of bone collagen matrix with increased bone fragility and multiple fractures. It is further classified based on severity, with type 1 being the least severe. Most individuals with OI have mutations in one of two genes encoding type 1 collagen, COL1A1 or COL1A2 (>200 different mutations described). We now report on identical twins with multiple fractures who were found to have a novel COL1A2 mutation. Twin 1 suffered 5 fractures by age 16, including wrist fractures sustained while tripping and trying to break his fall. Twin 2 suffered 3 fractures in the same time period. A complete metabolic workup for each brother showed only increased bone turnover (elevated alkaline phosphatase and urinary crosslinked N-telopeptides). The spinal bone mineral density of twin 1 was Z=-2.6, and that of twin 2 was Z=-2.3 (2-3 standard deviations below the mean). A review of the family history revealed that the twins mother had sustained one fracture, a tibial fracture after falling on grass at age 13. She has been diagnosed with osteopenia (T-score =-1.5) and has been treated with residronate and alendronate. The patients father has not had any fractures. Sequence analysis for each twin revealed a C3495>G missense mutation in COL1A2. No other mutations were found in COL1A1 or COL1A2. Sequence analysis of the parents revealed the same C3495>G mutation in the mother but not in the father. This mutation is predicted to cause an D1165E change in the encoded protein, alpha-2(I) collagen. This substitution occurs in the C-propetide region of the protein, and the substitution of aspartic acid with glutamic acid is a conservative change. Alterations of this amino acid have not been previously described as associated with OI or as a known polymorphism. In fact, there are only a few known mutations in the C-propetide region of alpha-2(I) collagen associated with OI, and most of those are associated with the more severe types. We postulate that although the mutation occurs in an apparently critical region, the substitution is conservative and thus the bone fragility in this family is relatively mild.

Haplotyping Human Leukocyte Antigen (HLA) and Killer Immunoglobulin-like Receptor (KIR) Genes with Haplotype-Specific Extraction. *G.S. Scavello[1], C. Turino[1], D. Ferriola[2], M. Kunkel[2], J. Dapprich[2], N. Murphy[1]* 1) QIAGEN, West Chester, PA; 2) Generation Biotech Lawrenceville, NJ.

Haplotype-Specific Extraction (HSE) is a simple automated technique that allows haplotype identification from genomic DNA, without familial knowledge, by physically separating a diploid sample into haploid components. Determining haplotypes, gene order and dosage are current foci for researchers in KIR and HLA genetics, which may be of particular interest when evaluating graft-versus-host-disease (GVHD) in well-matched transplants. Since each KIR haplotype comprises 7-14 genes (A haplotypes include 7 genes, B haplotypes comprise many combinations of 7 to 14 genes), haplotyping an individual with two B haplotypes is virtually impossible without familial studies. Samples were haplo-extracted from genomic DNA at the HLA and KIR loci. Generic PCR primers were designed to amplify from intron 8 to intron 1 of the KIR genes including all intragenic and intergenic regions. Amplicons were sequenced to verify gene presence and orientation. Heterozygous polymorphisms were then used to tile the extractions and form a contiguous KIR haplotype spanning 150kb. HLA-B, HLA-Cw, HLA-DRB1, and HLA-DQB1 extractions were amplified at the extraction points to verify haploid state. The extractions were genotyped by real-time PCR at SNPs flanking and intermediate to the targeted genes to form a contiguous 128kb haplotype encompassing HLA-B to HLA-Cw and an 89kb haplotype spanning HLA-DQB1 to HLA-DRB1. Two complete KIR and two abbreviated HLA haplotypes were defined using a combination of HSE, real-time PCR and DNA sequencing. The samples were genotyped and allele level typing was performed for all genes in each haplotype. Haplotype construction with HSE should prove a useful method for validating statistically derived haplotypes from population studies, for directly evaluating gene dosage (copy number) without long-range PCR and for assigning KIR haplotypes when familial studies are not possible.

Impact of Long Term Storage and Purification of Whole Genome Amplified DNA on High Throughput Genotyping Technologies. *R. Tewhey[1], C. Guiducci[1], A. Rachupka[1], L. Gianniny[1], L. Ziaugra[1], S. Gabriel[1], L. Groop[2], N.P. Burtt[1], D. Altshuler[1,3,4,5,6,7]* 1) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 2) Department of Endocrinology, University Hospital MAS, Lund University, Malmö, Sweden; 3) Center for Human Genome Research, Massachusetts General Hospital, Boston, MA; 4) Department of Molecular Biology, Massachusetts General Hospital, Boston, MA; 5) Diabetes Unit, Massachusetts General Hospital, Boston, MA; 6) Department of Medicine, Harvard Medical School, Boston, MA; 7) Department of Genetics, Harvard Medical School, Boston, MA.

DNA integrity is central to the success of any genotyping technology. Whole genome amplification (WGA) offers a robust means of extending limited DNA supplies for future use. The fidelity of this method has been assessed for several technologies, yet the impact of long term storage and components of the WGA reaction on various genomic assays has not been formally investigated. We evaluated genotyping success rates and accuracy for 980 DNA samples isolated from whole blood, where each sample was whole genome amplified, and stored at -80C for 10 months. Using the Sequenom MassARRAY hME and iPLEX platforms, we genotyped 30 polymorphic SNPs and observed call rates of 95.1% (hME), 79.2% (iPLEX) for stored wgaDNA, with an accuracy of 95.3% (hME), 97.2% (iPLEX). As a control, we genotyped the 980 native genomic DNA counterparts with an average call rate of 99.2% and an accuracy of 99.8%. Concerned that either poor amplification or DNA degradation was the origin of such a decrease in performance, we purified the 980 WGA samples, by ultrafiltration. Surprisingly, both call rate and accuracy increased to levels comparable to genomic DNA (98.3% and 99.7%, respectively). This observation is key to our growing understanding of the behavior of wgaDNA. Presently, we are assessing the role different storage concentrationS and buffers may play in maintaining the integrity of wgaDNA. Additionally, we are testing freshly amplified wgaDNA product for genotyping success. Finally, we plan to demonstrate the impact of purification and stored wgaDNA on both the Illumina GoldenGate Assay and the Affymetrix 500K Array Set.

Females with X-linked Fabry disease frequently have significant organ involvement. *W.R. Wilcox[1], D.P. Germain[2] for the Female Working Group of the North American and European Fabry Registry Board of Advisors* 1) Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Hôpital Européen Georges Pompidou Paris, France.

Fabry disease (FD, OMIM 301500) is an X-linked lysosomal storage disease caused by deficiency of alpha-galactosidase A activity. Until recently, females with FD were thought to be infrequently clinically affected. The Fabry Registry (www.fabryregistry.com) is a global program to collect longitudinal clinical data on FD patients, regardless of whether or not they are receiving enzyme replacement therapy (ERT). Although registries tend to preferentially enroll more symptomatic patients, there has been a special effort to enroll females regardless of symptomatology. 809 females have been enrolled with a mean age at enrollment of 39.617.0 years. 82.6% had symptoms and signs of FD, but only 33% have ever received ERT compared to 77% of males. The mean age of symptom onset was 19.115.3 years but the diagnosis was not made until 16.415.4 years later. 81% reported a family history of FD. The most common presenting symptom in symptomatic patients was acroparesthesia pain in 41.4% beginning at an age of 13.811.6 years, but 10.7% presented with renal disease. 20.5% have had a major cerebrovascular, cardiac, or renal event at an average age of 45.114.1 years. 17.7% had stage 3 or worse chronic kidney disease (CKD). An even greater percentage, 61.2%, had a GFR < 90 ml/min. Proteinuria greater than 300 mg/24 hours, a major risk factor for renal disease progression, was present in 36.6%. 19.7% had more than 1 g of proteinuria per day. 16.9% had left ventricular hypertrophy and 6.8% had a cardiac arrhythmia. Quality of life measured by the SF-36 survey declined significantly with age. We conclude that females with FD have a significant risk for major organ involvement and decreased quality of life. Females with Fabry disease should be regularly monitored and ERT initiated, when indicated, before there is irreversible end-organ damage. Guidelines for FD monitoring and management are available (Eng et al. Genet Med, in press).

Deficiency of alpha-aminoadipic semialdehyde dehydrogenase in lysine metabolism; another cause for vitamin B-6 responsive seizures in the newborn. *G. Scharer[1,3], S. von Kaenel[3], A. White[2], E. Spector[3], G. Creadon-Swindell[3], J. van Hove[1]* 1) Div. of Clinical Genetics and Metabolism, Children's Hospital/UCDHSC, Denver, CO; 2) Div. of Neurology, Children's Hospital/UCDHSC, Denver, CO; 3) DNA Diagnostics Laboratory, Dept. of Pediatrics, UCDHSC, Denver, CO.

While rare, pyridoxine-dependent seizures (PDS) are a serious complication in the newborn period if not recognized and treated immediately. Psychomotor retardation and death can result. Mills et al. (Nature Medicine, 2006) have shown that defects of the alpha-aminoadipic semialdehyde dehydrogenase (-AASA) in the lysine degradation pathway lead to accumulation of a metabolite, which inactivates pyridoxal 5-phosphate. Subsequent depletion of active vitamin B-6 in the brain results in seizures typically within hours of birth and resistant to conventional anticonvulsants. Mutations in the *ALDH7A1* gene coding for -AASA are responsible for this type of PDS. We report a case of PDS in a now 4-year old female, who presented at 7 days of life with intractable seizures unresponsive to standard antiepileptic medications. A trial of IV pyridoxine resulted in cessation of seizures and normalization of the EEG. Shortly after weaning from pyridoxine seizures returned and stopped only after reintroducing the vitamin. The patient has been seizure free on 100mg of pyridoxine daily. Serum pipecolic acid level was measured in the twice normal range suggesting -AASA deficiency as the likely cause for this patients phenotype. Direct sequencing of all exons and exon/intron boundaries of *ALDH7A1* revealed two new base changes that are thought to be disease-causing mutations including a novel splice-site mutation. A heterozygous G477R mutation in exon-17, a heterozygous IVS 16(5) A>G mutation in intron-16 and two likely polymorphisms were identified. While classic PDS does present in the neonatal period, genotypic variations have to be considered resulting in atypical phenotypes, and therefore patients may present with milder symptoms and later in life. PDS should be considered in a patient with intractable seizures and no other recognizable etiology. Molecular analysis will allow for diagnostic confirmation and prenatal diagnosis.

Fast computation of large numbers of LOD scores for genetic linkage analysis via a novel ''polynomial'' implementation. *H. Wang[1], A. Segre[1,2], Y. Huang[1], J. O'Connell[3,1], V. Vieland[1]* 1) Center for Statistical Genetics Research, The University of Iowa, Iowa City, IA; 2) Department of Computer Science, The University of Iowa, Iowa City, IA; 3) Department of Medicine, University of Maryland, Baltimore, MD.

LOD scores are usually computed assuming specific values for parameters of the trait model. However, for complex disorders the specified parameter values are almost certainly incorrect. Under some circumstances, maximizing over the trait parameters is a statistically correct way to redress this difficulty, basing inference on the MOD (Clerget-Darpoux et al. 1986). A second way to handle the unknown trait model is via integration, e.g., with inference based on the PPL (Vieland 1998, Logue et al. 2003). Both approaches generally rely on use of an exhaustive grid search (or average) over several trait parameters, calculating the LOD for each parameter vector in turn, and this can entail very large numbers of calculations. For instance, a typical genome scan utilizing a simple trait model allowing for heterogeneity can easily entail calculating millions of LOD scores; and recent extensions to incorporate multipoint analysis, trait-marker linkage disequilibrium, and quantitative trait models have exacerbated this difficulty. Here, we propose an alternative computational approach, replacing the usual LOD calculation based on a fixed parameter value by an algebraic expression, essentially "compiling" the calculation over a pedigree into a symbolic form and then evaluating the compiled expression with different parameter values. That is, rather than processing each pedigree (including pedigree peeling) one time for each parameter vector, the pedigree is processed one time to construct a polynomial expression, which can then be rapidly evaluated an arbitrary number of times. Here we present initial results showing that this approach can speed up genetic linkage calculations by a factor of between 10 and 1000, when LODs are evaluated for large numbers of parameter vectors .

CGH-based microarray analysis in a Caucasian newborn with NSD1 deletion and Sotos syndrome: Identification of chromosome 5q35.2 microdeletion. *J.D. Ranells[1], A. Patel[2], P. Eng[2], K. Pham[2], J.R. Lupski[2], S.W. Cheung[2]* 1) Dept Peds/Div Genetics, University of South Florida Tampa, FL; 2) Dept Molec and Human Genetics, Baylor College of Medicine, Houston, TX.

Sotos syndrome is an autosomal dominant condition characterized by pre- and postnatal overgrowth, facial dysmorphology including macrodolichocephaly, hypertelorism and down-slanting palpebral fissures, and intellectual impairment. A point mutation or genomic deletion of the NSD1 gene has been identified in the majority of affected individuals. An NSD1 deletion, detected by FISH analysis, has been reported in approximately 50% of patients of Japanese heritage, but in only 10% of non-Japanese. Rarely, a cytogenetic abnormality involving the 5q35 locus may be present.

We describe a newborn Caucasian male with multiple congenital anomalies and features of Sotos syndrome in whom deletion of NSD1 was detected by FISH analysis. Initial chromosome analysis on cultured amniocytes was normal. Birth weight at term was 3385g (80th centile), length 49.7cm (70th centile) and OFC 38 cm (90th centile). In addition to facial dysmorphia, ASD, VSD, PDA and hydronephrosis consistent with Sotos syndrome, the infant had imperforate anus, excess nuchal folds, preauricular pit, simian creases and minor digital anomalies. Chromosomal microdeletion involving the Sotos syndrome locus at 5q35 was suspected.

High resolution chromosome analysis revealed a 46,XY,del(5)(q35.2q35.3) chromosome pattern. A CGH-based microarray designed to interrogate clinically relevant genomic regions revealed a loss of copy number in the subtelomeric region on the distal long arm of chromosome 5, detected by 6 clones encompassing approximately 5 Mb. This large deletion involving the breakpoint region upstsream of the Sotos critical region may explain the unusual clinical findings. Detailed genotype and phenotype correlation will be presented.

Concordance between the definitive diagnostic status and reference diagnoses of birth defects and genetic diseases: The Harris County experience. *F. Suarez[1], L. Potocki[2]* 1) Inst de Genetica Humana, Univ Javeriana, Bogota, Colombia; 2) Department of Molecular and Human Genetics, Baylor College of Medicine. Ben Taub Genetics Clinic.

To describe the concordance between the reference diagnostic of birth defects and genetic diseases and the final diagnosis in a birth defects clinic. All the active clinical histories of the clinic of congenital defects of the Hospital of Ben Taub were reviewed; we analyzed, registry of definitive diagnose specified in the clinical chart, and the diagnostic by which the proband was sent to the clinic. To demonstrate differences between groups a chi square was used, to compare the concordance between groups we use the Kappa index. The total number of reviewed clinical histories was of 542. A definitive diagnose was reached in 302 cases (55.7%) .Of the 240 undiagnosed cases, 91 cases (37.9 %) consisted of patients with mental retardation or development delay with one or more minor anomalies. A total of 131 patients (24.1 %) were referred with a precise diagnosis, disease name or the eponym of the suspected genetic syndrome, from this group 80 cases (61.7 %) correspond to Down syndrome and 6 patients (4,6 %) of Turner syndrome, 77 Down syndrome cases were confirmed in the Hospital and the other two cases were considered to be healthy patients, 8 patients (6.1 %) had a different diagnostic from the initially referred. 5 cases (3.8 %) did not have a final diagnose. Between the referred cases with a specific diagnostic compared with the cases only referred for physical features anomaly, there was a more precise diagnostic in the first group (p=0.0). When comparing the concordance between the reference diagnostic and the definitive diagnostic after the evaluation at the clinic we found agreement of 0,402 (95% Confidence Interval: 0.042-0.12. Kappa: 0,081). Very low concordance were found between reference diagnostic from the non specialist and definitive final diagnostic at the birth defects clinics, it affirms the necessity of medical genetic evaluation in difficult cases related to dysmorphology, developmental delay and birth defects, in order to reach a conclusive and definitive diagnostic.

Genomic Evolution in Myelodysplastic Syndrome (MDS). *C. Szych, R. Felgar, J. O'malley, J. DeFeo, M.A. Iqbal, N. Wang* Pathology, University of Rochester Medical Center, Rochester.

To define the genomic aberrations associated with the genesis and progression of MDS, 366 cases with an indication of myelodysplastic syndrome were analyzed using G-banding. Chromosomal aberrations were detected in 101 cases. Of these, single genomic aberrations were detected in 66 cases; 9.09% with del(5q), 7.58% with del(20q), 7.58% with +21, 4.55% with -7, 4.55% with +8 and 28.79% with -Y. Multiple genomic aberrations were detected in 35 cases; 54.28% with del(5q)/-5, 34.28% with del(7q)/-7, 22.86% with del(20q)/-20, 22.86% with -18, 20.00% with -13, 17.14% with +8, 8.57% with +21 and 17.14% with -Y. The incidence of -5/5q- and -7/7q- is high in both cases with single aberrations and multiple aberrations. This suggests that these abnormalities are associated with genomic instability which leads to multiple chromosomal aberrations. In contrast, the aberrations of +8, +21, -13, del(20q) and -Y are more prominent in the cases with a single aberration than those in multiple aberrations, which suggests that these abnormalities are primary aberrations with less genomic instability toward chromosomal evolution. The aberration of -Y was identified only in cases over the age of 55 indicating that aging contributes a great deal to the loss of the Y chromosome. Statistical analysis is being conducted to verify the concordance and discordance of the various chromosomal aberrations identified in MDS.

***CNR1* variation modulates risk for drug and alcohol dependence.** *L. Zuo[1,2], J. Covault[3], X. Luo[1,2], H.R. Kranzler[3], J. Gelernter[1,2]* 1) Dept Psychiatry, Yale Univ Sch Medicine, West Haven, CT; 2) VA CT Healthcare System, West Haven, CT; 3) Dept Psychiatry, Univ CT Sch Med, Farmington, CT.

Human cannabinoid receptor 1 (CB1) may play an important role in the development of drug dependence (DD) and alcohol dependence (AD), potentially via interaction with dopaminergic signaling in brain reward circuits. Following initial reports of the association of the *CNR1* gene (which encodes CB1) with DD or AD, we examined the association in a large case-control sample. Ten *CNR1* markers and 38 ancestry-informative markers were genotyped in 451 healthy controls and 550 substance dependent (SD; i.e. AD and/or DD) patients [including European-Americans (EAs) and African-Americans (AAs)]. The ancestry proportions of each subject were derived using the program STRUCTURE. Haplotype and diplotype probabilities for each subject were estimated using the program PHASE. The common confounding effects on association analysis from admixture, age, and sex, were controlled for using logistic regression analysis, Haplotype Trend Regression analysis or Diplotype Trend Regression analysis. The disease risk and protective alleles were fine-mapped using a linkage disequilibrium measure (). In EAs, risk for each SD subtype significantly increased with the number of G alleles at rs6454674 (SNP1). The frequencies of T alleles at rs806368 (SNP2) in the cases with DD or comorbid DD and AD were suggestively higher than in controls. SNP1^G+ (the genotypes containing a G allele) and SNP2^T/T genotypes had significant interaction effects on risk for each SD subtype (p=0.0003 for comorbid DD and AD, 0.0002 for DD, and 0.007 for AD). The peak values among all the markers were seen for SNP1 and SNP2. The magnitude of the odds ratios and positive likelihood ratios for SNP1 and SNP1×SNP2 in different SD subtypes was in the following order: comorbid DD and AD > DD > AD. In AAs, SNP1 was suggestively associated with each SD subtype (nominal p<0.05). These results suggest that *CNR1* variation and interactions play important roles in risk for both DD and AD and that the putative disease-influencing loci for SD are close to SNP1 or SNP2.

Homozygosity mapping in 13 families with autosomal recessive primary microcephaly: Linkage of three families to MCPH3 locus on Chr. 9q34. *A.J. Parsian[1], M.A. Karim[1], M. Cleves[1], A. Jankhah[2], S.M. Elsayed[3], E. Elsobky[3], A. Parsian[1]* 1) Dept Pediatrics, Univ Arkansas Medical Sci, Little Rock, AR; 2) Shiraz Medical Genetic Counseling Center, Shiraz, Iran; 3) Medical Genetic Center, Cairo, Egypt.

Autosomal recessive primary microcephaly (MCPH) is a neurodevelopmental disorder characterized by global reduction in brain size affecting mostly the cerebral cortex. The individuals with MCPH suffer from mental retardation of variable degrees. MCPH is a heterogeneous disorder and six loci (MCPH1-6) have been identified so far. MCPH5 that is caused by the mutations in ASPM that encodes the human homologue of fly abnormal spindle gene (asp) is the most common. We did homozygosity mapping and linkage analysis by using 47 microsattelite markers across the six loci in the affected individuals from 13 consanguineous families. We mapped the MCPH3 locus to a 1.55 cM region of chromosome 9q34 in three independent MCPH families. The marker D9S1881 produced a LOD score of 3.33 at the recombination fraction of zero using the sub-program Mlink in the software package Linkage 5.1 (Lathrop and Lalouel, 1984). The gene for this locus is CDK5RAP2. We excluded any mutation in the exon 4 and exon 27 including the splice sites (S81X and E385fsX4, Bond et al. 2005) of this gene by sequencing genomics DNA from three affected patients from these three linked families. Currently, we are in the process of sequencing the other translated exons of CDK5RAP2 gene. The remaining ten families did not linked to any of the MCPH reported loci. Our data strongly suggests MCPH locus heterogeneity and the existence of additional novel MCPH loci elsewhere in the human genome.

Dissection of the roles of collybistin, a neuron-enriched GDP-GTP exchange factor, in synapse formation and function.*ARHGEF9*. *A. Sertie, G. Alencastro, R. Passos Bueno* CEGH, Sao Paulo, Brazil.

Inhibitory glycine and many $GABA_A$ receptors subtypes are clustered at axon terminal contacts by the scaffold protein gephyrin, which in turn is targeted to the cell membrane by collybistin. Collybistin is a neuron-enriched member of the guanine nucleotide exchange factor (GEF) family for Rho GTPases. Mutations in *ARHGEF9* gene (Xq22.1), encoding human collybistin, were identified in a patient with hyperekplexia (exaggerate startle reflex and neonatal hypertonia), epilepsy and mental retardation and in patients with mental retardation (2 isolated cases and 1 familial). Although these findings reveal that collybistin is an important determinant of inhibitory synaptogenesis and neuron plasticity, our understanding about collybistin functions and regulation is far from complete. In order to gain further insights into collybistin function, we sought to identify novel collybistin-binding proteins by yeast two-hybrid screening. Screening a human fetal brain cDNA library with human collybistin as bait, we identified eigth different positive cDNA clones fused in frame with the Gal4 activation domain. After retesting each protein interaction in yeast, only three interesting cDNA clones were defined truly positives. We are currently performing coimunoprecipitation, immunocytochemistry and GST-pull down experiments to substantiate these interactions biochemically. In additon, in order to investigate the involvement of *ARHGEF9* gene in the etiology of hyperekplexia and epilepsy associated with mental retardation in Brazilian patients, affected individuals are being examined for mutations in this gene by dHPLC and sequence analysis. We have analysed a total of 6 hyperekplexia patients (4 males and 2 females) and 8 males with epilepsy and mental retardation and no pathogenic mutations were identified. We are currently attempting to collect DNA samples from other patients. This study may contribute to the understanding of collybistin roles in neurons, its regulation, the spectrum of clinical variability associated with mutations in *ARHGEF9* gene and how these mutations affect neuronal development and function. Functional and physical interaction between ZIC3 mutants and GLI3 *in vitro*. *L. Zhu, S. Poole, J.W. Belmont*
Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Mutations in *ZIC3* (OMIM 306995), a zinc finger transcription factor, cause X-linked Heterotaxy (HTX1), a congenital disorder resulting from failure to establish normal left-right asymmetry during embryonic development. A targeted deletion of the murine *Zic3* locus has been created and the phenotype of Zic3 null mice correctly models the defects found in human HTX1. Multiple abnormalities in the central nervous system (CNS) and axial skeleton were observed in Zic3 null mice and the patients with the majority of *ZIC3* mutations. Previous studies indicate that Gli proteins are involved in multiple aspects of neural and skeletal development. In this study we provide evidence that human ZIC3 protein can bind to the GLI consensus binding site (GLIBS) and physically interact with GLI3 protein. Investigation of the ZIC3 mutants identified in HTX1 patients revealed that all five intact zinc finger domains were necessary for the binding of ZIC3 to GLIBS. Although the role of GLIBS in the activation of TK promoter by ZIC3 is modest, ZIC3 can synergistically activate TK promoter with GLI3 in the presence of GLIBS. All the nonsense and frameshift ZIC3 mutants lacking one or more of the zinc finger domains could not physically interact with GLI3; however, the missense mutant K405E, located in the fifth zinc finger domain, retains its binding ability to GLI3, as well as the missense mutant P217A located in the N-terminal region before the zinc finger domains. Luciferase reporter assay indicated that both P217A and K405E mutants could still co-activate the reporter gene expression with GLI3, while all the GLI3-nonbinding ZIC3 mutants were unable, suggesting that physical interaction between ZIC3 and GLI3 is required for their functional interaction. Interestingly, no CNS or skeleton abnormalities were observed in the human patients associated with P217A or K405E mutants.

Approaches to whole genome association analysis: estimation of global and local genomic sharing using genome-wide SNP data. *S.M. Purcell[1], B.N. Neale[2], M.J. Daly[1,3], P.C. Sham[2,4]* 1) CHGR, Massachusetts General Hospital, Boston, MA, USA; 2) SGDP Centre, Institute of Psychiatry, Kings College London, UK; 3) The Broad Institute of Harvard & MIT, Cambridge, MA, USA; 4) Genome Research Centre, University of Hong Kong, Hong Kong.

Recent technological developments have made possible the efficient genotyping of hundreds of thousands of SNPs in individual DNA samples. Genetic data of this quantity and detail will provide information on the ancestry of individuals and on the relationship between pairs of distantly-related individuals. We have developed a simple identity-by-descent method to estimate the global genomic sharing between any two individuals from the same population. This method was used to detect previously unknown relationships among individuals in the HapMap population samples. We are now developing a Hidden Markov Model (HMM) to obtain estimates of local genomic sharing between pairs of individuals, given the genotype data and the estimated global genomic sharing. The methodology will take some account of complications such as genotyping errors and linkage disequilibrium between SNPs, and results in estimated probabilities of sharing none, one or both haplotypes by descent, at any section of the genome. The method is be implemented in the PLINK software (http://pngu.mgh.harvard.edu/purcell/plink/) and applied to the HapMap Phase 2 data. PLINK is a whole genome association analysis toolset, offering both computationally efficient implementations of existing methodologies (data management, summary statistics, sample matching based on inferred ancestry and a variety of association statistics) as well as novel approaches such as IBD estimation. Finally, we will discuss the potential use of this methodology to gene-mapping studies of complex diseases and quantitative traits.

Assay development and quantitative high through-put screening of -glucocerebrosidase: the search for pharmacological chaperones. *D. Urban[1], W. Zheng[2], A. Simeonov[2], E. Goldin[1], J. Padia[2], A. Jadhav[2], O. Goker-Alpan[1], E. Sidransky[1]* 1) MGB/NHGRI, NIH, Bethesda, MD; 2) NCGC/NHGRI, NIH, Bethesda, MD.

Gaucher disease is the inherited deficiency of the lysosomal enzyme -glucocerebrosidase (GC). The most common alterations found in Gaucher disease are missense mutations, which can lead to conformational changes in the protein structure. It has been reported that chemical chaperones might correct misfolding of the mutant enzyme and restore normal function. We have developed a fluorogenic enzyme assay to screen libraries of compounds to identify potential chaperones. Two profluorophore-labeled synthetic GC substrates, one yielding a blue fluorescent product and the other a red fluorescent product, were developed for these screens. The use of two different substrates helps to eliminate false positives from the compound screening. Approximately 62,000 compounds were screened in a quantitative high throughput screening (qHTS). We identified 299 inhibitors and 56 activators with a hit rate of 0.57 percent. Selected compounds were then tested in a cell-based assay using a lysosomotropic substrate to examine their potential to act as chaperones by restoring -GC activity in the mutant cells. This strategy may ultimately identify a set of novel small molecules that can be tested as therapeutic agents for the treatment of Gaucher disease.

A Rare Form of Dextrojuxtaposition of the Left Atrial Appendage. *M. Thompson[1], S. Keating[1], T. Cavalle-Garrido[2], D. Chitayat[3,4]* 1) Dept Pathology & Lab Medicine, Mount Sinai Hospital, Toronto, ON, Canada; 2) Div of Cardiology, Dept of Pediatrics, Hospital for Sick Children, Toronto; 3) The Prenatal Diagnosis Medical Genetics Programme, Mount Sinai Hospital, Toronto; 4) Div of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto.

Juxtaposition of the atrial appendages is a rare congenital cardiac anomaly with a previously reported incidence of 0.28% of patients referred for echocardiogram to a tertiary medical centre. Dextrojuxtaposition of the left atrial appendage is 6 to 8 times less common than levojuxtaposition of the right atrial appendage.

We report a rare case of dextrojuxtaposition of the left atrial appendage (JLAA) found at autopsy. The karyotype was that of a normal female, and no deletion was detected at 22q11.2. Both atrial appendages were placed to the right of the great arteries, the left atrial appendage superior to the right. There was atrial situs solitus and atrioventricular discordance. The left atrium emptied into a superoanteriorly positioned hypoplastic right ventricle and tricuspid valve. The mitral valve and a large left ventricle with right hand topology were connected to the right atrium. Atrial and ventricular septal defects were noted. An overriding, left ventricle-dominant aortic trunk provided a single outlet and the pulmonary artery, with an atretic valve, originated posteriorly at the aortic root. As in other reported cases, no pattern of associated non-cardiac malformations was apparent while a JLAA syndrome of cardiac anomalies has been described.

This form of juxtaposition is a rare finding and likely occurs as a result of abnormal looping of the embryologic tubular heart resulting in both atrial appendages situated to the right of the great arteries.

Using a murine model to identify genes important in pulmonary arterial hypertension (PAH). *M.W. Pauciulo[1], L. Liu[2], W.A. Tuchfarber[1], P.T. Hale[1], T. Foroud[2], W.C. Nichols[1]* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Medical and Molecular Genetics, Indiana University Medical Center, Indianapolis, IN.

PAH can be an autosomal dominant disorder characterized by occlusion and remodeling of the pulmonary arteries which leads to sustained elevation of pulmonary vascular resistance and progressive right heart failure. We previously performed a survey of 11 inbred mouse strains and identified substantial strain specific differences with respect to the development of hypoxia-induced pulmonary hypertension (PH). The CAST/EiJ strain displayed the highest susceptibility to hypoxia-induced PH as measured by the % increase (50%) in the size of the right ventricle relative to the left ventricle and the septum (RV/LV+S). Muscularization of CAST/EiJ distal pulmonary arteries confirmed PH. Relative to normoxic controls, hypoxic CAST/EiJ mice also demonstrated increases in right ventricle relative to body weight (RV/BW)(150%), left ventricle and septum relative to body weight (LV+S/BW)(64%), and hematocrit (70.5 vs. 48.3). To map loci contributing to PH in CAST/EiJ mice, F1 and F2 animals were generated by matings with FVB/nJ mice, which demonstrated a 2.5 fold lower increase in RV/LV+S after chronic hypoxia as compared to CAST/EiJ mice. RV/LV+S, RV/BW, LV+S/BW, and hematocrit were determined for 316 F2 animals after chronic hypoxia exposure. A genome screen was performed using 93 microsatellite markers spaced 20 cM, and data were analyzed with Mapmaker/QTL. For RV/LV+S as the quantitative trait, chromosome 9 exhibited a LOD score of 3.76 while chromosomes 5, 8 and 11 each showed a LOD score >2. Chromosome 11 showed a LOD score of 3.64 for RV/BW. Using LV+S/BW, chromosome 17 showed a LOD score of 4.07. For hematocrit, a high LOD score of 4.70 was detected on chromosome 9. Additional LOD scores >2 were seen across the genome for the latter 3 phenotypes. In conclusion, we have presented evidence that multiple loci may be contributing to murine hypoxia-induced PH. Identification of the specific genes at these murine loci may further our understanding of genetic factors important in human pulmonary hypertension.

Identification of *EFHC2* as a quantitative trait locus for fear recognition in Turner Syndrome. *L.A. Weiss[1,2], S. Purcell[1,2], S. Waggoner[2], K. Lawrence[3], D. Spektor[3], M.J. Daly[2,4], D. Skuse[3], P. Sklar[1,2]* 1) Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School, Boston, MA; 2) Medical and Population Genetics Group, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Behavioural and Brain Sciences Unit, Institute of Child Health, Univ. College London, London, UK; 4) Department of Medicine, Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School, Boston, MA.

Interpretation of facial expressions is critical for functioning in society. This can be seen clearly in autism; someone with average IQ can be profoundly disabled by social impairment. A third of women with Turner syndrome (45,X) have social difficulty similar to autism. Deletion mapping of the X-chromosome implicated a region of Xp11 critical for recognizing fearful faces. Our aim was to identify a gene influencing fear recognition by dense mapping of the 5 Mb locus. 93 (45,X) females were assessed by Schedules for the Assessment of Social Intelligence. Regression-based association mapping in the critical region was performed by the program *whap* using genotype data generated by mass spectrometry at 252 single nucleotide polymorphisms (SNPs). Initial quantitative analyses identified three regions of interest with association evidence ($P < 0.01$). To increase the SNP density in associated areas, 52 additional SNPs were genotyped in the three regions of interest. After analysis including the additional data, the third region contained four SNPs associated with decreased fear recognition ($P < 0.003$). Replication was performed in another 77 (45,X) females genotyped for 77 SNPs in the three regions of interest. Only the third region showed association of the same variation with fear recognition (rs7055196, rs7887763; $P = 0.022$ each). The associated SNPs span 40 kb within a novel gene, EF-hand domain containing 2 (*EFHC2*). The most strongly associated allele ($P = 0.00007$) has a frequency of 8.8% and accounts for 13% of the variance in fear recognition in the combined sample. *EFHC2* is now an excellent candidate to influence variation in social skills in the general population and in autism.

Investigation of the CCND1 gene in a variant t(9;22;11)(q34;q11.2;q13) chronic myeloid leukemia. *I. Yudelman[1], M.J. Macera[2,3], R. Zeng[2,3], J. Breshin[2,3], P. Chandra[3], A. Babu[2,3]* 1) Dept Medicine, Lenox Hill Hospital, New York, NY; 2) Div Molec Medicine & Genetics; 3) Dept Medicine, Wyckoff Heights Medical Ctr, Brooklyn, NY.

Five to ten percent of all Ph positive cases have a variant translocation and involves at least one additional chromosome in the rearrangement. There have been a number of studies done to determine prognostic value of the variant' translocation in response to Gleevec therapy. There appears to be no prognostic difference in the two groups. Recently, it has been described that some CML patients have a deletion in the 5 ABL1 gene and/or the 3 BCR gene. It has been reported that such deletions may have a survival disadvantage. Approximately 10% of the typical t(9;22) cases were shown to have a deletion in ABL and/or BCR; deletions are more frequent in the variant cases (up to 40%), some with deletions in the additional chromosome involved. A variant translocation, 46,XY,t(9;22;11)(q34;q11.2;q11), was seen in a patient referred for CML. FISH with a dual color-dual fusion BCR/ABL probe showed three signals of ABL1 (ABL1 x3) and three signals of BCR (BCR x3) with a single fusion of BCR/ABL (ABL1 con BCR x1). A second fusion was not seen as the 3BCR translocated to 11q13. The BCR/ABL1 probe showed no loss of signal and, therefore, no detectable deletion. The chromosome region 11q13 is the second most frequent in variant translocations. Oncogene cyclin D1 (CCND1/BCL1) is located in 11q13. To determine the role, if any, and location of the cyclin D1 oncogene and detect any loss of chromosome material, the CCND1/MYEOV break-apart probe was applied. The entire CCND1/MYEOV probe was translocated to the der(9), suggesting that the breakpoint is proximal to CCND1. No deletions at the breakpoints of this translocation were detected by this probe. The patient was treated with a standard Gleevec therapy and has shown a complete hematological response and a partial cytogenetic response. It is becoming clear that although there appears to be a higher percentage of variant translocations with deletions at the breakpoints, additional data will help to delineate clinical response in these patients.

MtDNA mutations in Leigh syndrome expression: recurrent incidence of the ND5 genetic defect. *S. Zhadanov[1,2], E. Grechanina[3,4], Yu. Grechanina[4], V. Gusar[3], N. Fedoseeva[3], S. Lebon[5], A. Munnich[5], T. Schurr[1]* 1) Department Anthropology, University of Pennsylvania, Philadelphia, PA; 2) Institute Cytology and Genetics SB RAS, Russia; 3) Kharkov Medical Genetics Center, Kharkov, Ukraine; 4) Department of Medical Genetics, State Medical University, Kharkov, Ukraine; 5) Department of Genetics, Hôspital Necker-Enfants Malades, Paris, France.

A variety of nuclear gene and mtDNA mutations has been reported to cause Leigh syndrome (LS) - a severe early childhood disorder characterized by bilateral necrotic lesions in the brainstem and basal ganglia. In our investigation of this disease, we conducted a genetic analysis of several LS cases carrying the novel 12706C mtDNA mutation that was earlier suspected to play a role in disease expression. Whole mtDNA genome sequencing revealed that each of these cases belonged to different Western Eurasian haplogroups, thereby pointing to the independent and recurrent occurrence of the 12706C variant. These findings also confirmed that this mutation was associated with LS regardless of the mtDNA background in which it occurred, or the presence of any additional changes in the mtDNA that would promote the expression of the LS phenotype. Thus, we conclude that this mutation plays a substantial deleterious role in LS development. The phylogenetic comparison of ND5 secondary structure in distant species further revealed that this subunit exhibits the highest sequence similarity to Na+/H+ antiporters. These results suggest a possible mechanism for ND5 dysfunction, and provide a further link between the pathogenesis of mtDNA defects and the LS phenotype.

Genetic analysis of 100 loci for coronary artery disease and associated phenotypes in a founder population. *G. Pare[1,2], D. Serre[1,2], D. Brisson[3], A. Montpetit[1], T.J. Hudson[1,2], D. Gaudet[3], J.C. Engert[2]* 1) Centre dInnovation Génome Québec, Montreal, QC; 2) McGill University, Montreal, QC; 3) Centre de médecine génique communautaire de lUniversité de Montréal, Chicoutimi, QC.

Coronary artery disease (CAD) is a major health concern for both developed and developing countries. With a heritability estimated at around 50%, there is a strong rational to better define the genetic contribution of CAD. This project involves the analysis of over 850 individuals from 142 families (with average sibships = 6.2) as well as a total of 558 cases and controls from the Saguenay Lac St-Jean region of Quebec using 1536 single nucleotide polymorphisms (SNPs) in 103 candidate genes for CAD. Candidate gene selection was based on published evidence of involvement in CAD risk as well as biochemical participation in pathways of interest (mainly lipoprotein metabolism). SNP selection was based on HapMap linkage disequilibrium data, common (MAF>5%) coding SNPs and previously published contributing SNPs. The gene and SNP panel was designed in collaboration with other laboratories involved in the Interheart project. Genotyping was done using the GoldenGate technology from Illumina and generated an overall call rate >99%. Since haplotypes of SNPs can be used as maximally informative markers, linkage analysis is possible with our dataset. Suggestive linkage for HDL cholesterol is seen on chromosome 1p36.22 (analysis done with MERLIN). Furthermore, both family-based and total association can be explored. Several Bonferroni-corrected significant associations are observed with lipoprotein-related traits as well as adiponectin plasma concentration (analysis done with QTDT). In particular, SNPs at the APOE locus are associated with apolipoprotein B levels and LDL cholesterol levels. APOA5 SNPs are associated with triglycerides levels. SNPs at the ADIPOQ (adiponectin precursor) locus are associated with adiponectin concentrations. Out of 13 different associations observed, 2 are new, whereas 11 are described in the current literature.

High frequency of sex differentiation impairment in males with 9p- : a series of ten patients. *L. Van Maldergem[1], C. Wetzburger[2], M. Francois[3], C. Heijmans[4], B. Candi[5], P. Mossay[6], J-P. Stalens[7], Y. Gillerot[8], C. Fourneau[9], D. Sartenaer[9], B. Parmentier[9], P. Deschamps[9], M. Fellous[10]* 1) Ctr Genetique Humaine, Université de Liège, Liège, Liège, Belgium; 2) Dept of Pediatrics,CHU, Charleroi; 3) Dept of Pediatrics,CHR du Val de Sambre, Auvelais; 4) Dept of Pediatrics,Hôpital de Jolimont, Haine St Paul; 5) Dept of Pediatrics, Clinique St Joseph, Lobbes; 6) Dept of Pediatrics, Clinique Ste Rosalie, Liège; 7) Dept of Pediatrics, Clinique Notre Dame Tournai; 8) Eurocat Hainaut-Namur; 9) Centre de génétique humaine, Institut de Pathologie et de génétique, Loverval; 10) Human Genetics Cochin Institute, Team 21 Pavillon Baudelocque Paris, France.

Deletion of the short arm of chromosome 9 is known to cause a characteristic 9p- syndrome associating mental retardation and typical dysmorphic features that include trigonocephaly, upward slanting of palpebral fissures, a long philtrum, a stunted tip of the nose, short neck, and dolichomesophalangy. Congenital heart disease, hernia and scoliosis may also be present. The critical region determining the typical phenotype is thought to be located in 9p22. Of interest is the fact that a number of male patients do present some degree of uncomplete sex differentiation. We report on ten males with a 9p- syndrome (pure in six cases, associated to duplication of another chromosomal segment in three cases and associated to Y chromosome inversion in one case) and discuss their sexual differentiation. All were mentally retarded. Seven of them (70%) had abnormalities of external genitalia, ranging from hypospadias to complete sex reversal. One of them (10%) developed a germ-cell tumour. These results confirm impaired male differentiation as a major clinical component of 9p- syndrome. Doublesex and mab3 related transcript (DMRT1) was identified as a candidate gene for human 9p24.3 associated sex reversal. In marsupials, DMRT1 protein was localized in the germ cells and the Sertoli cells of the testis, but in addition it was detected in the Leydig cells, peri-tubular myoid cells and within the acrosome of the sperm heads. However, its exact role in human remains to be elucidated.

Comprehensive Scanning of the mitochondrial genome in patients with kidney oncocytoma. *S.A.H. Zanssen[1], X. Hong[1], E. Kessel[1], B. Gunawan[2], L. Fuzesi[2], D. Warburton[3,4], E. Schon[1,4]* 1) Dept. of Neurology, Columbia University, New York, NY; 2) Dept. of Pathology, University of Goettingen, Goettingen, Germany; 3) Dept. of Pediatrics, Columbia University, New York, NY; 4) Dept. of Genetics and Development, Columbia University, New York, NY.

Mitochondrial defects have been associated with both severe neurodegenerative disorders and primary human cancers. Mutations of mtDNA have also been identified in various human cancers. Hereditary nuclear mutations in succinate dehydrogenase and fumarase genes cause a predisposition to paraganglioma and kidney cancers. Oncocytomas are mostly benign epithelial tumors and their predominant feature is a massive accumulation of mitochondria in the cytoplasm. Oncocytomas of the kidney are classified cytogenetically into 3 different groups characterized by loss of chromosome 1, by rearrangements involving chromosome 11q13, and by absence of cytogenetic aberrations but presence of mtDNA alterations. We performed a comprehensive scanning of the mitochondrial genome for point mutations in the latter group applying high resolution techniques such as SSCP and fluorescent sequencing. We detected new point mutations with a cluster in mitochondrial cytochrome c oxidase genes. We discuss these novel findings in the context of our previous findings in 11q13-aberrated oncocytomas with breakpoints near CCND1.

Rare Copy Number Changes Identified In Congenital Heart Disease Using ROMA. *D. Warburton[1], V. Jobanputra[1], K. Targoff[1], K. Anyane-Yeboa[1], M. Chen[2], J. Sebat[2], W. Chung[1], M. Wigler[2]* 1) Columbia Univ, New York, NY; 2) Cold Spring Harbor Laboratories, Cold Spring Harbor, NY.

Genomic microarray analysis has recently revealed small-scale changes in gene copy number to be a major form of human variation. Congenital heart disease (CHD), the most common congenital malformation, has a strong genetic component, yet most cases remain unexplained. Since CHD is a feature of most segmental aneuploidy syndromes, heart development must be sensitive to copy number changes (CNCs) in numerous parts of the genome. We hypothesize that small CNCs not detectable by standard cytogenetic analysis may be a significant cause of CHD.

We present preliminary data using ROMA (Representational Oligonucleotide Microarray Analysis) and an 85K NimbleGen chip with 35K resolution to search for CNCs on 24 patients with hypoplastic left heart syndrome and 13 patients with conotruncal defects. Reverse color CGH was performed using a normal control DNA. Segmentation analysis used a Hidden Markov Model to compute the most likely event. CNCs were considered rare and of interest if they were not observed in a comparison sample of 500 previously studied cases that include 175 normal individuals and 325 with other conditions not associated with CHD.

As expected, all CHD patients differed from the control in 7 to 14 regions of the genome. Most of these changes were observed frequently in the comparison sample and are presumably polymorphic normal variants. Using a cut-off probability of ?.70, there were 18 rare CNCs, including one of 3.2 Mb, which is very rare among normal variants. Nine of these CNCs contained known genes, and one contained a gene known to be involved in heart development. While intriguing, these studies are very preliminary. Verification by FISH and parental analyses to identify de novo changes are in progress. In addition, all confirmed de novo CNCs will be reanalyzed at a higher 6kb resolution using a 390K chip. While illustrating the significant problems involved in interpreting copy number variation, these data suggest that rare CNCs may contribute to the cause of CHD.

Linkage Analysis of Obesity Related Traits on Chromosomes 3, 7, 10 and 17 in a Yupik Eskimo Population. *R. Plaetke[1], Y. Wang[1], A. Goropashnaya[1], S. Hopkins[1], A.G. Comuzzie[2], G.V. Mohatt[1], B.B. Boyer[1]* 1) The Center for Alaska Native Health Research, University of Alaska, Fairbanks, AK; 2) Southwest Foundation for Biomedical Research, San Antonio, TX.

Prevalence of obesity and obesity-related chronic diseases are increasing among Alaska Native people. For example, in the CANHR sample of Yupik Eskimos, 64% of participants are overweight or obese; the prevalence of type 2 diabetes mellitus is approximately 3%. To investigate the genetic background of obesity-related phenotypes in a sample of extended pedigrees of Yupik Eskimos, we performed a 10 cM genome scan in 648 individuals 14-94 yrs of age using variance component analysis (VCA). Since family ascertainment is still on-going, we present preliminary results from the scan of the four chromosomes 3, 7, 10, and 17.

Markers from the ABI Prism Linkage Mapping Set vers. 2.5 were genotyped. Genotypic data and pedigree structure were checked by applying the programs infer, preswalk, and simwalk2. Phenotypic data were analyzed regarding normality; appropriate transformations were applied to reduce kurtosis and skewness. Narrow-sense heritabilities were determined for a variety of (transformed) phenotypes by including significant effects of covariates, including age, sex, and BMI (if appropriate). The following phenotypes with narrow-sense heritability 0.2 were selected for VCA: BMI, adiponectin, bodyfat %, fasting plasma glucose, and HDL-cholesterol. Two-point and multi-point VCA was performed with 56 extended pedigrees; 45% (25) of the pedigrees consisted of at least 6 individuals (range: 3-529; average: 22.5).

Multi-point analyses showed lodscores 1.4 in chromosomal regions covering known candidate genes for obesity related phenotypes: chrom 3q27: lod= 1.9, phenotype: adiponectin; 7q32: 2.3, glucose; 10p13-14: 1.5, BMI; 10q23-26: 1.4, adiponectin; 17p11: 1.6, bodyfat %. Including pleiotropy on BMI & HDL-cholesterol, multipoint analysis resulted in a lod=2.1 on 10p13-14.

[Grant support: P20 RR16430, R01MH59490].

CTCF regulates ataxin-7 gene expression through promotion of an anti-sense non-coding RNA: a novel system of transcriptional control linking CTCF with non-coding RNAs. *V.V. Pineda[1], R.T. Libby[1], G. Dunn[1], S. Baccam[1], A.C. Smith[1], S.J. Tapscott[2], G.N. Filippova[2], B.L. Sopher[1], A.R. La Spada[1]* 1) Lab Medicine, Univ. of Washington, Seattle, WA; 2) FHCRC, Seattle, WA.

Recent surveys of transcriptional units in the mouse and human genomes suggest the existence of >150,000 non-coding RNA (ncRNA) transcripts. A considerable fraction (~ 70% in the FANTOM survey) corresponds to anti-sense transcripts. CTCF is a multifunctional protein with a role in transcriptional regulation. Spinocerebellar ataxia type 7 (SCA7) is a polyglutamine disease characterized by retinal and cerebellar degeneration. The CAG repeat in ataxin-7 (Atx7) is flanked by two binding sites for CTCF. In order to understand the role of CTCF in regulating repeat instability and Atx7 transcription, we introduced Atx7 mini-genes into transgenic mice. Studies of these animals demonstrated the existence of an alternative Atx7 gene promoter whose activity is regulated by CTCF. We report the existence of an anti-sense non-coding RNA (AS ncRNA) at the Atx7 locus and have found that its expression is inversely correlated with the activity of the alternative promoter. Chromatin IP analysis indicated that CTCF occupancy correlated with expression of the AS ncRNA, suggesting that CTCF modulates Atx7 expression through the promotion of this AS ncRNA. To test this hypothesis, we have validated two different CTCF shRNAs and have derived a dual CTCF knock-down vector, using a lentiviral delivery system to transduce Y-79 retinoblastoma cells. Real-time RT-PCR analysis showed a significant reduction in the expression level of the Atx7 AS ncRNA message ($p < .001$ by t-test) concomitant with CTCF knockdown. We have surveyed human tissues and documented a reciprocal relationship between the levels of expression of the Atx7 sense transcript and Atx7 AS ncRNA. As Atx7 is a core component of the STAGA complex, our findings implicate CTCF in the regulation of the STAGA co-activator complex through an AS ncRNA whose expression modulates the activity of the Atx7 alternative promoter. Our findings support a model in which CTCF can regulate a transcriptional co-activator by promoting the expression of an AS ncRNA.

Cohesin association to chromatin is deregulated in Roberts syndrome. *H. Vega[1], O. Gualdron[1], M. Gordillo[1,2], E.W. Jabs[2]* 1) Universidad Nacional de Colombia, Bogota,Colombia; 2) Johns Hopkins University, Baltimore,MD.

Roberts Syndrome (RBS) is an autosomal recessive disorder characterized clinically by growth retardation, phocomelia, and craniofacial anomalies, and cytogenetically by the lack of cohesion at heterochromatic regions in the pericentromeric area of all chromosomes and the long arm of chromosome Y. Previously we reported that RBS is caused by mutations in ESCO2, one of the two human homologs of ECO1, a gene essential for establishment of cohesion in yeast. Sister chromatid cohesion is mediated by a multi-subunit complex called cohesin in a process that involves loading of cohesin onto chromatin, establishment during S phase, maintenance in G2, and dissolution in mitosis. To gain insight into the function of ESCO2, we investigated in RBS lymphoblastoid cell lines (LCLs) the association of cohesin subunits Rad21, SA1 and SA2 to chromatin during S and G2. By immunofluorescence we found that in control LCLs SA1 was distributed in a fine-granular nuclear pattern that was more intense in S phase than in G2. Despite a similar staining pattern, the intensity of the signal in RBS cells did not decrease at G2 and was even stronger when compared to control LCLs. Immunoblot of SA1, SA2 and Rad21 in cellular fractions enriched in chromatin-bound proteins confirmed the increase in the amount of chromatin associated cohesin complexes in RBS cells during G2/M. Although cohesin could not be detected in mitotic chromosomes, analysis of maintenance of arm cohesion in RBS cells treated with nocodazole for different periods of time showed that arm cohesion persists for up to twelve hours. This suggests that the normal dissociation of cohesin complexes from arm chromosomes in prometaphase is delayed or deregulated in RBS and explains the characteristic railroad track appearance of RBS chromosomes. Remarkably, inhibition of cohesin dissociation, persistence of arms cohesion and loss of centromeric constriction is observed in prometaphase arrested human cells lacking Plk1 or Aurora B activity. We propose that in addition to its role in establishment of sister chromatid cohesion during S phase, ESCO2 might regulate directly or indirectly the dissolution of cohesion in mitosis.

Ultra-high resolution oligonucleotide array CGH evaluation of a whole genome amplification protocol. *R.R. Selzer, T.A. Richmond, S.M. Rupp, J.M. Geoghegan, P.S. Eis* NimbleGen Systems Inc, Madison, WI.

Microarray-based comparative genomic hybridization (array CGH) methods have been widely used to investigate chromosomal abnormalities associated with cancer, developmental disorders, and population studies of normal copy number variation. Many of these studies are limited in the amount of sample collected, for example by microdissection of tumor samples or buccal swabs for which DNA quantities are limited. As higher resolution array CGH assays are becoming increasingly important for investigation of genomic rearrangements in both normal and disease populations, it is essential to validate that sample amplification does not introduce copy number bias into the results. We have used Qiagens Repli-G whole genome amplification service, which uses the Phi29 DNA polymerase multiple displacement amplification, on immortalized cell line DNA from Burkitts lymphoma, DNA from disease-free individuals, and DNA from primary tumors. From 100 ng of genomic DNA, 1000-fold amplification was obtained. The unamplified and the WGA samples were assayed on a two-color oligonucleotide-based array CGH platform, which contains 390K unique probes per array, to observe whether the WGA has introduced any bias into the data. Data from both a whole-genome, tiling-path design and a much higher resolution fine-tiling design will be presented. Initial analysis by the highest resolution array CGH available suggests this WGA method provides high fidelity amplification with virtually no introduction of noise or bias.

Mutations of a novel tight junction protein are associated with DFNB49 nonsyndromic hearing loss. *S. Riazuddin[1], Z.M. Ahmed[1], A.S. Fanning[2], K. Ramzan[3], A. Lagziel[1], R. S. Shaikh[3], P. Chattaraj[1], P.L. Friedman[4], J.M. Anderson[2], I.A. Belyantseva[1], A. Forge[5], S. Riazuddin[3], T.B. Friedman[1]* 1) SHG, LMG, NIDCD, NIH, Rockville, MD; 2) Dept of Cell and Mol Physiol, Univ of NC, Chapel Hill, NC; 3) CEMB, Univ of the Punjab, Lahore, Pakistan; 4) IMCS, CRC, NIH, Bethesda,MD; 5) CAR, UCL Ear Institute, London.

We mapped profound congenital deafness segregating in two families to chromosome 5q12.3-q14.1 (Ramzan et al 2005). The meiotic information from six additional families refined the disease linked haplotype to 2.4 megabases. One of the genes in the refined interval is *TRIC* which encodes tricellulin, a tetraspan integral-membrane tight junction (TJ) protein. Tricellulin is localized at the tricellular attachment points of most epithelial cells. Antibodies generated to the N-terminus of tricellulin show that tricellulin is concentrated at the tricellular TJs in epithelial cells of the inner ear including hair cells, their supporting cells, Reissners membrane and the stria vascularis. In the organ of Corti tricellulin is localized along the structurally complex junctions between supporting and neurosensory hair cells. Given the expression of *Tric* in a variety of tissues, the deafness phenotype caused by these mutations is surprising. In eight DFNB49 families we found four different mutations of *TRIC* including a nonsense and three splice site mutations. Exon trapping and RT-PCR data using RNA from lymphocytes of DFNB49 subjects show that the splice site mutations cause aberrantly spliced mRNA, resulting in frameshifts and premature truncations of the protein. These mutations remove a conserved domain of this protein which is predicted to bind the cytosolic scaffolding protein ZO-1. We provide data showing the affect of these mutations on the binding ability to ZO-1. There are some isoforms of tricellulin which remain unaffected by the mutant alleles and may play a role in maintaining the epithelial barrier of other tissues. Further studies of mouse models of mutant *Tric* will provide insight and give us an explanation as to why mutations in *TRIC* selectively affect inner ear function.

Novel mutations in the *OTOF* gene in Brazilian subjects with auditory neuropathy. *J. Romanos[1], M.L. Fávero[2], P.A. Otto[1], R.C. Mingroni-Netto[1]* 1) Depto de Genética e Biologia Evolutiva, Instituto de Biosciências, Univerisidade de São Paulo, São Paulo, Brazil; 2) Divisão de Educação e Reabilitação dos distúrbios da Comunicação, Pontificia Universidade Católica de São Paulo, São Paulo, Brazil.

Nonsyndromic prelingual inherited deafness is mainly autosomal recessive. The *OTOF* gene is one of the 23 identified genes responsible for autosomal recessive deafness. To date, there are 22 different pathogenic mutations from populations of variable origins. A Q829X mutation was found to be the most frequent in Spain. Some affected individuals are reported to present auditory neuropathy (AN), characterized by an absent or severely abnormal auditory brainstem response, with preservation of otoacoustic emissions and/or cochlear microphonics. We enrolled 64 Brazilian unrelated probands and family members with either autosomal recessive nonsyndromic deafness, or AN or both, for mutation screening and evidence of phenotype linkage to the *OTOF* gene. All families were genotyped for microsatellites linked to the *OTOF* gene, tested for the Q829X mutation and for the previously identified mutations. Families with microsatellite segregation patterns consistent with linkage and subjects with diagnosis of AN (7 and 11 subjects, respectively) were further screened for mutations in all 48 coding exons of the *OTOF* gene. To date, no causative mutations were found in the linkage group. Among the 11 cases of AN, we found four novel variants in three cases: c.1552-1567del16, c.3400C>T (R1134X) in homozygous form and c.1841G>A (G614E), and c.3239G>C (R1080P) together in a compound heterozygote. The c.1552-1567del16 and R1134X mutations are probably the cause of deafness in two patients. The two other mutations, G614E and R1080P, were considered potentially harmful based on amino acid changes; further studies are needed to verify if they are pathogenic. In the heterozygote for c.1552-1567del16, a further mutation remains to be identified. Further, homozygosity for the mutation R1134X probably results from consanguinity. While our study shows that mutations in the *OTOF* gene are frequent causes of auditory neuropathy in Brazil (3 of 11 families), we fail to confirm the high frequency of Q829X mutation found elsewhere.

Severe phenotypic expression of Beckwith-Wiedemann syndrome associated with high levels of paternal uniparental disomy for chromosome 11p15. *A. Smith[1,2], C. Shuman[3,4], L. Steele[5], P. Ray[5], R. Weksberg[1,2,3,4]* 1) Genetics & Genomic Biology, Hosp Sick Children, Toronto; 2) Inst of Medical Science, U of Toronto, Toronto; 3) Div of Clinical and Metabolic Genetics, Hosp for Sick Children, Toronto; 4) of Medical Genetics and Microbiology, U of Toronto, Toronto; 5) Dept of Ped and Lab Med, Hosp for Sick Children, Toronto, CANADA.

Beckwith-Wiedemann syndrome (BWS) is an overgrowth syndrome characterized by macrosomia, macroglossia, omphalocele, increased tumor risk and hemihyperplasia. BWS can be associated with genetic and/or epigenetic alterations that alter imprinted gene expression on chromosome 11p15.5. Somatic mosaicism for chromosome 11p15 paternal uniparental disomy (UPD), found in 20% of BWS cases, is associated with specific features of BWS including hemihyperplasia, Wilms tumor and hepatoblastoma. Despite the fact that tissue sampling may not always reflect the level of constitutional UPD we hypothesized that extremely high levels of UPD might drive severe phenotypic expression of BWS. We report two patients with severe presentations of BWS and high levels of UPD (>70%) in DNA from lymphocytes. Patient A was a male infant, delivered at 32 weeks gestation, with coarse facies, macrosomia and hypoglycemia. At 3 months of age, he was admitted for persistent hypoglycemia. At that time he had hemihyperplasia, hypertrophic cardiomyopathy with valvular pulmonary stenosis and respiratory compromise due to abdominal organomegaly. Abdominal imaging revealed enlarged dysplastic kidneys, hepatomegaly, hepatoblasoma, enlarged pancreas and spleen. Ventilatory support was reduced and he died at 5 months of age. Patient B was a female infant delivered at 35 weeks gestation. She was noted to have macrosomia, extreme macroglossia, umbilical hernia, hepatomegaly, hemihyperplasia and hypoglycemia. Abdominal imaging revealed hepatoblastoma and nephromegaly. She developed dramatic hyperplastic cardiomegaly, abdominal distention, upper airway congestion and died at 5 months. In order to determine whether the high levels of UPD are etiologically important for severe presentations of BWS it will be important to undertake analysis in further cases.

Analysis of the markedly increased incidence of cancer in individuals with Blooms Syndrome. *W. Shi[1], A. Zauber[1], M. Sanz[2,3], J. German[3]* 1) Dept. Epidemiology and Biostatistics, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Dept. Biology, Molloy College, Rockville Centre, NY; 3) Dept. Pediatrics, Weill Medical College of Cornell University, New York, NY.

Blooms syndrome (BS) is a rare recessively transmitted form of proportional dwarfism. A single locus is mutated*BLM* that encodes the nuclear protein BLM that when absent or non-functional also results in a mutator phenotypethe clinical consequence is cancer of a wide variety of cellular types and anatomical sites. We determined the standardized incidence ratio (SIR) of specific types of cancers diagnosed in 237 individuals with BS (BSI) ascertained since 1954 by the Blooms Syndrome Registry. The number of cancers expected to arise was calculated based on age, sex, and calendar interval-specific rates published by the Surveillance, Epidemiology, and End Results (SEER) program, NIH. 138 primary invasive cancers were diagnosed in 108 BSI during 4952 person years of follow-up. The mean age of diagnosis of the first primary cancer was 23 years (SD=12). The SIR (95% CI) by sex (M=128, F=109) is given below. An almost 100 fold increased risk of cancer existed for BSI as compared to the general population. A markedly increased risk of developing cancer exists for both males and females with BS. Early and continued surveillance for cancer is critical for affected individuals.

Type of cancer	No. of cancers	SIR for All BSI	SIR for Males	SIR for Females
All Sites	138	99 (83-117)	106 (84-131)	90 (68-117)
Lymphoma	32	166 (114-234)	141 (83-223)	215 (118-361)
Leukemia	29	152 (102-218)	191 (120-289)	92 (37-191)
Colorectal	20	521 (318-804)	607 (339-1001)	365 (118-852)

.

12q14: A novel linkage region in extended autism families. *M.A. Pericak-Vance[1], D.Q. Ma[1], D.A. Skaar[1], A.L. Collins[1], I. Konidari[1], J. Crowley[1], J. Jaworski[1], R.K. Abramson[2], H.H. Wright[2], M.L. Cuccaro[1], J.R. Gilbert[1], J.L. Haines[3]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) School of Medicine, University of South Carolina, Columbia, SC; 3) Center for Human Genetic Research, Vanderbilt University Medical Center, Nashville, TN.

Autism is a common neurodevelopmental disorder, with a significant genetic component and substantial locus heterogeneity. No consensus linkage region or associated candidate gene from any proposed region has emerged despite extensive studies. However, the primary substrate for the linkage studies has been small nuclear families. A contrasting and powerful alternative is the use of large, extended pedigrees to identify significant linkage results, as these families contain more potential linkage information than sibpair families. We collected 26 extended autistic families (65 affected, 184 total individuals), with each family having two to four affected individuals comprised of either avuncular or cousin pairs. We then performed a genome-wide linkage analysis using a high-density single-nucleotide-polymorphism (SNP), Affymetrix GeneChip Human Mapping 10K array and identified a genome-wide significant linkage signal on chromosome 12q14-15. Nine more microsatellites covering the interested region have now been typed on these families and confirm the linkage signal with the peak at D12S1686 [78.75 cM] (heterogeneity LOD [HLOD]: 3.49 [recessive model]). The linkage signal was enhanced in 17 male affected only families with a 4.56 HLOD under the recessive model. Using the power of the extended pedigrees, we constructed haplotypes and narrowed the minimum candidate region to a 4 cM segment from 75cM to 79 cM. This region contains 10 known genes, including interesting candidates AVPR1A; SRGAP1; WIF1; GRIP1 and TPH2. Analysis of these genes is underway.

Pharmacogenetic Study of 10 Dopamine Receptor DRD3 Gene Polymorphisms and Tardive Dyskinesia in Caucasians with Schizophrenia. *C. Zai[1], V. DeLuca[1], D.J. Muller[2], G. Remington[1], H.Y. Meltzer[3], J.A. Lieberman[4], S.G. Potkin[5], J.L. Kennedy[1]* 1) Dept Neurogenetics, CAMH, Toronto, ON, Canada; 2) Dept Psychiatry, Charite University Medicine Berlin, Campus Charite Mitte, Berlin, Germany; 3) Psychiatric Hospital at Vanderbilt University, Nashville, Tennessee, USA; 4) New York State Psychiatric Institute, Columbia University Medical Centre, New York City, New York, USA; 5) Brain Imaging Centre, Irvine Hall, University of California at Irvine, California, USA.

Tardive dyskinesia (TD) is a motor adverse effect of chronic exposure to antipsychotic medications. Its severity is measured by the Abnormal Involuntary Movement Scale (AIMS). The pathophysiology of TD has not been clarified, but changes in dopamine neurotransmission have been hypothesized to be involved. The role of the dopamine D3 receptor, coded by the DRD3 gene, in TD is supported by gene expression and pharmacological studies. The Ser9Gly polymorphism of DRD3 has been associated with TD in several (Basile et al, 1999; Lerer et al, 2002) but not all studies. Other DRD3 polymorphisms have not been assessed in TD. In addition, other genes, like Brain Derived Growth Factor (BDNF), may influence DRD3 expression and TD development. In the present study, we investigated 10 polymorphisms spanning DRD3 for association with TD. Our schizophrenia sample was restricted to European Caucasians (N=196). The rs905568 polymorphism in the promoter region of DRD3 was significantly associated with TD occurrence (p=0.004) and AIMS scores (p=0.003), while the other nine polymorphisms were mostly negative. We also tested if the DRD3 polymorphisms are associated with the diagnosis of schizophrenia; preliminary results with rs905568 did not reach statistical significance. Taken together, the present study suggests that DRD3 may contribute to the risk of TD development in European Caucasians, but replication studies are required. Preliminary data for five BDNF polymorphisms as well as genetic interaction analysis of BDNF and DRD3 in TD will also be presented.

Combined cytogenetic, aCGH and gene expression analyses of cisplatin resistant ovarian cancer cells. *A. Tsalenko[1], M. Prasad[2], J. Paderova[2], C.-H. Lee[2], P. Marrano[2], Z. Yakhini[1], A. Ben-Dor[1], J. Squire[2], M. Barrett[1]* 1) Agilent Laboratories, Santa Clara, CA; 2) Ontario Cancer Institute, Princess Margaret Hospital, University of Toronto, Toronto, Canada.

Chemotherapies are often restricted by the development of acquired resistance. We use a combination of array-based comparative genomic hybridization (aCGH), high resolution cytogenetics and gene expression (GE) to study the genomic basis of such phenotypes. To demonstrate the utility of combined analyses for studying drug resistance we compared the genomic profiles of A2780 ovarian cancer cells and a cisplatin-resistant derivative (A2780cis). Copy number aberrations were detected with Agilent prototype 95k 60mer oligonucleotide CGH arrays; GE was measured with Agilent 44k GE arrays. Aberrant intervals were identified using an efficient aberration detection algorithm ADM1 and integrated with spectral karyotyping (SKY) and chromosome-specific m-banding analyses. The majority of differential aberrations were deletions in A2780cis cells associated with down-regulation of GE relative to parental A2780 cells. These included deletions on 1p22.1-cen with a nested homozygous deletion targeting the SNX7 locus at 1p21.3, 2pter-p25.2, Xq12.2-qter, and loss of one copy of chromosome 13 but with focal (<1Mb) duplication at 13q12.12. In addition A2780cis cells had gain of a single copy of 8q11.22-qter. Derivative chromosomes in A2780cis cells, including der(8)t(1;8)(p22;p23) and der(X)t(X;1)(q12;q11) that were associated with differential copy number aberrations, were identified by SKY and mBAND and their breakpoints mapped to a single gene resolution. A significant enrichment of differentially expressed genes is observed in these regions including chromosomes 1p (p-value 3.5E-07), 13q (p-value 0.003) and 8q (p-value 0). Gene Ontology analysis revealed functional enrichment of down-regulated genes within the 1p interval in the hydrolase activity category (p-value 6.08E-07), with more specific terms of GTPase activity (p-value 5.85E-06) and ATPase activity (p-value 0.002). Mitosis (p-value 0.0002) and cell cycle (p-value 0.003) pathways are overrepresented in differentially down-regulated genes on chromosome 13.

Array-CGH increases detection rate of constitutional chromosome abnormalities. *D.L. Pickering, D.M. Golden, R.J. Stroebele, B.J. Dave, W.G. Sanger* Human Genetics Laboratories, Munroe Meyer Institute, Omaha, NE.

The identification of unbalanced chromosome abnormalities is an important aspect in the diagnosis and management of constitutional disorders however, many affected individuals have normal FISH and/or karyotype results. Array-CGH (aCGH) has emerged as an effective tool in the cytogenetics laboratory for the detection of chromosomal deletions and duplications that are associated with constitutional disorders because of its ability to rule out multiple genetic abnormalities in a single test. This is particularly beneficial in newborn studies and in older individuals lacking a unifying diagnosis following normal cytogenetic investigations. Our laboratory analyzed 445 individuals by aCGH utilizing a commercially available constitutional array platform covering genetic loci implicated in known diseases. Fifty-four of the cases were newborn patients less than 2 months old with dysmorphic features and the remaining cases were older individuals with clinical findings suggestive of a genetic disorder. All of the cases had a previous or concurrent normal karyotype and in some cases, normal FISH studies. Thirty-two out of 445 cases (7.2%) were abnormal by aCGH studies. Deletions were observed in 19/32 abnormal cases, duplications were identified in 11/32 abnormal cases and 2/32 unbalanced translocations were detected. Three of the abnormal cases represented newborn studies. The incorporation of aCGH in our laboratory for the study of constitutional disorders in which there was a normal cytogenetics study has increased the overall chromosomal abnormality rate by 7.2%. Additionally, aCGH has curtailed the effort, time, and expenses spent in performing multiple FISH tests in cases with nonspecific clinical features. Our findings demonstrate the usefulness of this technology in identifying chromosomal abnormalities, particularly in cases that remain a diagnostic enigma and in newborn studies where establishing a diagnosis upfront will improve patient management.

The gene encoding *ECT2*, a candidate substrate of the Angelman syndrome protein E6-AP, is associated with autism. *L.T. Reiter[1], R.J. Delahanty[2], J.S. Sutcliffe[3]* 1) Department of Neurology, University of Tennessee HSC, Memphis, TN; 2) Department of Molecular Physiology & Biophysics and; 3) Center for Molecular Neuroscience, Vanderbilt University, Nashville, TN.

Autism is a neurodevelopmental disorder affecting ~1 in 500 individuals with deficits in language, social reciprocity, and patterns of repetitive behaviors and restricted interests. Despite a recognized complex genetic etiology, locus heterogeneity has confounded efforts to identify loci broadly contributing to idiopathic disease. Maternal chromosomal duplications of 15q11-q13 are the most frequent cytogenetic abnormalities found in autism. Data suggest that dup(15) phenotypes result from over-expression of contiguous loci including the maternally-expressed E6-AP ubiquitin ligase (*UBE3A*) gene. Maternal deficiency of *UBE3A* causes the neurodevelopmental autism spectrum disorder Angelman syndrome (AS). The E6-AP protein targets other proteins through ubiquitinylation for subsequent ubiquitin-dependent degradation. Altered expression of *UBE3A* is therefore predicted to result in dysregulation of E6-AP substrates. We used a proteomics strategy in *Drosophila* to identify E6-AP targets and determine if they correlate with phenotypes potentially-relevant to AS and autism. In our first proteomic screen, we identified the Rho-GEF gene *pebble* as a neurologically-relevant target of Ube3a in *Drosophila* and mouse. We hypothesize that genetic variation at E6-AP target protein loci, like the *pebble* ortholog *ECT2*, contributes to autism susceptibility. An initial test of this hypothesis involved an association study in 546 combined multiplex and simplex autism families using tag SNPs representing common alleles at *ECT2*. Transmission data revealed significant association (P=0.02), predominantly in males (P=0.04), at a marker in intron 20. We are currently designing additional SNP association assays in and around the *ECT2* locus to extend these findings.

Has the consanguineous marriage any effect in infertility? *S.M. Seyedhassani[1,2], A. Aflatoonian[1], N. Tabibnejad[1], S.M. Kalantar[1], M. Houshmand[2]* 1) Medical Genetic Department, Research & Clinical Center for Infertility, Yazd, Yazd, Iran; 2) National Institute for Genetic Engineering and Biotechnology,Tehran, Iran.

Introduction: A consanguineous relationship is one between blood relatives who have at least one common ancestor no more remote than a great-great grandparent. Infertility is most commonly defined as the absence of pregnancy for one year of unprotected intercourse. Many studies have shown that among the offspring of consanguineous marriages there is an increased incidence of both congenital malformations and other conditions which will present later. Material and methods: We studied 5200 married defined couples in 260 randomized clusters that were divided in ten different rural and urban areas. These couples were interviewed based on using a structured questionnaire to ascertain the prevalence of consanguinity, infertility and related epidemiological findings . Results: There were consanguineous marriages in 2153 cases (41.1%)(CI 95% from 41.2%to 42.7%) in different degrees including degree 2 (0.04%), degree 3(27.3%), degree 4 (7.4%), degree 5(6.7%). Thus, 58.9%of population had nonfamilial or more remote than five degree marriages. Among these couples , 276 cases of infertility were encountered and the overall prevalence of infertility was about 5.52%(CI 95%from 4.9%to 6.14%) containing of primary 3.48% and secondary 2.04%. In infertile couples 135 had consanguineous marriage (48.9%)(p= 0.009 and Odds Ratio= 1.38,1.07<OR<1.77). Infertile males (56 cases) and females(114 cases) were born from consanguineous marriage in 42.9%(p=0.826) and 35.1%(p=0.175) respectively. Conclusion: In Iran, there was an incidence of consanguineous marriage near to neighboring countries such as Pakistan, Kuwait and Saudi Arabia. Consanguinity was related to in expression of infertility, but, there wasnt significant difference in primary and secondary infertility separately.These findings can implicate the probability of bilateral recessive genetic effects leading to preclinical abortion in encountered couples.

Gene mutations for NELF in 75 patients with Kallmann syndrome and cellular localization of NELF in GnRH neurons. *N. Xu[1,2], W.C. Xiong[2,3], R.S. Cameron[2,4,5], L.C. Layman[1,2]* 1) Dept. Obstetrics & Gynecology; 2) Developmental Neurobiology Program, IMMAG; 3) Dept Neurology; 4) Dept Cellular Biology and Anatomy; 5) Dept Medicine, Medical College of Georgia, Augusta, GA, United States, 30912.

Kallmann syndrome (KS) is a developmental disorder with the combination of idiopathic hypogonadotropic hypogonadism (IHH) and anosmia or hyposmia. Nasal embryonic luteinizing hormone-releasing hormone factor (NELF) is a candidate gene for KS, and has been proposed to affect the GnRH neuron migration pathway from the olfactory placode region to the hypothalamus. The human NELF cDNA was cloned previously, and it is hypothesized that mutations in NELF are present in patients with KS but not in controls. In addition, we wanted to determine the precise cellular localization of Nelf in immortalized GnRH neurons. Primers were designed to amplify 16 exons of NELF and splicing junctions. 75 patients with KS were analyzed for NELF mutations by direct DNA sequencing, and three putative mutations were found in introns near splice junctions: IVS8-21G>A, IVS11-13C>T, and IVS10-49G>T. None of these was reported in the SNP database, or identified in controls. Nelf mRNA was expressed in the GnRH neuronal cell lines (NLT, GN11 and GT1-7). To determine the localization of Nelf in GnRH neurons, endogenous Nelf was predominantly detected in the nuclei by western blot and immunofluorescence using anti-Nelf antibodies. These findings were consistent with the program PSORT II, which predicted two putative nuclear localization signals (NLS) in the Nelf protein. By site direct mutagenesis, two mutants changing either of two putative NLS (RRKR->AAKA and RK->AA), and one reported missense mutant in a KS patient (T480A) were constructed, and all three mutated constructs were overexpressed in GnRH neurons. One NLS mutant (AAKA) reduced the nuclear to cytoplasmic ratio by more than 5-fold. In summary, we found 1) putative NELF mutations around the splicing junctions of NELF in patients with KS, and 2) the protein Nelf resides predominantly in the nuclei of GnRH neurons and a putative NLS was identified. These results suggest that NELF plays an important role in the process of the GnRH migration.

Inter-individual Epigenetic Variation in Healthy Human Subjects. *M. Shinawi, E. Montz, P. Fang, A.L. Beaudet*
Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX.

Epigenetic regulation refers to stable changes in gene expression that are not mediated by a change in DNA sequence. The biochemical basis of epigenetic regulation includes DNA methylation, histone modifications, and the action of nonhistone proteins in chromatin. DNA methylation is crucial for the embryo development and has an essential role in X chromosome inactivation, genomic imprinting, and chromatin modifications. In addition, early nutrition at critical ontogenic stages affects DNA methylation and changes the expression of specific subsets of genes. Although a major effort is being made to elucidate the genetic variations (e.g.SNPs and the Haplotype Map) in the human genome, little has been done to assess the epigenetic variability. Principal challenges for the future will be to assess the variation of DNA methylation and whether environmental conditions influence these factors. We are testing the hypothesis that epigenetic variations are common and might contribute to the phenotypic differences between healthy individuals and to disease, particularly complex disease traits. The aim of this study is to perform methylation analysis at different genomic regions to detect epigenetic variations between healthy individuals. The methylation status is being analyzed in 50 females and 50 males by using gel-based radioactive bisulfite sequencing in the CpG islands of the following genes and regions: *SNRPN*, *MEG3*, DMR1 of *IGF2* (three imprinted genes), *28S rDNA*, *Satellite 2* (repetitive DNA), and *MAOB* (X-linked gene subject to X inactivation). Our preliminary analysis on 30 individuals showed minor variations in the methylation of the imprinted genes *SNRPN*and *MEG3*, and of the X-linked *MAOB* gene. For 7% of individuals, there was significant hypermethylation of the DMR1 of *IGF2* compared to the majority. However, the most remarkable degree of variation was detected in the *28S rDNA* repetitive sequence. Additional studies are underway to test more samples and to statistically evaluate the DNA methylation differences. Our data provides evidence for inter-individual epigenetic variability in human which might have a role in human variation and disease.

A new case with Clavicular Hypoplasia, Zygomatic Arch Hypoplasia and Micrognathia. *L.E. Wong-Ley[1], J.E. Garcia-Ortiz[1], A. Serralde[2], L.E. Figuera[1]* 1) GENETIC, CIBO-IMSS, Guadalajara, Jalisco, Mexico; 2) Unidad de Medicina Familiar No.54, IMSS, Tlaquepaque, Jalisco, Mexico.

In 2000, Ponzio and Cunningham reported a patient with an unique phenotype characterized by cleidocranial hypoplasia, mild frontonasal malformation (FNM), micrognathia and hypoplastic zygomatic arches; this phenotype was later named with the acronym CHZAM (clavicular hypoplasia, zygomatic arch and mandibular hypoplasia, OMIM 605040) and it was proposed to be part of a continuum spectrum of CCHA and mandibulofacial dysostosis presentations and mutations. Here, we describe a 30 year-old female with multiple anomalies including the leading features of CHZAM in addition to short neck, pterigium colli, bilateral Sprengel anomaly, Tanner II-III breast development and external genitalia; upper extremities with bilateral camptodactyly and clinodactyly of 5th digit, ungueal streaks in 1st, 3rd and 4th digits of right hand and 4th digit of left hand; lower limbs with bilateral clinodactyly of 3rd and 4th digits and postaxial polydactyly of left foot. X-ray examination showed cranial digital impressions and dysplastic changes in the basiocciput, hypoplastic sinuses, verticalization of hypoplastic clavicles, cervical fusion C2-C3, hypoplastic scapulae, delayed ossification of pubic bone, hypoplastic iliac wings, large femoral neck, large epiphyses, short middle phalanges and metacarpals/tarsals III-V, hypoplastic distal phalanges, accessory epiphyses especially of 2nd metacarpal, long 2nd metacarpal, cone shaped epiphyses and supernumerary teeth. A psychological evaluation showed mental retardation. Karyotype (GTG banding technique at 550-650 band resolution) was normal. Our patient fits all the diagnostic criteria for CHZAM is, in the best of our knowledge, the second one reported in the literature and the first reported female and adult leading us to further delineate the clinical spectrum of this rare condition previously reported in a 6-year-old boy; both cases have been sporadic but Mendelian inheritance can not be ruled out.

Demonstration of Genetic Interactions between TRIM32 and other Bardet-Biedl Syndrome Genes. *M.K. Tayeh[1,2,3], H-J. Yen[1,2,3], R.F. Mullins[4], A.P. Chiang[1,2,3], J.S. Beck[1,3], C.C. Searby[1,3], T.A. Westfall[5], H. Griesback[5], E.M. Stone[3,4], D.C. Slusarski[5], V.C. Sheffield[1,3]* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Genetics Ph.D. program, Univ Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute; 4) Dept Ophthalmology, Univ Iowa, Iowa City, IA; 5) Dept Biology, Univ Iowa, Iowa City, IA.

Bardet Biedl syndrome (BBS) is a pleiotropic, genetically heterogeneous, autosomal recessive disorder with the primary clinical features of obesity, retinopathy, polydactyly, learning disabilities, renal abnormalities and hypogenitalism. To date, 11 BBS genes have been identified and experiments suggest that BBS proteins play a role in the function of cilia and intracellular transport. We have used antisense oligonucleotides (morpholinos) for knock down of BBS gene expression in zebrafish to demonstrate a role for BBS genes in cilia maintenance and retrograde intracellular transport, as well as to evaluate novel BBS candidate genes. In addition, we have used the zebrafish model system to investigate genetic interactions between paired combinations of BBS genes. Interactions in the zebrafish were analyzed by double knock down of BBS genes using pair wise co-injection of low dose BBS morpholinos. Injected embryos were analyzed for cilia and intracellular transport defects, as well as other abnormalities. Of the 28 possible paired combinations of eight BBS genes (BBS1-BBS8), we detected only two combinations of BBS gene double knockdowns that resulted in evidence of genetic interaction in the zebrafish model system. We recently identified TRIM32, an E3 ubiquitin ligase gene, as BBS11. We investigated genetic interactions between the zebrafish orthologue of TRIM32 and other BBS genes. Our data demonstrate interactions between zebrafish trim32 and multiple other BBS genes. These data suggest a likely role for TRIM32 in the ubiquitination of BBS gene products and indicate a possible role for TRIM32 in the modification of BBS phenotypes in human patients.

A familial cases of LEOPARD syndrome associated with childhood onset behavioral disorder and Asperger syndrome. *Y. Watanabe[1], S. Yano[2], M. Yoshino[1], T. Matsuishi[1]* 1) Dept Pediatrics, Kurume Univ, Kurume, Japan; 2) Pediatrics/Genetics Div, 1G24, Univ SC, Women & Child Hosp, Los Angeles, CA.

LEOPARD syndrome is a rare autosomal dominant disorder characterized by Lentigines, Electrocardiogram abnormalities, Ocular hypertelorism, Pulmonic valvular stenosis, Abnormalities of genitalia, Retardation of growth, and Deafness. This syndrome is caused by germ line missense mutations in the PTP catalytic domain of PTPN11. The mutations induce catalytically impaired defective protein-tyrosine phosphatase SHP2 by dominant negative effect (Kontaridis, 2006). Approximately 50 % of Noonan syndrome patients are due to PTPN11 mutations that are scattered over the entire SHP2 regions including the catalytic domain. The mutations resulting in Noonan phenotype are the gain of function mutations and they exhibit substantially increased catalytic ability (Kontaridis, 2006). It has been known that SHP2 positively controls the activation of the RAS/MAPK. Recently, SHP2 negative Noonan syndrome patients have been identified to have KRAS mutations (Schubbert, 2006). SHP2 is widely expressed in both embryonic and adult tissues. Mutations in PTPN11 result in abnormal axial and paraxial mesodermal structures. Mutations in PTPN11 are also known to cause rapid apoptosis in trophoblast stem cells (Yang, 2006). We report a family with three affected individuals (father and two affected sons) with typical LEOPARD syndrome. The father has developed severe behavioral problems over the past 10 years with aggressive behavior. His sons have childhood onset behavioral problems and learning difficulties and diagnoses was made with ADHD in one and Asperger syndrome in the other. Although it is well known that patients with LEOPARD syndrome are often associated with developmental delay/mental retardation, there have been no reports about cases of LEOPARD syndrome who satisfied a criteria for ADHD or Asperger syndrome. Although considerable progress has been made in molecular pathology in Noonan syndrome and LEPARD syndrome, understanding the mechanisms how these molecular changes affect central nervous system function remains unknown.

Systematic analysis of tumor genetic alterations on Cancer Genome WorkBench (CGWB). *J. Zhang, R. Finney, W. Rowe, M. Edmonson, T. Dracheva, J. Jen, J. Struewing, K. Buetow* Lab Population Genetics, NCI, Bethesda, MD.

Systematic investigations of genetic changes in tumor such as The Cancer Genome Atlas (TCGA) project are expected to lead to molecular approaches to the diagnosis and the treatment of cancer. To facilitate such studies, we have developed Cancer Genome WorkBench (http://cgwb.nci.nih.gov), an integrated bioinformatics platform able to perform high-throughput data analysis, construct mutation profiles, and permit evaluation of the effect of mutations on protein coding and 3-D structural changes. A novel algorithm, IndelDetector, has been developed to find insertion/deletion changes. It is integrated with SNPdetector, a software tool we developed previously for finding substitution variations, in an automated tumor mutation analysis pipeline. Somatic mutations, germline mutations and copy number changes in paired tumor-normal samples discovered by this pipeline are assembled into mutation profiles. These clinical mutation profiles are then integrated to the reference human genome in our enhanced version of UCSC genome browser. Using this approach we have analyzed three data sets. The first is resequencing of candidate genes in paired tumor-normal lung cancer samples. In this data set, a tumor sample can have a tumor-to-normal allele ratio as low as 20%. Clinical samples with two inactivated copies of tumor suppressor gene LKB1 (one inactivation caused by LOH and the other by somatic mutation) have been found. The second is a re-analysis of 156 genes resequenced by the SeattleSNPs. The results show that our method is able to find 90% of the 1,250 insertion/deletion polymorphisms manually identified by SeattleSNPs. In addition, 500 novel insertion/deletion polymorphisms have been discovered with a projected 90% validation rate based on manual data review. The third discovers germline mutations in familial ovarian cancer. Our experience demonstrates the feasibility of finding tumor suppressor genes that fit the double-hit model using an integrated analytical system. Access control of CGWB has been implemented and a user data submission portal is under development to facilitate large-scale data analysis centers as well as individual research laboratories.

Spinocerebellar ataxia type 8: bidirectional expression of CUG and CAG expansion transcripts and intranuclear polyglutamine inclusions. *T. Zu[1], M.L. Moseley[1], Y. Ikeda[1], W. Gao[2], A.K. Mosemiller[1], R. Daughters[1], G. Chen[2], M.R. Weatherspoon[1], H.B. Clark[3], T.J. Ebner[2], J.W. Day[1], L.P.W. Raumn[1]* 1) Inst. Hum. Genet; 2) Neuroscience; 3) Lab. Med. Pathology, Univ Minnesota, Minneapolis, MN.

We previously reported that a (CTG)n expansion causes spinocerebellar ataxia type 8 (SCA8), a slowly progressive ataxia characterized by reduced penetrance. The (CTG)n-expansion mutation is transcribed, alternatively spliced, and polyadenylated in the CTG orientation. Because initial sequence analysis revealed no likely ORFs spanning the repeat in either direction, and because of the known pathogenic properties of CUG expansion transcripts in myotonic dystrophy, we initially proposed that SCA8 is caused by an RNA gain-of-function mechanism. To elucidate the molecular events that cause SCA8, we developed a transgenic murine model in which the full length human SCA8 gene is expressed using its endogenous promoter. (CTG)116 expansion, but not (CTG)11 control lines, develop a progressive neurological phenotype and in vivo optical imaging studies show a loss of cerebellar cortical inhibition. Surprisingly, we found 1C2-intranuclear inclusions in Purkinje cells in SCA8 expansion mice and human SCA8 autopsy tissue result from translation of a nearly pure polyglutamine protein (ataxin 8) encoded on a previously unidentified anti-parallel transcript spanning the repeat in the CAG direction. Experiments are now being performed to define the sequences that control transcription and translation and to characterize the expression pattern of this newly identified gene (*ATXN8*). The neurological phenotype in SCA8 BAC-expansion but not BAC-control lines demonstrates the pathogenicity of the (CTGCAG)n expansion. Moreover, the expression of non-coding (CUG)n expansion transcripts (*ataxin 8 opposite strand*, *ATXN8OS*) and the discovery of intranuclear polyglutamine inclusions suggests SCA8 pathogenesis involves toxic gain-of-function mechanisms at both the protein and RNA levels.

Effect of *APOH* promoter SNPs on gene expression and plasma levels of APOH. *S. Suresh[1], R.L. Minster[1], F.Y. Demirci[1], M. Kenney[1], P. Shaw[2], A. Kao[2], C. Kammerer[1], F. Bontempo[3], S. Manzi[2], M.I. Kamboh[1]* 1) Dept. of Human Genetics; 2) Lupus Center of Excellence; 3) Dept. of Medicine, Univ. of Pittsburgh, Pittsburgh, PA.

APOH has been implicated in several physiologic pathways, including coagulation, production of antiphospholipid antibodies and lipid metabolism. Plasma APOH levels vary significantly among individuals, ranging from immunologically undetectable to as high as 35 mg/dL. Family and heritability data suggest that APOH plasma variation is under genetic control; however, the exact underlying molecular basis of this variation is largely unknown. Our initial studies demonstrated that the -32 promoter SNP, which is in LD with the codon 316 mutation, was significantly associated with changes in plasma APOH levels and in reporter (luciferase) gene expression. However, this did not preclude the possibility of other promoter variations regulating gene expression. The purpose of this study was to search for additional promoter functional variants that are associated with altered gene expression and plasma APOH levels. For this purpose, we have focused on a ~1.4 kb fragment in the immediate 5 flanking region of the APOH gene. Six promoter SNPs, including -32, were genotyped by Pyrosequencing in 238 Caucasian SLE women and 195 healthy Caucasian women and plasma APOH levels were determined by the modified capture-ELISA method. The functional effects of these promoter SNPs were analyzed using in vitro dual-luciferase reporter assays in COS-1 cells. The variant alleles of three SNPs at positions -1219, -643 and -32 showed lower luciferase gene expression (51%, 40% and 37%, respectively) as compared to the respective wild-type alleles. Due to LD between these 3 SNPs, only the -32 SNP showed significant association with plasma APOH levels in the ANOVA ($p<0.0001$). The variant alleles of the other two SNPs were in LD with the wild type allele of the -32 SNP that is associated with higher gene expression and thus nullifying the lowering effects of these two variants in ANOVA. The characterization of *APOH* promoter and its functional variants will help to further delineate the molecular basis of plasma APOH levels.

Prenatal diagnosis of inherited mental retardation: subtelomeric rearrangement mimicking an autosomal recessive condition. *A. Perez-Juana del Casal, M.A. Ramos-Arroyo, M. Artigas, S. Moreno, A. Alonso, A. Valiente* Dep. Genetics, Hospital Virgen del Camino, Pamplona, Navarra, Spain.

A 29 year-old epileptic woman was referred to the Genetics Clinic in her 8 week of gestation (twin pregnancy), because of her husbands family history of unexplained mental retardation. He (SG) had three out of his seven siblings, one man and two women, moderately mentally retarded. Their parents had normal intelligence and both of them came from the same small area in Navarra. Initially, the pedigree analysis suggested a recessive condition. We examined the oldest mentally retarded brother, no definite dysmorphy suggestive of any particular syndrome was observed. A routine karyotype and a Fragile-X study were normal. A DNA sample was checked for submicroscopic subtelomeric aberrations, using multiplex ligation dependent probe amplification MLPA (SALSA PO70 and PO36). This technique revealed a 20qtel duplication. Then, FISH analysis (ToTelVysion, Vysis) was carried out to confirm the rearrangement identified by MLPA, and an unbalanced subtelomeric translocation, between chromosomes 14 and 20 was identified: 46,XY,ish t(14;20)(qter+,qter+;qter-,qter+). It is remarkable that the recombinant chromosome 14 had not lost his qtel regions (confirmed by MLPA and FISH). This is probably due to the fact that this subtelomeric portion is highly repetitive and appears to be a hot spot for recombination.

Subsequently, karyotype and FISH analysis for subtelomeric regions of chromosomes 14 and 20 (ToTelVysion Vial 7 and 17), were performed on the healthy brother (SG) detecting a balanced translocation between both subtelomeric regions: 46,XY,ish t(14;20)(qter-,qter+;qter-,qter+). After all, an amniocentesis was performed. First, we analyzed the subtelomeric regions by FISH (ToTelVysion Vial 7 and 17) in uncultured amniocytes, showing a normal dosage of both subtelomeric regions (14qtel and 20qtel). Later, the study of cultured amniocytes, demonstrated a normal female karyotype, and the hybridization on the metaphase spread showed that the fetuses had not inherited the familial subtelomeric translocation: 46,XX,ish(14qtel,20ptel,20qtel)x2.

Detecting Copy Number Polymorphism in CGH Tiling Array Data from Multiple Individuals using Hidden Markov Models. *S. Zollner[1], N. Vinckenbosch[2], G. Abeçasis[1], H. Kaessmann[2]* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Cent Integrative Genomics, Lausanne, Switzerland.

Recent reports have revealed that considerable segmental copy number polymorphism (CNP) in the human genome contributes to genomic variation among individuals. CNPs range in length from a few to several hundred kb and often span genes. Thus they are functional candidates for common phenotypic traits and diseases. The distribution and allele frequencies of these polymorphisms is not yet well known, as large-scale CNP datasets are only beginning to emerge. Here, we used Comparative Genomic Hybridization (CGH) arrays together with a new statistical to model to examine the distribution of CNPs in a sample of 30 individuals. CGH arrays can detect copy number polymorphisms at high resolution. In this technology, the DNA sequence of a test subject is competitively hybridized to together with a reference sequence. Differences in hybridization intensity indicate a difference in copy number between the tested sequence and this reference. Analyzing CGH data is challenging, due to experimental noise and other confounding factors. In previous screens for CNPs, each hybridization experiment was analyzed separately. Since common CNPs are expected to occur in several individuals, jointly analyzing a population sample provides a more powerful method to detect CNPs from CGH data. Therefore, we have developed an approach based on a hidden Markov Model (HMM) where each hybridization experiment is treated as one realization of the same Markov process. The unobserved states represent the presence or absence of a CNP and the transition probabilities are dependent on its population frequency. We apply a variation of Baums algorithm to estimate these transition probabilities and the likelihood of each individual to carry a given CNP variant, combining information from all hybridization experiments. To assess the significance of a signal, we generate a null-distribution by permuting the hybridization intensities among loci. We present applications of our method to simulated data as well as to genomewide hybridization data generated for 30 humans using Nimblegen CGH arrays.

Comparison of a functional human gene network with a network reconstructed by applying genetical genomics.

C. Wijmenga[1], L. Franke[1], M. Egmont-Petersen[2] 1) DBG-Department of Medical Genetics, University Medical Centre Utrecht, Utrecht, The Netherlands; 2) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

Gene networks could provide important clues to which genes may cause disease, by assuming that most of the causative genes in complex diseases are functionally closely related (Franke *et al*, AJHG 2006). To improve the reliability and extent of these networks, we used recent human genetical genomics data sources that combine genotypes and expression data from HapMap individuals. We first generated a network solely from these repositories and then compared it to our functional human gene network, available at www.genenetwork.nl. As expected, the majority of the most significant *trans* interactions had not been reported in the literature: Within this set of interactions, we saw an under-representation of interactions that were already described in KEGG, HPRD, BIND or Reactome. However, when we compared the identified significant genetical genomics interactions with the interactions predicted by our functional gene network, there was concordance. Additionally, the average distance between the significant interactions in our functional gene network was significantly shorter than expected, indicating that the majority of these inferred interactions represent indirect biological relationships that are yet unknown. Based on these observations, we propose a novel method that can help to reconstruct direct interactions, opening avenues for the generation of accurate regulatory gene networks that describe causal interactions. We show that these networks are helpful in identifying disease genes, allowing researchers to rely solely on microarray expression data. Such analyses result in sets of differentially expressed genes, for which the differences can be traced back to the causative genes, when using these regulatory gene networks.

Evidence for a susceptibility locus for mammographic density. *C.M. Vachon[1], V.S. Pankratz[1], J.M. Cunningham[1], E.C. Carlson[1], C.A. Hilker[1], A.H. Wang[1], R.L. Smalley[1], T.A. Sellers[2]* 1) Mayo Clinic, Rochester, MN; 2) H Lee Moffitt Cancer Center, Tampa, FL.

Introduction: Mammographic density, or the proportion of nonfatty tissue on the mammogram, is a strong risk factor for breast cancer and appears to be genetically influenced. We report the first genomewide linkage scan and follow-up fine mapping of mammographic density.

Methods: Families were selected from the Mayo Breast Cancer Family Study based on the availability of female relatives with mammograms. Percent density (PD) was estimated on both the Craniocaudal and Mediolateral oblique views using a thresholding technique. The mean PD from the two views served as the primary phenotype. The genomewide scan was based on 400 markers from the ABI Mapping Set, version 2.5, with an average spacing of 10 cM. Follow-up genotyping of 56 additional markers, with an average intermarker spacing of 1.7 cM in two regions implicated in the scan, was performed by deCODE Genetics. Multi-point IBDs were estimated using SIMWALK. Tests for linkage to PD were performed using EMVC, software for variance components linkage analyses. All analyses included covariates associated with PD in our sample.

Results: A total of 889 relatives (756 women, 133 men) from 89 families formed the sample for our linkage analyses. 658 (87%) women had available mammograms and estimates of PD. The maximum LOD score from the genomewide scan was 3.1, and a second highest peak reached a LOD of 2.5. The 1-LOD credible intervals for these regions identified by these peaks were 23.6 and 33 cM wide, respectively. Fine mapping resulted in stronger evidence for linkage in the first region (LOD=3.3) and a narrower 1-LOD interval (10.2 cM), but did not improve the strength of evidence for linkage in the second (LOD=2.3; 14.8 cM).

Conclusion: We provide evidence for a promising susceptibility locus for mammographic density. We are pursuing further studies in the region and hope to identify a gene accounting for our linkage signal while demonstrating an association with mammographic density.

24-Months on Treatment: Open-Label Phase I/II Long-Term Study of Enzyme Replacement Therapy (ERT) with Gene-Activated Human Glucocerebrosidase (GA-GCB) in Patients with Type 1 Gaucher Disease. *A. Zimran[1], G. Altarescu[1], C. Fratazzi[2], R. Mensah[2], D. Elstein[1]* 1) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Shire Human Genetic Therapies, Inc., Cambridge, MA, USA.

AIM: To evaluate the long-term safety and clinical activity of Gene-Activated human glucocerebrosidase (GA-GCB), a novel ERT for patients with type 1 Gaucher disease.

BACKGROUND: GA-GCB is produced in a continuous human cell line using proprietary gene-activation technology and has an identical amino acid sequence to the natural human enzyme.

METHODS: Ten of 11 patients who completed the Phase I/II study enrolled in the extension study. One patient discontinued treatment for reasons unrelated to GA-GCB. Patients continued to receive 60U/kg GA-GCB every other week for 12 months of treatment. At about Month 12, patients who qualified (based on Therapeutic Goals for ERT in type 1 Gaucher disease; Seminars of Hematology, 2004) began a step-wise dose reduction from 60U/kg to 45U/kg (for 13 weeks), then to 30U/kg.

RESULTS: GA-GCB was well tolerated at a 60U/kg dose every other week for approximately 12 months of treatment. Patients were dose reduced to 30 U/kg successfully and without incident. To date, no drug-related serious adverse events have been reported. One patient experienced an infusion-related adverse event (during the extension study) without interrupting treatment. Notably, no patient developed anti-GA-GCB antibodies by Month 18. Statistically significant mean increases from the core study baseline were observed for hemoglobin and platelet counts by Month 3 and continued through Month 18. Month 24 clinical activity, plasma chitotriosidase, and CCL18 data will be presented.

CONCLUSION: GA-GCB was well tolerated and demonstrated clinical activity in disease parameters in adult patients with type 1 Gaucher disease. These results suggest that GA-GCB holds promise as a new ERT and deserves further evaluation in clinical trials including in children.

Two ABCC6 gene polymorphisms are not associated with variation in plasma lipid levels in the Ludwigshafen Risk and Cardiovascular Health Study. *B. Struk[1], W. Renner[2], K. Lindpaintner[3], B.R. Winkelmann[4], B.O. Boehm[5], W. Maerz[2]* 1) Helios-Clinic, Charité and Max-Delbrueck-Centrum, Berlin, Germany; 2) Clinical Institute of Medical and Chemical Laboratory Diagnostics, Medical University, Graz, Austria; 3) Hoffmann-La Roche Ltd, Roche Genetics, Pharmaceuticals Division, Basel, Switzerland; 4) Cooperation Unit Pharmacogenomics, Applied Genomics, University of Heidelberg, Heidelberg, Germany; 5) Division of Endocrinology and Diabetes, University of Ulm, Ulm, Germany;.

Mutations in the ATP dependent transporter protein ABCC6 cause Pseudoxanthoma elasticum (PXE), a mendelian disorder that affects the elastic tissue in skin, eye and the cardiovascular system and leads to premature cardiovascular disease. Other ABC transporters play a significant role in lipid transport. A recent study showed the association of the Q allele of the R1268Q polymorphism in ABCC6 with higher plasma HDL and lower plasma triglyceride levels in a small Canadian Inuit population. In contrast, HDL plasma levels showed a 25 % reduction in an ABCC6 knockout mouse model in comparison with the wild type. To further evaluate potential associations of ABCC6 single nucleotide polymorphisms (SNP) with plasma lipid levels in the general population, we genotyped two SNP (V614A, R1268Q) in a total of 3316 participants of the LURIC study, a prospective cohort study. There was no allelic association of V614A and R1268Q genotypes with total plasma cholesterol, plasma HDL, LDL, plasma triglycerides or plasma lipoprotein a (Lp a) levels within the study population. These results from the total study population did not differ in the sub group of study participants younger than 50 years (n=433) Our data do not demonstrate an allelic association of two common missense SNPs with variation in plasma lipid levels in a population of sufficient sample size. We conclude that common allelic variants of ABCC6, do not represent susceptibility markers for variation in plasma lipid levels.*R1268QV614A*, *R1268QV614AR1268Q*.

Mutations in the SPG8 gene cause hereditary spastic paraplegia. *P.N. Valdmanis[1], I.A. Meijer[1], A. Reynolds[2], A. Lei[1], P. MacLeod[3], D. Schlesinger[4], M. Zatz[4], P. Dion[1], P. Drapeau[2], G.A. Rouleau[1]* 1) Centre de recherche du CHUM, Hopital Notre-Dame, Montreal, Canada; 2) Center for Research in Neuroscience, Department of Neurology and Neurosurgery, McGill University, Montreal, Canada; 3) Children's & Women's Health Center, Vancouver, Canada; 4) Univ de Sao Paulo dept of Biology, Sao Paulo, Brazil.

Hereditary spastic paraplegia (HSP) is a debilitating upper motor neuron disorder which leads to a spastic gait phenotype. Thirteen genes and over thirty loci have been identified for this highly heterogeneous disorder. Three adult-onset dominant families with a pure HSP phenotype were used to map the *SPG8* locus to chromosome 8q23-24. We have identified three additional families by linkage analysis which map to this locus. Key recombinants in our families enable a candidate interval to be defined between markers D8S1832 and D8S1774, containing 10 known genes. These genes have been sequenced in their entirety, leading to the identification of two mutations in the *SPG8* gene. Both mutations occur in amino acids that are conserved across all species, and neither mutation is present in over 1000 control chromosomes. Three European families have a valine to phenylalanine missense mutation, and a Brazilian family has a leucine to phenylalanine change. Bioinformatic analysis and protein modeling of the expected *SPG8* protein product predict that these amino acids are adjacent in 3D space within an alpha-helix and that the mutations potentially disrupt this helix. Furthermore, studies in zebrafish indicate that knocking-down *SPG8* using morpholino oligonucleotides causes a severe morphological phenotype which can be rescued with a wildtype, but not mutant, human form of *SPG8*. Little has been described about the gene; however, cell transfection studies indicate a diffuse distribution of the *SPG8* protein in the cytoplasm, and its possible involvement in the cytoskeletal structure of the cell. *SPG8* is expressed ubiquitously, including in various regions of the brain. The elucidation of the nature of this gene and its potential interactions with other HSP genes will aid in the understanding of this neurodegenerative disease.

Estimation of X chromosome effects on human quantitative traits. *L. Pan, C. Ober, M. Abney* Department of Human Genetics, The University of Chicago, Chicago, IL.

Recently, we evaluated the sex specific genetic architecture for 17 quantitative traits in the Hutterites (Weiss et al., 2006 Nat Genet 38:218-222). Estimates of heritability revealed significant interactions with sex for five of the 17 traits examined. The sex specific genetic architecture of these traits could be due to autosomal genes that are differentially expressed in males and females, or to X-linked genes. In this study, we extended the variance component, maximum likelihood method to evaluate the relative contributions of sex specific effects on both the X chromosome and the autosomes, to overall estimates of heritability of 20 quantitative human phenotypes. Seven of the 20 phenotypes showed significant X-linked effects: systolic blood pressure (SBP), adult height, fasting insulin, triglycerides, lipoprotein (a) [Lp(a)], serotonin, and age at menarche. Three traits (SBP, adult height, and triglycerides) showed significant X-linked effects only in males. The proportion of the total heritability due to X-linked effects was 33% for SBP (broad heritability $H^2 = 0.48$), 10% for adult height ($H^2 = 0.90$), 47% for fasting insulin ($H^2 = 0.71$), 34% for triglycerides ($H^2 = 0.59$), 53% for Lp(a) ($H^2 = 0.88$), and 39% for serotonin ($H^2 = 1.00$). For the female specific trait age at menarche, the X chromosome accounted for 100% of the genetic effects ($H^2 = 0.46$). Our findings suggest that sex specific genetic effects may not only be common in human quantitative traits, but also that the X chromosome plays both a large role in these effects and has a variable influence between the sexes. This work was supported by NIH grants HD21244, HL56399, HL66533, HG02899 and DK55889.

Further delineation of the Williams syndrome genotype/phenotype correlation using a unique 3-generation familial deletion. *A.S. Parikh[1,3], E.S. Siwik[2], C.A. Curtis[1,3], L.J.B. Jeng[1,3], S.E. McCandless[1,2,3]* 1) Departments of Genetics; 2) Pediatrics; 3) and Center for Human Genetics, Case Western Reserve University, University Hospitals of Cleveland, Cleveland, OH.

Williams syndrome (WS, MIM 194050) is a microdeletion syndrome involving the cardiovascular, CNS, and other systems. The typical deletion at 7q11.23 is ~1.5Mb. Genotype/phenotype correlations have been suggested for deletion of specific genes. Isolated elastin (ELN) deletions produce autosomal dominant arteriopathy, while LIMK1 and WBSCR1 deletions may be associated with the characteristic personality and mental retardation in WS. The role of other gene deletions in the region is less clear. We identified an ELN deletion by FISH in a proband with apparent elastin arteriopathy, but no other findings of WS. We identified deletions in three additional individuals with learning difficulties and mild cardiovascular abnormalities in three generations of this family. The facial appearance of only one individual (grandmother) was suggestive of WS. Each individual had a physical examination, echocardiography, and neurocognitive testing when possible. FISH analysis with additional BACs allowed further characterization of the deletion to ~340Kb in the WS region. BAC RP11-52A3 is deleted and attenuated signals define proximal and distal breakpoints within RP11-731K22 and RP11-805G2, respectively. Deleted genes include ELN, LIMK1, and WBSCR1. Two genes recently suggested to play a role in the WS phenotype, CYLN2 and GTF2IRD1, are not deleted. Two genes, LAT2 and RFC2, are near the distal breakpoint defined by the BAC studies, and ongoing microsatellite analysis will further define the breakpoints and determine if these two genes are present. **Discussion:** Familial deletions of WS are rarely reported, and this unique 3-generation family with a variant of WS contributes valuable information about the role of several genes in the region to the phenotype. More importantly, the obvious intra-familial phenotypic variation associated with this deletion illuminates the need for caution when making genotype/phenotype correlations based on single or rare cases of chromosomal deletions and rearrangements.

Study of the Involvement of the Fanconi Anemia Proteins in ALT Telomere Maintenance. *H. Root*[1,2], *M.S. Meyn*[1,2] 1) Genetics & Genomic Biol, Hosp for Sick Children; 2) Mol & Med Genet, Univ of Toronto, Toronto, ON.

Fanconi anemia (FA) patients have short telomeres, suggesting that FA proteins may play a role in telomere maintenance. We have shown a role for FA proteins in the recombination-based Alternative Lengthening of Telomeres (ALT) pathways that function in ~10% of human tumors. We find that FANCA, G, D1, and D2 localize to telomeric foci in ALT, but not telomerase-positive fibroblasts. FANCD2 colocalizes with telomeric proteins within PML bodies in late S/G2 and co-IP experiments indicate ALT-specific in vivo interactions between FANCD2, BLM, and TRF2 in late S/G2. Some ALT telomeric foci contain H2AX, a marker of DNA damage, and FANCD2 is almost always present in these foci. This suggests that FANCD2 may aid in the response to dysfunctional telomeres.

We are now investigating the events required for FANCD2 localization to ALT telomeric foci. Following DNA damage and in S phase, FANCD2 forms nuclear foci, is monoubiquitinated and phosphorylated. Initial results suggest that FANCD2 localization to ALT telomeric foci is independent of the ATM kinase. The role of ATR in ALT-specific localization is currently under investigation. FANCD2 focus formation is thought to be dependent on a core complex of FA proteins. FANCA depletion disrupts the core complex and reduces both FANCD2 monoubiquitination and focus formation in ALT cells. Strikingly, FANCD2 foci remaining after FANCA depletion are 3 times more likely to be associated with telomeric foci than in controls, suggesting that FANCD2 monoubiquitination is not required for FANCD2 localization to ALT telomeric foci. Furthermore, siRNA depletion of FANCA does not affect the apoptosis, senescence or growth rate of ALT cells relative to controls. This may differ from FANCD2, which can be stably suppressed with shRNA in telomerase positive but not in ALT cells. Our data support a model in which FANCD2 plays multiple roles in ALT cells and can be recruited to sites of dysfunctional DNA in both a core complex dependent and independent manner. RNA depletion studies also indicate a critical role for FANCD2 in ALT telomere maintenance that is independent of the core complex.

Alcohol dehydrogenase genes, alcohol consumption and risk of orofacial clefts. *P.A. Romitti, K.L. Rose, L. Sun, K. Malville-Shipan, J.C. Murray* The University of Iowa, Iowa City, IA.

Studies of periconceptional alcohol exposure and orofacial clefts have been mixed perhaps due in part to unexplored genetic susceptibilities. Specifically, little attention has been given to the impact of variants in alcohol dehydrogenase (ADH) genes. Using Iowa data from a population-based case-control study, we examined the risk of clefting associated with potential ADH gene-alcohol interactions. Cases were deliveries diagnosed with a cleft lip palate (CL/P) or cleft palate only (CP) between 1997 and 2002 and controls were unaffected deliveries during the same time period. Case (n=156) and control (n=329) mothers provided reports of periconceptional alcohol use (one month prior through the first three months of pregnancy) by telephone interview, and birth parents and infants provided buccal samples by mail. Gene variants examined by Applied Biosystems TaqMan assays were those designed manually, ADH1B (rs1229984) and ADH1C (rs698), and those generated by the vendors design service, ADH4 (rs1800759, rs1800761, T-192A). Risk estimates for CL/P and CP associated with any maternal alcohol consumption, maternal genotype (1 or 2 copies of the allele of interest versus none) and the joint risk of each exposure were estimated using odds ratios (ORs) and 95% confidence intervals (CIs). For periconceptional alcohol use, ORs adjusted for infant sex and family history and maternal age, education, body mass index, smoking and folic acid use were 0.8 (CI=0.5,1.3) for CL/P and 1.4 (CI=0.7,2.5) for CP. For both phenotypes, ORs for maternal genotypes adjusted for infant sex and family history tended to differ by gene variant (ADH1BADH1CADH4), and a statistically significant increase in risk of CL/P was found for mothers who carried the C allele for ADH4 rs1800759 (OR=2,8; CI=1.2,6.7). The joint risk associated with each exposure was most elevated for mothers who drank and carried the C allele for ADH4 rs1800759 (OR=4.4; CI=1.1,17.8). Our findings suggest that risk of clefting associated with periconceptional alcohol exposure may be influenced by select ADH gene variants. We will attempt to replicate our analyses using data from a second Iowa case-control study.

***SUMO1* haploinsufficiency can cause cleft lip and palate.** *I. Saadi[1], F.S. Alkuraya[1], J.J. Lund[1], A. Turbe-Doan[1], C.C. Morton[2], R.L. Maas[1]* 1) Division of Genetics, Department of Medicine; 2) Departments of Obstetrics & Gynecology, Reproductive Biology, and Pathology, Brigham & Women's Hospital and Harvard Medical School, Boston, MA.

Human birth defects represent an example of a complex genetic disease, in which multiple genetic and environmental factors play a role. Cleft lip with or without cleft palate (CL/P) is among the most common human birth defects, with an incidence between 1/500 and 1/2000 births, depending on the population. Monogenic forms and variants in several genes have been identified that contribute to CL/P, but the full spectrum of such genes and whether and how they interact is unknown. As part of the Developmental Genome Anatomy Project (DGAP), we have studied *de novo* balanced translocation cases with CL/P to discover genes involved in CL/P that may be difficult to determine by other means. We ascertained a patient with isolated cleft lip and palate and a 46,XX,t(2;8)(q33.1;q24.3)dn that disrupts *SUMO1* in intron 2. To validate the role of *SUMO1* in clefting, we confirmed expression of *Sumo1* in the developing mouse lip and palate. We also established a hypomorphic *Sumo1* gene-trap allele, $Sumo1^{Gt}$, that produces an incompletely penetrant cleft palate phenotype. Furthermore, the *Sumo1* hypomorphic allele interacts genetically with a loss-of-function allele for *Eya1*, a gene involved in palatogenesis in mouse and human, such that $Sumo1^{Gt/+}/Eya1^{+/-}$ mice show a significant increase in the incidence of cleft palate (17%) compared to $Sumo1^{Gt/+}$ (5%) ($p<0.008$, Fisher exact test) or $Eya1^{+/-}$ (0%). We also demonstrate that Eya1 is sumoylated at multiple sites *in vivo*, and thus joins a growing list of proteins implicated in clefting that are sumoylated, including Msx1, Satb2, and Pax9. Sumoylation is a post-translational modification in which a SUMO peptide is transferred to a target protein, altering its transcriptional activity, nuclear localization or other functional properties. Our data suggest that through its potential impact on a number of proteins involved in palatogenesis, *SUMO1* haploinsufficiency may reduce the overall genetic threshold required to cause CL/P.

Mapping Genes Affecting Age-at-onset of Alzeihmer Disease in the Chromosome 8. *J. Vance, J. Deng, GM. Mayhew, J. Grimsley, X. Huo, MA. Pericak-Vance, YJ. Li* Prof, Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC.

Identification of genes that affect age-at-onset (AAO) of AD has profound impact in understanding the genetics of AD, and will potentially improve prevention and treatment in this aging-related neurodegenerative disorder. We previously conducted a whole genome screen for AAO of AD using 449 families and identified several linkage regions including chromosome 8q. The initial linkage region of chromosome 8q covers 46cM interval (between 119 to 165cM; LOD>1.0) with a peak multipoint LOD score of 2.09. To refine the interval, we genotyped the same four microsatellite markers under this linkage region on the additional new 158 families. We applied the variance component linkage analysis method implemented in SOLAR (Almasy and Blangero 1998) to screen the chromosome 8 using this expanded dataset (607 families). AAO was treated as a quantitative trait and sex was treated as a covariate. We obtained an updated two-point LOD score of 2.34 at the marker D8S1179. In addition, the new analysis narrowed the peak region to about 20cM (between 128 to149cM; LOD>1.0). These data strengthen the evidence for a potential gene(s) in this region contributing to the genetic etiology of AAO in AD. We then follow up the interval that covers one LOD score below the peak marker (1-LOD down region) using Illumina custom SNP arrays. A 1536 Illumina Goldengate SNP OPA will be used to fine map the ~24mb area between q23.3 to q24.23 in Chromosome 8 in these data. Identification of the chromosome 8 AD AAO gene will increase our understanding of susceptibility genes in AAO of AD.

Detection using QMPSF of partial deletions and duplication of the *NSD1* gene in Sotos syndrome. *P. Saugier-Veber[1], C. Coubes[2], M. Holder[3], V. Drouin-Garraud[1], J. Roume[4], D. Bonneau[5], S. Férenbach[1], T. Frebourg[1], L. Burglen[6]* 1) Department of Genetics, University Hospital, Rouen, France; 2) Department of Medical Genetics, University Hospital, Montpellier, France; 3) Department of Medical Genetics, University Hospital, Lille, France; 4) Department of Medical Genetics, Hospital of Poissy-Saint Germain en Laye, Poissy, France; 5) Department of Medical Genetics, University Hospital, Angers, France; 6) Department of Genetics, Trousseau Hospital, Paris, France.

Sotos syndrome is an overgrowth syndrome characterized by pre- and postnatal overgrowth with advanced bone age, macrocephaly, characteristic facial features and variable mental retardation. Large 5q35 microdeletions encompassing the *NSD1* gene detected by FISH, and intragenic *NSD1* mutations have been reported in 60-90 % Sotos patients and in some patients affected with Weaver syndrome. We and others recently reported partial deletions of the *NSD1* gene. We have now developed a QMPSF (Quantitative Multiplex PCR of Short Fluorescent Fragments) assay covering exons 2 to 23 of the *NSD1* gene and have integrated this QMPSF assay in the molecular diagnosis of Sotos syndrome. This QMPSF assay allowed us to identify 4 partial *NSD1* deletions removing exon 2, exons 6-7-8, exons 18-19 and exons 22-23 and the first partial duplication of *NSD1*, involving exon 4. All patients exhibited characteristic features of Sotos syndrome and cannot be distinguished from patients with point *NSD1* mutations. These results highlight the importance of systematic detection of such genomic rearrangements in the molecular diagnosis of Sotos syndrome by using molecular methods such as QMPSF since these *NSD1* genomic rearrangements cannot be detected by FISH. From our experience, we estimate that the partial deletions and duplications represent 5 % of the *NSD1* alterations whereas complete *NSD1* deletions represent 12.5 % of the *NSD1* alterations.

EMPIRICAL DETECTION OF NATURAL SELECTION AT TWO BRAIN-RELATED GENES (FOXP2 AND AHI1) BUT FAILURE TO CONFIRM EVIDENCE AT ASPM. *F. Yu[1, 2], R.S. Hill[2, 3, 4], A.A. Mignault[1], R.J. Ferland[3,4], C.A. Walsh[2,3,4], D. Reich[1,2]* 1) Dept Genetics, Harvard Med. School; 2) Broad Inst. of MIT & Harvard; 3) Div. of Neurogenetics & Howard Hughes Med. Inst., Beth Israel Deaconess; 4) Dept. of Neurology, Harvard Med. School.

A startling hypothesis is that genes cause neurodevelopmental defects have been subject to natural selection during human evolution. Dorus (2004) showed that this has been the case over the past tens of millions of years of primate history, and anecdotal studies have suggested that the selection may have continued into the last tens of thousands of years. The most striking evidence has been at FOXP2 (Enard 2002), ASPM (Mekel-Bobrov 2005), and Microcephalin (Evans 2005). However, the evidence is based on comparing the pattern of variation at the genes to computer simulations, which cannot capture all features of real data. To empirically assess whether the brain-related genes indeed stand out compared with random genomic regions, we studied two genes with previous evidence of selection, FOXP2 and ASPM, and two that cause neurodevelopment defects but with no previous evidence, AHI1 and GPR56. We resequenced 15-30 kb from each in 16 European Americans and 16 West Africans, and genotyped the SNPs in HapMap samples. This was identical as method used to study 5 ENCODE regions, providing a large empirical comparison data set. Both FOXP2 and the AHI1 stand out compared with the pattern of variation in European Americans in the ENCODE regions. The results at AHI1 constitute new evidence and are particularly striking, with the pattern more extreme than anything seen in comparable segments of the ENCODE regions by various tests(all $P<<0.006$). There is no evidence for selection ASPM, even though a recent study suggested positive selection within the last 6,000 years. Our analysis suggests it arose tens of thousands of years ago, and the gene does not stand out from empirical data by multiple tests. Thus, comparison to simulations can mislead inferences. To provide the most compelling arguments for selection, multiple lines of evidence should be brought to bear, and comparison to empirical data can be an important resource.

Examination of *LAMB1* and *EN2* as autism candidate genes. *D.A. Skaar[1], J.M. Jaworski[1], J.L. Benton[1], E.R. Martin[1], H.H. Wright[2], R.K. Abramson[2], M.L. Cuccaro[1], J.R. Gilbert[1], M.A. Pericak-Vance[1]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) University of South Carolina School of Medicine, Columbia, SC.

Multiple linkage peaks for Autism have been identified on chromosome 7q, primarily from 7q21.3 to 7q31.3. Many candidate genes on 7q have been tested for autism association, mostly from this prime region of linkage peaks. *RELN*, *NRCAM*, *EN2*, and *WNT2* have all been examined based on their functions in neurological development, and brain and behavior phenotypes in mouse models of *RELN*, *EN2*, and *WNT2*, with significant association seen in all. Significant associations have also been seen for other candidates in the peak region, *UME2* and *LAMB1*. We have previously shown association in *RELN*, and have screened a 10Mb region of 7q containing several of the linkage peaks. This region is also centered around *RELN* and a chromosomal inversion seen in all autistic members of one family. This screen identified two significant SNPs near *LAMB1*, and stronger associations distal to *LAMB1*. These results, combined with studies showing significant PDT associations for the *LAMB1* SNPs LAMB1x30 (p= 0.0466, Bonora et al., 2005) and rs2249956 (p=0.01, Hutcheson et al., 2004), led us to replicate the SNPs from these studies, and add tagging SNPs for blocks of linked SNPs in *LAMB1*. *EN2* was also examined in our dataset, based on PDT associations previously reported (rs1861973 and rs1861973, p=0.0296 and 0.0121, Benayed et al., 2005) and the unusual location of *EN2*, 7q36.3, well outside the usual focal region defined by the linkage peaks.

In 363 Caucasian families (multiplex and singleton) ascertained by Duke and USC, PDT association was calculated for these SNPs, with no significance seen for any *LAMB1* or *EN2* SNPs. Subdivision based on family history does show significant associations for *LAMB1* SNPs rs11770141 and rs3735599 (p=0.0159 and 0.0094) in families with no autism history. Similar subdivision still showed no significance for any *EN2* marker. These results in the Duke dataset indicate *LAMB1* may be a susceptibility gene for sporadic cases of autism, but do not support *EN2* as a candidate gene.

A functional SNP in proteolipid protein 2 (PLP2) promoter increases ER stress induced apoptosis and confers increased risk of neonatal hypoxic-ischemic brain injury. *L. Zhang[1], T. Wang[1], D. Valle[1,2]* 1) Dept Human Genetics, IGM, JHMI; 2) Howard Hughes Med. Inst., Baltimore, MD.

We identified a SNP (-113C>A) in the promoter of proteolipid protein 2 (PLP2) gene that results in significant reduction (> 4 fold) of PLP2 mRNA and protein. PLP2-(-113C>A) is over-represented in males with X-linked mental retardation (frequency: control 1.56%, XLMR 5.86%, P<0.001). To delineate PLP2 function in CNS, we generated PLP2 deficient mice by gene targeting. We found PLP2-deficient MEFs have elevated levels of pro-caspase 12 and cleaved caspase 12, an ER stress specific caspase, as well as increased GRP78, an ER chaperone, suggesting increased basal level of ER stress. By immunofluroescence and electron microscopy, we showed PLP2 deficient MEFs have dilated ER lumen and inefficient protein trafficking from ER to Golgi as visualized by ts-VSVG-GFP, supporting the idea of increased basal ER stress. Furthermore, we found the increased ER stress is specifically associated with enhanced eIF2-alpha signaling, as evident by the increased eIF2-alpha phosphorylation and increased expression of downstream genes, such as ATF4 and CHOP. PLP2-deficient MEFs and cultured primary neurons show increased apoptosis following ER stress induction, but are indistinguishable from control cells in response to intrinsic and extrinsic apoptosis stimuli. In addition, PLP2-deficient neurons show increased sensitivity to pharmacologically induced hypoxia. Using a model of neonatal hypoxia-ischemia, we demonstrated that the hippocampal injury of PLP2 deficient neonatal mice is 10 fold more than the wild type littermates. Finally, we found that male human fibroblasts with PLP2-(-113C>A) also have increased susceptibility to cell death when exposed to ER stressors. In summary, our results suggest that the human PLP2 polymorphism is an important modifier of genetic or environmental stress of the ER and that individuals with PLP2-(-113C>A) have increased risk to neonatal brain injury related to genetic and/or environmental stress on the ER machinery. This mechanism may account for the association of the PLP2 promoter polymorphism and XLMR.

Multiple genes in the A processing pathway have susceptibility alleles that show significant, replicable association with LOAD. *S.G. Younkin[1], S.G. Younkin[1], M.M. Carrasquillo[1], T.A. Dincman[1], R.I. Budjak[1], S. Singhal[1], M. Allen[1], F. Zou[1], N. Graff-Radford[1], R.C. Petersen[2], N. Taner[1,2], L.H. Younkin[1]* 1) Mayo Clinic, Jacksonville, FL; 2) Mayo Clinic, Rochester, MN.

The mutations in APP, PS1,and PS2 that cause early onset familial Alzheimers Disease increase A42, which aggregates to form senile plaques in AD brain. ApoE, which is the only widely accepted gene with susceptibility alleles for late onset AD (LOAD), also fosters A aggregation. Our working hypothesis is that novel LOAD genes have been difficult to identify because most LOAD genes have multiple susceptibility alleles with effects smaller than the well known ApoE alleles. To develop a paradigm for identifying novel LOAD genes, we analyzed many good candidate genes in the A processing pathway in multiple, large case control series. Functional variants are most likely to be found in regions conserved between human and rodent genomes. For this reason, we genotyped all variants that we could find in conserved regions of the A processing genes. These putative functional variants were analyzed thoroughly by logistic regression at the single variant, haplotype, and multilocus genotype level. As the size and statistical power of the case control series available to us increased, many genes in the A processing pathway began to show significant, replicable association. A good example of this is the APP gene, which has a set of variants in the conserved regions of two adjacent haplotypes blocks that show highly significant association with AD. At this meeting, we describe significant association for additional A proceesing genes in the abstracts by Zou et al. (MME), Carrasquillo et al. (IDE, PLAU), and Taner et al (VR22, LRRTM3).

Expression analysis of the IRF6 gene in placental tissue. *F. Rahimov*[1], *J.C. Murray*[2] 1) Interdisciplinary Genetics PhD Program, University of Iowa, Iowa City, IA, 52242 USA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA, 52242 USA.

Non-syndromic cleft lip with or without cleft palate (CL/P) is the most common craniofacial malformation of multifactorial etiology in humans. Mutations in the gene for interferon regulatory factor (*IRF6*) have been shown to cause the dominant Van der Woude syndrome (VWS), a common syndrome displaying CL/P as a feature of its phenotype. VWS is an excellent model for studying the non-syndromic forms of clefts. Strong association of *IRF6* variants with non-syndromic CL/P have shown in multiple studies, however, no coding mutations in *IRF6* have been detected in non-syndromic cases. Haploinsuffiency of *IRF6* is thought to underlie the pathogenesis of VWS. Since no structural mutations were detected in *IRF6* in non-syndromic CL/P cases we hypothesize that genetic variants in the regulatory regions of the IRF6 gene might affect its expression level and could predispose to non-syndromic CL/P.

To test our hypothesis, we performed quantitative gene expression analysis in placental tissue. *IRF6* expression in the placenta was confirmed by *in situ* hybridization. Placental tissues from 16 newborns without any orofacial defects were examined for expression of IRF6 mRNA by quantitative real-time RT-PCR analysis to determine the association between different genotypes and expression level of *IRF6*. Three single nucleotide polymorphisms (SNP) (rs1319435, rs2013162 and rs4844880) in and around *IRF6* were chosen based on previously reported results showing an association with non-syndromic CL/P in Danish, Iowan and Filipino populations and tested for their correlation with the expression level of the gene.

Our preliminary results showed no significant ($p<0.7$) association between various genotypes (haplotypes) in and around *IRF6* and its expression level in the placental tissue. Further studies on *IRF6* expression in additional placental samples and in the palatal tissues collected during surgery from patients with cleft lip and palate is underway.

Patterns of linkage disequilibrium reveal genotyping errors and copy number polymorphisms. *P. Scheet, M. Stephens* Dept Statistics, Univ Washington, Seattle, WA.

While average genotyping accuracy for large-scale studies of population genetic variation is now very accurate, a small number of individual SNPs may exhibit unusually high error rates, either due to pathological patterns in the intensities on which genotype calls are based, or because the SNP lies within a copy number polymorphism (CNP). Simple filters, particularly a test for Hardy-Weinberg equilibrium (HWE), are usually applied to attempt to identify any suspicious SNPs. Here we introduce a new filter based on identifying SNPs whose genotypes produce unusual patterns of linkage disequilibrium. By using a flexible model for variation in a sample of unphased multilocus genotypes, we scan the observed genotype data, evaluating the potential for a marker position to have at least one error by constructing a likelihood ratio (LR) statistic for each SNP in the sample. We also calculate the expected number of errors at each SNP among all sampled individuals. We test these criteria for error identification and quantification on two independent data sets. We applied the method to unfiltered data of unrelated CEU individuals from the HapMap Project, computing LRs at SNPs which showed a signature of genotype error and comparing these to the number of Mendelian incompatibilities (MI) obtained from trio information. Sites with multiple MIs show a different distribution for the criteria than do SNPs with 0 or 1 MI. Inspection of raw genotype data confirmed the presence of errors or a CNP at the 1 relevant SNP for which we had access to the intensities. Additionally, we scanned data from the early phase of an association study, consisting of 192 people typed at 105,000 SNPs genome-wide. We were able to confirm the presence of errors and CNPs at suspicious SNPs from the genotype intensities. Although these data are sparse compared with forthcoming studies, our method identified SNPs which would have been overlooked by deviations from HWE alone. For the more dense HapMap data, our method offers considerable improvement over deviations from HWE. These methods have been incorporated into fastPHASE and will be available in a future release of the software.

Multiplex, quantitative analysis of learning and memory related gene expression in rat hippocampus. *Y. Wu[1], L. Tong[2], H.C. Chi[1], J. Luo[1], C.W. Cotman[2], S.K. Boyer[1]* 1) Nucleic Acid Testing Business Center, Beckman Coulter, Inc., 4300 N Harbor Blvd, Fullerton, CA 92834; 2) 1226 Gillespie Neuroscience Facility, Institute for Brain Aging and Dementia, University of California, Irvine, CA 92697-4540.

Quantitative analysis of multiplex gene expression in a single reaction from a limited amount of total RNA is of great interest to research scientists. Currently available techniques either utilize arrays to detect the expression of a high number of genes per reaction at high cost and low throughput, or utilize real-time PCR† to detect the expression of a few genes at moderate throughput. However, researchers are more often interested in 20 or more genes in a given signal transduction or metabolic pathway. Here we present a highly multiplexed method that can quantitatively detect the expression of 34 genes related to learning and memory in a single reaction from as little as 25 ng of total RNA. This method is capable of producing over 7600 gene expression results in 24 hours. The genes for this study were selected based on the current evidence that their biological role is directly or indirectly related to learning and memory process. This multiplex method was used to test the effects of selective cytokines on neurotrophic factor or neurotransmitter-induced gene expression in hippocampal slide cultures. † The PCR process is covered by patents owned by Roche Molecular Systems, Inc. and F. Hoffman-LaRoche, Ltd.

Prioritizing disease genes through a protein map of yeast mitochondria. *F. Perocchi* gene expression, European Molecular Biology Laboratory, Heidelberg, heidelberg, Germany.

A challenge in systems biology is to enable a transition from the study of individual genes in a pathway to the understanding of entire sub-cellular processes as complex networks of interconnected components. Here we reconstruct the protein network of an organelle, the yeast mitochondrion, by integrated analysis of a comprehensive set of genome-scale data. We predict 346 proteins as novel candidates for mitochondrial localization and support our prediction experimentally. The functional network covers the known mitochondrial biology to greater extent than existing databases, and it brings together annotated and new modules into one framework. Based on the defined map, properties of the system were derived for the network connectivity, mutant phenotypes, regulation, evolution of yeast mitochondria and their conservation in humans. We propose human candidate genes for mitochondrial disorders through assessment of network properties of yeast orthologs to human disease genes.

Investigation of common disease-associated polymorphisms within Asian Indians. *T.J. Pemberton, N. Mehta, H. Allayee, P.I. Patel* Institute for Genetic Medicine, University of Southern California, Los Angeles, CA.

Asian Indians display a high prevalence of diseases linked to changes in diet and environment that have arisen as their lifestyle has become more westernized. In the case of coronary artery disease, Asian Indians exhibit unique characteristics that distinguish them from the other populations, suggesting that unique causative factors underlie this and possibly other related diseases. Recent STRUCTURE analysis using 1200 genome-wide polymorphisms in 432 individuals from 15 Asian Indian language groups has shown that: (i) Indians constitute a distinct cluster, and (ii) despite the geographic and linguistic diversity of the groups they exhibit a low level of genetic differentiation. We have now investigated the prevalence of disease-associated polymorphisms that have recently been reported to be risk factors for atherosclerosis, hypertension, diabetes, prostate cancer, Hirschsprung disease, and age-related macular degeneration within 576 individuals from the same Indian groups. All of these diseases have a high prevalence in Asian Indians. Analysis of the data revealed no allele frequency differences between the different language groups. We did however find allele frequency differences between this Asian Indian cohort and previously reported populations for certain polymorphisms. Most striking was the high abundance of the DG8S737 allele associated with an increased risk of prostate cancer (24.5%) but only a relatively moderate abundance of the disease-associated allele of the SNP, rs1447295 (12.9%). These two polymorphisms were found to be in high linkage disequilibrium (LD) within the other populations; however our data suggests that they are not in LD within the Asian Indian population. Further studies in Asian Indian disease cohorts will be needed to confirm an association between DG8S737 and the SNP rs1447295 with prostate cancer in Asian Indians.

TAPVR: A Cardiac Defect Associated with Alagille syndrome. *P.A. Sanchez-Lara[1,2], I.D. Krantz[1,2], N.B. Spinner[1,2]*
1) Division of Human Genetics and Molecular Biology, The Childrens Hospital of Philadelphia, Phila., PA; 2) The University of Pennsylvania School of Medicine, Phila., PA.

Alagille syndrome (AGS) is a genetically heterogeneous disorder caused by mutations in either Jagged1 or NOTCH2. Cardiovascular anomalies are present in almost all AGS patients (94%) with the vast majority (82%) having right sided lesions; branch pulmonary artery stenosis being the most common. Only one patient has been reported with both AGS and total anomalous pulmonary venous return (TAPVR). Here we present three additional cases in two unique families that give insight to genetic and environmental factors involved in TAPVR.

TAPVR is a rare congenital heart defect that occurs when all four pulmonary veins connect to the systemic venous circulation. Its frequency is 6.8 cases per 100,000 live births and accounts for 1.5% of children with congenital heart disease. TAPVR is usually an isolated anomaly but has been associated with cat-eye syndrome, Holt-Oram syndrome and asplenia syndrome. There is also evidence from the Baltimore-Washington infant study (BWIS) of a possible association between paternal lead exposure and TAPVR.

We reviewed records from our cohort of 245 AGS families with JAG1 mutations and found two with TAPVR. The first had paternal transmission of both a JAG1 mutation (c.693delAG) and a defect of the pulmonary venous system. The father had peripheral pulmonic stenosis, an atrial septal defect and partial anomalous pulmonary venous connection. The proband had infra-cardiac TAPVR requiring surgical repair. In the second family, identical AGS twins with a JAG1 splice site mutation (c.2916+1G>C) had discordant heart phenotypes. Twin A had a physiologic murmur with no significant gradient while Twin B had cor triatriatum and TAPVR.

The fact that identical twins were discordant with respect to their heart phenotype points to other environmental factors (e.g. placental insufficiency) which may also modify cardiac defects. Our findings suggest that Jagged1 plays a role in the development of TAPVR although a mutation alone is not sufficient.

Achievement of twin pregnancy with spermatozoa from a globozoospermic man after ICSI treatement. *A.B. Sallemi[1], Dh. Sallemi[3], A. Amouri[2], J. Cherif[1], T. Rebai[1], N.B. Abdelmoula[1]* 1) Laboratory of Histology, University of Medicine, Sfax, Tunisia; 2) Laboratory of Cytogenetics, Pasteur Institute, Tunis, Tunisia; 3) Private Sector.

Abnormal sperm morphology is associated with male infertility globozoospermia is an uncommon severe form of teratozoospermia characterized by round-headed sperm with an absence of acrosomes. Family cases of globozoopermia suggest that this pathology has genetic origins, but the mode of inheritance remains unknown. So far, no responsible genes have been identified. Pregnancies and live birth are rarely reported even with ICSI treatment. We report a successful achievement of a twin pregnancy in a Tunisian couple in which the male partner had globozoospermia and referred to us for cytogenetic evaluation. A 35 year old man and his 24 year old partner, a consanguineous couple sought assisted conception after 2 years of primary infertility. Semen sample revealed the following characteristics: volume 4 ml; sperm concentration 121.2x106/ml; 25 percent progressive motility at 30 min and 65 percent vitality. All the spermatozoa were round-headed. Hormonal profile was within normal range. The karyotypes of the two partners were normal. The couple proceeded, after a first unsuccessful cycle of ICSI, to a second cycle of ICSI in a Belgium centre. Of 12 oocytes retrieved, 11 were micro-injected and 6 fertilized normally. Four compacting embryos with eight or more cells were obtained. Two embryos were transferred 72 h after micro-injection and two others were cryopreserved for future use. A twin clinical pregnancy results and culminates in a spontaneous vaginal delivery of live twin, a female and a male. The infant's birth weight was respectively 2.3 and 2 kg. The twin show normal development after 3 months. Genetic counselling was very hard in this situation. Infact, if some genetic causes of male infertility have been identified and are clearly explained to patients, many others genetic facors of infertility remain largely unexplored.

Array-based comparative genomic hybridization (array CGH) for rapid prenatal diagnosis of cytogenetic abnormalities. *I. Van den Veyver[1,2], T. Sahoo[2], C. Shaw[2], S. Kang[2], D. Del Gaudio[2], S. Darilek[2], A. Patel[2], P. Ward[2], J. Li[2], C. Chinault[2], B. Roa[2], J. Lupski[2], A. Beaudet[2], S. Cheung[2], C. Eng[2]* 1) Dept Ob-Gyn; 2) Dept Mol Hum Genet, Baylor Col Medicine, Houston, TX.

We have shown in a prospective validation study that an array CGH test was highly accurate for rapid detection of chromosomal aneuploidies and deletions or duplications on fetal DNA samples in a clinical prenatal diagnostic setting. Here we present our updated "post-validation phase" experience with this test. All women underwent chorionic villus sampling (CVS) or amniocentesis for standard indications, received genetic counseling and provided informed consent. DNA was prepared directly or after whole genome amplification (WGA) from CVS and amniotic fluid (AF) and tested for maternal cell contamination (MCC). Back-up cell cultures were established and standard karyotypes performed for all samples. A blood sample from both parents was requested to determine the origin of copy number variants (CNV) detected in the fetus if needed. After initial validation on 98 samples, 45 additional clinical cases have been referred. Of these 45, there were 36 AF, 23 of which were analyzed after WGA only, 5 after WGA with confirmation on cell culture DNA. For 8 AF, only cultured-cell analysis was requested. There were 9 CVS, 3 were analyzed after WGA, 3 on direct DNA preparations and 3 on cell culture DNA. We detected one trisomy 21 and identified a marker to have originated from chromosome 12. There was 100% concordance with the karyotype. We also found one level II mosaic trisomy 11 that most likely arose during extended cell culture. There was no MCC. We detected 9 benign CNVs, inherited from a phenotypically normal parent (overall CNV rate was 19/143 or 13.2%). The combined data on all samples establishes a detection rate of 7/143 (4.9%) for cytogenetic abnormalities. In 90% the result was available before the karyotype. In conclusion, our data confirms that array CGH yields highly accurate results on CVS and AF in 2 weeks in most cases. Further large scale studies are needed to assess whether array CGH can replace karyotyping and FISH for rapid and expanded prenatal detection of chromosomal imbalances.

A unique case of Alveolar Rhabdomyosarcoma with two translocations:t(2;13) and t(1;13), and amplification of N-myc in a 5-year-old child. *R. Mosely[1], M. Liu[1], B. Myers[1], M.A. Thompson[2], T. McCurley[2], S. Shankar[3], V.G. Dev[1], A. Yenamandra[1]* 1) Genetics Associates Inc., Nashville, TN; 2) Dept of Pathology, Vanderbilt University School of Medicine, Nashville, TN; 3) Dept of Medicine,Vanderbilt University School of Medicine, Nashville, TN.

The most common type of rhabdomyosarcoma is alveolar rhabdomyosarcoma (ARMS), characterized by the specific translocation t(2;13)(q35;q14) or its rarer variant, t(1;13)(p36;q14), producing the fusion genes PAX3-FKHR and PAX7-FKHR, respectively. The N-myc gene is also reported to be amplified in a few cases of ARMS. We report a previously healthy, 5-year-old girl who presented with a four-week history of severe back pain and parasthesias in lower extremities. Radiographs of her spine showed a collapsed vertebral body. Further evaluation revealed a large paraspinal mass with intraspinal extension and spinal cord compression. She had widespread metastatic disease involving multiple bony sites and bone marrow. The differential diagnosis was sarcoma or neuroblastoma. The histopathological studies of the biopsy demonstrated that the tumor cells were positive for the muscle marker MyoD1, desmin, CD99, and NSE. The specific neuroendocrine markers chromogranin and synaptophysin were negative, as were antibodies to lymphoid markers and to keratin. Cytogenetic analysis of the patient revealed the translocations t(2;13) and t(1;13). FISH with FKHR breakapart DNA probe revealed that the 3 end of the FKHR sequences of one chromosome 13 had moved to 2q35 whereas the 3 end of the second chromosome 13 that had moved to 1p was deleted. N-myc gene was amplified 15-20 times in about 50% of the cells. PAX3-FKHR and PAX7-FKHR overexpression has been reported to result from two distinct genetic mechanisms. The PAX3-FKHR from altered transcriptional regulation and the PAX7-FKHR from fusion gene amplification. In our case PAX3-FKHR fusion gene seems to be intact while the PAX7-FKHR gene appears to be deleted at the 3end of FKHR along with the N-myc gene amplification. Further analysis of the regulation mechanisms will lead to the understanding of the critical level of gene product for the oncogenic effects of these fusions.

Genetic and cellular analysis of Meckel syndrome. *R. Punyashthiti[1], B. Consugar[1], C.J. Ward[1], V. Kubly[1], R. Bacallao[2], V.H. Gatton II[2], V.E. Torres[1], P.C. Harris[1]* 1) Nephrology, Mayo Clinic , Rochester, MN; 2) Indiana University School of Medicine, Indianapolis, IN.

Meckel Syndrome (MKS) is a lethal autosomal recessive disorder, involving bilateral cystic kidney, hepatic fibrosis, CNS malformations, and polydactyly. MKS is genetically heterogeneous with 2 loci identified. MKS1 has 18 exons with 70% of described MKS1 patients homozygous for a 29-bp deletion in intron 15, a founder mutation originating in the Finnish population. MKS3 has 28 exons and different mutations were found in five consanguineous families of south Asian origin. The MKS3 protein product, meckelin, is predicted to contain 7 transmembrane domains with a cysteine rich domain. Both gene products are widely expressed and may have some primary cilia involvement, similar to other cystic kidney disease-related proteins. To further analyze the mutations associated with MKS, DNA from a cohort of 8 families has been collected, 4 with at least 2 affected sibs. All cases have PKD, and encephalocele and/or polydactyly was noted in 6 families. Most cases were of northern European origin and identified in the US. Initial analysis by PCR revealed that 2 out of 6 families were heterozygous for the Finnish type MKS1 mutation. Total gene sequencing of the remainder of MKS1 and MKS3 is now underway to identify the importance of these two loci in this population. To study the location and the possible role of MKS proteins, we generated a full-length rat Mks3 construct with a V5 tag inserted after the signal peptide of the protein to facilitate detection. Western analysis revealed a protein size of ~110kDa, with the dimerized form of 220kDa. Deglycosylation reduced the protein size, consistent with the predicted five N-glycosylation sites. The construct was stably transfected into IMCD cells, a polarized mouse collecting duct cell line, to study the protein sub-cellular localization. Preliminary analysis demonstrated signals from the pericentriolar region in addition to plasma membrane, suggesting possible ciliary/ basal body involvement in the disease pathogenesis. Analysis of the endogenous protein in MDCK cells with a meckelin antibody is also consistent with a ciliary localization.

Pleiades Promoter Project: Genomics Resources Advancing Therapies for Brain Disorders. *E.M. Simpson[1,2,3], W.W. Wasserman[1,2], R.A. Holt[3,4], S.J. Jones[2,4], D. Goldowitz[5], S. Ward[6], S. Kingsley[7]* 1) Centre for Molecular Medicine and Therapeutics, Child & Family Research Institute; 2) Department of Medical Genetics, University of British Columbia (BC), Canada; 3) Department of Psychiatry, University of British Columbia, Vancouver, BC, Canada; 4) Canada's Michael Smith Genome Sciences Centre, BC Cancer Agency, Vancouver, BC; 5) University of Tennessee Research Center of Excellence in Genomics and Bioinformatics, Department of Anatomy and Neurobiology, University of Tennessee Health Sciences Centre, Tennessee, USA; 6) School of Journalism, University of British Columbia, Vancouver, BC, Canada; 7) International BioPharma Solutions Ltd., Vancouver, BC, Canada.

Brain disorders represent an enormous growing social and economic burden and a major unmet treatment need. However, gene therapy directly or via stem cells, holds great therapeutic promise. The Pleiades Promoter Project (www.cisreg/pleiades.org) aims to generate 160 fully characterized, human DNA MiniPromoters (less than 4 kb) to drive gene expression in defined brain regions of therapeutic interest for diseases such as Alzheimer, Parkinson, Huntington, Amyotrophic Lateral Sclerosis, Multiple Sclerosis, Spinocerebellar Ataxia, Depression, Autism, and Cancer. As part of the Mouse Atlas project (www.mouseatlas.org), seventeen brain regions of therapeutic interest have been isolated from mouse by laser capture microscopy and SAGE (Serial Analysis of Gene Expression) libraries have been prepared. We are presently using these data and existing genomic expression resources to identify genes with medium- to high-level, region-specific expression. For each gene, four MiniPromoter constructs will be generated by PCR (often stitching together non-contiguous DNA) and cloned into gene-targeting vectors to make 200 new stains of knock-in mice. Detailed histological analyses will be conducted to document the region and cell-type specificity of these MiniPromoters. Intermediate deliverables will include embryonic stem cells, promoter constructs, and promoter-design software. Thus, we will develop a richly characterized tool-set of resources for both basic and therapeutic research.

Oculo-Facio-Cardio-Dental (OFCD) syndrome: two female patients with novel mutations in the BCOR gene. *S. Whalen[1], S. Manouvrier[2], P. Bitoun[3], M-P. Cordier[4], I. Bailleul-Forestier[5], M. Goossens[1], A. Verloes[5], I. Giurgea[1]* 1) Dpt génétique and INSERM 654, Hôpital Henri Mondor, Creteil, France; 2) Service de génétique clinique, Centre Hospitalier Régional Universitaire de Lille, France; 3) Dpt génétique, Bondy, France; 4) Dpt génétique, Lyon, France; 5) Dpt génétique médicale, Hôpital Robert Debré, Paris, France.

OFCD syndrome is caracterised by congenital cataract, microphthalmia, dysmorphia, cardiac septal defects, dental and digital abnormalities. Dental abnormalities are oligodontia, radiculomegaly, delayed tooth eruption and dental fusion. OFCD syndrome results from mutations in the BCOR gene, located on Xp11.4, which is a key transcriptional regulator during early embryogenesis, particularly in the eye, skeleton and central nervous system. OFCD syndrome is an X-linked dominant condition with skewed X inactivation in female carriers and presumed male lethality. However, a missense mutation was described in males from a family with Lenz microphtalmia syndrome. To delineate further the clinical spectrum of OFCD syndrome, we studied two girls with OFCD syndrome and two boys with Lenz microphtalmia. Patient 1, a 12 years old girl, presented with bilateral congenital cataract, oligodontia, radiculomegaly, scoliosis, camptodactyly and syndactyly of the toes. She had no developmental delay, or cardiac malformation. Patient 2, a 14 years old girl, presented with congenital cataract, microphthalmia, glaucoma, dysmorphia, oligodontia, dental fusion and subnormal developmental delay. She had no heart defect. BCOR gene mutations were screened by direct sequencing, and intragenic deletions by QMF-PCR. Both female patients carried a deletion of a single nucleotide, creating a premature stop codon: c.863delC (p.Pro288ArgfsX90) for Patient 1 and c.570delC (p.Pro190ProfsX26) for Patient 2. No mutation or deletion in the BCOR gene were found for the male patients with Lenz microphtalmia. In conclusion, we report two novel frameshift mutations in the BCOR gene in two unrelated females presenting an OFCD syndrome, without heart defect. These results broaden the clinical spectrum of OFCD syndrome associated with BCOR gene, and suggest underdiagnosis of the disease.

The Effect of Genetic Essentialism and Exceptionalism on Law and Policy. *M.W. Sharp, T.A. Caulfield* Health Law Inst, Univ Alberta, Edmonton, AB, Canada.

Introduction: Genetic determinism and genetic essentialism are ideas that have been part of the latter half of the twentieth century. Some believe these ideas have shaped a reductionist approach to genetic research, including the human genome project - an ethos that has been criticized by many in the ELSI community. Genetic exceptionalism is associated with the idea that genetic material and information is different from other types of biological material or medical information and requires special governance for its acquisition, possession, and use. As a result of genetic exceptionalism, laws and policies around the world in the areas of reproductive technologies, informed consent, privacy, and discrimination, have been influenced in different ways and at varying levels. The purpose of our study is to examine this influence. Methods: An analysis of pertinent legislation, policy statements, and case law was performed to examine the extent to which essentialist and exceptionalist messages have been adopted. Background justifications for the incorporation of these messages into law and policy were also examined. Results: The field of genetics has been afforded special treatment in many laws and policies around the world. This has often been done in a proactive manner, to prevent future potential harms rather than to address specific, current, issues. Conclusions: Contemporary genetic theory has moved well beyond the one gene-one trait paradigm into the multifaceted network model of understanding gene expression and the complex role of environmental factors. Genetic essentialism and reductionism have been largely abandoned, but the idea of genetic exceptionalism is still prevalent and informing law and policy. These new laws, for the most part, remain untested in the courts and their impact is unclear. The courts could take into account the current understanding of genetics when applying these laws and can treat genetic material or information the same as other biological material or medical information. A more detailed analysis of specific laws and policy statements can lead to policy reform recommendations that would reflect the more complete, current, genetic theory.

45,X/46,XY Turners syndrome girl with complex congenital heart defect history. *A. Sahnoun[1], I. Trabelsi[2], A. Ahlem[3], M. Meddeb Cherif[4], S. Kammoun[2], T. Rebai[5], N.B. Abdelmoula[5]* 1) Urology department, Habib Bourguiba Hospital, Sfax, Tunisia; 2) Cardiology department, Hedi Chaker Hospital, Sfax, Tunisia; 3) Cytogenetic laboratory, Pasteur Institute, Tunis, Tunisia; 4) Genetic laboratory, Tunis, Tunisia; 5) Histology laboratory, University of Medicine, Sfax, Tunisia.

Congenital heart defects occur in approximately 30% of patients with Turner syndrome. Left-sided obstructive defects predominate, especially bicuspid aortic valve (BAV) and coarctation of the aorta (COA). Aortic root dilatation is uncommon, but potentially devasting if rupture occurs. It is usually associated with a risk factor such as BAV, COA or hypertension. Herein, we report the case of a 16-years-old girl for whom it was conducted a cytogenetic evaluation as part of our screening project of genetic abnormalities in congenital heart defects. She had a COA associated to a BAV not repaired since she develops an ascending aortic aneurysm and an acute aortic dissection evolution at the age of 5 years. She had repair of COA and aneuvrysm rupture in two-staged resection-interposition grafts at the ascending and isthmus levels. Immediate postoperative chest X-ray showed a dissected hematoma in the interposed isthmus graft but which is quiet until now. She remains also with an hypertension requiring beta-blocking drugs treatment. At genetic counselling, the girl has characteristic physical features of Turners syndrome with short stature, pubertal delay and dysmorphic stigmata especially very important neck webbing. Cytogenetic evaluation at lymphocytic level showed a mosaic formula 45,X[8]/46,XY[42]. FISH analysis is conducted to investigate Y chromosome structure and to estimate more precisely the mosaicism ratio. An adequate management based on international recommendations is also performed to increase this girls chances of the best quality of life. Due to a high prevalence of cardiovascular malformations in Turner syndrome, karyotype should be considered earlier in these cases.

Choosing the optimal platform and analysis for prostate cancer array CGH. *A. Pearlman[1,2], T. Anantharaman[2], B. Mishra[2], H. Ostrer[1]* 1) Dept Pediatrics, NYU Sch Medicine, New York, NY; 2) Courant Inst of Mathematical Sciences, NYU, New York, NY.

Prostate cancer cells incur somatic alterations that can be measured as chromosomal gains and loses with genomic DNA microarrays. These events may be associated with the initiation and progression of disease. Numerous array CGH platforms and analysis tools have been developed in recent years, presenting researchers with uncertainty in designing experiments. In deciding on an approach we tested Affymetrix 10K (affy), Nimblegen 347k tiling (ngen), and 19K BAC (bac) arrays with 3 sets of Gleason 7 tumors with matched normals. For analysis, we used segmentation algorithms vMAP (PNAS. 2004; 101:16292-7) and DNAcopy (Biostatistics. 2004; 5:557-72.). These tools performed comparably using default parameters on a simulated benchmark dataset (Bioinformatics. 2005; 21:3763-70). However, vMAP outperformed DNAcopy with lower signal to noise data when each corresponding algorithms threshold parameter was optimized. In this context, we improved the analysis by incorporating a function that automatically selects the threshold parameter used for the segmentation thus, minimizing the false discovery rate. Analysis of the three tumors assayed across three platforms revealed 33 segments (16 amplifications and 17 deletions). Forty percent of the events were concordant across all three array platforms whereas 61% percent were concordant with at least two platforms. Three, five and six platform unique segments were called with affy, ngen, and bac respectively. The 40% discordance is attributed to variable probe representation resulting in false negative and false positive calls. The overall performance of the arrays as gauged by signal to noise (ratio of segment mean to standard deviation) resulted in affy having the highest, bac second and ngen lowest. Also, affy provides genotype information that could be used for loss of heterozygosity and snp association analysis. In conclusion, arrays providing the greatest density and highest signal to noise will greatly influence the choice of platform while dynamic analysis tools are needed to adjust for sample and platform dependencies.

Detecting genomic regions subject to natural selection by examining deviations of genealogies from neutral models. *Y. Wang, B. Rannala* Genome Center and Section of Evolution and Ecology, University of California, Davis, CA.

There is much interest in detecting genomic regions that have been under natural selection because of the potentially functional importance of selected loci. Different types of natural selection have different signatures in DNA sequence and single nucleotide polymorphism (SNP) data, reducing or maintaining local genetic polymorphism in natural populations. For mutilocus data the effect of selection and recombination are combined. Given the observed pattern of genetic variation within a chromosome interval containing an allele that has been under recent selection, the underlying genealogy of the sample will deviate from that expected under neutral coalescence and recombination models. We developed a Bayesian framework to identify genomic regions that depart from neutral genealogical models by comparing the distances between the prior and the posterior probability distributions of the genealogy underlying a sample of chromosomas, and by examining variations of the estimated posterior distributions of the population size under neutrality among chromosomal intervals. The performance of the method is examined by simulation, and the method is applied to SNP data from the International HapMap project.

Gene expression profiles and pathway analysis of early mouse inner ear development. *S.A. Sajan[1], M. Warchol[2], M. Lovett[1]* 1) Depts of Genetics and; 2) Otolaryngology, Washington Univ School of Medicine.

To identify new inner ear genes and pathways, we have expression-profiled the early stages of embryonic mouse inner ear development at half-day intervals on Affymetrix MOE430Av2 chips. From E9 to E10 (early category) whole inner ears were profiled, and from E10.5 to E12 (middle category) the cochleae and vestibular organs were profiled separately. In the late category, from E12.5 to E15, the cochleae, utricles, and saccules were profiled individually. We first identified genes over-expressed by 1.5-fold or more in all possible unique and pair-wise combinations of these categories with an estimated false discovery rate of less than 0.5%. Some genes over-expressed in the early category included *Trp53*, *Slc2a3*, *Lin28*, and *Hoxb1*, out of a total of 1,312 genes. Estrogen receptor, PI3/AKT, and chemokine signaling pathways, among others, were significant in this category. We then analyzed the middle and the late categories through analysis of variance (ANOVA) tests to identify genes differentially-expressed based on tissue-type, developmental-stage, or both. In the middle category, genes such as *Rgs3*, *Kctd10* and *Nfkb2*, out of a total of 240 genes, were highly expressed in younger stages (E10.5 and E11) while some of the 326 genes high in older stages (E11.5 and E12) were *Six5*, *Nfib*, and *Lnx2*. Significant pathways included B-cell receptor and cardiac beta-adrenergic signaling in younger stages, and TGF-beta and apoptosis signaling in older stages. In the late category, the cochlea had high levels of *Clu*, *Irx5*, *Gata3*, and *Scara3*, out of a total of 90 genes; the utricle had *Pthlh*, *Timp3*, *Hes5*, and *Foxp1*, out of a total of 162 genes; the saccule had *Otoa*, *Foxd1*, *Ror2*, and *Sall3*, out of a total of 178 genes. A burst of expression for 212 genes at E14 relative to all other late stages was also observed. Such genes included *Fzd6*, *Pdgfc*, *Trim26*, and *3110056o03Rik*. We have validated expression patterns of numerous genes by RNA *in-situs*. Of the 5,136 genes differentially-expressed across all time-points, 11.2% currently have no known function, and 14.4% fall within uncloned human genomic deafness intervals, serving as candidates for deafness-causing genes.

Deletion of the entire FBN1 gene is a recurrent mutation in Marfan syndrome. *G. Pals, R. van Spaendonk, A. Nygren* Dept Clinical Genetics, VU Medical Ctr, Amsterdam, Netherlands.

Large deletions or duplications in the FBN1 gene are a frequent cause of Marfan syndrome. Using MLPA (multiplex ligation dependent probe amplification) tests for the FBN1 gene we detected a large deletion or duplication in 23 independent families (4.5% of mutations in FBN1 in a series including 445 point mutations). Most of these were unique deletions or duplications of one or more exons, but deletion of the entire gene was the most common mutation and was found in seven independent families. We have used DNA repeat markers and additional MLPA probes to determine a possible founder mutation and get information about the size of the deletion. The results show no common haplotype for patients that have a deletion of the entire FBN1 gene. The size of the deletion is variable between families and ranges from more than2 Mb 5 to more than 3 Mb 3 of the FBN1 gene. The gene itself covers approximately 240 kb of genomic DNA. The deletions encompass at least 44 other genes. Despite the large number of heterozygously deleted genes there are only a few phenotypical differences between families with different sizes of the deletion.

Mutations in *PLA2G6* cause infantile neuroaxonal dystrophy and neurodegeneration with brain iron. *S.K. Westaway[1], N.V. Morgan[2], A. Gregory[1], S. Sonek[1], J.E.V. Morton[2], J. Coryell[1], P. Gissen[2], H. Cangul[2], N. Canham[3], S. Pasha[2], N. Nardocci[4], D. Rodriguez[5], I. Desguerre[6], B. Wilmot[1], P. Kramer[1], J. Gitschier[7], S.J. Hayflick[1], E.R. Maher[2]*
1) Molec & Med Genet, Oregon Health & Science University, Portland OR; 2) Med & Mol Genet, Univ of Birmingham, UK; 3) Birmingham Women's Hospital, Birmingham, UK; 4) Istituto Nazionale Neurologico, Milan, Italy; 5) Hôpital Armand Trousseau, Paris, France; 6) Hôpital Necker Enfants Malades, Paris, France; 7) School of Med & Howard Hughes Med Inst, UCSF, CA.

Neurodegenerative disorders with high brain iron include Parkinson and Alzheimer disease as well as the genetic neuroaxonal dystrophies. These include infantile neuroaxonal dystrophy (INAD), neurodegeneration with brain iron accumulation (NBIA) and Schindler disease, all of which show the distinctive pathologic feature of distended axons (spheroids) throughout the central nervous system. INAD is characterized by progressive motor and sensory impairment with spheroids found also in peripheral nerves, while NBIA is characterized by neurodevelopmental regression and dystonia with basal ganglia iron deposition. We performed genetic linkage studies in families with INAD and NBIA and mapped a locus for both to chromosome 22q. We found mutations in *PLA2G6*, encoding a calcium-independent phospholipase A2, in 38 families representing a broad clinical spectrum. We found 44 unique mutations throughout the gene, including missense, nonsense, splice and deletion mutations, most occurring at highly conserved positions. Our findings enable the molecular diagnosis of INAD and NBIA, obviating the need for a tissue biopsy. This phospholipase A2 is involved in membrane lipid remodeling, cellular signaling, and the mitochondrial apoptotic cascade. Our gene discovery links the pathogenesis of NBIA with INAD and ties these as well to pantothenate kinase-associated neurodegeneration, a related form of NBIA caused by defective mitochondrial coenzyme A biosynthesis. Moreover, this discovery implicates phospholipases in the pathogenesis of neurodegenerative disorders with brain iron dyshomeostasis and identifies a new target for neuroprotection in common diseases.

Second trimester prenatal triple marker screening for Down syndrome: the associations in the levels of serum markers in successive pregnancies. *A.M. Summers, T. Huang* Genetics Program, North York General Hosp, Toronto, ON, Canada.

Women who have been screen positive for Down syndrome by triple marker screening in the second trimester in one pregnancy tend to have a positive screening result again in their next pregnancy. This reflects the consistency between markers from one pregnancy to the next. Various adjustment methods have been proposed to eliminate recurrent false positives; however, the influence of the adjustments on detection rate (DR) has not been well evaluated due to insufficient data available from affected pregnancies. This study investigated the association between the levels of second trimester serum markers in first and subsequent pregnancies and assessed the impacts of including a previous screening result in the current risk estimation on the false positive rate (FPR) and DR of the current pregnancies. The study was based on 57,151 women who had triple marker screening in two or more singleton pregnancies in the Ontario Maternal Serum Screening Program between October 1993 and September 2000. Screening results were compared between different pregnancies in the same individual. Associations in the levels of serum markers were estimated using correlation analysis. A published method was used to adjust the current risk estimation for previous screening results and the effect of this adjustment was assessed by comparing DR and FPR before and after the adjustment. Women who screened positive in one pregnancy were twice as likely to be screen positive in subsequent pregnancies. Adjusting for previous screening results may reduce the risk of a recurrent false positive from 26.4% to 10.7% without significantly altering the DR (72.5% and 74% before and after the adjustment respectively). In conclusion, the risk estimation for the current pregnancy may be adjusted for the screening results from a previous pregnancy. This adjustment may significantly reduce recurrent FPR without compromising DR.

Genotype-phenotype correlation: a comparison between MPS II sibilings. *T.A. Vieira, I.V. Schawrtz, L.L.C. Pinto, M.V. Muñoz, A. Pires, R. Giugliani* Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Porto Alegre, RS, Brazil.

PURPOSE: to compare clinical findings between MPS II affected brothers. METHODS: data was obtained from medical charts of four pairs of siblings attending at Medical Genetics Service-HCPA. RESULTS: Sibling pair A: mutation p.P231L, proband A1: 20 yrs and A2: 15 yrs, respectively presenting iduronate sulfatase activity (IDS) 2 nmoles/4h/m and undetectable, GAG urinary excretion: 1.56 and 4.1 fold normal upper limit(FNUL), FVC: 52.4% and 48.7% predicted normal, 6MWT: 540m and 480m. Cardiology findings: (A1) incomplete right bundle branch block, moderate aortic/mitral valve regurgitation and (A2) mild mitral/moderate aortic valve regurgitation. Both present normal intelligence. Sibling pair B: mutation A85T, proband B1: 18 yrs and B2: 14 yrs, respectively presenting IDS 6.2 and 2.4, GAG urinary excretion: 4.8 and 2.4 FNUL, FVC: 54.6% and 58.8% predicted normal, 6MWT: 427m and 404m. Cardiology findings: B1 incomplete right bundle branch block, mild aortic/mitral/tricuspid valve regurgitation and B2 mild mitral/aortic valve stenosis, left ventricle relaxing deficit and left atrium overload. Both siblings present normal intelligence. Sibling pair C: mutation c.708G-A, proband C1: 9 yrs and C2: 7 yrs, respectively presenting IDS 1.2 and 1.2, GAG urinary excretion: 4.4 and 2.8 FNUL, FVC: 62.7% and 46% predicted normal, 6MWT: 456m and 405m. Cardiology findings: C1 1st grade atrium-ventricle block, moderate aortic/ mild mitral valve regurgitation and C2 mild mitral/aortic valve regurgitation. IQ was 53 and 78. Sibling pair D: mutation unknown, proband D1: 14 yrs and D2: 10 yrs, respectively presenting IDS 10 and 5, GAG urinary excretion: 3.4 and 2.9 FNUL, FVC: 28.8% and 45% predicted normal, 6MWT: 412m and 475m. Cardiology findings: D1 mild aortic valve stenosis, mild mitral/aortic valve regurgitation and D2 moderate aotic and mild mitral valve regurgitation. IQ was 50 and 50. CONCLUSION: All pair of siblings (A-D) presented different phenotypes which can not be explained by genotype. Albeit, except for sibling pair C, such differences were not enough to alter neurological phenotype.

Skeletal Muscle Phenotype on Autopsy in Paternal Uniparental Isodisomy of Chromosome 14. *M.F. Wangler[1], E.M. McKay[2], M.B. Bhattacharjee[2], V.R. Sutton[3]* 1) Pediatrics, Baylor Col Medicine, Houston, TX; 2) Pathology, Baylor Col Medicine, Houston, TX; 3) Molecular and Human Genetics, Baylor Col Medicine, Houston TX.

Paternal uniparental disomy of chromosome 14 (upd(14)pat) produces a characteristic phenotype that includes axial skeletal anomalies, dysmorphic facial features, joint contractures and developmental delay. Although the condition is associated with a poor prognosis, no autopsies on children with this condition have been reported and no microscopic examination of skeletal muscle has been reported. We present a case of upd(14)pat in a Latin-american male who expired due to complications of sepsis and respiratory failure. At autopsy, a striking variability in muscle fiber size was noted on microscopic examination. Muscle phenotypes are present in the two animal models of upd(14)pat . In the ovine Callipyge model there is loin muscle hypertrophy due to a relative increase in number and size of fast-twitch glycolytic (type II) fibers and in the murine upd(12)pat, abnormally large fibers with centrally located nuclei are reported but there is no detailed histology published. This case suggests that in humans with upd(14)pat, as in the animal models, there is an imprinted region on chromosome 14 that is involved in skeletal muscle development during embryogenesis that results in abnormal fiber size and development. The hypotonia in upd(14)pat may be due, in part, to myopathy.

Data Quality Assessment of STR Fragment Analysis on the 3730xl DNA Analyzer. *M. Vogel, D.V. Walker, D.D. Einum, C.L. Mouritsen* Research & Development, Sorenson Genomics, Salt Lake City, UT.

Multiplex PCR analysis of short tandem repeats (STRs) for genetic discovery, clinical diagnosis and human identification applications is nearly ubiquitous in high throughput laboratories. The Applied Biosystems 3730xl DNA analyzer is a recently developed capillary electrophoresis platform designed to increase sensitivity, accuracy, precision and throughput compared its predecessor, the 3700. To optimize the use of the 3730xl for human identification applications, an internally validated multiplex PCR panel was utilized to examine multiple quality parameters of STR fragment detection. Direct sensitivity studies using a commercial sizing standard revealed that optimal fragment sizing quality occurs on the 3730xl with 40% less DNA than is required for optimal sizing on the 3700. Instrument accuracy was examined by processing samples with known genetic profiles on the 3730xl using a Y chromosome STR panel and high levels of concordance were obtained. Precision of the 3730xl was also assessed and reveals that the sizes of PCR fragments generated from the same templates processed on distinct instruments in independent runs deviate by an average of 0.07 base pairs, thus underscoring the high degree of data reproducibility exhibited by the 3730xl. Finally, the sample failure rate was 0.3% on the 3730xl and is 40-fold lower than that exhibited by the 3700. In summary, this study provides evidence that the 3730xl is a reliable detection platform for PCR fragment analysis in human identification applications. Together with the high throughput component (96 capillary capability), the significant data quality improvements of the 3730xl will position the instrument as a indispensable tool for the myriad disciplines that benefit from the power of genetic analysis.

Genome-wide mapping of susceptibility to epilepsy-related photosensitivity identifies a novel locus on chromosome 13q13. *D. Pinto[1], U. Tauer[2], S. Lorenz[3,4], H. Muhle[2], B.A. Neubauer[5], S. Waltz[6], K.P. Lenzen[3,4], G. Rudolf[7], G-J. de Haan[8], D. Lindhout[1], B.P. Koeleman[1], T. Sander[3,4], D.G. Kasteleijn-Nolst Trenité[1], U. Stephani[2]* 1) Complex Genetics Section, DBG -Dept. Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 2) Clinic for Neuropediatrics, Kiel Univer sity, Germany; 3) Gene Mapping Center, Max -Delbrück-Center, Berlin, Germany; 4) Dept. Neurology, Charité University Medicine, Berlin, Germany; 5) Clinic for Neuropediatrics, University Giessen, Germany; 6) Childrens Hospital, Cologne, Germany; 7) Strasbourg University, Strasbourg, France; 8) Stichting Epilepsie Instellingen Nederland, Heemstede, The Netherlands.

Photosensitivity or photoparoxysmal response (PPR) is an abnormal cortical response to visual stimuli that can be evoked by standardized intermittent photic stimulation. It is a highly heritable EEG trait, which occurs frequently associated with IGEs. Given its strong association with IGEs, PPR is a potential endophenotype for IGEs. Recently two genome-wide linkage scans on PPR identified 4 susceptibility loci at 7q32, 16p13 and 6p21, 13q31, varying on the familial background of epilepsy syndromes. In this study, we searched for risk factors that are independent of the familial epilepsy background by pooling genotype data from all 75 multiplex PPR families and performing a combined nonparametric linkage (NPL) analysis. To account for genetic heterogeneity, family members were classified under a broad (all PPR types I-IV) and a narrow (only PPR types III-IV) trait definition. We found evidence for a novel, shared locus on 13q13.2 at D13S1493 under broad ($P_{NPL} = 3.64x10^{-4}$) and narrow ($P_{NPL} = 6.81x10^{-5}$) trait definitions, achieving empirical genome-wide significance for the narrow model ($P_{gw} = 0.0132$). Accentuated linkage under the narrow trait definition (generalized PPRs) suggests an increase in phenotypic homogeneity, underscoring the close genetic relationship between generalized PPRs (types III-IV) and IGEs. Our findings suggest that the locus at 13q13.2 represents a common genetic component for visually-induced and spontaneously occurring generalized spike-and-wave EEG discharges, underlying generalized PPR in IGE patients.

Genome-wide detection of human copy number variations using high density DNA oligonuceotide arrays. *M.H. Shapero[1], F. Shen[1], W. Chen[1], V. Truong[1], K.R. Fitch[1], D. Komura[2], S. Ishikawa[2], J. Zhang[1], G. Liu[1], H. Aburatani[2], K.W. Jones[1], J. Huang[1]* 1) Genotyping Research, Affymetrix, Inc. Santa Clara, CA; 2) Genome Science Division, Research Center for Advanced Science and Technology, University of Tokyo.

DNA sequence diversity within the human genome may be more greatly affected by copy number variations (CNVs) than single nucleotide polymorphisms (SNPs). Although there are increasingly clear examples of how CNVs can influence , for example, drug responses and disease susceptibility, a global biological understanding of the roles of CNVs is not yet currently available. We have previously reported a comprehensive view of CNVs among 270 HapMap samples using high density (500K) SNP genotyping arrays which revealed greater than 1,000 CNVs spanning a broad size range from less than 1kb to over 3Mb. In order to improve probe coverage for genome-wide CNV identification, especially in regions such as segmental duplications that are rich in CNVs, an array has been synthesized which uncouples copy number detection from SNP genotyping. A probe selection algorithm has been used to design 8 independent non-polymorphic probes for each *in silico* predicted Nsp I restriction fragment in the 200-1000bp size range. This Nsp I fragment array, in conjunction with PCR-based, complexity-reduced DNA target, provides high resolution, querying 1,330,354 restriction fragments, which translates to a 3.24 fold increase in marker density as compared to the 500K arrays. The median inter-marker distance is reduced from 2,709bp to 776bp and has allowed the continuing identification of CNVs in the human genome. QPCR has been used as an independent method to verify array-based CNV calls. Initial results suggest that non-SNP-based arrays can detect both simple and complex CNVs in the HapMap set. The increasing precision of CNV boundary delineation should allow a more complete analysis of their genomic organization.

***LRRK2* G2019S in Families with Parkinson's Disease Originating from Europe and the Middle East: Evidence for Two Distinct Founding Events Beginning Two Millennia Ago.** *C.P. Zabetian[1,2], C.M. Hutter[3], D. Yearout[1,2], A.N. Lopez[1,2], S.A. Factor[4], A. Griffith[5], B.C. Leis[5], T.D. Bird[1,2], J.G. Nutt[6], D.S. Higgins[4], J.W. Roberts[7], D.M. Kay[8], K.L. Edwards[3], A. Samii[2,9], H. Payami[8]* 1) GRECC, VA Puget Sound HCS, Seattle, WA; 2) Dept of Neurology, Univ of Washington, Seattle, WA; 3) Dept of Epidemiology, Univ of Washington, Seattle, WA; 4) Parkinsons Disease & Movement Disorder Clinic, Albany Medical Center, Albany, NY; 5) Booth Gardner Parkinsons Care Center, Evergreen Hospital, Kirkland, WA; 6) Dept of Neurology, Oregon Health & Science University, Portland, OR; 7) Virginia Mason Medical Center, Seattle, WA; 8) Genomics Institute, Wadsworth Center, NY State Dept of Health, Albany, NY; 9) PADRECC, VA Puget Sound HCS, Seattle, WA.

The Leucine-Rich Repeat Kinase 2 (*LRRK2*) G2019S mutation is the most common genetic determinant of Parkinson's disease (PD) identified to date. It accounts for approximately 1-7% of PD in patients of European origin, and has a remarkably high prevalence (20-40%) in Ashkenazi Jews and North African Arabs with PD. Previous studies concluded that families from these populations shared a common founder who lived in the 13th century. We sought to test this hypothesis by performing a haplotype analysis of 22 families (13 of European and nine of Jewish ancestry) with G2019S recruited from movement disorder clinics in North America. We genotyped 25 markers (12 SNPs, 13 microsatellites) that spanned 9 Mb across the *PARK8* region and used the program PHASE to reconstruct haplotypes. We discovered two distinct haplotypes in our sample. Haplotype 1 was present in 19 families of Jewish and European ancestry and was consistent with that reported in the literature. Haplotype 2 occurred in three European-American families and spanned a minimum distance of 6 Mb. Using a maximum likelihood method we estimated that the families with haplotype 1 shared a common ancestor approximately 2,000 years ago, while those with haplotype 2 shared one more recently. Our data suggest two separate founding events for G2019S in these populations, beginning at a time far earlier than the 13th century which coincides with the end of the Jewish diasporas.

Use of Array-CGH for Analysis of Patients with a Laboratory Referral Diagnosis of Autism Spectrum Disorder.
T. Sahoo, W. Wells, S.W. Cheung, A. Patel, A.L. Beaudet Dept Human & Molec Gen, Baylor Col Medicine, Houston, TX.

Children with autism and related diagnoses are often found to have obvious cytogenetic abnormalities such as sex chromosome aneuploidy or isodicentric (15)(q11.2). In addition, subtle cytogenetic abnormalities are present in a small percentage of cases including dup(15)(q11q13) and a variety of telomeric deletions, particularly 22q. Array comparative genomic hybridization (CGH) provides a new opportunity to diagnose these more subtle abnormalities with greater sensitivity, particularly for submicroscopic duplications such as 15q11q13 which would not be detected even by metaphase FISH. The Cytogenetic Laboratory at Baylor College of Medicine has offered array-CGH as a clinical service since Feb. 2004, with 4065 samples analyzed through May 2006. Of these, 254 samples were received with a sole diagnosis of autism and 44 with a complex diagnosis including autism or autistic features. This referral information was based solely on the information provided with submission of the sample. Normal array-CGH results were obtained for 254 of the 304 cases. There were 12 definite abnormalities including four cases with a previous abnormal kayotype [two 47,XXY, one dup(21)(q), one del(7)p14.1)], and all were confirmed by array-CGH. Of the 8 cases with previous normal karyotype, there were 3 males with duplication of the RETT gene at Xq28 (Mat pending), one del(10)(p12p14) (parents pending), one de novo dup(17)(p13.3), one de novo del(22)(q13.33), one dup15q11q13 of maternal origin, and one del(9)(q34.3). There were 38 autistic cases with copy number variation, most of which were benign familial variants, and some still awaiting parental studies. Other findings of interest in which autism was not mentioned in the referral included one case with previously identified marker chromosome that proved to be isodicentric 15q, two cases of dup(15)(q11q13) (parents pending), 18 cases with duplications and 12 cases with deletions of the breakpoint 1-breakpoint 2 interval of the PWS-AS critical region at 15q11.2, three del(22)(q13.33), and nine cases (5 female and 4 male) with gain of the STS region at Xp22.32; all of which were familial in cases where parents were analyzed.

The effect of heating rate on DNA duplex melting: implications for mutation scanning and real-time PCR. *O. ELENITOBA-JOHNSON[1], R. M. WATSON[2], C. T. WITTWER[1]* 1) PATHOLOGY, UNIVERSITY OF UTAH SCHOOL OF MEDICINE, SALT LAKE CITY, UT; 2) ROCHE MOLECULAR SYSTEMS INC ALAMEDA, CA.

High-resolution DNA melting analysis is a powerful tool for genotyping and mutation scanning. The effect of heating rate on melting curve results is unclear. Historically, high quality melting data was obtained using absorbance at rates of 0.1 - 1C/min. Today, it is more common to monitor melting with fluorescence in conjunction with real-time PCR at rates of 0.1 - 1.0 C/s. Prior work suggests that melting temperatures (Tms) of PCR products increase by up to 1-3C as the heating rate increases. A high-resolution melting instrument (HR-1, Idaho Technology) and a custom prototype fluorimeter were used to study the effect of heating rate on Tm and melting curve shape. Rates between 0.01 and 1.0C/s were examined using PCR products and synthetic oligo duplexes in the presence of the dsDNA dye, LCGreen 3 (Idaho Technology). The custom fluorimeter replaced the HR-1 optics with a custom bifurcated fiber optic cable (04-08719, RoMack), a wavelength variable monochromator (DeltaRam, PTI), an emission spectrograph (FCS 77443, Oriel) and a CCD camera (DV 420-OE, Andor). A J-type thermocouple (TT-J-40-50, Omega), was inserted into each 10 ul sample for temperature monitoring. Using both the HR-1 and custom fluorimeter, the Tms of homozygous PCR products varied less than 0.2C over the heating rate range of 0.01 - 1.0C/s. The melting curves showed changes in shape over this range with apparent broadening of the transition at higher rates, possibly due to internal sample temperature heterogeneity. Results with amplified heterozygotes depended on duplex size and melting rate. Heteroduplexes were best observed at faster rates, particularly with short amplicons. Melting rates between 0.01 and 1.0C/s do not affect the Tm of homoduplexes determined by fluorescent melting analysis and results from amplified heterozygotes suggest that melting analysis for mutation scanning is best performed at higher melting rates. Still, melting analysis during each cycle of real-time PCR should be possible given adequate instrument resolution and accurate temperature monitoring of the sample.

Discovery of novel recurrent genomic disorders from the duplication architecture of the human genome. *A.J. Sharp[1], S. Hansen[1], R.R. Selzer[2], Z. Cheng[1,7], R. Regan[3], J.A. Hurst[4], C.A. Fitzpatrick[5], T.A. Richmond[2], D. Pinkel[6], P.S. Eis[2], S. Schwartz[5], S.L. Knight[3], E.E. Eichler[1,7]* 1) Genome Sciences, Univ. of Washington, Seattle, WA; 2) NimbleGen Systems Inc, Madison, WI; 3) Wellcome Trust Centre for Human Genetics, Oxford, UK; 4) Dept of Clinical Genetics, Churchill Hospital, Oxford, UK; 5) Dept of Human Genetics, Univ. of Chicago, IL; 6) Comprehensive Cancer Center, UCSF; 7) Howard Hughes Medical Institute.

Genomic disorders are characterized by large, highly homologous flanking segmental duplications that predispose these regions to recurrent rearrangement. Based on the duplication architecture of the genome, we mapped 130 intervals that we hypothesized as candidate sites for novel genomic disorders. We tested 330 patients with mental retardation and congenital abnormalities using a custom BAC array targeted to these sites (Sharp 2005, Am J Hum Genet 77:78). We identified 19 pathogenic rearrangements that were never observed in 316 controls. These included six patients with an identical *de novo* microdeletion of 17q21.31, identifying this as a novel site of common recurrent rearrangement. Two of these were ascertained on the basis of a similar phenotype to the first four cases. We used high-density oligonucleotide arrays to refine the breakpoints of this microdeletion, identifying multiple copy number polymorphisms in this region and defining a 478kb critical region containing six genes that was deleted in all six cases, but invariant in controls. Breakpoints were mapped to flanking paired segmental duplications that likely mediate this rearrangement. We also characterized five other pathogenic rearrangements using oligo arrays. In four of these, the breakpoints also localized to large clusters of flanking segmental duplications, strongly suggesting that these are also sites of recurrent rearrangement. In common with the 17q21.31 deletion, we observed that in each case the breakpoint regions are also sites of copy number polymorphism in controls, suggesting that these may be inherently unstable genomic regions prone to chromosomal breakage. Our strategy based on genomic architecture represents a powerful approach for the identification of novel genomic disorders.

Newborn Screening Programs in Asia - Program Implementation and Strategic Policy Formulation. *C. Padilla*
Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila, Manila, Philippines.

Newborn Screening is a well recognized public health program aimed at the early identification of infants who are affected by certain genetic/metabolic/infectious conditions. Early identification of these conditions is particularly crucial, as timely intervention can lead to a significant reduction of morbidity, mortality, and associated disabilities in affected infants. The establishment of newborn screening programs in developing countries poses major challenges as it competes with other health priorities like control of infectious diseases, immunization, malnutrition, etc. Despite this, it is imperative that developing countries recognize the importance of newborn screening as it has been proven through decades of experience, that it can save thousands of babies from mental retardation, death and other complications. Some of critical factors necessary for the success of a national newborn screening program are 1) inclusion of newborn screening among the government priorities; 2) funding of newborn screening fees; 3) general public acceptance; 4) cooperation of the health practitioners; 5) government participation in institutionalizing the newborn screening system. This paper will present 1) highlights of the newborn screening programs (statistics, disorders, problems, strategies etc) and 2) policies that supported the implementation of newborn screening in both developed and developing countries. Data from the following countries will be presented -Australia, Bangla Desh, China, Indonesia Japan, Korea, Malaysia, Mongolia, New Zealand, Philippines, Singapore, Thailand , Vietnam.

The Familial Mediterranean Fever (FMF) gene (MEFV) as a disease susceptibility gene in Inflammatory Bowel Disease (IBD). *A.C. Villani[1], M. Lemire[2], E. Louis[3], M. Silverberg[4], Y. Renaud[2], S. Brunet[2], C. Collette[1], G. Fortin[1], C. Libioulle[3], A. Bitton[1], D. Gaudet[5], A. Cohen[1], D. Langelier[6], J. Rioux[7], P. Rutgeerts[8], G. Wild[1], S. Vermeire[8], T.J. Hudson[2], D. Franchimont[1]* 1) McGill University Health Center, Canada; 2) McGill University & Genome Quebec Innovation Centre, Canada; 3) CHU of Liège, Belgium; 4) Mount Sinai Hospital IBD Center, Canada; 5) Centre Hospitalier de la Sagamie, Canada; 6) Centre Hospitalier de Sherbrooke, Canada; 7) University of Montreal, Canada; 8) KUL, Belgium.

FMF is a hereditary auto-inflammatory disease caused by mutations in the MEFV gene. Since epidemiological studies revealed a higher prevalence of IBD in FMF non Ashkenazi Jewish patients, we evaluated MEFV as a susceptibility gene for IBD. **Methods**: DNA samples were obtained from 5 centers and divided into 3 cohorts: Belgian (Liege 190 IBD trios;Leuven 435 IBD trios), Canadian (Quebec 125 IBD trios;Toronto 190 IBD trios), Edinburgh (521UC,300 controls). The haplotype structure and fine-mapping of MEFV was done by genotyping 65 SNPs over 96.5kb using SNPstream UHT, FP-TDI and sequencing technologies. Standard measures of LD were estimated using EM algorithm, and association testing was done using TRANSMIT and Chi-Square test. **Results**: Association analysis revealed that haplotype A,covering the MEFV promoter to intron 2 and its 5 flanking region,was positively overtransmitted in both the Belgian ($p<0.03$),Canadian ($p<0.018$),and combined UC cohorts ($p<0.0012$). Although present,Haplotype A was not found to be significant in the Edinburgh cohort. Haplotype B,also covering the same region, was found to be positively overtransmitted in the Belgian ($p<0.27$), Canadian ($p<0.0031$), and combined CD cohorts ($p<0.005$). All exons and promoter regions of genes encompassed by haplotypes A and B were sequenced and the 6 observed coding variants were genotyped in the 3 cohorts. No coding variants could explain the observed associated haplotypes A and B. **Conclusion**: MEFV appears to be a disease susceptibility gene for IBD. Interestingly, this study suggests that a gene associated with a rare inflammatory disorder could be implicated in the susceptibility of more common inflammatory diseases, such as IBD.

Identification of a variant RAR gene rearrangement in a patient with acute promyelocytic leukemia. *B.M. Shearer[1], J.G. Keefe[1], C. Rubin de Celis[2], A. Vendrell[2], R.F. McClure[1], E.C. Thorland[1], R.P. Ketterling[1]* 1) Dept. of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) Brackenridge Hospital, Austin, TX.

Acute promyelocytic leukemia (APL) comprises approximately 10% of all acute myelogenous leukemias (AML). The hallmark genetic aberration is a translocation between chromosomes 15 and 17 resulting in the gene fusion of PML (promyelocytic leukemia) at 15q22 and RAR (retinoic acid receptor alpha) at 17q21 in approximately 95% of cases. Infrequently, RAR gene fusion with variant gene partners has been observed in APL. Variant gene partners include PLZF at 11q23, NuMA at 11q13, NPM at 5q35, and Stat5b at 17q21.2. Treatment with all-trans retinoic acid (ATRA) induces a transient complete remission and when consolidated with conventional chemotherapy produces a cure in 70-90% of patients. Herein, we describe a 42 year old male presenting with AML whose bone marrow contained nearly 100% promyelocytes with secondary granules and Auer rods. Chromosome analysis revealed a 46,XY karyotype and both RT-PCR and D-FISH failed to demonstrate PML-RAR fusion. However, interphase FISH analysis demonstrated a small split of the RAR probe, which was found to co-localize on the abnormal chromosome 17 by metaphase FISH. Break-apart FISH for RAR revealed a deletion of the centromeric portion of the probe. In combination, these results suggest a cryptic rearrangement on chromosome 17q, which may represent an inversion/deletion mechanism resulting in aberrant expression of RAR with a new partner. A candidate gene of interest includes Stat5b for which a sole APL patient demonstrated Stat5B-RAR fusion due to an interstitial deletion of 17q. However, since subsequent ATRA treatment of our patient induced remission and the previously described Stat5b-RAR patient was refractory to ATRA, a novel gene may be the target of RAR upregulation in our patient. Additional studies to identify the partner gene have been initiated. Detailed genetic results for this patient, a review of the literature, and a discussion of the pathogenetic model for this variant RAR gene rearrangement will be presented.

Genomic convergence to prioritize candidate genes for primary open-angle glaucoma. *V. Raymond[1], N. Boivin[1], P. Belleau[1], E. Deilhes[1], A. Marquis[1], R. Arseneault[1], J. St-Amand[2], E. Calvo[2], M.A. Rodrigue[1], J.L. Anctil[3]* 1) Ocular Genetics & Genomics, CREMO, Laval University Hospital (CHUL) Res Ctr, Québec City, PQ, Canada; 2) Endocrinology & Oncology (CREMO), CHUL Res Ctr; 3) Ophthalmology dept, St-Sacrement Hosp, Québec City.

Eleven *GLC1* loci have been mapped for primary open-angle glaucoma (POAG), but only 3 genes have been characterized: *TIGR/myocilin*, *OPTN* and *WDR36*. Five French-Canadian families displayed haplotypes compatible with segregation of a disease gene at three *GLC1* loci. However, the relatively small sizes of these families hampered confinement of the loci. We exploited genomic convergence, a multistep approach that combines gene expression analysis with genetic linkage, to prioritize candidate genes for POAG within these loci. Serial analysis of gene expression (SAGE) and Affymetrix microarrays (HG U133 plus 2.0) were used to probe transcripts in the retina and ciliary body. Tissues were obtained from 1 asymptomatic 67 year old male, 1 asymptomatic 75 year old female and 1 POAG female (76 year old). 21,025 species of SAGE tags were detected in a total of 46,096 sequenced tags from the retina. Specific tags, detected at least 5 times, corresponded to 784 transcripts of which 9 mapped (7 genes) within 1 of the 8 *GLC1* loci encoding a POAG gene not yet characterized. In our microarrays experiments, 684 and 421 transcripts were differentially expressed, respectively, in the retina and ciliary body of our patient as compared to controls. The transcripts that mapped to 1 of the 8 *GLC1* loci, for which a POAG gene remains to be identified, corresponded to 30 genes. Five of these genes localized within *GLC1B*, 3 within *GLC1C* and 2 within *GLC1D*. None of the 7 genes identified by SAGE corresponded to the 30 characterized by microarrays. The most interesting genes were *REEP1* (*GLC1B*), *TFDP2*, *ZBTB38* (*GLC1C*) and *ENY2* (*GLC1D*). In conclusion, our transcriptomic analyses of the retina and ciliary body revealed 37 genes that mapped within *GLC1* loci encoding unknown glaucoma genes. Twelve of these genes mapped at *GLC1B, 1C or 1D* and therefore represent primary candidate genes to be investigated in our families.

Noonan's syndrome children with valvular pulmonary stenosis and left hypertrophic cardiomyopathy: clinical assessment and cytogenetic analysis. *I. Trabelsi[1], S. Kammoun[1], M. Meddeb[2], T. Rebai[3], N.B. Abdelmoula[3]* 1) Cardiology department, Hedi Chaker Hospital, Sfax, Tunisia; 2) Genetics Laboratory, Tunis, Tunisia; 3) Histology Laboratory, University of Medicine, Sfax, Tunisia.

Noonan's syndrome is an autosomal dominant dysmorphic syndrome in characterized by craniofacial anomalies with hypertelorism, a downward eyeslant and webbing of the neck; as well as skeletal deformities such as short stature and other organ anomalies, mainly cardiac valve disease. Diagnosis of Noonan's syndrome still remains on its clinical features but mutations in PTPN11 gene which maps to 12q24.1 have been reported in approximately 40 percent of patients. As part of our screening project of genetic abnormalities in congenital heart defects, a prospective study about valvular pulmonary stenosis is conducted. We report the first part of this study in which we describe clinical features of nine children (four males and five females) in whom Noonan's syndrome is suspected. In three of these nine children, mother or father, seem to be affected with cardiac murmura and, or facial dysmorphy. Two of them are a twin. All children have a normal karyotype. All have valvular pulmonary stenosis associated with left hypertrophic cardiomyopathy.

The human single-strand DNA binding protein RPA rapidly associates with DNA breaks *in vivo*. *I. Pasic*[1, 2], *M.S. Meyn*[1, 2] 1) Genetics & Genomic Biology, Hosp for Sick Children; 2) Molecular & Medical Genetics, Univ of Toronto, Toronto, ON.

RPA is a single-strand DNA-binding protein involved in DNA metabolism. In response to DNA double-strand breaks (DSBs), its RPA2 subunit is phosphorylated by the damage response kinase ATM. While phosphorylation alters RPA's interactions with replication and repair factors, it is unclear how it affects interactions between RPA and DSBs. We therefore studied the effect of ATM deficiency on recruitment of RPA2 to photo-induced DSBs in human fibroblasts.

Endogenous RPA2 is detectable at DSBs by 30s and remains localized to DSBs 150s post-irradiation. RPA2 phosphorylated at T21 (T21~P) is also present at DSBs 30s post-irradiation, but by 90s is diffusely distributed throughout the nuclei of irradiated cells. This suggests that unphosphorylated RPA2 rapidly associates with DSBs, where it is then phosphorylated, thereby promoting RPA dissociation from DSBs. In support of this notion, the association of a T21DS33D phosphomimetic GFP-RPA2 mutant with induced DSBs is impaired and a T21DS23DS33D phosphomimetic GFP-RPA2 mutant associates with DSBs very poorly.

To further examine the negative role for phosphorylation in control of RPA's association with DSBs, we studied the association of RPA2 with DSBs in ATM-deficient cells. While RPA2 is seen at DSBs in ATM-deficient cells 30s post-irradiation, RPA2-T21~P is not detectable, suggesting DSB-induced phosphorylation of RPA2 at T21 is ATM-dependent, but T21 phosphorylation is unnecessary for RPA2s association with DSBs. Interestingly, in the absence of ATM, GFP-RPA2 associates with DSBs more slowly than in wild type cells. This may reflect a defect in an early processing step needed for RPA2 to associate with DSBs rather than lack of RPA2 phosphorylation. Such a step may involve the MRN complex, which promotes nucleolytic processing of DSBs. In support for this idea, we find that the association of GFP-RPA2 to DSBs in NBS1-deficient cells is severely impaired. Our results suggest that the association of RPA with DSBs is rapid and MRN-dependent; enhanced by ATM-dependent activation of MRN; and decreased by phosphorylation of RPA2, which likely occurs at DSB sites.

Bruck Syndrome Seen in Consecutive Siblings. *A..M. Zoumberakis[1], D.L. Broome[1], R.S. Lachman[2], R.W. Hassan[1]* 1) Dept Genetics, Kaiser Permanente, Downey, CA; 2) Cedars-Sinai Medical Center Los Angeles, CA.

Genetic counseling was done for a family who had two consecutive infants with multiple anomalies. The first child was born at 36 weeks by cesarean section for breech presentation with oligohydramnios. At birth, multiple anomalies were seen including contractures of hands and shoulders, microcephaly, hip dislocation, atrial and ventricular septal defects, small pulmonary artery and facial anomalies. The baby died 2 hours post delivery. Autopsy report revealed lung hypoplasia, with abnormal rotation of the forearms and hands, cauliflower appearing ears and lower limb deformities as well as the above findings. Chromosome studies were normal. The mother presented to us for genetic counseling during her second pregnancy. A targeted ultrasound and fetal echocardiogram were performed and reported as normal. The baby was born at 34 weeks by repeat cesarean section for breech presentation with intrauterine growth retardation and oligohydramnios. The baby was noted to have similar anomalies as in the previous infant. Additional findings included multiple bone fractures, 11 ribs and joint ankylosis. The baby died at 2 months of age due to respiratory distress. X-ray films were sent to the International Skeletal Dysplasia Registry through Cedars-Sinai Medical Center. Findings included very severe generalized osteoporosis, very thin long bones, thin ribs and dentinogenesis imperfecta. The diagnosis was consistent with Bruck syndrome. Bruck syndrome is a rare, autosomal recessive syndrome that consists of a combination of arthrogryposis multiplex congenita and osteogenesis imperfecta (OI). It is a progressive disease that leads to severe limb deformities, multiple fractures and short stature. Therefore, it is imperative to obtain a radiological assessment to rule out a possible underlying diagnosis of OI when arthrogryposis is suspected.

Gene Expression Differences between Patients and Controls in Type 1 Diabetes weakly correlates with Gene Divergence Rate. *A. Solidar[1], K. Kover[2], S. Svojanovsky[3], W.V. Moore[2], G.J. Wyckoff[1]* 1) Div Molec Biol & Biochemistry, Univ Missouri, Kansas City, Kansas City, MO; 2) Childrens Mercy Hospital & Clinics Kansas City, MO; 3) 2University of Kansas Medical Center Kansas City, KS.

Type 1 Diabetes is a multigenic disorder with a high prevalence, and identifying and characterizing genes and their products associated with Type 1 diabetes is a major goal of the Kansas City Diabetes Consortium. We are also interested in understand the large scale trends surrounding genes involved with this disease. Using microarray technology we have generated a gene expression profile of patients with new onset Type 1 diabetes. Peripheral blood was collected from 4 females and 4 males (7 -14 yrs old) upon diagnosis of Type 1 diabetes. Our analysis shows that of the 22,277 genes probed 6341 genes were upregulated and 5558 were down regulated in males with Type 1 diabetes compare to control males while 5415 genes were upregulated and 6740 were down regulated in females with Type 1 diabetes compared to female controls. The intersection showed 2627 genes were upregulated and 2921 were down regulated; upregulated genes include interferon induced genes, immunoglobulin light chain , MHC Class II DRB3, integrin beta 3 while down regulated genes include cell division related genes, homeobox protein NKX3, cathepsin W, and granzyme B. Several significantly differentially regulated genes show signs of positive selection. We analyzed the divergence of these proteins, looking at evolutionary rate measures (Ka/Ks) between humans and rodents to determine if differences in expression were correlated with differences in evolutionary rate. We found a small but significant ($r^2=0.04$, p-value < 0.05) correlation between expression difference and Ka/Ks, with genes having a higher expression difference more likely to have a high Ka/Ks between species. Recent studies suggested that evolutionary rate correlates with disease involvement (Kondrashov; Smith and Eyre-Walker). We suggest that the evolutionary plasiticity of a gene, measured in terms of scaled protein change rate, may correlate with disease involvement, and may have utility in picking candidates for further study in multigenic diseases.

Brain Imaging As A Strategy for Genome Wide Scan Data Reduction for Neuropsychiatric Illness. *S. G. Potkin[1], F. Macciardi[2], L. Friedman[1], J. Turner[1], J.H. Fallon[3], W. Bunney[1], D. Keator[1], D. Goldstein[4], N. Schork[5]* 1) Psychiatry and Human Behavior, UCI, Irvine, CA; 2) Dip. di Scienze e Tecnologie Biomediche, Università degli Studi di Milano, Milan, Italy; 3) Anatomy and Neurobiology, UCI, Irvine, CA; 4) Center for Population Genomics and Pharmacogenetics, Duke University, Durham, NC; 5) Psychiatry, UCSD, San Diego, CA.

Genetic association studies look for genetic contributions related to diagnostic status. These are inevitably small effects for complex disorders and require unrealistic sample sizes. The integration of intermediate phenotypes in imaging genetics holds promise for finding more specific and larger genotypic effects. This integrative approach incorporates 500+K SNPs and 20+K imaging voxels but creates additional statistical concerns. We utilize an ordered analysis incorporating candidate genes and genomewide strategies, a novel extension of a method for identifying significant results, and the use of a number of replication/validation strategies. Initially, imaging phenotypes are defined from the fMRI activation patterns that distinguish schizophrenic from healthy controls. The effects of genotype and diagnosis on the imaging phenotype is then analyzed. This analysis is not an association of genotype with diagnosis, but a combined general linear model (GLM) analysis of the effects of genotype, diagnosis, and their interaction, on the quantitative trait of the imaging phenotype. Initial attention in the ordered analysis is focused on a priori selected candidate genes, and followed with a genome-wide analysis, with appropriate significance adjustments for each level of analysis. Replication of results in new samples is essential. This approach combines the advantages of both the genome-wide scans and the candidate gene approach and addresses the concern of false positives in combining imaging and genome-wide scan approaches. Given the known importance of genetics in brain function, and the role of neuroimaging in revealing brain dysfunction, the integration of genetics with brain imaging can enhance our fundamental understanding of disease.

The Founder Contribution to the Old Order Amish of Lancaster County. *T.I. Pollin[1], R. Agarwala[2], A.A. Schäffer[2], A.R. Shuldiner[1,3], B.D. Mitchell[1], J.R. O'Connell[1]* 1) University of Maryland, Baltimore, MD; 2) NCBI, NIH, DHHS, Bethesda, MD; 3) Baltimore VA Medical Center, Baltimore, MD.

We previously confirmed the accuracy and completeness of the genealogical records of the Old Order Amish (OOA) of Lancaster County by analyzing the transmission of Y chromosome short tandem repeat genotypes through male lineages. We now provide a comprehensive analysis of the founder structure and the founders' genetic contribution to the 3,615 individuals (approximately 10% of the Lancaster OOA) who are currently enrolled in our ongoing studies of diabetes, osteoporosis, cardiovascular disease and other conditions at the University of Maryland. Using the Anabaptist Genealogy Database, we constructed a 14 generation pedigree containing 7,499 individuals that connected our 3,615 study subjects through all common paths to their common ancestors. All of these individuals were descended from a total of 275 founders (106 men and 169 women). We measured the average expected genetic contribution of each of the 275 founders to each of the 3,615 descendants and found that 76 founders (31 men and 45 women) accounted for over 95% of the average founder contribution. Each of these 76 founders was a direct ascendant of between 78 and 3598 study participants, with the average expected contribution ranging from 0.2% to 7.8%. All 76 were born in 1867 or earlier, and 69 were born prior to 1800. Only 75 founders were estimated to be born in 1800 or later, and these accounted for only 5% of the founder contribution; the 20 founders born in 1900 or later accounted for 0.5% of the founder contribution and were generally not active members of the Amish Church. The number of female founders (169 total, 45 of the top 76) may be an overestimate due to the difficulty of tracking relationships between women with different married surnames. Further genealogical studies and mitochondrial studies, currently in progress, may reduce the estimate of the number of female founders. These data quantify the extent to which the OOA are a closed founder population ideal for elucidating the role of genetic variation in complex diseases.

CHARACTERIZATION OF AORTIC DISEASE CAUSED BY MYH11 MUTATIONS. *H. Pannu[1], V. Tran-Fadulu[1], S. Scherer[2], R. Gibbs[2], D. Divecha[1], C. Papke[1], Y. Liu[1], S. Duraisamy[1], D. Guo[1], A. Estrera[1], H. Safi[1], A.J. Marian[2], M. Buja[1], D.M. Milewicz[1]* 1) The Univ of Texas Medical Sch, Houston, TX; 2) Baylor College of Medicine, Houston, TX.

Mutations in the smooth muscle myosin heavy chain gene, *MYH11*, have been reported in two families with thoracic aortic aneurysms/dissections (TAAD) and patent ductus arteriosus (PDA). To characterize *MYH11* mutations in familial TAAD, *MYH11* was sequenced in 96 unrelated TAAD probands, including 3 families with TAAD and PDA. Missense mutations in the ATPase head region and the C-terminal coiled-coil domain of MYH11 were identified in 2 families with TAAD/PDA (R712Q, L1264P); no disease causing variants were identified in the other 94 families. Aortic aneurysms in these families involved the ascending aorta distal to the sinuses of Valsalva, unlike aneurysms due to *FBN1*, *TGFBR1*, and *TGFBR2* mutations. Pathologic examination of an aneurysm due to a *MYH11* mutation (no dissection) showed typical loss of elastic fibers and increased proteoglycans. Atypical for TAAs was the observation that smooth muscle cells (SMCs) in the media were in disarray, with cells oriented at oblique angles to each other, similar to cardiac pathology observed for hypertrophic cardiomyopathy (HCM) due to cardiac myosin heavy chain mutations (*MYH7*). Unlike HCM, the SMCs in the mutant aorta were not hypertrophied as assessed by merosin staining. Another atypical finding was that aneurysm was highly vascularized with the vasa vasorum increased in the adventitia and penetrating into the media. Inflammatory CD68+ and CD3+ cells were observed in the initima, adventitia, and periadventitial media. Cytokine/chemokine analysis of aneurysm tissue by organ culture using the Luminex cytokine 25-Plex kit revealed a 5-8 fold increase in macrophage inflammatory proteins (MIP and), confirming inflammation. Increased staining of nuclear phospho-Smad in aneurysm versus control aortas indicated the TGF- pathway was activated. These findings suggest that *MYH11* mutations alter similar molecular pathways as *MYH7* mutations in cardiac tissue in HCM, including disarray of SMCs, increased angiogenesis, inflammation, and TGF- activation.

Haplotype variation and linkage disequilibrium within 36 genomic regions in two Indian language groups. *P.I. Patel[1], T.J. Pemberton[1], J.D. Wall[2], J.K. Pritchard[3], N.A. Rosenberg[4]* 1) Institute for Genetic Medicine and; 2) Department of Biological Sciences, University of Southern California, Los Angeles, CA; 3) Department of Human Genetics, University of Chicago, Chicago, IL; 4) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

We have recently studied variation at 1200 polymorphic loci (729 microsatellite and 471 indel polymorphisms) in 432 individuals from 15 language groups across India. STRUCTURE analysis of these data revealed (i) Indian populations constitute a distinct cluster when compared to 52 other worldwide populations and (ii) despite the vast geographical region surveyed, there was very little genetic differentiation among the Indian language groups. A detailed analysis of haplotype structure and linkage disequilibrium within Indian populations would be useful in guiding the design of disease association studies. Together with similar information from other worldwide populations, such an analysis would also be valuable in the detection of natural selection as well as in inference of the history of migrations to and from India. Towards this goal, we have obtained genotypes at 3024 SNPs in 30 unrelated individuals who were part of the initial genome-wide survey - 15 whose grandparents were Bengali (from W. Bengal) and 15 Tamilians (from Tamil Nadu). The SNPs are spaced across 36 genomic regions, including 32 autosomal regions and 4 regions on the non-pseudoautosomal X chromosome, covering a total of ~12 megabases. To facilitate inferences about both fine-scale and long-range LD, each genomic region contains a central high-density core of 60 SNPs at 1.5 kb average spacing, as well as additional SNPs at lower density outside the core region, extending 120 kb in each direction at 10kb spacing. Hence each region spans a total of ~330 kb. To maximize the degree to which the regions were representative of the human genome, they have been chosen across the range of local gene densities and meiotic recombination rates. Analysis of these data is in progress and will include a comparison to genotypes of the same SNP set in 927 unrelated individuals from 52 populations in the HGDP-CEPH Human Genome Diversity Cell Line Panel.

microRNA Variants in patients with neuropsychiatric disorders. *J. Yan[1], J. Feng[1], K. Noltner[1], C. Katz[1], R. Schroer[2], C. Skinner[2], C.E. Schwartz[2], S.S. Sommer[1]* 1) Dept Molecular Genetics, City of Hope, Duarte, CA; 2) J.C. Self Research Institute, The Greenwood Genetic Center, SC.

MicroRNAs (miRNAs) are small (~18-24 nt) noncoding RNAs that are cleaved from larger (~80 nt) precursors. They negatively regulate gene expression at the post-transcriptional level and play important regulatory roles in animals and plants by targeting mRNAs for cleavage or translational repression. Alterations in microRNAs or target sites for miRNAs may be a significant but unrecognized source of human genetic disease, including psychiatric disorders. To explore the possibility that structural variants in the microRNA genes could predispose to neuropsychiatric disorders, 18 microRNA genes on the X chromosome were scanned in patients with these disorders. We used DOVAM-S (Detection of Virtually All Mutations-SSCP) to scan the precursor genomic region of the 18 microRNA genes on the X chromosome in 216 unrelated patients (96 with schizophrenia; 72 with mental retardation and 48 with autism). Two promising variants and nine other variants were identified. The first promising variant was identified in a patient with schizophrenia. It is a single base substitution at mature miRNA Let-7f-2. This site is highly conserved through C. elegans. This variant is not present in 6,700 controls and 616 patient samples (330 schizophrenia; 149 psychosis; 41 schizoaffective; 96 autism). Another promising variant is a deletion of microRNA hsa-mir-384 in a male patient with mental retardation. While more work is necessary to prove causation, the data herein are consistent with a role for microRNA mutations in the etiology of neuropsychiatric disorders.

Single Gene Transcriptome Analysis of Combinatorially Spliced Calcium Channels. *X. Zhong[1], M.C. Emerick[1], D.A. Hanck[2], W.S. Agnew[1]* 1) Department of Physiology, Johns Hopkins University School of Medicine, Baltimore, MD; 2) University of Chicago School of Medicine,Chicago,IL.

Alternative RNA splicing may greatly diversify the proteome. For a growing number of genes unexpectedly large numbers of variable sites permit combinatorial expression of large arrays of alternative products - mini-transcriptomes, or single-gene transcriptomes (SGTs) -- with mechanistically different proteins expressed in different cells. Single-gene transcriptome analysis, which includes cloning of hundreds or thousands of full-length cDNA products, reveals the inventory of physiological forms, variations in molecular function, and patterns of developmental expression. The human pacemaker calcium channel genes CACNA1G and CACNA1H can potentially generate thousands of alternative transcripts encoding core subunits of multimeric channel complexes. Full-length cloning reveals the expression of scores of functional variants with biophysical differences sufficient to markedly alter neuronal firing. Analyzed at the protein level, some domains alter channel biophysics in modular fashion, while others interact in cooperative ensembles. Combinatorial splicing must thus be regulated in concert and patterns of splicing must be gene specific. Each full-length cDNA constitutes a diary of concerted splicing decisions made in expressing cells. Surveys of full-length cDNA libraries reveal changes in variable domain linkages invisible to microarray tiling methods that identify individual variable sites. Multivariate analyses reveal highly concerted splicing patterns: for CACNA1G, each of 30 human brain reading frames are strongly developmentally regulated. We present a paradigm for the integrated regulation of splicing at multiple sites. Surveys of exonic splicing enhancer and silencer sites (ESEs, ESSs) reveal hundreds of candidate regulatory motifs near both constitutive and alternatively spliced junctions. Mutations of CACNA1H linked to human Idiopathic Generalized Epilepsies include SNPs that alter protein coding and channel gating, and others that alter ESE and ESS patterns, suggesting the relevance of the splicing regulatory paradigm in genetic disease analysis.

Genetic study of a large Chinese motor neuron diseases (MND) family. *Y.Q. Song[1, 2], G.C.Y. Fong[3], W.L. Ho[3], H.H. Kwok[3], C.Y. Chu[3], Y. Li[1], P. Sham[2, 4], S.L. Ho[3]* 1) Dept Biochemistry; 2) Genome Research Centrre; 3) Dept Medicine; 4) Department of Psychiatry, Univ Hong Kong, Hong Kong, China.

We have identified a large multigenerational Chinese family in Hong Kong with motor neuron diseases (MND). So far, we have documented over 130 members and collected 70 DNA in this four-generation family. Most interestingly, a major branches of this family displayed typical ALS, with onset in the 30s to 40s of mixed upper and lower motor neuron degeneration, bulbar dysfunction and rapid progression to respiratory failure. However, a part of this family has been revealed that the hereditary motor sensory neuropathy II (HSMN II, also known as Charcot-Marie-Tooth disease II- CMT2) phenotype. We have screened all five exons of the SOD1 gene for mutations using both single-strand conformational polymorphism (SSCP) and direct nucleotide sequencing methods. A mutation of T/C transition, at I149T in exon 5 was identified and this mutation is thought to affect the formation of dimers in SOD1. This SOD1 mutation was not detected in all affects of the CMT2 branch. We also sequenced for mutations in a known causative gene (mitofusin) to determine whether mutations in this gene were responsible for this neuropathic phenotype (CMT2). No mutations were detected in the CMT2 branch. At the same time, we have done a genome wide screen using the Illumina 5,900 SNP panel. Two suggestive results were detected in the genome-wide survey. One was on the chromosome 15 at 49 cM (NPL score of 1.46), while the other was on chromosome 10 at 165 cM (NPL score of 1.41). We are collecting additional family members for future linkage studies to clarify these results.

Elevated rates of sister chromatid exchange at chromosome ends. *K. Rudd, C. Friedman, E. Linardopoulou, B. Trask* Fred Hutchinson Cancer Res Ctr, Seattle, WA.

Subtelomeres are the transition zones between chromosome-specific sequences and the arrays of telomere repeats at the end of chromosomes. The frequency of inter-chromosomal exchanges at subtelomeres combined with enrichment of markers of double-strand breaks at chromosome ends led us to postulate that subtelomeres might be subject to more double-strand breaks than elsewhere in the genome. Using chromosome orientation fluorescence in situ hybridization (CO-FISH), Cornforth and Eberle (2001) observed an unusually high frequency of sister chromatid exchange (SCE) as compared to harlequin chromosome studies, which they attributed to the terminal ~10 Mb of chromosomes. We designed a series of CO-FISH experiments to measure the amount of SCE in subtelomeres and telomeres of human chromosomes. In normal lymphoblastoid cells, we find 16% of all SCEs occurred within the most distal 100 kb of the chromosome. Analyzing over 1000 chromosomes per experiment, we found that 0.6% of chromosomes have an SCE in the telomere and 1.3% of chromosomes have an SCE in the terminal 100 kb region (subtelomere + telomere). Only 1.6% of chromosomes have an SCE in the distal 10 Mb of the chromosome; thus, the majority of SCE occurs in the subtelomeric and telomeric regions. When the rate of SCE is calculated per basepair for each interval, we find a very sharp reduction in SCE rate with increasing distance from the telomere. The telomere, distal 100 kb (subtelomere + telomere), and distal 10 Mb have rates of ~4000 x 10-9, ~400 x 10-9 and ~4 x 10-9 SCE/bp, respectively. Thus, the terminal 10 kb of a chromosome incurs over 1000 times more SCEs than an equivalently sized interval in the body of the chromosome. We also find evidence of SCE "clustering"; there are more double SCEs per chromosome than expected if SCEs are independent events. The enrichment of SCEs in the subtelomeres and telomeres suggests that either chromosome ends are subject to more double-strand breaks or that they are more likely to be repaired by SCE. These data, coupled with our experiments on subtelomeric inter-chromosomal sequence transfers, suggest that subtelomeres are hotbeds of exchange and DNA repair.

Succinate dehydrogenase deficiency associated with chronic neutropenia. *F. Scaglia[1], A.M. Adesina[2], J.V. Hunter[3], L-J.C. Wong[1]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Pathology, Baylor Col Medicine, Houston, TX; 3) Dept Radiology, Baylor Col Medicine, Houston, TX.

Neutropenia has been previously reported in mitochondrial cytopathies, namely in Barth syndrome (MIM # 302060) and Pearson marrow pancreas syndrome (MIM # 557000). However, it has not been reported in association with succinate dehydrogenase deficiency. We report a 2-year-old Native-American child born to consanguineous parents. The proband presented at 2 months of age with hepatomegaly and cholestasis that eventually subsided. Urine organic acid analysis revealed large amounts of 3-methylglutaconic and smaller amounts of 3-methylglutaric and glutaric acids. Acylcarnitine profile exhibited increases of hexanoylcarnitine and decenoylcarnitine. Global developmental delay, hypotonia and persistent neutropenia were noted at 8 months of age. Bone marrow aspiration and biopsy were done and revealed predominance of early myeloid precursors in bone marrow with significant maturational delay of myeloid series. Episodic treatments with filgrastrim reversed episodes of severe neutropenia. Brain MRI revealed moderate cerebral volume loss, abnormal signal in the globus pallidi and ventrolateral thalami, cerebellar volume loss, and a region of restricted diffusion in the right posterior temporal and occipital lobes. No mutations were found in the coding regions of *G4.5* ruling out Barth syndrome. Mitochondrial DNA mutation analysis in blood did not reveal common point mutations, duplications or deletions ruling out Pearson syndrome. On muscle biopsy, there was increased deposition of glycogen but no mitochondrial abnormalities on electron microscopy. Mitochondrial enzyme assays exhibited significant reproducible deficiency of complex II. The presence of persistent hematological abnormalities in this subject with complex II deficiency demonstrates that neutropenia can be observed in other mitochondrial cytopathies besides Barth syndrome and Pearson syndrome expanding the clinical spectrum of mitochondrial cytopathies. Sequencing of genes encoding subunits of succinate dehydrogenase is ongoing to ascertain the molecular basis of this condition.

X-linked heterotaxy: a disease of the cilia? *S. Ware, S. Wang* Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Abnormal function or assembly of cilia is associated with congenital anomalies including hydrocephalus, neural tube defects, polydactyly, and situs abnormalities. In addition, recent data suggest a requirement for normal cilia function in convergent extension movements during gastrulation and neurulation. Previously we demonstrated that mice with loss of function of Zic3, the gene mutated in X-linked heterotaxy (MIM 306955), have gastrulation defects and situs anomalies consistent with heterotaxy. We further demonstrate that morpholino mediated knock down of Zic3 expression in Xenopus embryos results in convergent extension defects, suggesting ciliary dysfunction. Zic3 is a zinc finger transcription factor member of the Gli superfamily that mediates hedgehog signaling. The data demonstrate that Zic3 and Gli3 synergize to activate transcription in vitro and co-localize in vivo. In addition to its role as a transcription factor, we show that Zic3 can shuttle from the nucleus to the cytoplasm via canonical signaling domains, and localizes to cilia in the node of the early embryo. Further immunohistochemical analyses of node cilia indicate that Gli3 is also present, suggesting that Zic-Gli interactions within cilia of the node may be important for sonic hedgehog signal transduction. Scanning electron microscopy and immunohistochemistry of node cilia in Zic3 null mouse embryos indicate that absence of Zic3 does not disrupt cilia formation, but rather results in abnormal node morphology in approximately 60 percent of null embryos. Node cells are smaller than those of wild type mice and arranged in irregular foci accompanied by disordered peripheral cells. These results suggest that Zic3 contributes to situs determination through regulation of node formation and structure, and indicate a novel role for Zic3 and Gli3 in cilia of developing embryos.

Quantitative in vivo mouse model for evaluating translational bypass therapy: geneticin multi-day response. *C. Yang[1], J. Feng[1], W. Song[1], J. Wang[1], B. Tsai[1], Y. Zhang[1], K.A. Hill[1], K.A. High[2,3], S.S. Sommer[1]* 1) Beckman Res Inst, Molec Gen, City of Hope, Duarte, CA; 2) Department of Pediatrics, university of pennsylvania School of Medicine and Division of Hematology, the children's Hospital of Philadelphia, philadelphia, PA, USA; 3) Howard Hughes Medical Institute, philadelphia,PA,USA.

Aminoglycosides have been reported to suppress nonsense mutations (translational bypass therapy, TBT). Since about 15% of inherited severe genetic disease is due to nonsense mutations and, since there are 20,000 genes in the human genome, the potential of TBT is immense. However, initial results demonstrate the need for more potent or efficacious drugs. In addition, nonsense mediated decay and sequence context effects may be problematic. No quantitative in vivo system is available. We described such a system for quantitating TBT in the presence of and absence of nonsense mediated decay. We demonstrate that geneticin is much more efficacious in vivo than gentamicin. After two doses of geneticin, residual factor IX antigen (two hours half-life) can be detected after three weeks. The mechanism of this dramatic response is unclear. These data demonstrate the utility of the mouse system for evaluating nonsense suppressors in vivo. Geneticin may have utility in the treatment of hemophilia B in developing countries where factor IX replacement is unavailable. Furthermore, geneticin or metabolites should be evaluated as a general treatment of severe genetic disease due to nonsense mutations.

Human somatic microindels. *W.A. Scaringe[1], K. Li[1,3], D. Gu[1], L. Chen[1,3], K.D. Gonzalez[1], K.A. Hill[1,2], S.S. Sommer[1]*
1) Dept Molecular Genetics, City Hope Natl Medical Ctr, Duarte, CA; 2) Department of Biology, The University of Western Ontario, London, ON Canada N6A 5B7; 3) SNP Institute, Nanhua University, Hegyang, Hunan, China.

Little is known about microindels. We present the first analysis of somatic microindels in an endogenous gene in human cancer. P53 somatic microindels were identified in the literature and analyzed in the context of other p53 mutations. 65 of 66 somatic microindels were unique, although an additional 3 pairs showed the same deletion with a similar insertion. Gender and tissue effects were seen ($p = 0.009$ and 0.04, respectively). Analysis of the microindels suggests size distributions and sequence contexts different from pure microinsertions and pure microdeletions. Microindel sequence contexts suggest heterogeneous mechanisms including insertions of nearby, but not directly adjacent, sequence in either the sense or antisense direction. The insertions are sometimes imperfect repeats, indicating an error-prone process. Despite the ascertainment of these p53 indels in cancers, analysis of endogenous microindels in the Human Germline Mutation Database and available somatic microindels in the HPRT gene show general similarities with p53 somatic microindels in cancer. We conclude that microindels are distinct from pure microinsertions and pure microdeletions and occur by heterogeneous mechanisms.

Polymorphisms in the Vitamin D Receptor (VDR) that influence levels of intact parathyroid hormone have pleiotropic effects on bone mineral density and calcification of the coronary arteries and aorta. *E. Rampersaud*[1], *D. McBride*[1], *E. A. Streeten*[1], *A. R. Shuldiner*[1, 2], *B. D. Mitchell*[1] 1) EDN, University of Maryland, Baltimore, MD; 2) GRECC, VAMC, Baltimore MD.

Vitamin D metabolism is critical to bone health, and arguably to cardiovascular health. To assess the impact of sequence variation within the vitamin D receptor (VDR) gene on these outcomes, we genotyped 9 SNPs in VDR and evaluated their associations with bone mineral density (BMD), intact parathyroid hormone (iPTH), and aortic/coronary artery calcification in 940 subjects from large Amish families. BMD was measured by dual energy x-ray absorptiometry (DXA), and calcification by electron beam computed tomography. Linkage disquilibrium (LD) among these SNPs was modest, with pairwise r2 ranging from 0.2 to 0.7. SNP association analyses were performed using a variance components framework implemented in the SOLAR program, which accounts for the relatedness of family members. After adjusting for age, gender and body mass index, two intronic SNPs included in our analyses were significantly associated with iPTH. The homozygous rare TT genotype for rs1540339 was significantly associated with increased levels of iPTH ($p<0.001$) and with decreased aortic artery calcification ($p=0.025$). In contrast, the homozygous rare TT genotype for BSM1 was significantly associated with decreased levels of iPTH ($p=0.025$) and decreased BMD at the ultradistal radius (RUS) ($p=0.021$). In sex-stratified analyses, the FOKI nonsynonymous coding polymorphism was significantly associated with increased coronary artery calcification ($p=0.008$) and increased aortic artery calcification ($p=0.025$) in women only. BSM1 ($p=0.033$) and rs1540339 ($p=0.001$) remained significant for iPTH in the subset of women, but not in men. Our analyses suggest that the VDR BSM1 polymorphism is jointly associated with decreases in both iPTH and RUS, lending support to a pleiotropic effect of vitamin D metabolism. Additionally, rs1540339, which is not in LD with BSM1, is jointly associated with increased levels of iPTH and RUS, and with decreased aortic artery calcification. These findings appear to be particularly pronounced among females in our study.

hnRNP E1 transcriptional and translational regulation profiles. *N. Zhong[1,2], L.R. Huo[1], J.H. Zou[1], M. Yan[1], D. Wu[1], W. Ju[2]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) New York State Institute for Basic Research in Developmental Disabilities.

The hnRNP E1 [heterogeneous ribonucleoprotein E1, also referred to as poly(rC)-binding protein1 (PCBP1) or aCPs] contains three KH domains and is a member of the hnRNP family. The family members are involved in several RNA-related biological processes, such as transcription, pre-mRNA processing, mature mRNA transport to the cytoplasm, and translation. The hnRNP E1 also has been described as regulating initiation of RNA replication and translation. Recent studies have shown that hnRNP E1 may increase the activity of the internal ribosome entry segment (IRES) of Bag-1 mRNA suggesting that hnRNP E1 is essential for IRES function. It was also shown that hnRNP E1, along with hnRNP D and K, have a remarkable binding specificity for the cystosine-block [(CCCTAA)n] repeated motif, which may be involved in telomere functions during cell replication. Furthermore, hnRNP E1 could play a critical role in mRNA processing and transport through interaction with nuclear actin in the hnRNP complex. Our recent study showed that hnRNP E1 is one of the progerin-interactive partner proteins. To study the transcriptional and translational regulation of hnRNP E1, we have investigated the RNAs and proteins profiles at a condition either the endogenous hnRNP E1 has been knocked down with lentiviral vector mediated siRNA or an exogenous hnRNP E1 was overexpressed. RNAs or proteins were extracted from the conditioned cells that had been sorted and cultured. The RNAs were analyzed by hybridization with a microarray chip and the proteins were fragmented with PF2D. As anticipated, differential expression profiles of both RNAs and proteins were obtained in hnRNP E1 knocked down and overexpression cells. These differentially expressed RNA or protein profiles suggested they have been up- or down-regulated by hnRNP E1.

LMNA mutations associated with familial and sporadic cases of dilated cardiomyopathy in Koreans. *K. Song[1], M.-P. Dube[2], J. Lim[1], I. Hwang[3], I. Lee[3], J.-J. Kim[4]* 1) Dept Biochem & Molec Biol, Univ Ulsan Col Medicine, Seoul, Korea; 2) Institut de Cardiologie de Montréal, Université de Montréal, Quebec, Canada; 3) Dept Pathology, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea,; 4) Dept Internal Medicine, Asan Medical Center, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

Dilated cardiomyopathy (DCM) is a disorder characterized by cardiac dilation and systolic dysfunction. So far sixteen genes have been shown to cause autosomal dominant familial dilated cardiomyopathy (FDC). We identified a large Korean family from the Cheju island showing a clear Mendelian inheritance of FDC. A genomewide linkage scan at 9 cM marker density identified a peak multipoint LOD score of 2.82 at D1S195. Haplotyping of the region with 15 additional markers defined a candidate interval that included LMNA, a known candidate gene encoding the lamin A/C. Sequencing of the LMNA exons revealed one missense mutation at C568T (Arg190Trp) in the -helical rod domain of the LMNA gene cosegregating with FDC with conduction-system disease. We found the same mutation in patients of a second Korean family with FDC without conduction-system disease. We then screened 14 sporadic DCM cases showing similar pathology to the familial cases. One had a previously described (Glu161Lys) mutation and two had novel (Glu53Val and Glu186Lys) mutations. Our results suggest that variable genotypes of laminopathy are implicated in not only familial but also considerable proportion of sporadic DCM.

Novel mutations in medium-chain acyl-CoA dehydrogenase gene. *B.Z. Yang, J.H. Ding, L. Sweetman, C.R. Roe* Inst Metabolic Disease, BRI, Baylor Univ Medical Ctr, Dallas, TX.

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common inherited defect of fatty acid oxidation, characterized by episodes of illness in early childhood. The disorder may present after fasting with symptoms resembling Reye Syndrome, coma, hypoglycemia, hyperammonemia, fatty liver, and sudden death. The reported cases show significant phenotypic heterogeneity of MCAD deficiency, even with the same genotype. In this report, two patients with MCAD deficiency have recently been detected by newborn screening . Acylcarnitine levels in dried blood spots were measured by tandem mass spectrometry (MS/MS), which showed highly elevated octanoyl carnitine and decenoyl carnitine, indicating MCAD deficiency. To investigate the molecular aspect, all 12 exons and their flanking intronic sequences were amplified from probands DNA. The PCR products were purified and sequenced. Sequence analysis revealed that both patients are compound heterozygous with a novel mutation 1011_1012ins 13-bp and 385 T>G respectively. These novel mutations were verified by a PCR/restriction test, but were not detected in the normal control subjects. In our group, eighteen unrelated babies with MCAD deficiency were detected by newborn screening and confirmed by mutation analysis. The common mutation 985A>G presented in 69% of all defective alleles. In addition, the patients follow-up had been discussed.

Mutation spectrum in non-ketotic hyperglycinemia. *J. Van Hove[1, 2], G. Scharer[1], E. Spector[1], V. Mahieu[2], E. Schollen[2], G. Matthijs[2], C. Freehauf[1], C. Wilson[3]* 1) University of Colorado at Denver Health Sciences Center, Denver, CO; 2) Catholic University Leuven, Leuven, Belgium; 3) Starship Children's Hospital, Auckland, New Zealand.

Patients with non-ketotic hyperglycinemia (NKH) have mental retardation and seizures. NKH is a disorder of glycine catabolism, characterized by deficient glycine cleavage enzyme activity. This system is composed of 4 peptides, the P, T, H and L proteins. Here we describe the mutational spectrum of patients with proven NKH. Methods: We characterized mutations in 58 patients with proven NKH by direct sequencing of all exons and intron-exon borders of the AMT, GLDC, and GCSH genes. Parental studies identified the phase. To identify deletions in GLDC, we analyzed a set of 6 highly polymorphic markers in the core family, and we used a new quantitative real-time PCR-based method. Results: Mutations were found in the AMT gene in 14 patients (24%), and in the GLDC gene in 40 patients (69%). In 4 patients (5%), most with proven deficient enzyme activity, no mutations were found in AMT, GLDC and GCSH. In AMT, 93% of the alleles were identified. In this gene, 68% of the alleles were missense mutations, with the common R320H accounting for 21% of the alleles. A founder mutation I106T in the Dutch population was associated with a mild phenotype. In GLDC, 95% of the alleles were identified. There were 43 alleles with missense mutations, 9 alleles with nonsense mutations, 11 alleles with splice-site mutations, and 2 small deletions. There was proof of a large deletion in 9 alleles varying in length and position, 6 of them including the 5' site of the gene. Recurring mutations were R515S, A389V, R424X, IVS19-1AG. A common mutation was present in the New Zealand patients. Patients with mutations with known residual activity had milder phenotype. This testing allows confirmation of diagnosis and has been successfully used in prenatal diagnosis. It further aids in the identification of patients affected with a milder disease.

Genetic characterization of the SCN5A gene in Korean patients with Brugada syndrome. *E.J. Seo[1, 2], J.O. Lee[2], K.J. Kim[2], G.B. Nam[3], Y.H. Kim[3], K.H. Han[3], I.S. Park[2,4]* 1) Dept. of Laboratory Medicine, Univ. of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 2) Genome Research Center for Birth defects and Genetic disorders, Asan Medical Center, Seoul, Korea; 3) Dept. of Internal Medicine, Univ. of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 4) Dept. of Pediatrics, Univ. of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Mutations in the cardiac sodium channel gene SCN5A cause various arrhythmia syndromes such as Brugada syndrome and long QT syndrome type 3. In addition, common polymorphisms of the SCN5A gene have been known to alter electrophysiology and S1103Y of them was associated with increased arrhythmia clinically. Therefore, we investigated whether genetic variations of the SCN5A gene implicate in risk of Brugada syndrome. Mutational analysis was performed in the SCN5A gene in sporadic 24 patients with Brugada syndrome by PCR based sequencing method. Nine common polymorphisms (R34C, R481W, S524Y, G552R, H558R, P1090L, S1103Y, R1193Q, V1951L) were genotyped in those patients and 100 healthy controls. We identified only one mutation among 24 patients (4.2%). The mutation was a novel heterozygous missense, c.874G>A:G292S, which was not found in 100 controls. Although H558R, P1090L and R1193Q are frequent in Asians, any common polymorphisms except H558R were not found in Korean population. The allele frequency of H558R was 8.3% in patients and 8% in controls, respectively, which was in Hardy-Weinberg equilibrium and not different between two groups. Our findings suggest that the SCN5A gene might not be the major cause of Brugada syndrome in Korean patients and common SCN5A polymorphisms also rare in Korean population.

Measured genotype analysis of neuropeptide Y levels in early-onset coronary artery disease. *S. Shah[1,2], C. Newgard[3], L. Wang[2], M. Muehlbauer[3], E. Dowdy[1], S. Nelson[2], C. Haynes[2], J. Rombaut[2], G. Ginsburg[5], P. Goldschmidt-Clermont[4], J. Vance[2], W. Kraus[1], S. Gregory[2], E. Hauser[2]* 1) Dept Medicine, Duke Univ Med Ctr, Durham, NC; 2) Center for Human Genetics, Duke University Medical Center, Durham NC; 3) Sarah W. Stedman Nutrition & Metabolism Center, Duke University School of Medicine, Durham NC; 4) Miller School of Medicine, University of Miami, Miami FL; 5) Institute for Genome Sciences and Health Policy, Duke University, Durham NC.

Introduction. We have previously reported linkage and association for NPY gene variants with early-onset CAD in two independent datasets, with stronger association seen in very early-onset CAD. We hypothesized that NPY and NPY receptor gene variant alleles and genotypes are associated with quantitative differences in NPY levels.

Methods. We identified 74 cases with very early-onset CAD (age-of-onset <38) and 74 sex- and race-matched controls with no CAD (age>60), from subjects undergoing cardiac catheterization. NPY and NPY receptor single-nucleotide polymorphisms (SNPs) were genotyped using Taqman. NPY levels were measured from fasting frozen whole blood collected at time of catheterization. Samples were assayed for NPY using a commercial RIA kit. Counts were measured with a Wallac Wizard 1470 automatic gamma counter. NPY concentration was determined as the average of two replicates, calculated relative to calibrated standards. Measured genotype analysis with ANOVA was used to assess significance in differences in NPY levels, by multiple NPY and NPY receptor SNPs.

Results. NPY SNPs previously shown to be associated with early-onset CAD were not associated with NPY levels. A rare NPY SNP showed a trend for association (p=0.06). However, two NPY1R SNPs were associated with differential NPY levels (rs1574637, p=0.02 and rs4518200, p=0.05).

Conclusions. NPY receptor, but not NPY, gene variants are weakly associated with quantitative differences in NPY levels. Further studies of the NPY pathway in early-onset CAD are ongoing.

Association study of conserved variants in MME with late-onset Alzheimers Disease (LOAD). *F. Zou[1], M. Raam[1], L. Ma[1], J. Lok[1], S.G. Younkin[1], M.M. Carrasquillo[1], L.H. Younkin[1], N. Graff-Radford[1], R.C. Petersen[2], S.G. Younkin[1]*
1) Mayo Clinic, Jacksonville, FL; 2) Mayo Clinic, Rochester, MN.

MME, which encodes the A degrading enzyme neprilysin, is an excellent functional candidate gene for late onset Alzheimers Disease (LOAD). To identify MME variants likely to be functional, we screened publicly available databases for variants in conserved regions (>70% human vs. mouse) and identified 22 SNPs with minor allele frequencies >1%. While using DHPLC to investigate a known variant, we discovered an additional novel SNP in exon 1 that converts methionine to valine. Using logistic regression, 6 SNPs have so far been tested for association with LOAD in a combined set of three case/control series with a total of 1524 AD patients and 2125 controls between the diagnosis ages of 60 and 85. When the 6 single variants were tested in an allelic dosage model, three had p values 0.028, 0.098, and 0.002 in the combined series, and all three were found in one haplotype block. The most significant (p=0.002) was the previously unreported coding SNP (met/val) in exon 1. These three SNPs formed 4 haplotypes. In the combined series, the four haplotypes showed significant association (global p=0.007). This association was primarily due to the haplotype marked by the novel coding SNP, which showed replicable association in each of the three case/control series with ORs of 1.8 -2.4 and p values of 0.068, 0.028, and 0.016. In the combined series, the OR for this haplotype was 1.8 (1.3-2.5) with a p value of 0.001. Of the three remaining haplotypes, two showed no evidence for association and the third showed suggestive association in the combined series with an OR of 0.89 (0.77-1.03) and a p value of 0.116. In the combined series, the multilocus genotypes formed by the three MME SNPs also showed significant association (global p = 0.024). PLAU and IDE, two other genes that encode proteins involved in A degradation, also have susceptibility alleles for LOAD (see Carrasquillo et al., these meetings).

Genome-wide Scan of Factors for the Metabolic Syndrome in Non-diabetic Hong Kong Chinese. *C.H.T. Tam, M.C.Y. Ng, V.K.L. Lam, J.C.N. Chan* Department of Medicine & Therapeutics, The Chinese University of Hong Kong, Shatin, Hong Kong.

Recent studies suggest shared genetic factors contribute to different components of metabolic syndrome (MES). The aim of this study was to identify loci contributing to the factors of MES derived from principal component factor analysis.

Factor analysis on 15 MES-related traits yielded 6 factors accounting for 77% of the total variance of the original variables. These included adiposity factor (body mass index, waist circumference and body fat percentage), glucose factor (glucose at OGTT for 0, 30 and 120 min, insulin at 120 min), insulin factor (insulin at OGTT for 0, 30 and 120 min), blood pressure factor (systolic and diastolic blood pressure), TC+LDL factor and TG+HDL factor. Variance component-based linkage analyses on these factors were conducted with 355 microsatellite markers on 797 non-diabetic subjects ascertained through 179 families participating in the Hong Kong Family Diabetes Study.

Significant evidence for linkage of the adiposity factor was found on chromosome (chr) 1 at 189cM (LOD = 4.30). In addition, suggestive evidence for linkage (LOD = 2.51-3.12) were observed for adiposity factor (chr 11 at 33 cM), glucose factor (chr 7 at 155 cM), insulin factor (chr 5 at 21 cM, chr 11 at 142 cM) and TG+HDL factor (chr 7 at 155 cM). In summary, our findings suggest the presence of susceptibility loci that influence either single (chrs 1, 5 and 11) or multiple factors (chr 7) for metabolic syndrome in non-diabetic Hong Kong Chinese.

A Structurally Abnormal X Chromosome with a Neocentromere in a Girl with Mosaic Turner Syndrome. *B.T. Wang[1], P.E. Warburton[2], F. Cheung[2], X.J. Yang[1], M. Ayad[1], F.Z. Boyar[1], M. El Naggar[1], C. Zapata[1], J. Neidich[1], B. White[1], A. Anguiano[1]* 1) Cytogenetics Dept, Quest Diagnostics,Nichols Inst, SanJuanCapistrano, CA; 2) Department of Human Genetics Mount Sinai School of Medicine, NY.

Neocentromere is a rare human chromosomal aberration where a new centromere has formed in a previously non-centromeric location. We report the finding of a structurally abnormal X chromosome with a neocentromere in a 15 year-old girl with clinical features suggestive of Turner syndrome including short stature and primary amenorrhea. G-banded chromosome analysis revealed a mosaic female karyotype involving two abnormal cell lines. One cell line (84% of analyzed metaphases) had a structurally abnormal X chromosome with duplication of the long arm and deletion of its short arm, and a normal X chromosome. The other cell line (16% of cells) exhibited monosomy X. C-banding studies were negative for the abnormal X. FISH analysis revealed lack of hybridization of the abnormal X chromosome with both the X centromere-specific probe and the all human centromeres probe, a pattern consistent with lack of the X chromosome endogenous centromere. FISH study using XIST gene probe for detection of the XIST gene on the abnormal X chromosome and R-banding for evaluation of X-inactivation status are underway. An assay for centromeric protein C (CENP-C) was positive on both the normal and the abnormal X chromosomes. The position of CENP-C in the abnormal X chromosome defined a neocentromere, which explains its mitotic stability. The karyotype is thus designated as 46,X,neo(X)(qterq12::q12q21.2neoq21.2qter)[42]/45,X[8], which is consistent with stigmata of Turner syndrome. The mother of this patient has a normal karyotype; however, the father was not available for study. Over 75 examples of human neocentromeres have been described. To our knowledge this is the second example of an analphoid X-derived chromosome with a proven neocentromere.

Improved Detection of Genomic Disorders: Will Denser Arrays Identify New Syndromes? *T.H. Shaikh[1], L. Medne[1], D. McDonald-McGinn[1], S. Saitta[1], C. Bonneman[2], E.H. Zackai[1]* 1) Div. of Human Genet; 2) Div. of Neurology, Children's Hosp Philadelphia, Phila., PA.

Microdeletions and microduplications are a leading cause of genomic disorders. Many of these rearrangements are submicroscopic and not detectable by standard clinical tests like karyotype analysis and subtelomeric FISH. Microarray-based analysis of copy number alterations has recently gained widespread usage for the detection of genomic rearrangements. We have successfully used high-density, oligonucleotide arrays for the detection of copy number aberrations. In our study we analyzed 62 patients with multiple congenital anomalies and normal karyotypes and subtelomeric FISH results. We detected de novo copy number alterations in 16 (26%) cases. These include microdeletions and microduplications in chromosomes 1p, 1q, 2p, 3p, 6q, 7q, 10q, 15q, 16q, 17p and 22q, ranging in size from 600 Kb to 10 Mb. Most of these rearrangements are novel and do not overlap with previously characterized genomic disorders or syndromes. It is possible that some of these novel rearrangements detected in our study represent a new genomic disorder or syndrome in which a rearrangement can be associated with a specific spectrum of phenotypic features. This is exemplified by one of our cases, CH-217, a twelve year old boy with a history of developmental delay, short stature, hypotonia and obesity. He had a normal karyotype and although his phenotype resembled Prader-Willi syndrome, no aberrations were detected in 15q by FISH and DNA methylation testing. We detected a 10 Mb deletion in 6q16-q21 using our approach. This is the fifth reported case of a Prader Willi-like phenotype associated with aberrations in 6q. Thus, it is likely that these cases represent a new 6q16-q21 deletion syndrome. We expect that new genomic disorders will be identified in the future as a result of improvements in detection techniques, in the form of higher density arrays and analysis tools, combined with the clinical characterization of associated phenotypic features. The creation and maintenance of a comprehensive, public database of rearrangement-based disorders should further improve our ability to identify new syndromes.

Multiplex Genotyping by Small Amplicon Melting and Unlabeled Probes: Application to HFE Genotyping. *R.J. Pryor, C.T. Wittwer* Pathology, University of Utah, Salt Lake City, UT.

Simple methods of genotyping by melting analysis without labeled probes have recently appeared. Small amplicon genotyping requires only two PCR primers and a generic DNA dye. Unlabeled probe genotyping incorporates an additional 3-blocked unlabeled probe. Small amplicon and unlabeled probe genotypes can be extracted from the same melting curve after multiplex PCR. This combined method was applied to genotyping all common alleles of the HFE gene (HLA-H). Mutations in the HFE gene are responsible for hereditary hemochromatosis, an autosomal recessive disorder of iron metabolism.

PCR was performed on a LightCycler (Roche) and an HR-1 (Idaho Tech.) was used for high resolution melting analysis. The dsDNA fluorescence dye LCGreen Plus (Idaho Tech.) was used to monitor PCR amplification and subsequent melting analysis. The PCR reaction used two primer sets. One amplicon incorporates H63D and S65C and the other C282Y. The unlabeled probe covers the H63D mutation and T189C polymorphism but does not span the S65C site. An unlabeled probe is needed to genotype the H63D site because a C is exchanged for a G which, due to nearest neighbor parameters of that particular sequence, makes the Tm of the homozygous mutant the same as wild type.

There are three main mutations associated with hemochromatosis: C282Y (G845A), H63D (C187G) and S65C (A193T). There is also a polymorphism, T189C which is a wobble at the third base of a histidine codon. The nine most common genotypes of HFE were all differentiated, including wild type, homozygotes for C282Y and H63D, heterozygotes for C282Y, H63D, S65C and T189C and the compound heterozygotes C282Y/H63D and H63D/S65C. Multiplex genotyping by melting of small amplicons and unlabeled probes is simple, inexpensive, and rapid. Regions of considerable sequence variation can be genotyped in a single color, closed-tube system by rapid PCR followed by high-resolution melting analysis.

High prevalence of IVS14+1G>A mutation in the *AAAS* (Allgrove Syndrome) gene among Puerto Rican newborns. *M.C. Schneider[1], P.J. Santiago Borrero[2], A. Morales Reyes[2], S. Ireland[1], A. Shouse[1], R.G. Leon[1]* 1) SIU Dept Ped, Div Gen/Metabol, SIU Sch Medicine, Springfield, IL; 2) Department of Pediatrics, University of Puerto Rico School of Medicine, San Juan, Puerto Rico.

Allgrove syndrome (MIM 231550) is an autosomal recessive entity initially described with the cardinal signs of achalasia, alacrima, and ACTH-resistant adrenocortical deficiency (hence also called Triple-A syndrome). The phenotype is broader; patients often show mild growth failure and slowly progressive neurologic and autonomic dysfunction, including mental retardation, hypotonic hyperreflexic spasticity, optic nerve atrophy, and autonomic dysfunction. It had been noted that 6/8 cases identified in the United States occurred in individuals with Puerto Rican ancestry, and a single IVS14+1G>A mutation in the AAAS gene accounted for over 80%; of the Allgrove alleles in this population. Using site-specific PCR followed by restriction digest, the presence of this mutation was assayed among 972 independent island-wide blood spot samples, and seventeen heterozygote carriers were found. Unlike other recessive conditions such as Hermansky-Pudlak, which are restricted to mainly to certain towns, carriers for Allgrove were distributed throughout the island and the major metropolitan areas. Heterozygote frequency is estimated to be 1 in 57 in Puerto Rico, which predicts that 1 in 13,000 newborns are affected. In our experience, the condition is underdiagnosed, and can lead to early demise. Since the prevalence of affected exceeds that of other entities screened among newborns, and treatment of the adrenal failure can prevent death, we recommend either universal newborn or carrier screening for this entity should be assessed among individuals of Puerto Rican descent.

Genetic services in satellite clinics: A model of delivery in three different communities. *N. Stewart[1], B. Crawford[1], R. Lee[1], J. Mak[1], P. Conrad[1], M. Beattie[1], J. Luce[3], J. McLennan[1], J. Ziegler[1], V. Caggiano[2]* 1) Cancer Risk Program, University of California San Francisco Comprehensive Cancer Center, San Francisco, CA; 2) Cancer Risk Program, Sutter Cancer Center, Sacramento, CA, United States, 95816; 3) Division of Hematology-Oncology, San Francisco General Hospital, San Francisco, CA, 94110.

Genetic counseling services are routinely offered in Comprehensive Cancer Centers, but are less available in community cancer centers and county hospitals. Barriers include lack of insurance coverage, funding, trained counselors, and language and cultural differences. The Cancer Risk Program (CRP) at the University of California San Francisco (UCSF), began offering genetic counseling, testing and 20 year follow up in 1996 through a clinic based research protocol, serving primarily insured families of high socioeconomic status. To reach underserved populations, the UCSF CRP expanded services by partnering with Sutter Cancer Center (SCC), a community cancer center 90 miles away, and with San Francisco General Hospital (SFGH), a county hospital serving a low income multi-ethnic population. Financial barriers for low income families were removed though scholarship funds at UCSF and SCC and Avon Foundation grant support at SFGH. A total of 1451 patients enrolled in the protocol and tested for BRCA1/2 with mutation detection rates of 20-26% at all three clinics. Patients and their families were provided with current, evidence-based recommendations for surveillance and protocols for prophylactic surgeries in mutation carriers. Patients identified at SCC and SFGH were more likely to choose both mastectomy and oophorectomy, whereas carriers at UCSF were evenly split between oophorectomy alone and oophorectomy and mastectomy. Prophylactic surgery has been shown to reduce the incidence of breast and ovarian cancer in these high risk populations, therefore there is a greater need to identify high risk families of all ethnicities, education levels, and geography. This outreach model of satellite clinics provides the benefits of a clinical research program with multidisciplinary long-term follow up care to underserved and/or distant populations.

Genetic analysis of large four generation families with idiopathic adolescent scoliosis. *K. Ward, M.C. Meade, L.M. Nelson, V. Argyle, T. Berry, S. Murphy, J. Braun, J.W. Ogilvie* Axial Biotech, Inc, Salt Lake City, UT.

Our aim was to study the genetics of adolescent idiopathic scoliosis (AIS) in large Utah families. Four-generation pedigrees were obtained from 85 probands. 83/85 probands were surgically treated. In 69 of the 85 families, probands reported a positive family history of AIS within the 4 generations. AIS was confirmed in these 69 probands and in 174 affected relatives either by x-ray(n=107) or medical records(n=136). An additional 53 female and 18 male relatives were reported to have scoliosis, but the diagnosis was unconfirmed for these patients. 21 family members had other spinal deformities (12 females, 9 males). Females tended to have more severe curves;female:male ratio for the confirmed AIS cases is 3.8:1.

	Cobb Angle	Total Aff	Female	Male	%ParentAff	Mat Trans	Pat Trans
Severe	>40	91	83(91%)	8(9%)	22(24%)	56(62%)	27(30%)
Moderate	25-39	36	30(83%)	6(17%)	9(25%)	19(53%)	13(36%)
Mild	10-24	116	79(68%)	37(32%)	24(21%)	64(55%)	36(31%)
Unknown	Various	71	53(75%)	18(25%)	9(13%)	25(35%)	14(20%)
Total		314	245(78%)	69(22%)	64(20%)	164(52%)	90(29%)

Excluding probands; assuming AD inheritance, penetrance in females was 55%. Penetrance in males is 21%. There were 18 reported instances of male: male transmission (confirmed diagnoses in both males for only 2 of these). Four probands reported scoliosis in both parents families. Conclusions: This study confirms the familial nature of adolescent idiopathic scoliosis and expands our understanding of the genetic parameters.

Abnormalities in endochondral bone development in the Apert syndrome mouse model. *Y. Wang, M. Sun, F. Yang, S.A. Shulby, J. Elisseeff, D.L. Huso, E.W. Jabs* Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD.

Fibroblast growth factor receptor 2 (FGFR2) plays an important role in skeletogenesis. FGFR2 S252W and P253R mutations are associated with Apert syndrome, an autosomal dominant disorder characterized by bone malformations of the skull and limbs. We created $Fgfr2^{+/S252W}$ and $Fgfr2^{+/P253R}$ heterozygous mice with craniofacial and skeletal defects that mirror the human Apert syndrome to study bone development in this condition. Previously, we reported the effect of these mutations on membranous bone. However, the effect of these mutations on endochondral bone formation is not well understood. Therefore, we studied the developing limbs of our mutant mice and littermates from E15.5 to P0. Histological analysis of mutant long bones revealed abnormal endochondral bone formation with disorganization of the growth plate, subtle irregularity of the hypertrophic zone, and more prominent cartilage mineralization of the ossification zone. TRAP staining showed a reduction in osteoclast number at the chondro-osseous junction of the growth plate, indicating a defect in recruitment of osteoclasts to the hypertrophic region. In situ hybridization of Col X revealed an abnormality in hypertrophic chondrocytes in the mutant growth plate. Alteration of expression of Mmp13, osteopontin and osteocalcin suggests abnormal cartilage matrix remodeling and osteoblast differentiation in the mutants. In vitro 3D hydrogel culture of osteoblasts isolated from the long bones of newborn mutant mice showed increased expression of osteoblastic markers collagen type I, bone sialoprotein and osteocalcin. Apert cells also demonstrated higher expression of Col X as compared to the controls. These in vitro results are consistent with our in vivo findings. The $Fgfr2^{+/P253R}$ heterozygous mice showed similar or less severe abnormalities and gene expression patterns of osteoblastic markers compared to those of $Fgfr2^{+/S252W}$mice, suggesting no clear genotype-phenotype correlation. Our data reveal that these two Fgfr2 gain of function mutations result in dysregulation of chondrocyte differentiation, cartilage extracellular matrix remodeling, and osteoblast differentiation during endochondral ossification.

Detection of mosaicism in pooled human genomic DNA by bi-directional pyrophosphorolysis activated polymerization allele-specific amplification. *J. Shi, Q. Liu, S. Sommer* Department of Molecular Genetics and Molecular Diagnosis, City of Hope National Medical Center, Duarte, CA.

The incidence of mosaicism is not well characterized. The frequency of mosaic mutations may be underestimated, because they are often missed during routine mutation analysis. Bi-PAP-A (Bi-directional Pyrophosphorolysis Activated Polymerization Allele-specific Amplification) is a derivative of PAP that uses two opposing pyrophosphorolysis activable oligonucleotides (Sleeping Beauties) with one nucleotide overlap at their 3 termini. Bi-PAP-A may amplify one copy of the mosaic mutation in the presence of 10^7~10^9 copies of wild type genome without any false positives. For large scale screening, six Bi-PAP-A assays with sensitivities of one molecular and selectivities equal to or greater than one part in 10^8 were utilized to detect somatic mosaicism in the *TP53* gene. Eight pooled DNA samples were initially screened, each containing 4 x 10^5 genome copies (1.3 g of genomic DNA). Each pooled sample contained human blood genomic DNA from 400 individuals. Positive samples were characterized further to identify the positive individual(s). Putative somatic mosaicism was detected. Bi-PAP-A can be utilized to estimate the frequency of somatic mosaicism for cancer predisposing somatic mutations in the *TP53* gene.

Rapid Analysis and Visualization of Genomewide Association Data with GWAVA. *J.E. Wigginton, G.R. Abecasis*
Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

The advent of the genomewide association (GWA) scan is clearly a watershed event for the field of complex disease mapping. While the opportunities presented by these data sets are considerable, sifting through and analyzing the enormous volume of data generated in a typical GWA scan will be a significant challenge and a barrier to success for many groups. Although a few existing software tools will be capable of handling GWA, most were not specifically designed for this purpose and will not be very efficient.

GWAVA (Genome-Wide Association Visual Analyzer) is an extensible software platform tailored to the unique computational and data storage requirements of GWA data sets. In addition to basic quantitative and qualitative tests of association, GWAVA implements a highly efficient EM algorithm for haplotype frequency estimation in SNP data with or without missing genotypes, and can use the resulting estimated haplotypes to test for association between genetic markers and one or more phenotypes using a linear model (for quantitative traits) or a logistic regression model (for discrete traits). GWAVA can execute quality control checks and incorporates a very rapid exact test of Hardy-Weinberg equilibrium. GWAVA can be run either as a command-line tool in batch mode or via a modern graphical user interface. The latter allows the user to interactively search, sort and filter data and analysis results, presenting raw data in table format and/or a variety of useful graphical summaries. Further information for individual tests or markers of interest may also be displayed with a simple mouse click, which will facilitate interpretation of results without presenting large volumes of extraneous information. GWAVA is specifically designed for rapid data input and output, is capable of handling large data sets with hundreds of thousands of markers on thousands of individuals, and balances computational efficiency with memory usage for graphics and analysis results. Source code, a tutorial and executables for Windows, Mac, UNIX, and Linux platforms are freely available at http://www.sph.umich.edu/csg/abecasis/gwava.

Genome-wide linkage scan for primary open angle glaucoma (POAG) loci in a Caucasian population. *A. Woodroffe[1], C.M. Krafchak[2], M. Soehnlen[1], N. Fuse[2], P.R. Lichter[2], S.E. Moroi[2], R. Schertzer[2], C.A. Downs[2], M. Boehnke[3], J.E. Richards[1,2]* 1) Dept Epidemiology, University of Michigan, Ann Arbor, MI; 2) Dept Ophthalmology, University of Michigan, Ann Arbor, MI; 3) Dept Biostatistics, University of Michigan, Ann Arbor, MI.

Glaucoma is characterized by neurodegeneration of the optic nerve, resulting in visual field loss and, if untreated, can lead to blindness. Over 60 million people world-wide are affected by glaucoma. Glaucoma has a strong genetic component. In addition to increased age, increased intraocular pressure (IOP), thin central cornea, and race, family history is one of the strongest risk factors for developing glaucoma. Several genes predisposing to glaucoma susceptibility have been identified, however these genes account for only a small proportion of glaucoma cases. Therefore, it is likely that more glaucoma genes will be mapped. To identify novel glaucoma loci, we conducted a genome-wide linkage scan on 25 multiplex, Caucasian families with primary open angle glaucoma. We included 167 individuals; 108 are affected. We tested 378 microsatellite markers across the genome, resulting in an average coverage of 7 cM. Preliminary results suggest a maximum multipoint non-parametric LOD (NPL) score of 2.0 at 176.2 cM on chromosome 4q and a maximum singlepoint NPL score of 2.6 at the same location. There was also modest evidence for linkage on 5p and 7p. We are following-up our results using microsatellites to fine-map the regions of interest.

Genome-wide search for linkage interactions: application to schizophrenia. *J. Shi[1], F. Amin[2], D.W. Black[3], N.G. Buccola[4], W.F. Byerley[5], C.R. Cloninger[6], R. Freedman[7], B.J. Mowry[8], J.M. Silverman[9], P.V. Gejman[10], D.F. Levinson[1]* 1) Stanford University, Stanford, CA; 2) Emory University, Atlanta, GA; 3) University of Iowa College of Medicine, Iowa City, IW; 4) School of Nursing, LSUHSC, New Orleans, LA; 5) UCSF, San Francisco, CA; 6) Washington University, St. Louis, MO; 7) University of Colorado School of Medicine, Denver, CO; 8) Queensland Center for Mental Health Research, Brisbane, Australia; 9) Mt. Sinai School of Medicine, New York, NY; 10) ENH/Northwestern University, Evanston, IL.

In common complex disorders, epistatic interactions among susceptibility genes are likely, but each locus could have an effect too small to be detected by linkage analysis. Therefore, it may be useful to search for interactions among loci. Here we do this with a score statistic, using genome scan data for 280 affected sibling pairs (ASPs) from 263 European-ancestry families (Molecular Genetics of Schizophrenia study, Suarez et al., AJHG 2006;78:315-33). For each ASP, IBD was computed (GENEHUNTER 2.1, multipoint analysis) at each autosomal marker location (N=385). We tested each pair of marker positions in the genome except pairs on the same chromosome. Z was computed for each marker pair, by taking the sum (across all ASPs) of [IBD(marker1)-1][IBD(marker2)-1], divided by the S.D. of the numerator. Interactions were considered distinct if they were separated by at least 36 cM (4 times the average inter-marker distance) on at least one chromosome. The four largest Z-scores (with marker locations in deCODE cM, and the SZ meta-analysis bin from Lewis et al., AJHG 2003;73:34-48, if it was significant) were: 4.13 (D2S405/44cM, D10S2325/29cM in bin 10.1); 3.97 (D5S1457/59cM, D19S245/49cM); 3.94 (D4S1647/92cM, D11S912/122cM in bin 11.5); and 3.84 (D10S2327/97cM, D12S1294/72cM). None of these interactions achieves genome-wide significance based on preliminary simulation studies. Computation of exact empirical significance levels is in progress. These results are exploratory, but they demonstrate the feasibility of this approach, which could prove useful for larger scans or for meta-analyses of multiple scans.

Identification of mouse miRNAs expressed exclusively or preferentially in retina. *P. Witmer[1], S. Xu[2], J. Mendell[1], D. Valle[1,3]* 1) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Dept Ophthalmology/Neurological Sciences, Rush Univ Medical Ctr, Chicago, IL; 3) Howard Hughes Medical Institute.

MicroRNAs (miRNAs) are small non-coding RNAs about 22 nucleotides in length found in all metazoans. Since their discovery in 1993, at least 100 different miRNA genes have been recognized in the Drosophila and C. elegans genomes and about 300 in vertebrate genomes. miRNAs have been shown to provide a newly-recognized level of regulation of gene expression potentially important in a wide variety of biological processes. In spite of this progress, little is known about the miRNAs and their roles in the development and function of vertebrate retina and in retinal diseases. To investigate miRNA expression in retina, we purified miRNA-enriched total retinal RNA from adult mice and performed miRNA profiling using Combimatrix miRNA microarray of our design that includes 323 miRNAs and their precursors. To discover the miRNAs expressed exclusively or preferentially in retina, we used adult mouse brain and heart miRNA-enriched total RNA for comparison. Our result showed at least 75 miRNAs are expressed in mouse adult retina at various levels. Among these 23 were expressed preferentially or exclusively in retina including a cluster of 3 miRNA genes in a 4.5 kb intergenic region on mouse chromosome 6q3.3 (corresponding to human chromosome 7q32.2). These are among the highest in terms of expression level and appear to be specific for retina. We confirmed the tissue specificity of the major retina-specific miRNAs with quantitative RT-PCR. To determine if miRNAs are involved in the circadian cycles characteristic of retinal gene expression, we performed miRNA profiling with retinal RNA harvested at noon and midnight and identified a subgroup of miRNAs with diurnal variation in expression pattern. These miRNAs are candidates for involvement in the regulation of the circadian cycle and rhythmic metabolism of retina. Currently we are examining the predicted targets of the retina-specific miRNAs and performing functional studies to determine their role in normal development of retina and circadian cycle regulation.

Mitochondrial DNA polymorphisms in the Amerindian: Tarahumara, Huichol, and Purépecha, and in one Mestizo Mexican population. *L.. SANDOVAL-RAMÍREZ[1,2], M.T. MAGAÑA-TORRES[1,2], M. CASAS-CASTAÑEDA[2], J.M. OLIVA-ORTIZ[1,2], G. VACA[1,2], F. RIVAS[1,2], J.M. CANTÚ[2]* 1) División de Genética, CIBO, IMSS, Guadalajara, MÉXICO; 2) Doctorado en Genética Humana, CUCS Universidad de Guadalajara, Guadalajara, MÉXICO.

OBJETIVE: To describe and compare mtDNA haplotypes among Mexican populations: Mestizo of the West, Tarahumara, Huichol and Purépecha. METHODS: mtDNA of 200 unrelated individuals was analyzed; 50 Mestizos from Western Mexico and 150 native of the three American ethnic groups: 50 Southeastern of Chihuahua Tarahumaras, 50 North of Jalisco and East of Nayarit Huicholes and 50 lake region of Michoacan state Purépechas. Twenty-one polymorphic sites were analyzed using the PCR-RFLP technique. First, the haplogroups A, B, C, D and M were identified. The samples that the origin of their mitocondrial haplotype could not be identified, 12 additional polymorphic sites and the sequenciation of the HVI region were analyzed with the purpose to assign them to some of the following haplogroups: X (European-American); H, I, J, K and U (European), L (African) and F (Asian). RESULTS: In 200 samples, 15 different haplotypes were identified by the analysis of nine ethnic-specific polymorphic sites. This allowed the assignation of the haplogroups A, B, C and D in 188 samples. The distribution in the mestizo population was: A(34%),B(24%),C(10%),D(10%)and A/B (4%),in Tarahumara: A(12%),B(30%),C(54%) and D(2%),in Huichol: A(46%),B(26%),C(26%)and D(0%)and in Purépecha: A(44%),B(24%),C(18%),D(0%),A/D(6%)and C/D(6%). Twelve samples did not pertained to the haplogroups A,B,C and D(nine Mestizos, one Tarahumara, one Huichol and one Purépecha). Eight Mestizos were assigned to European haplogroups H, K and U. Haplogroup X was not observed among these four populations, and a high number of compound haplotypes (12%) was present in the Purépecha population. CONCLUSIONS: mtDNA was of Amerindian origin in its majority (82% Mestizos and 98% Tarahumaras, Huicholes and Purépechas). The genes flow of European origin that conform the cluster of Mexican pool genes came through males. There was no evidence of maternal African component in this population sample.

Loss of Y chromosome in patients with hematological disorders. *E. Shin[1], L. Zhang[3], Z. Yu[2], H. Tian[2], Y. Fei[2], R. Aldrich[2], J.J. Mulvihill[2], S. Li[2]* 1) Department of Pediatrics, OUHSC, Oklahoma City, OK; 2) Department of Pathology, OUHSC, Oklahoma City, OK; 3) Department of Hematology, the First Teaching Hospital of China Medical University, Shenyang, P.R. China.

To investigate whether a loss of Y chromosome is an age related phenomenon or a cytogenetic marker indicating a malignant change, we have studied twenty-four patients with a median age of 73 years-old (range 41-87) from a cohort of 592 consecutive male patients referred to us for chromosome evaluation because of hematological disorders. Two patients had acute myeloid leukemia (AML), 2 patients had chronic myeloid leukemia (CML), 2 patients had chronic myeloproliferative disorder (MPD), 3 patients had multiple myeloma, 5 patients had lymphoma, and 10 patients had myelodysplastic syndrome (MDS). Conventional cytogenetics studies were carried out according to our standard laboratory protocols. Fluorescence in situ hybridization (FISH) analysis was also performed utilizing DNA probes specific for the centromeres of chromosomes X and Y. The probes were purchased from a commercial source (Vysis, Downers Grove, Illinois, USA) and the tests were performed according to the manufacturer's protocols with minor changes. Twenty-one out of 24 patients had a loss of Y chromosome as sole anomaly and the remaining three had a loss of Y chromosome accompanied with other structural changes by conventional cytogenetic analysis. FISH analysis confirmed the routine cytogenetic results. All 24 patients had a loss of Y chromosome with a range of 17.5-98.5% of cells. Two of the patients one with AML and another with CML, had karyotype and FISH testing done both at the initial diagnosis and in the remission, and showed a loss of Y chromosome at initial diagnosis and had normal 46,XY karyotype during remission. In this study, it is demonstrated that the loss of Y chromosome is associated with a neoplastic change.

EGFR somatic mutations in lung cancer: of microindels, smoking and drug response. *S.S. Sommer[1,2], W.A. Scaringe[1,2], K. Li[1], J. Saldivar[1], K.A. Hill[1], Z. Chen[1], K.D. Gonzalez[1,2], D. Gu[1,2]* 1) Dept Molecular Genetics, City of Hope National Medical Center, Becker Research Inst, Duarte, CA; 2) Clinical Molecular DIagnostic Laboratory (CMDL), Department of Molecular Diagnosis, City of Hope National Medical Center, Duarte, CA.

We created an EGFR Molecular Epidemiology Database website that curates somatic EGFR mutations in non-small cell lung cancer (NSCLC) and associated epidemiological and methodological data including response to the tyrosine kinase inhibitors Gefitinib and Erlotinib. Herein, we analyze 809 mutations collected from 26 publications. The EGFR mutations are consistent with strong biological selection for gain of function. Four super hotspots account for 70% of reported mutations while two-thirds of 132 unique mutations have occurred only once, yet these single reports account for only 11% of reported mutations. The mutations are missense or in-frame microdeletions or microinsertions, consistent with gain of function mutations. Microdeletions and microindels are common in a small region of exon 19. Microdeletions are predominantly in-frame and delete 15 or 18 bp. Microindels, which account for 8% of mutations, have smaller inserted sequences (95% are 1 to 5 bp) and are elevated 16-fold relative to mouse somatic mutations and to human germline mutations in the Human Gene Mutation Database (HGMD). The 1-2 microindel commonly observed in mouse somatic mutations, human p53 somatic mutations and human germline mutations (HGMD) was NOT observed in EGFR. EGFR mutations in smokers DO NOT carry signatures of mutagens in smoke. Microdeletions/microindels are more frequent in responders to Gefitinib or Erlotinib (p=0.007). The pattern of mutation counts does not differ significantly with respect to gender, age, or tumor histology. The EGFR Mutation Database is designed as a central resource of EGFR mutation epidemiology data for clinicians, geneticists and other researchers. These data and data from animal studies suggest that the EGFR mutations found in elderly patient with lung cancer generally derive many years earlier from mutational events during lung development i.e. before direct exposure of the lung to cigarette smoke.

Enzyme replacement therapy on hypophosphatasia by using C-terminus-anchorless tissue-nonspecific alkaline phosphatase. *S. Tomatsu, H. Oikawa, T. Nishioka, M. Gutierrez* Dept Pediatrics, Ped Res Inst, St Louis Univ, St Louis, MO.

Hypophosphatasia is caused by deficiency of activity of the tissue-nonspecific alkaline phosphatase (TNSALP), resulting in a defect of bone mineralization. Plasma infusions were attempted but little clinical improvement was achieved. There is no definitive treatment available. Enzyme replacement therapy for hypophosphatasia was thought to be quite difficult since the TNSALP enzyme is membrane-bound and functions physiollogically when the enzyme is present at the cell membrane. The tissue TNSALP knock-out mouse is a model of infantile hypophosphatasia displaying impaired bone mineralization, epileptic seizures, apnoea, abnormal apoptosis in the thymus, abnormal lumbar nerve roots, and postnatal death before the weaning. To investigate clinical effectiveness with ERT for hypophosphatasia, we deleted the c-terminus of TNSALP cDNA and transfected into Chinese hamster ovary (CHO) cell line. The resultant secreted form of rhTNSALP secreted by CHO cells was purified and characterized in vitro. The weekly infusion of enzyme replacement therapy onto TNSALP knockout mice was administered. In vitro mineralization assays with the rhTNSALP in the presence of high concentrations of pyrophosphate provided evidence of bone mineralization with the bone marrow from a hypophosphatasia patient. Weekly intravenous administration of the purified rhTNSALP enzyme with 5 mg/kg dose into TNSALP knockout mice increased dramatically the life span with the increased body weight, showing that the treated mice lived at least 6 times as long compared to the untreated mice. Treated mice had no epileptic seizures at least till 3 months old. These results show the C-terminus-anchorless TNSALP functions bioactively in vivo and that is a potential therapeutic agent of ERT for hypophosphatasia.

Delineation of chromosome 9p rearrangements: A model for diverse chromosomal mechanisms of formation. *S. Schwartz[1], C. Crowe[2], M. Graf[3], H. Mashek[1], S. Lillis[4]* 1) University of Chicago, Chicago, IL; 2) MetroHealth Med Center, Cleveland, OH; 3) TGEN, Pheonix, AZ; 4) Children's Mercy Hospital, Kansas City, MO.

Over the past decade our knowledge of the phenotypic abnormalities associated with chromosomal abnormalities and the mechanisms responsible for the formation of these abnormalities has increased. While considerable work has been undertaken regarding many deletions, much less has been done with duplications. We have had the opportunity to study 24 chromosomal abnormalities involving the duplication of a portion of chromosome 9 of which 87.5% of the abnormalities were de novo and 12.5% of these were familial. Of the 24 abnormalities, seven different mechanisms have been identified as responsible for the abnormalities. This includes the formation of acentric, dicentric, segmental duplicated and duplicated/deleted chromosomes. A large proportion of these abnormalities are found to be more complex than expected from standard G-banding. Analysis of these cases along with other reported cases implicate an approximate 4 Mb region as a critical region for the characteristic phenotype in this syndrome. Results from these studies are interesting and reveal important information including: (1) Duplications of 9p are formed by a variety of mechanisms, probably due to both the lack of genes in 9p as well as the nature of DNA in 9p; (2) All of the accessory chromosome involving the entire short arm of 9p were dicentric containing all of 9p and two copies of the centromeric and pericentromeric region; (3) There are more complex abnormalities than expected. These complex rearrangements include acentric, dicentric and duplicated/deleted chromosomes. (4) The 4 Mb region identified as the critical region overlaps the critical region identified for the 9p deletion syndrome; (5) As the distal region of the chromosome arm is gene poor, much of the phenotype seems similar regardless of the amount of material duplicated, providing that the critical region is included. (6) One of the familial cases had a very mild phenotypes, in both the parent and proband, and did not involve a duplication of the critical region, but rather involved duplication of material distal to the critical region.

***PRODH* sequence variants in 22q11 deletion syndrome (22q11DS).** *A.S. Willis[1,2], J.A.S. Vorstman[3,4,5], M. De Sain-van der Velden[6], B. Dorland[6], B.S. Emanuel[3,7], D. Valle[1,2]* 1) Inst Genetic Medicine, Johns Hopkins Sch Med, Baltimore, MD; 2) Howard Hughes Medical Inst; 3) Human Genetics, Childrens's Hospital of Philadelphia, PA; 4) Child & Adolescent Psych, Univ Med Ctr, Utrecht, Netherlands; 5) Rudolf Magnus Inst of Neurosciences, Utrecht, Netherlands; 6) Metabolic Diseases, Univ Med Ctr, Utrecht, Netherlands; 7) Pediatrics, University of Pennsylvania Sch Med.

PRODH is located in the 22q11DS critical region and encodes proline oxidase (POX), which the first enzyme in the proline (Pro) degradation pathway. Several *PRODH* variants are known, and some have been suggested to contribute to the 25-fold increased risk 22q11DS patients have for schizophrenia (Sz). Previous studies have shown that about half of 22q11DS patients have hyperprolinemia. We are testing the hypothesis that sequence variants in the remaining *PRODH* allele account for the hyperprolinemia and relate to the risk for Sz and other neurological abnormalities in these patients. We sequenced the remaining *PRODH* allele in 53 22q11DS patients who have also undergone neuropsychiatric and psychophysiologic testing. We identified 11 missense and 9 synonymous variants. Two missense variants, Q19P and R185W, result from known SNPs and occur in 41 and 32 of the 53 *PRODH* genes, respectively, with 30 alleles having both. We have not considered these common variants in our initial analysis. We detected the remaining 9 missense variants in 1-6 individuals, each. Previously, we tested 5 of these for effect on enzyme activity (Bender et al, AJHG 76:409, 2005) and are in the process of testing the remaining 4. Pending full functional data, we divided the patient sample into thirds based on plasma Pro levels. We find that 8 of 17 in the high Pro group had missense variants as compared to 3 in the middle and 4 in the low Pro group, including 2 variants we previously showed to encode POX with increased activity. These results support our hypothesis that genotype at the remaining *PRODH* allele correlates with the plasma Pro levels and suggests that this variable should be considered in analyzing the phenotypic spectrum in 22q11DS.

A role for the developmental gene NOTCH2 in hepatoblastoma. *R.A. Schultz[1], G.E. Tomlinson[2,3,8], D. Rakheja[1], T. Chen[3], N.R. Schneider[1], K. Wilson[1], C. Echebiri[3], B.A. Hirschman[3], A.R. Brothman[4], P. Eis[5], T.A. Richmond[5], R.R. Selzer[5], J.H. Feusner[6], M. Malogolowkin[7], R.L. Stallings[9], Children's Oncology Group* 1) Dept Pathology, UT Southwestern, Dallas, TX; 2) Dept Pediatrics, UT Southwestern, Dallas, TX; 3) Hamon Center for Therapeutic Oncology Research, UT Southwestern, Dallas, TX; 4) University of Utah, Salt Lake City; 5) NimbleGen Systems, Inc. Madison, WI; 6) Childrens Hospital of Oakland, Oakland California; 7) Childrens Hospital of Los Angeles, Los Angeles, CA; 8) Children's Medical Center of Dallas, Dallas, TX; 9) Childrens Cancer Research Institute, UT Health Science Center at San Antonio, TX.

Hepatoblastoma, the most common malignant liver tumor in children, typically occurs between birth and five years of age, after which tumor development becomes uncommon. Histologically these tumors resemble fetal and embryonal liver elements in a disorganized growth pattern. We have determined that cytogenetically hepatoblastoma is characterized by numerical increases in chromosomes 2, 8 and/or 20 and by unbalanced translocations involving a recurrent breakpoint at 1q12. Using FISH, BAC-CGH arrays with 1 megabase resolution, and fine-tiling oligonucleotide array CGH with 60-80 base pair spacing, we have characterized tumors bearing chromosome 1q12 translocations. The results demonstrate that NOTCH2, a gene involved in liver development and differentiation, is disrupted in each of these tumors. Disruption appears to occur through a mechanism involving pericentric inversion prior to translocation. Immunohistochemical studies on hepatoblastoma tumor tissues and adjacent liver revealed strong staining for NOTCH2 in hepatoblastoma tumor cells and not in adjacent liver cells. Aberrant expression of NOTCH2 could contribute to tumor formation by expanding or maintaining that population of immature cells in the liver that are the substrate for hepatoblastoma. The results provide another strong link between alterations in normal development and the pathogenesis of embryonal tumors in children. The power of fine-tiling oaCGH in the characterization of translocation breakpoints in cancer is again demonstrated.

Structural and DNA binding differences between VWS and PPS mutations in IRF6. *N.K. Rorick[1,3], L. Gakhar[2], T.R. Waldshmidt[3], D. Schipper[3], J.C. Murray[3], B.C. Schutte[3]* 1) Genetics PhD Program, Univ Iowa, Iowa City, IA; 2) Biochemistry Dept, Univ Iowa, Iowa City, IA; 3) Pediatrics Dept, Univ Iowa, Iowa City, IA.

IRF6 is a member of the IRF family of transcription factors that contain a penta-tryptophan DNA binding domain (DBD) and a protein-binding domain. Mutations in Interferon Regulatory Factor 6 (IRF6) cause two dominantly inherited forms of cleft lip and palate, Van der Woude (VWS) and popliteal pterygium syndromes (PPS). Missense mutations in the DBD are observed in cases of both VWS and PPS; however, the phenotype of PPS is more severe, with skin and limb abnormalities along with cleft lip and palate. The goal of this study is to delineate potential differences in structural and functional effects of VWS- and PPS-associated missense mutations in the DBD. The affect of missense mutations on protein secondary structure was predicted with NNpredict and ProteinPredict . We observed that VWS mutations were more likely to perturb secondary structure than PPS mutations ($p = 0.037$). To test the predicted structural effects biochemically, circular dichroism spectrophotometry was performed on R84G (VWS-causing), R84C (PPS-associated), and wild-type DBDs. We observed a loss of secondary structure in the R84G, but no effect with the R84C mutation. These results support the structural effects predicted computationally. To examine the DNA binding function of the mutants, gel shift assays were performed on 5 VWS and 8 PPS mutants. Nearly all mutations abrogated DNA binding activity. Exceptions were normal binding with one VWS mutant, G70R, and very weak binding by two PPS mutants, L22P and Q82K. The general loss of DNA binding by VWS missense mutations is consistent with the predicted changes in secondary structure. The G70R exception suggests an alternative effect on IRF6 function. One possibility is an alteration in tertiary structure. Our data suggests that most PPS mutations retain their structure, but are unable to bind to DNA. The structural and functional data coupled with the phenotypic data are consistent with the hypothesis that PPS mutations have a dominant negative effect on IRF6 function.

Euchromatic duplication 9q21-9q22. A benign variant? *D.M. Stenberg, E.N. McDonald, G.S. Sekhon* Cytogenetics Lab., Genzyme Genetics, Santa Fe, NM.87505.

We identified 10 families (7 prenatal and 3 postnatal) with duplication of band 9q21-9q22. Four of the amniotic fluid samples were studied due to advanced maternal age, two due to nuchal thickening, and one for positive serum screen. The indication for all of the postnatal blood was phenotypic abnormalities. Chromosome analysis follow-up of the prenatal families showed that the duplication was of paternal origin in 4, maternal origin in 2 and de novo in 1. The parental follow-up studies of postnatal cases were performed in 2 of the families and in one of the family parents were not available. One was paternal and 1 was maternal. Using different banding techniques and fluorescence in situ hybridization with specific DNA probes, and C-banding, the structural rearrangements involved were considered. We suggest that possibly duplication of 9q21-9q22 can be regarded as euchromatic variant without any phenotypic effects as in the case of chromosome 9 variant with an extra G-dark band within the heterochromatic region. The strategy at present has been to offer parental chromosome study. If inherited from a phenotypically normal parent, it is most likely a euchromatic variant. In future studies, array comparative genomic hybridization (CGH) analysis will be a useful tool to more completely characterize the rearrangement.

Potential pharmacological chaperones for late-onset GM2 gangliosidosis. *M. Tropak[1], G.H.B. Maegawa[1,2], F. Kok[3], J.T.R. Clarke[1,2], D.J. Mahuran[1]* 1) Metabolism - Research Institute, Hospital for Sick Children; 2) Div of Clinical/Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 3) Div of Neuropediatrics, Sao Paulo University, Brazil.

GM2 gangliosidosis (GM2) is an inherited neurodegenerative disorder caused by lysosomal -hexosaminidase A (Hex A) deficiency. Objective: test in fibroblast cell lines from patients diagnosed with late-onset GM2, both Tay-Sachs (TSV) and Sandhoff variants (SV), potential chemical compounds identified by high throughout screening (HTS). Results: Patients fibroblasts with diverse types of mutations were cultured in media with two compounds, N-acetylglucosamine thiazoline (NGT) and one of the hits from the HTS (H1). Following 5 days of treatment, Hex A activities were determined using MUGS. TSV cell lines with -G269S/null allele showed over 3-fold increases in Hex A activity with H1, and over 6-fold increase with NGT. Among the SV cell lines, one patient cell line homozygous for C137Y mutation showed close to 6-fold increase of Hex A activity in media with both H1 and NGT. The -R505E/IVS11+5G>A cell line showed 4 to 5-fold increased Hex A activity under H1 and NGT, respectively. The -G353R/IVS12-27G>A showed approximately 3-fold increase of Hex A under H1, and 2-fold increase under NGT. TSV patient cell lines with other juvenile mutations, such as R178H, R499C and R499H show mild Hex A activity to either H1 or NGT. Other lysosomal enzyme activities such as -galactosidase and -glucosidase remained unchanged. Western blots correlated with the observed Hex A activity increases revealed in cells exposed to the two studied compounds. Conclusion: The NGT and H1 can function as pharmacological chaperones for specific *HEXA* and *HEXB* mutations in late-onset GM2. We hypothize that these chemical compounds are able to stabilize the native-like conformation of the enzyme and, consequently, increasing the amount of Hex A exiting the endoplasmatic reticulum and reaching lysosomes. The identified compounds constitute a potential alternative as specific therapeutic approach for the subacute and late-onset forms of GM2. Key words: GM2 gangliosidosis; hexosaminidase; pharmacological chaperone.

Population pharmacokinetic modeling using diplotype configuration. *A. Saito[1], K. Tanikawa[2], M. Takeuchi[3]* 1) Central Research Laboratory, Hitachi, Ltd., Tokyo, Japan; 2) Life Science Group, Hitachi, Ltd., Saitama, Japan; 3) Division of Biostatistics, Kitasato University Graduate School, Tokyo, Japan.

For optimizing drug regimens in individual patients, it is important to predict individual pharmacokinetic behavior with high accuracy. The differences in individual pharmacokinetics are attributed to genetic information, although the effects of other factors, such as age, gender, and disease, are not negligible. To estimate the influences of genetic variation on pharmacokinetic differences, we present a new pharmacokinetic analysis method which combines population pharmacokinetic modeling with population genetic approach. The presented method is based on non-linear mixed effect modeling which is the most used method for population pharmacokinetic analysis. We include information of haplotype or diplotype configuration into non-linear mixed effect model as a covariate on fixed (population-typical) or random (population-variability) effect parameters. We have validated our method with the datasets from extensive simulation studies, comparing the estimated results to those obtained by the conventional ethnicity-based modeling. The results showed that our method could make more accurate prediction of individual pharmacokinetic behavior than the conventional methods.

A loss-of-function mutation in the *FTSJ1* gene causes non-syndromic mental retardation in a Japanese family. *K. Takano[1], E. Nakagawa[1], K. Inoue[1], F. Kamada[2], S. Kure[2], Y. Goto[1]* 1) Department of Mental Retardation and Birth Defect Research, National Institute of Neurology NCNP, Tokyo, Japan; 2) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan.

A prevalence of mental retardation (MR) is thought to be 0.6-1.3 % in Japanese children from three to twelve years old. Although the etiology of MR remains largely unknown, genetic abnormalities appears to be a major factor. Recent large-scale linkage studies mainly performed in European and North American countries, have successfully identified many X-linked mental retardation (XLMR) genes including *FTSJ1*. Here we identified a family with a mutation in *FTSJ1* through a screening of genetic abnormalities in XLMR genes using a cohort of 41 Japanese families. *FTSJ1* is a human homolog of the *Escherichia coli 2-O*-rRNA methyltransferase FtsJ/RrmJ gene, but its function in the central nervous system is unknown. The family has five affected males with non-syndromic mental retardation consisting with X-linked recessive inheritance. Sequence analysis of the proband and his mother revealed a GA substitution at the donor consensus splice site in intron 8 (IVS8+GA) in the *FTSJ1* gene. This mutation resulted in an abnormal transcript longer than the wild type fragment due to the involvement of the entire intron 8 into the transcripts. By conceptual translation, incorporation of the intronic sequence leads to a frameshift in the *FTSJ1* mRNA resulting in a premature termination codon in exon 9. Quantitative RT-PCR showed significant reduction of mutant *FTSJ1* transcript in patients lymphoblast cells, which was upregulated by suppression of nonsense-mediated mRNA decay (NMD) using cycloheximide. Therefore, this mutation resulted in a lack of *FTSJ1* transcript and the loss-of-function is likely responsible for the phenotype of this patient. The frequency of *FTSJ1* mutation in one out of 41 families in Japanese families appears to be compatible with the frequency described in a European study wherein four families have been found out of 249 non-syndromic XLMR families. Supported by the Research Grant (15B-4, 18A-5) for Nervous and Mental Disorders from the Ministry of Health, Labour and Welfare, Japan.

High resolution CGH of breast cancer. *D.N. Roberts[1], C.A. Carmack[1], A. De Witte[1], S. Milligan[1], E. Lin[1], J. Gao[1], S. Giles[1], S. Shchegrova[1], E. LeProust[1], P. Webb[1], D. Amorese[1], J. Gregg[2]* 1) Integrated Biology Solutions, Agilent Technologies, Santa Clara, CA; 2) UC Davis Medical Center, Sacramento, CA.

Array based Comparative Genomic Hybridization (CGH) provides a means for the determination of DNA copy number aberrations. We have designed a CGH array consisting of ~244,000 in situ synthesized 60-mer oligonucleotides spanning the entire human genome, resulting in an average genomic distance between probes of ~12 Kbp. Using these arrays, we performed an analysis of copy number changes in breast carcinomas and in breast carcinoma cell lines. In several cases displaying amplifications around ERBB2, we utilized a second, high definition CGH array with >20,000 probes dedicated to chromosome 17, with particular emphasis on the region encompassing ERBB2 (17q21.2-q21.3). Using these data in combination, we define multiple common aberrations in our sample set. Further, we analyze patient chromosomal/gene copy number with respect to the levels of ERBB2 protein, clinical classification, and outcome.

Whole Genome Association Studies in Admixed Populations. *N. Risch[1], H. Tang[2]* 1) Univ California, San Francisco, San Francisco, CA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

Admixture mapping (AM) is a method that exploits ancestral allele frequency differences to map disease susceptibility genes in recently admixed populations such as African Americans and Latinos. With the advent of high density genotyping platforms with as many as 500K SNPs or more for whole genome association (WGA) studies, a question arises as to the relative power of direct association versus admixture mapping in such populations. Previously we have shown that even with lower density platforms (100K), it is possible to reconstruct the ancestry block structure of an admixed individual, making AM essentially completely informative. Here we show that in a direct association analysis comparing allele frequencies between cases and controls in an admixed population, the chi-square statistic can be partitioned into two nearly additive components, one chi-square (one df) corresponding to the local ancestry difference between cases and controls, and the other a Mantel-Haenszel (MH) chi-square (one df) stratified on the local ancestry of the chromosomes. We evaluate the relative magnitude of these two components across a range of values of disease allele frequency, admixing proportions, genotype relative risk, and the ancestral allele frequency difference (delta). We show that the MH component generally dominates the overall chi-square for delta values up to .6 (accounting for up to 65 percent); for delta values of .4 it accounts for 85 percent or more; for delta values greater than .7 (which are rare), the ancestry component begins to dominate. Hence, it is likely that in the large majority of cases, direct association will be more powerful than admixture mapping. However, this conclusion depends on the assumption that the causal SNP or one in very strong LD is included in the high density platform.

We also note an additional advantage of high density SNP analysis in admixed populations. The MH analysis stratified on local ancestry provides an internal cross-ethnicity replication study since the allelic odds ratios can be studied within each ancestral group of chromosomes (between cases and controls) and compared.

Genetic differences across Finland using genomewide SNP data. *C.J. Willer[1], L.J. Scott[1], H.M. Stringham[1], T.T. Valle[2], N.A. Rosenberg[3], R.N. Bergman[4], K.L. Mohlke[5], J. Tuomilehto[2,6], F.S. Collins[7], M. Boehnke[1]* 1) Dept of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Dept of Epidemiology and Health Promotion, National Public Health Institute, Helsinki, Finland; 3) Dept of Human Genetics & Life Science Institute, University of Michigan, Ann Arbor, MI; 4) Dept of Physiology and Biophysics, Keck School of Medicine, University of Southern California, Los Angeles, CA; 5) Dept of Genetics, University of North Carolina, Chapel Hill, NC; 6) Dept of Public Health, University of Helsinki, Helsinki, Finland and South Ostrobothnia Central Hospital, Seinäjoki, Finland; 7) Genome Technology Branch, National Human Genome Research Institute, Bethesda, MD.

We are carrying out a genomewide association scan of 300,000 SNPs on 2363 Finnish individuals using the HumanHap300 BeadChip from Illumina. Here we evaluate possible geographic stratification of SNP allele frequencies across 12 historical provinces of Finland. Our sample consists of type 2 diabetic individuals and non-diabetic controls, matched for province of birth. Each province is represented by 78 to 300 genotyped individuals. In our initial analysis of autosomal SNPs genotyped for 1743 individuals, we find an excess of significant allele frequency differences among the 12 provinces and between all pairs of provinces. Even the most similar provinces show a 9-fold excess of significant allele frequency differences at p .0001. The pairs of provinces showing the strongest genetic differences are geographically distant (for example, Vaasa on the west coast and North Karelia in the east) and our results are in agreement with reported historical migration patterns and regional subisolates. These results suggest that careful case-control matching may be required to avoid false-positive results in genomewide association scans, even in populations often described as homogeneous.

Variance Component Linkage Analysis Allowing for Heterogeneity in Effect Sizes due to Measured Covariates.
J. Zheng, W.M. Chen, G.R. Abecasis Department of Biostatistics, University of Michigan, Ann Arbor, MI.

A common approach for quantitative trait linkage analysis in human pedigrees involves the use of variance component models. In a conventional variance components model, the genetic effect and environmental effect are modeled as random effects and the fixed effect due to covariates are assumed to be independent of random effects. In some situations, measured covariates may actually modify the size of genetic effects rather than directly affecting the trait mean. In these cases, especially when the interaction between the covariate effect and genetic effect are strong, failure to model the interaction may result in a much reduced power to detect linkage. In two recent papers, Pilia et al. (2006) found that among 98 cardiovascular and personality traits, about half showed heterogeneity in variance components by age, by sex or both, and Weiss et al (2006) also found substantial evidence for heterogeneity by sex in several human QTLs. Here, we extend the variance-component method to model genetic and random environmental variance components for each individual as linear functions of measured covariates. This model can conveniently incorporate the effects of binary or continuous covariates, or even multiple covariates in one analysis. Through simulations, we show that in the presence of interactions between measured covariate and genetic effects, our extended variance component model maintains correct type I error rates and demonstrates improved power to detect linkage. In contrast, the conventional variance component model only has very limited power to detect linkage when there is substantial heterogeneity in QTL effect sizes. For example, when we simulated traits whose heritability varied with age by a factor of 2 to 3 fold, we found several situations where the standard variance component model had <20% power but our model provided >80% power. We believe that our approach will be helpful in the mapping of the many human quantitative trait loci whose effects vary according to age, sex or another covariate.

Genetic dissection of male infertility-related molecular pathways by transcriptional profiling of testicular biopsies from patients with non-obstructive azoospermia. *A. Tajima[1], Y. Sakamoto[1], H. Okada[2], A. Tanaka[3], K. Shichiri[4], K. Tanaka[2], I. Inoue[1]* 1) Div Genetic Diagnosis, IMS, Univ Tokyo, Tokyo, Japan; 2) Dep Obstet & Gynecol, Niigata Univ School of Medicine, Niigata, Japan; 3) Saint Mother Obstet & Gynecol Clinic, Fukuoka, Japan; 4) Tachikawa Hospital, Niigata, Japan.

Male-factor infertility accounts for about half the cases in which assisted reproductive techniques are recommended. Many factors such as spermatogenic failure could cause male infertility, however, the etiologies and pathogenesis of this disease remain poorly understood. To identify new genes and/or pathways underlying male infertility with spermatogenic dysfunction, we performed a microarray-based gene-expression profiling in infertile testes. Infertile testicular biopsies were obtained under informed consent from non-obstructive azoospermia (NOA; n=47) and obstructive azoospermia (OA; n=11) patients. We found 2,611 transcripts as differentially expressed between NOA and OA testes, using Agilent Human 1A(v2) Oligo microarrays. Gene ontology-based profiling of the 2,611 transcripts revealed a significant association with biological processes involved in male gamete generation. To find novel NOA subclasses, the 2,611 transcripts were further examined with non-negative matrix factorization (NMF) method, a recently introduced clustering approach in class discovery. The NMF analysis provided three robust NOA subclasses, among which there were statistically significant differences in NOA-related clinical characteristics such as testicular pathological score. Subsequent statistical analysis showed that 149 transcripts (P<0.05) were differentially expressed among three NOA subclasses. The among-subclass differences in testicular expression for 53 transcripts with highly statistical significance (P<0.01) were confirmed by quantitative real-time RT-PCR method. These findings indicate that our strategy is successful in disclosing a group of transcripts related to spermatogenic defects and NOA classification. The 149 transcripts would therefore be diagnostic markers for NOA phenotypes, as well as potential candidates for susceptibility to NOA.

How mutations at the 3' end region of exons cause aberrant splicings? - *In silico* and *in vitro* analyses to answer the question -. *K. Sahashi[1,2], J. Shinmi[1], G. Sobue[2], K. Ohno[1]* 1) Division of Neurogenetics and Bioinformatics, Center for Neurological Diseases and Cancer, Nagoya University Graduate School of Medicine; 2) Department of Neurology, Nagoya University Graduate School of Medicine.

In the spliceosomal formation, U1 snRNA recognizes the 5 splice site and initiates pre-mRNA splicing. We constructed *SNCA*, *PARK2*, *PINK1*, and *PARK7* minigenes harboring exonic mutations causing Parkinson's disease, and tested if any of these mutations cause aberrant splicings. We found that an A-to-G substitution at position -2 of *PINK1* exon 6 predicting E417G and a G-to-C substitution at position -1 of *PARK7* exon 2 predicting E64D cause aberrant skipping of the mutation-harboring exon. We comprehensively analyzed nucleotide frequencies at positions -3 to +6 of the whole human genome comprised of 179,917 5' splice sites. The analysis revealed that non-consensus nucleotides at positions -3, -2, and -1 are complemented by consensus nucleotides at positions +4, +5, and +6. Next, we constructed minigenes harboring five exonic mutations of five different genes at position -2, which are known to cause aberrant splicings. We also constructed minigenes carrying four exonic mutations of four different genes at positions -3, -2, and -1, and found that these mutations also affect pre-mRNA splicings. Using the eleven minigenes above, we introduced a consensus nucleotide one by one, and found that a consensus nucleotide at position +4, +5, or +6 ameliorates aberrant splicings, whereas a consensus nucleotide at position -3 or -2 has no effect. We also confirmed that introduction of a single complementary nucleotide into U1 snRNA corresponding to position +4, +5, or +6 restores normal splicing, whereas mutagenesis corresponding to position -3 has no effect. Both *in silico* and *in vitro* analyses disclose a scenario that a mutation at the 3' end region of an exon causes aberrant splicing when nucleotides at positions +4, +5, and +6 are not complementary to U1 snRNA. When we identify a mutation at position -3, -2, or -1, we should see nucleotides at positions +4, +5, and +6, as we should take different therapeutic strategies for missense and splicing mutations.

SLC3A1 knockout mice model human cystinuria. *A. Sahota[1], E. Cui[1], H.J. Vernon[2], M. Yang[1], J. Chen[1], C. Osborne[1], E. Stambrook[1], S. Bledsoe[3], A.P. Evan[3], J.A. Tischfield[1]* 1) Dept. Genetics, Rutgers Univ., Piscataway, NJ; 2) Dept. Pediatrics, Johns Hopkins Univ., Baltimore, MD; 3) Dept. Anatomy & Cell Biol., Indiana Univ. Med. Sch., Indianapolis, IN.

Cystinuria is an inherited metabolic disorder caused by mutations in the diabasic amino acid transporter system rBAT/b0,+AT. Based on phenotypes in heterozygotes, cystinuria is classified as type I or non-type I. The type I form is fully recessive, resulting from mutations in the SLC3A1 gene, encoding rBAT. The non-type I form is incomplete recessive, and is caused by mutations in b0,+AT, encoded by SLC7A9. Cystine accumulation leads to stone formation, recurrent infections, and subsequent renal failure. We are using SLC3A1-/- mice to determine whether the initial sites of crystal deposition within the renal system and the mechanisms of crystal-induced renal injury are unique for each crystal type or whether different crystal types share common pathways. Urine from 4-months-old SLC3A1-/- mice was analyzed by HPLC for cystine and the dibasic amino acids. Urinary crystals were examined by light microscopy and infra red spectroscopy, and kidney and bladder sections by light microscopy. Changes in the renal expression of a set of early response genes were examined by real time PCR. At age 4 months, null mice excrete cystine (including crystals) and dibasic amino acids in the urine. At this age, there are very few cystine stones in the kidney, but there is massive stone accumulation in the bladder. There is no evidence for gene-level changes in kidneys from 1-month-old SLC3A1-/- mice compared with wild type mice. Our initial studies suggest that SLC3A1 knockout mice mimic the etiology and clinical manifestations of human cystinuria type I, but the initial site of crystal deposition and the initial pathophysiology is markedly different compared with a knockout mouse model for another stone disease, adenine phosphoribosyltransferase (APRT) deficiency. Cystinuria is a disease of obstructive uropathy, rather than intra-renal crystal deposition (APRT deficiency), suggesting that different crystal types induce different cellular and molecular responses.

Results from a Multi-national, Multi-center, Prospective, Observational Study in Patients with Late-onset Pompe disease. *J. Wokke[1], D. Escolar[2], A. Pestronk[3], P. Laforet[4]* 1) Neurology, University Hospital Utrecht, Utrecht, Netherlands; 2) Children's National Medical Center, Washington, DC; 3) Washington University, St Louis, MO; 4) Hopital de la Salpetriere, Paris, France.

Objective: The objective of this study was to better characterize the clinical presentation of patients with Late-Onset Pompe disease for the purpose of identifying the best outcome measures for the assessment of efficacy in future clinical trials. **Methods:** This was a multi-center, multinational, 12-month observational study. Eligible patients had to be both ambulatory and non-invasively ventilated. Baseline measurements included -glucosidase acid residual enzyme activity, genotyping, manual muscle testing (MMT) of 34 muscle groups, quantitative muscle testing (QMT) of seven muscle groups, functional activities and grades, pulmonary function testing (PFT), and quality of life (QOL) assessments. Pulmonary and muscle function testing was repeated at 1, 3, 6, and 12 months. A 6 minute walk test (6MWT) was introduced at the Month 12 visit. **Results:** Fifty-eight patients (22 males and 36 females), aged 24-69 years completed the study. Age at symptom onset was 28.9 11.6 years. Disease duration was 15.6 9.2 years. Almost all patients (93%) presented with proximal lower limbs muscle weakness, with mean QMT knee extensors and flexors of 39 and 48% of predicted normal, respectively. 6MWT distances were less than 80% of predicted values for 96% of tested patients. Mean FVC % at baseline was 66.8% (sd = 21.5), mean postural drop from upright to supine was -27.5% (SD = 17.6), and 22.4% of patients were using nocturnal ventilation. Significant correlations were observed between FVC %, 6MWT distance, QMT and MMT. Mean FVC% predicted and mean QMT Leg Score declined by 3.5% and 3.2% respectively over the 12-month period. **Conclusion:** In this largest cohort of late-onset Pompe Disease patients ever described, a slow progression of pulmonary or muscle weakness has been observed over 12 months. The outcome measures in this study were found to be sensitive and reliable for use in clinical trials. Relationships between clinical features and genotype will be analyzed.

An Ancient Haplotype Pinpoints *IGF1's* Role In Determining Dog Body Size. *N.B. Sutter[1], M. Gray[2], K. Chase[3], P. Quignon[1], H.G. Parker[1], S. Davis[1], E. Karlins[1], G. Johnson[4], M. Nordborg[5], C.D. Bustamante[6], R.K. Wayne[2], K.G. Lark[3], E.A. Ostrander[1]* 1) National Human Genome Res Inst, Bethesda, MD; 2) University of California, Los Angeles, CA; 3) University of Utah, Salt Lake City, UT; 4) University of Missouri, Columbia, MO; 5) University of Southern California, Los Angeles, CA; 6) Cornell University, Ithaca, NY.

Dog breeds vary 50 fold in adult mass from tiny Chihuahuas to 200 pound Mastiffs and Irish Wolfhounds. Previously, a microsatellite genome-wide scan was completed in the mid-size Portuguese Water Dog (PWD). Using 91 skeletal measurements from radiographs of 500 dogs several quantitative trait loci (QTL) for skeletal size were found. The marker FH2295 QTL is positioned within 1 Mb of the *insulin-like growth factor 1* gene (*IGF1*), a strong genetic determinant of body size in mice.

Our sequencing identified no explanatory mutations in *IGF1* exons. We sought evidence that the genes action controls body size in dogs by genotyping 75 *IGF1* SNPs in Portuguese Water Dogs, 350 dogs from 15 giant and 18 small breeds, and grey wolf, coyote, jackal, and fox samples.

We found a striking association between body size and *IGF1* haplotypes both in the PWD and in giant and small breeds ($p < 10^{-60}$). Small PWDs carry the same 13 SNP *IGF1* haplotype as dogs from all but one of the 18 small breeds. No dogs from 15 giant breeds carry this haplotype. Dogs from giant breeds primarily carry one of two divergent haplotypes. One of these haplotypes occurs in the PWD population and dogs carrying it are largest in size. The grey wolves carry haplotypes very similar to both of the large haplotypes but not the haplotype found in small dog breeds. Our data support a model in which an *IGF1* mutation that arose early in the history of dogs is responsible for much of the variation in body size in modern pure breeds. These findings aid our understanding of growth regulation and set the stage for mapping complex traits of interest to human and companion animal biologists by taking advantage of the breed structure within the canine population.

Admixture mapping identifies 8q24 as a locus explaining >39% of prostate cancer cases in younger African American men. *D. Reich[1,2], M.L. Freedman[2,3], C.A. Haiman[4], N. Patterson[2], G.J. McDonald[1,2], A. Tandon[1,2], A. Waliszewska[2,5], K. Penney[2,3], C. Montague[1,2], K. Ardlie[2,6], E.M. John[7,8], I. Oakley-Girvan[7,8], A.S. Whittemore[7,8], K.A. Cooney[9], S.A. Ingles[4], D. Altshuler[1,2,10], B.E. Henderson[4]* 1) Harvard Med School; 2) Broad Inst of Harvard & MIT; 3) Dana Farber Cancer Inst; 4) Univ Southern California; 5) Brigham & Women's Hospital; 6) Genomics Collaborative Inc; 7) Northern California Cancer Center; 8) Stanford Univ; 9) Univ Michigan; 10) Massachusetts General Hospital.

We carried out an admixture scan for prostate cancer genes in 1,597 African Americans cases and 873 controls typed at 1,365 SNPs. Admixture mapping works by screening through the genome in a population of mixed ancestry, searching for regions where cases have an unusually high rate of inheritance from the ancestral population with higher risk. Since African Americans have a ~1.6-fold higher incidence of prostate cancer, we hypothesized that a risk locus would be detectable as a rise in African ancestry compared to the average of 78%.

We identified a 3.8 Mb interval that is associated with higher African ancestry in prostate cancer cases (LOD=7.1). The region spans 125.68-129.48 Mb in Build 35 of the human genome reference sequence, and contains 9 predicted genes including *MYC*. An allele at 8q24 was also independently found by Amundadottir (2006), confirming the importance of this locus in prostate cancer. Here we also report two novel results: (i) the locus has the strongest effect in men diagnosed at age <72 ($P<0.0003$), and (ii) the previously identified allele can explain at most a small fraction of the admixture signal. We estimate that the rate of prostate cancer in younger African Americans would be reduced by 39-59% if one could treat the additional risk conferred by African chromosomes.

This study confirms that admixture mapping is a powerful and practical way of localizing genes for complex disease. Molecular identification of prostate-cancer causing variants at 8q24 has promise for prostate cancer prevention and treatment. We conclude by reporting a fine-mapping scan of ~1,700 SNPs to comprehensively search for these variants.

Variation and Selection in the UCSC Genome Browser. *D. Thomas*[1, 2], *H. Trumbower*[2], *A. Kern*[2], *D. Haussler*[1, 2], *W.J. Kent*[1, 2] 1) Biomolecular Engineering, UC Santa Cruz, Santa Cruz, CA; 2) Center for Biomolecular Science and Engineering, UC Santa Cruz, Santa Cruz, CA.

Variation and Selection data in the UCSC Genome Browser is described (http://genome.ucsc.edu). This group of tracks covers primary data from dbSNP, HapMap phase II, Perlegen, Affymetrix, and structural variants from the literature. Polymorphisms, population derived allele frequencies, linkage disequilibrium, and haplotypes are displayed visually and are available for online analyses. Results from several recent studies in natural selection have also been added to this collection. The site provides a number of tools that allow visualization and analysis of the data as well as access to download data for offline analyses.

Novel mutations in the deoxyguanosine kinase gene and viral infection predispose previously healthy children to liver failure. *J.T.C. Shieh[1], L.J.C. Wong[2], G.M. Enns[1]* 1) Dept Pediatrics, Stanford Univ, Stanford, CA; 2) Dept Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Mutations in the deoxyguanosine kinase gene (DGUOK) cause a hepatocerebral form of mitochondrial DNA depletion syndrome. Although recent reports have characterized hypotonia, nystagmus, developmental delays, and liver failure in individuals with DGUOK mutations, the clinical spectrum of this disorder and pathogenesis of acute clinical decompensation remain unclear. In this study, we show that severe liver dysfunction can manifest in otherwise normal children and we identify associated novel mutations in the deoxyguanosine kinase gene. Importantly, we illustrate that a viral infection can trigger fulminant liver failure in the context of DGUOK mutation. A previously healthy 10 month-old twin male presented with fulminant liver failure and died, and post-mortem examination demonstrated herpes simplex virus type I infection. The living twin male sibling did not have evidence of herpes simplex virus infection but demonstrated episodic elevations in liver enzymes and an abnormal liver biopsy. We hypothesized that an underlying liver abnormality predisposed these children to liver disease and sequenced DGUOK to support a mild form of mitochondrial DNA depletion syndrome. We identified novel compound heterozygous mutations of the deoxyguanosine kinase gene (encoding p.N46S/R118C) in each of the twins and verified that the parents each carried one of the mutations. Furthermore, amino acids N46 and R118 are evolutionarily conserved from C. elegans to humans. This study illustrates three key findings: 1) Novel mutations in the deoxyguanosine kinase gene can lead to liver disease without cerebral manifestations, 2) Viral infection such as herpes simplex virus can lead to fulminant liver failure and death in the setting of a predisposing genetic alteration, and 3) Liver disease or failure should prompt investigation into an underlying mitochondrial DNA depletion syndrome as a potential etiology. This study suggests that although liver dysfunction may be attributed to infection, a genetic predisposition to disease may be under-recognized.

Mouse embryonic stem cell-derived myogenic stem cells have the potential for cell-based therapy of muscular dystrophies. *B. Yang, J. Qu, X. Cao* Dept OB/GYN, Univ Iowa, Iowa City, IA.

The muscular dystrophies are inherited myogenic disorders characterized by progressive muscle wasting and weakness of variable distribution and severity, and there are no cures for these diseases. Replacement of an aberrant copy of the relevant gene through gene therapy or engraftment of normal cells into affected muscles seems to be attractive therapeutic options. Isolation of a population of myogenic lineage committed stem cells from the pluripotent embryonic stem (ES) cells would have the great potential to be used for cell-based therapy of muscular dystrophies. We have devised an in vitro differentiation method for generating myogenic stem cells (MSC) from ES cells via embryoid bodies. The MSC can be maintained in culture for more than 30 generations without obvious changes in the culture characteristics and morphology. Upon switching to muscle differentiation medium, ~90% of the MSC can form myotubes in vitro. Cell surface marker characterization revealed that the MSC are positive (>95%) for CD34 and Sca1, negative for c-Kit, and the expression levels of CD45 and Flk1 are low (~20%). Those cells are also positive for myogenic markers, Myf5 and MRF4, while the expression levels of myogenin and MyoD are low. No teratoma was observed in scid mice injected with MSC in 8 weeks while similar number of ES cells resulted in tumor formation within 2 weeks after injection. When those cells were transplanted into -SG null/scid mice via intraarterial injection through the femoral artery, sections of recipient targeted muscles exhibited 10% and 20-30% of skeletal muscle fibers expressing donor-derived protein (-SG), 3 and 9 weeks post transplantation, respectively. This is the first report that a near homogeneous population of MSC can be isolated from ES cells via in vitro differentiation. Further detailed testing of the MSC will be conducted for their ability as myogenic precursors to populate, differentiate and persist in skeletal muscle. These results will not only enrich our understanding of basic knowledge of muscle differentiation but also facilitate and promote future studies of these cells as reagents for cell-based therapies of muscular dystrophies.

Development of High Throughput Genotyping Assays for Pharmacogenomics using Multiple Technology Platforms. *M.S. Phillips, I. Mongrain, N. Gaudreault, A.M.K. Brown, Y. Renaud, P. Guelpa, A. Mallah, C. Beck, T. Van Rooij* Université de Montréal Pharmacogenomics Centre, Montréal, PQ, Canada.

Approximately half of the variability that has been observed in drug response can be explained by genetic variation that occurs in both drug target proteins and in a collection of proteins that affect drug **A**bsorption, **D**istribution, **M**etabolism and **E**limination (ADME). Our laboratory has developed a set of gene specific panels for an extensive group of targeted ADME/Tox genes; such as: CYP2D6, 2C9, 2C19, 3A4/3A5, and UGT1A1. We have developed these panels in parallel on several technologies simultaneously like the Beckman SNPstream and Sequenom MassArray platforms. This parallel development using different biochemistries and technologies has allowed us to identify known controls, to rapidly cross validate these assays against each other and to efficiently transfer them onto additional technology platforms that are more suitable for the clinic, such as, the Autogenomics Infiniti platform.

To aid in our development, we have also developed a flexible operational QA/QC software tool (SNiPer) that can capture operational information, confirm calls on known controls, perform automated clustering with confidence scores, perform Pass/Fail determination and perform haplotype assignment to patients.

Furthermore, we have developed several broad-based ADME/Tox panels on the Illumina Bead Array platform that are capable of interrogating over 200 ADME/Tox genes at once in a single assay. These panels provide a distinctive advantage and cost savings over other approaches for screening for many gene variants in ADME pathways. We are presently utilizing these ADME/Tox candidate gene panels in large pharmacogenomic research projects to identify genomic biomarkers that can be predictive for patients that might experience adverse drug reactions or variable efficacy when exposed to various medications.

Geography-dependent difference in allele frequencies of immune-related loci presumably under malarial selection pressure in Vanuatu. *M. Yasunami[1,2], M. Kikuchi[1,2], N. Okuda[1,2], T. Tsukahara[3], C. Sato[1], M. Matsuo[1], R. Ubalee[1], K.J. Lum[5], A. Kaneko[3,4], K. Hirayama[1,2]* 1) Department of Immunogenetics, Institute of Tropical Medicine, Nagasaki University, Nagasaki, Japan; 2) Center of International Collaborative Research, Nagasaki University, Nagasaki, Japan; 3) Department of International Affairs and Tropical Medicine, Tokyo Women's Medical University, Tokyo, Japan; 4) Malaria Research Laboratory, Karolinska University Hospital, Stockholm, Sweden; 5) Department of Anthropology, Binghamton University, Binghamton, NY, USA.

The frequencies of genetic polymorphisms are maintained by adaptation to the environment. Like HbS mutation in African descendents, several otherwise deteriorating genetic variants seem to be even selected against pressures of life-threatening infectious agents including malaria. Within the archipelago of Vanuatu in Melanesia, there is a decreasing cline of malarial parasite incidence from North to South. We previously reported the estimation of frequencies of TNFA promoter(TNFP) alleles for the population in six islands of Vanuatu, where parasite incidence varied, and negative correlation between the frequency of TNFP-D allele and parasite incidence (Ubalee et al. 2005). TNFP-D allele conferred a significant risk in patients with severe cerebral malaria in Myanmer, and thus we concluded that this allele is under the negative selection pressure of malaria in Vanuatu population. In the present study, we further sought genetic variations which could be selected for or against malarial infection. The polymorphic microsatellite loci linked to FASL, ACP1, CR1, STAT1 TLR2, HFE and LTA were examined to estimate the allele frequencies in 95 individuals from each of six islands. Among them, alleles of TLR2-linked and LTA-linked microsatellites exhibited significant correlation to parasite incidence. The result suggested that there are some other traces of selection among these immune-related loci. We are currently identifying polymorphisms within these loci which can confer functional divergence to elucidate the underlying mechanism of natural selection.

Wilson Disease: A Pilot Study of Newborn Screening. *S. Zafari, C.A. Kroll, J.E. Brown, M.A. Pogatschnik, S.J. Minnich, M.J. Kurke, M. J. Ferber, S.H. Hahn* Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Background: Wilson disease (WD) is an autosomal recessive disorder of copper transport with an estimated incidence of 1 in 30,000. The disease is progressive and ultimately fatal if untreated. WD is treatable, and serious symptoms can be avoided if an early diagnosis is made. We recently reported that the newborns (NB) affected with WD had significantly lower ceruloplasmin (CP) levels in blood spots than unaffected newborns. **Method:** We investigated the feasibility of newborn screening for WD using the sandwich ELISA method to support a presymptomatic NB screening for WD. The concentration of CP was measured in the dried blood spots from 6862 blinded NB samples following routine MSMS NB screening with IRB approval. The blood spot samples with CP concentrations lower than 5.0 mg/dL were followed by ATP7b gene mutation analysis to establish an appropriate cut off. **Result:** The mean CP value was 46.9 20.7 mg/dL (range: 0.1 to >60). Birth weight (BW) ranged from 200g to 5653g and gestational weeks (GW) from 23 to 43. In NB with BW >1800g, the mean CP was 48.3 20.2 mg/dL for those >37 weeks and 33.8 20.0 mg/dL for those <37 weeks. Of these two groups, 0.35% had CP <5.0 mg/dL. In premature NB with BW <1800g (n=124), CP ranged from 0.1 mg/dL to 84.6 mg/dL with a mean of 30.5 23.4 mg/dL. Sixteen of them (12.9%) had CP <5.0 mg/dL, however, we observed an increase in CP in 9 of the 11 premature NB with additional tests over a period of 1 month. In one newborn with a CP of 4.9 mg/dL (BW=3030g), one copy of H1207R alteration was found in the ATP7b gene suggestive of a carrier. No patients were detected in 10 samples sequenced so far and others are yet to be analyzed. **Conclusion:** 93.8% of NB already reached their CP value >15mg/dL at birth. The repeated tests can significantly reduce false positive rates in premature newborns and will help avoid any unnecessary anxieties to their families and costs for confirmatory tests. Although a pilot study with larger sample number over a longer period is necessary to determine the efficiency of this method, our findings strongly support that presymptomatic newborn screening for WD is feasible.

Variable phenotype of 5p13 duplication involving NIPBL region by microarray analysis. *A.C. Tsai[1], A.S. Teebi[2], R. Klatt[2], B.A. Bejjani[3], L.G. Shaffer[3], D. Terespolsky[4]* 1) Div Clinical Gen & Metabolism, Childrens Hosp, Denver, University of Colorado; 2) Division of Clinical & Metabolic Genetics, The Hospital for Sick Children Department of Medical Genetics & Microbiology, University of Toronto; 3) Signature Genomic Laboratories, LLC, Spokane, WA; 4) The Credit Valley Hospital, Department of Laboratory Medicine, Mississauga,.

Teebi and Klatt [2005] reported a 2.5-y/o child with unilateral cleft lip and palate, hypotonia, dysmorphism, normal brain MRI and mild developmental delay(DD)with de novo 5p13 duplication by microarray analysis as a gain of three BACs containing the NIPBL region. At 4.5 y, child has mild autistic-like behaviors and attention deficits. We herein report three additional cases from two families with similar microarray findings yet variable presentations. The first patient is a 5-y/o-boy with DD, classic autistic spectrum disorder features, hypotonia and constipation. An MRI at age 3 showed increased signal in frontal white matter and along the peritrigonal region. Karyotype at 525 band and FISH for 15q11 were normal. Parental microarray assays were normal. The second patient is a 4.5 y/o male with DD, Siezure, microcephaly and dysmorphism. An MRI showed partial agenesis of the corpus callosum with left colpocephaly, decreased white matter volume and medial frontal pachygyria. Karyotype was normal at 550 band. He has profound DD: no expressive language, not walking and behavioral problems. His mother has the same duplication by microarray but has normal physical features and cognitive function. However, his 7 y/o brother with autism has not been tested. The variable phenotype in 4 individuals might be explained by dosage effect of the genes of specific function, parental origin, polygene and multifactorial threshold effect. While cautious interpretation of the microarray data is required, as many polymorphisms that previously were not understood can be uncovered, the importance of academic endeavor to describe individual phenotypes cannot be overemphasized. The clinical description of our patients also suggests that not all familial gene changes are polymorphisms. More cases are required to better understand this duplication.

An investigation into the ability of molecular modeling to explain the biochemical properties of a common mutation of the androgen receptor that allows prostate cancer tissues to grow in the absence of androgens. *J. Southwell[1,3], S. Chowdhury[1,2], B. Gottlieb[1,3,5], L.K. Beitel[1,4], R. Lumbroso[1], E. Putisima[2], M. Trifiro[1,3,4]* 1) Lady Davis Institute for Medical Genetics,; 2) Biotechnology Research Institute, National Research Council of Canada; 3) Dept of Human Genetics; 4) Dept of Medicine, McGill University; 5) Dept of Biology, John Abbott College, Montreal , Quebec, Canada.

Prostate cancer (PCa) may progress by circumventing ablation therapy due to mutations in the androgen receptor (AR) gene. The most intensively studied is the mutation T877A in the ligand binding domain (LBD) which causes the AR to become promiscuous, i.e., respond to a number of different ligands. Previous studies using X-ray crystallography have shown changes in the ligand-binding pocket that have been presumed to be the cause of this promiscuity, but have revealed very little regarding the mechanism. We have used a novel molecular modeling approach involving the receptor, as well as the coactivator TIF2 that plays a critical role in N/C terminal interactions. The T877A mutation altered the inverse relationship between exon 1 CAG repeat length and transactivation, and increased N/C terminal interactions but decreased TIF2 binding. We used modeling to compare the crystal structure of the wild type (wt) and T877A AR bound to dihydrotestosterone. This revealed both an increase in flexibility of amino acid residues in the LBD, as well as a larger solvent accessible surface for T877A compared to wt AR. The N-terminal domain FxxLF containing peptide was predicted to bind with greater affinity into the mutant than wt LBD, and the co-activator TIF2 peptide (LxxLL) to bind better with the wt receptor. The improved induced fit of the FxxLF motif containing peptide into the LBD thus appears to be due to the increased flexibility and solvent accessibility of the residues present in the peptide-binding pocket of the mutant LBD. The fact that these observations confirmed our biochemical data indicates the promise of this novel approach. We believe that such a dual modeling approach is likely to lead to advances in understanding hormone-refractory PCa.

Higher Incidence of Chromosome Duplications Identified by Array CGH Compared with FISH. *J.H. Tepperberg, I. Gadi, B. Williford, D. Fuentes, J. Whaley-Davis, C. Legacki, J. Kesler, P. Papenhausen* Cytogenetics, LabCorp, RTP, NC.

Genetic imbalances are generally associated with multiple birth defects, developmental delay, growth retardation, and dysmorphic features. The incidence of common chromosome microdeletion syndromes is estimated to be 1 in 1000-2000 while the detection rate of clinically significant subtelomere abnormalities in individuals with normal chromosomes was recently shown to be approximately 2.5% (Ravnan et. al. 2005). The relative incidence of terminal subtelomere duplications was found to be 1.12% (4/357 abnormal subtelomere cases), while interstitial duplications are considered very rare. Array based Comparative Genomic Hybridization (aCGH) is used as an adjunct to cytogenetics and FISH to detect cryptic dosage imbalance (microdeletions, duplications, insertions and unbalanced subtelomere rearrangements) associated with developmental delay and mental retardation. Array CGH analysis of 405 clinical cases submitted for aCGH (Spectral Genomics 434 BAC array) showed 5.19% (21/405) of cases with clinically significant unbalanced rearrangements. Eighteen of the 21 cases were either cryptic or extremely subtle alterations. Nine cases (23.8%) showed apparent terminal deletions, five cases (23.8%) showed interstitial duplications, four cases (19.0%) were unbalanced derivative rearrangements, and three cases (14.3%) were large unbalanced chromosome abnormalities. Although these numbers are relatively small, the percentage of interstitial duplications is significantly higher compared with what is reported in the literature. Theoretically, an unbalanced meiotic recombination event should result in a deletion and duplication. Small chromosome microduplications are thought to have a less severe phenotype compared to microdeletions and are generally not targeted by a FISH analysis. Furthermore, FISH may not be sensitive enough to detect small microduplications, even by interphase analysis. Thus, chromosome duplications may be significantly under represented in patients with unexplained MR and developmental delay. Array CGH appears to be an efficient high throughput whole genome assay to detect clinically significant chromosome microduplications.

Low serum carnitine in patients with phenylketonuria may not be due to inadequate carnitine intake. *S. Yano[1], K. Moseley[2], E. Baldwin[2], R. Koch[2]* 1) Genetics, Pediatrics Women's & Children's Hosp, LAC+USC Medical Center, Los Angeles, CA; 2) Medical Genetics, Pediatrics, Childrens Hospital Los Angeles, USC, Los Angeles, CA.

An observation of decreased serum carnitine concentration in phenylketonuria (PKU) has been reported by Bohles (1991) and others. Strict protein intake restriction is believed to be directly responsible for low serum carnitine. Iron deficiency, secondary to protein restriction, is also believed to be one of the factors leading to low serum carnitine through the reduction of carnitine synthesis which requires iron as a cofactor. Carnitine synthesis is also known to be inhibited by phenylacetic acid (PAA) which is one of the byproducts of phenylalanine (phe)in patients with PKU who have defective phenylalanine hydroxylase. Fisher et al (2000) reported that phenacetyl-carnitine was identified in urine in patients with PKU and approximately 5-10% of urine total carnitine was in the form of phenacetylcarnitine. We recently identified a group of patients with PKU (age 4-44 y), whose serum phe levels were in the recommended range (except for one), who are on a PKU medical product or large neutral amino acid supplementation, and who have low serum carnitine with normal free/acyl ratio. A high PAA is unlikely the primary cause of low serum carnitine since PAA should be low under strict diet control. Among these patients, we have identified patients with abnormal serum amino acids with a few amino acids being lower than the reference ranges: lysine, ornithine, and/or glycine have been noted to be low. Patients with PKU who have low serum carnitine and lysine are treated with a PKU Medical product which provides lysine above the dietary recommendation. Urine lysine excretion was measured and was found not to be increased in these patients. Lysine absorption may be decreased in these patients. Serum amino acids have not been routinely measured in patients with PKU as a routine metabolic evaluation. We believe that it is important to monitor serum amino acids periodically in patients with PKU since they can develop various amino acids deficiencies regardless their status of the diet treatment.

The Developmental Genome Anatomy Project (DGAP): Finding genes critical in human development. *R. Williamson[1,2], F. Alkuraya[1,2], Y. Fan[1,2], H. Ferguson[1,2], J. Gusella[1,3], D. Harris[1,4], C. Kelly[1,2], K. Kocher[1,2], A. Ligon[1,2], W. Lu[1,2], R. Maas[1,2], B. Quade[1,2], F. Quintero-Rivera[1,3], I. Saadi[1,2], C. Morton[1,2]* 1) Harvard Medical School, Boston, MA; 2) Brigham and Women's Hospital, Boston, MA; 3) Massachusetts General Hospital, Boston, MA; 4) Children's Hospital, Boston, MA.

DGAP (dgap.harvard.edu) is a collaborative effort to identify genes critical in human development from chromosomal rearrangements, utilizing a high-throughput approach of (1) patient ascertainment and collection, (2) FISH-based breakpoint localization, (3) breakpoint cloning and candidate gene identification, and (4) functional analysis in model organisms. We have mapped 151 breakpoints in 73 cases and discovered 25 disrupted genes. Twenty-five breakpoints are cloned and sequenced, and 13 knock-out mouse models evaluated. The phenotype of one case, DGAP056 [t(2;13)(p24;q21)], includes includes blepharophimosis, coloboma of upper eyelid, fundal coloboma, exotropia, profound sensorineural hearing loss, low set and posteriorly rotated ears, and mitral valve prolapse. This translocation disrupts a hypothetical gene, *FLJ21820*. *FLJ21820* is expressed in a very select number of cells in the cochlea further supporting its importance in the hearing pathway. DGAP 113 [t(1;3)(q32.1;q13.2)], has bilateral congenital cataracts, mild developmental delay, a head circumference > 95th percentile, and prominent extra-axial CSF spaces. The chromosome 1 breakpoint lies ~125 kb upstream of the *NEK7* gene. *NEK7* is highly conserved and the mouse ortholog is expressed in the murine developing brain. Studies of *Nek7*-deficient mice are ongoing. DGAP095 [t(X;2)(p11.2;q37)], exhibits seizures, developmental delay, infantile hypotonia, obesity and livedo reticularis. Diacylglycerol kinase delta (*DGKD*) is disrupted by the breakpoint on chromosome 2. DGKD is a member of a family of proteins that have been linked to the regulation of seizure susceptibility. We have created a mouse model for *DGKD* deficiency and are assessing the DGAP095 epilepsy and vascular phenotype in the mouse model.

Accelerated evolution of conserved noncoding sequences in the human genome. *S. Prabhakar*[1,2,4], *J.P. Noonan*[1,2,4], *S. Paabo*[3], *E.M. Rubin*[1,2] 1) US DOE Joint Genome Institute, Walnut Creek, CA; 2) Lawrence Berkeley National Laboratory, Berkeley, CA; 3) Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany; 4) These authors contributed equally to this work.

Changes in gene regulation likely influenced the profound phenotypic divergence of humans from other mammals, but the extent of adaptive substitution in human regulatory sequences remains unknown. Here we survey 129,405 conserved noncoding sequences (CNSs), which studies have revealed to be enriched in gene regulatory elements, for evidence of accelerated evolution in humans. We identified 1,119 conserved noncoding sequences (CNSs) with a statistically significant excess of human-specific substitutions after correcting for the local neutral substitution rate, the degree of CNS constraint in non-human lineages, unevenness of constraint within a CNS, and genome-wide relaxation of constraint in primates. These accelerated elements were disproportionately found near genes involved in neuronal cell adhesion. To assess the uniqueness of human noncoding evolution, we examined CNSs accelerated in chimpanzee and mouse. Although we observed a similar general trend towards neuronal adhesion in chimpanzee, the accelerated CNSs themselves exhibited almost no overlap with human, suggesting independent evolution towards different neuronal phenotypes in humans and chimpanzees. CNSs accelerated in mouse showed no bias toward neuronal cell adhesion. Our results indicate that widespread cis-regulatory changes in human evolution may have contributed to the rise of uniquely human features of brain development and function.

Y Chromosome and Mitochondrial DNA Analysis of a Large Dataset from Mali, Africa. *S.R. Woodward, U.A. Perego, J.E. Gomez, J. Ekins, A. Nelson, M. Nelson, J. Jensen, M. Lunt, T. Tolley, K. Ritchie, I. Masannat, S. Masek, M. Purnell, R. Hughes, N. Angerhofer, N.M. Myres* Sorenson Molecular Genealogy Foundation, Salt Lake City, UT.

The unique history of ancient Mali places it in the trans-Saharan crossroads of West Africa for the trade of slaves, gold, ivory, and salt. The genetic junction of these ancient interactions is reflected in the present-day inhabitants of Mali. An extended Y-chromosome and mtDNA analysis of 700 inhabitants of various regions of Mali is presented, with corresponding genealogical and historical information. All samples were typed at 43 Y-chromosome STR loci and sequenced for mtDNA HVR1 and HVR2, to assess the levels of admixture with known interacting historical populations and demonstrate recent events contributing to the gene pool of present-day Mali.

Admixture mapping for acute inflammatory markers in African Americans: Results from the Health and Body Composition Study. *E. Ziv[1], N. Patterson[2,3], G.J. McDonald[2,3], A. Tandon[2,3], D. Hu[1], L. Pawlikowska[1], P.Y. Kwok[1], Y. Liu[4], A. Reiner[5], W.C. Hsueh[1], J. Zmuda[6], R. Ferrell[6], R. Liu[9], T. Harris[7], S. Cummings[1,8], D. Reich[2,3]* 1) Univ California, San Francisco, San Francisco, CA; 2) Broad Inst, Boston, MA; 3) Harvard Med School, Boston, MA; 4) Wake Forest Univ, Winston-Salem, NC; 5) Univ of Washington, Seattle, WA; 6) Univ of Pittsburgh, Pittsburgh, PA; 7) National Institute on Aging, Bethesda, MD; 8) Calif Pacif Med Cntr Res Inst, San Francisco, CA; 9) Univ of Tennessee, Memphis, TN.

We used an admixture mapping approach to find genetic variants that determine serum levels of acute inflammatory markers. These markers may be important mediators of chronic diseases including atherosclerosis. Several acute inflammatory markers have different levels in African Americans and Caucasians; admixture mapping may be feasible for these phenotypes. We used samples from 1100 participants in the Health and Body Composition cohort who described their race/ethnicity as Black." The cohort included men (43%) and women who were ages 70-79 and ambulatory. We typed 1,322 ancestry informative markers to estimate locus specific ancestry and used this data to perform an admixture mapping scan for serum levels of C-reactive protein, Interleukin-6, soluble IL6 receptor (sIL6R), Tumor Necrosis Factor-a and Plasminogen Activator Inhibitory-1. Data were analyzed using ANCESTRYMAP and confirmed by ADMIXMAP and structure/MALDSOFT. We found a strong locus for sIL6R levels on chromosome 1 (LOD score=5.8 by ANCESTRYMAP, p=0.0000008 by ADMIXMAP) that exceeded the threshold for whole genome significance. The region includes the IL6R gene. The association suggests that an allele which increases sIL6R levels is more common with European ancestry and explains the admixture peak. We are currently testing candidate polymorphisms in the IL6R gene to determine which accounts for the admixture mapping peak. Our results provide empirical proof that admixture mapping can not only obtain coarse localization of a phenotypically important variant, but can also fine map it. Finding the genes that control acute inflammatory markers may help explain the relationship between inflammation and disease.

Very-high-resolution mapping of DNA copy-number alterations using high-density tiling oligonucleotide arrays.

A.E. Urban[1], J.O. Korbel[1], F. Grubert[1], C. Hart[1], R. Selzer[2], T. Richmond[2], R. Green[2], B.S. Emanuel[3], K. Kidd[1], M. Gerstein[1], S.M. Weissman[1], M. Snyder[1] 1) Yale University, New Haven, CT; 2) NimbleGen Systems, Inc., Madison, WI; 3) University of Pennsylvania, Philadelphia, PA.

Studying the emerging phenomenon of pervasive human genomic segmental aneuploidy is expected to allow for a better understanding of the basis of human phenotypic variation, in norm variants and in disease states. We have developed high-density oligonucleotide tiling microarray based High-Resolution CGH (HR-CGH). This technology allows us to detect, with sub-kilobase accuracy, the presence and extent of chromosomal aberrations ranging in size from 600 bp to several million bp, in confirmatory and ab initio studies. We first used arrays covering the beta-globin locus on Cs11 (9 bp tiling density, isothermal tiling) and all of Cs22q (85 bp tiling, isoTm). Analyzing full-complexity genomic DNA from patients with a variety of disease-causing aberrations (various heterozygous deletions, duplications, partial trisomies and partial tetrasomies) we could map breakpoints with high accuracy (typically up to 200bp resolution when confirmed by DNA sequencing following PCR) [Urban, Korbel et al., PNAS, 2006] We have extended this approach beyond the initial Cs22q experiments and have now carried out more than 120 additional hybridizations using HR-CGH arrays covering the sequence of human chromosome X (111bp or 35bp tiling, isoTm) or the ENCODE regions (38bp tiling, fixed-length oligomers) in addition to the Cs22q array. We probed these arrays with DNA from patients with developmental disorders, especially of the nervous system, as well as with DNA from healthy probands from various ethnicities (i.e. a subset of the HapMap samples as well as samples from S.W. Asia, Siberia, Pacific Islands and South America) and can observe a large number of copy number variations (13 with very high confidence, 104 with high to medium confidence and 600 with medium to lower confidence in a preliminary analysis of CsX data from 12 healthy individuals from 5 ethnicities) that are currently being experimentally verified and cataloged.

A novel mitochondrial DNA A4401G mutation is involved in hypertension in two Chinese pedigrees. *S. Wang[1], H. Zhu[1], L. Yang[2], C. Lu[1], M. Guan[2]* 1) Geriatric Cardiology, Chinese PLA General Hospital, Beijing, Beijing, China; 2) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio.

Left ventricular hypertrophy (LVH) is one of the most important target organ damage of hypertension. Despite the involvement of multiple factors, the genetic factors including the mitochondrial genomes have been implicated to play an important role in the pathogenesis of hypertension. Recently, a systematic and extended mutational screening of mitochondrial genome has been initiated in the large clinical population of Geriatric Cardiology Clinic at the Chinese PLA General Hospital, China. In the present study, 200 sporadic Chinese subjects with left ventricular hypertension were recruited. Further genetic evaluation found that two of these Chinese families seem to be transmitted maternally. The sequence analysis of complete mitochondrial genome identified a novel A-G mutation in the junction of tRNA-Met and tRNA-Glu. This mutation appears to affect the processing of these mitochondrial tRNAs, thereby reducing the steady-state levels of these two tRNAs. As a result, it causes the defect in mitochondrial protein synthesis, thereby impairing the respiration. These genetic and biochemical data imply that the novel A4401G mutation is involved in the pathogenesis of hypertension.

Quantitative determination of gangliosides in the cerebrospinal fluid of patients with GM2 gangliosidosis using tandem mass spectrometry. *C.J. Tifft[1], J. Gu[2], J. Kurtzberg[3], R.L. Proia[4], S.J. Soldin[2]* 1) Div Genetics & Metabolism, Children's Natl Medical Center, Washington, DC; 2) Bioanalytical Core Laboratory, GCRC, Georgetown University, Washington, DC; 3) Pediatric Blood and Bone Marrow Program, Duke University Medical Center, Durham, NC; 4) Genetics of Development and Diseases Branch, NIDDK, NIH, Bethesda, MD.

Tay-Sachs (TS), caused by a deficiency of the subunit of lysosomal enzyme -hexosaminidase A, is a rapidly progressive neurodegenerative disorder for which no therapy is currently available. Massive accumulation of GM2 ganglioside in neurons of affected individuals is a hallmark of the disease. Biochemical markers of disease progression are limited in this primarily CNS disorder. We have used tandem mass spectrometry to measure ganglioside content in CSF of patients with infantile TS disease that have undergone umbilical cord blood transplantation. **Methods:** 40 l of patient or control CSF was added to 400 l of methanol containing the internal standards. The mixture was injected onto a Supelco Cosil C-18 column, washed with 20% methanol, and gangliosides were eluted using a methanol gradient. Samples were analyzed on an Applied Biosystems API-4000 System. **Results:** Sixteen CSF samples and 4 control samples were analyzed. For one of the patients, diagnosed prenatally, 9 serial samples were available for analysis. The pre-transplant sample taken at 1 month of age showed a 100-fold elevation of GM2. A progressive decline in GM2 levels was observed following transplantation although levels remained elevated and did not decrease relative to GM1 levels. **Conclusions: (1)** Tandem mass spectrometry is a reliable method for quantitating gangliosides from a small volume of CSF. **(2)** Although a decline in GM2 levels was observed following transplantation, the decline did not result in improved clinical outcome. **(3)** MS/MS can readily detect a marked elevation of GM2 ganglioside in TS disease patients prior to the onset of clinical symptoms. Modification of the technique to utilize plasma or dried blood spots may be applicable for therapeutic monitoring or newborn screening.

The difference of crossover pattern between male and female. *H. Xi, Z. Jiang, R. Deka* Dept Environmental Health, Univ Cincinnati, Cincinnati, OH.

It is well known that the recombination rate in females is much higher than in males but the underlying mechanisms have not been revealed yet. Here we present a hypothesis that the number and locations of chiasmata are important to maintain the chromosome stability during meiosis. Since eggs have a much longer stage of Prophase I, we suspect the recombinant chromosomes need more chiasmata or stable form of chiasmata to keep their stability. Therefore, the number of recombination events is much higher in females and locations of recombination sites are much stricter in females than in males. Through the analysis of several whole genome scan data, we observed the locations of recombination events in female are not uniformly distributed across the chromosome, i.e. the recombination site on the chromosomes with only one crossover seldom happens in the terminal region (which may be the unstable form). These results partially confirm our hypothesis.

Glaucoma-causing myocilin mutations require association with the Peroxisomal Targeting Signal-1 Receptor (PTS1R) to elevate intraocular pressure. *V.C. Sheffield[1,2,3], A.R. Shepard[4], N. Jacobson[4], J.C. Miller[4], I.-H. Pang[4], H.T. Steely[4], C. Searby[4], E.M. Stone[1,3], A.F. Clark[4]* 1) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA; 3) Department of Ophthalmology, University of Iowa, Iowa City, IA; 4) Glaucoma Research, Alcon Research, Ltd., Fort Worth, Tx.

Primary open angle glaucoma (POAG) is a clinically and genetically heterogenous group of optic neuropathies and a leading cause of blindness. Specific mutations in the myocilin (MYOC) gene have been shown to cause POAG with varying age-of-onset and degree of severity. Myocilin associated glaucoma is inherited as an autosomal dominant disorder and this form of glaucoma is the single leading cause of POAG accounting for up to 4% of all POAG cases. The mechanism by which myocilin mutations lead to increased intraocular pressure has not been determined, and attempts to develop animal models of POAG have been unsuccessful. Neither elimination of the myocilin protein by mutation of one or both alleles, nor overexpression of myocilin is sufficient to result in POAG. Therefore, it appears that a deleterious gain-of-function is required for pathogenesis. We present data showing that specific mutations of the myocilin protein result in a physical interaction between myocilin and the peroxisomal targeting signal type 1 receptor (PTS1R) due to mutation-induced exposure of a cryptic peroxisomal signaling site at the carboxy-terminus of the human myocilin protein. Our data show that more severe early-onset POAG mutations have a stronger association with PTS1R. We further demonstrate that the association of mutant myocilin with PST1R causes elevated intraocular pressure (IOP) in a rodent model. This is the first demonstration of a disease resulting from mutation-induced exposure of a cryptic signaling site that causes mislocalization of mutant protein to peroxisomes and the first disease-gene-based animal model of human POAG.

Two new cases of analphoid markers from novel regions, 14q32 and Yp11.2/15q fusion. *P. Papenhausen[1], I. Gadi[1], J. Tepperberg[1], P. Warburton[2], B. Pletcher[3], P. Chang[4]* 1) Dept Cytogenetics, Labcorp of America, Res Triangle Park, NC; 2) Mt Sinai Med. Center, NY, NY; 3) 90 Bergen St., Newark, NJ; 4) Jersey City Med. Center, Jersey City, NJ.

Two cases characterized by highly unusual cytogenetic findings were referred for high resolution evaluation. Case 1, a 17 y.o. male showed moderate MR(3rd grade level), strabismus, and hypomelanosis of Ito. The latter indication is often associated with mosaicism and indeed, an unsatellited supernumerary marker was found in 5 of 40 cells examined. Since C-banding was negative, a subtelomere FISH study was pursued which revealed a 14qter signal on both ends of the marker. Centomeric 14/22 FISH confirmed the analphoid nature of the apparent i(14)(qter>q32.1>neo>qter). The inbalance in this patient was therefore, tetrasomy for 14q32.1>qter in about 12% of peripheral lymphocytes. Only one apparently unpublished case of involvement of the 14qter region could be found. Case 2 involved a two week old male with a web neck, long fingers, undescended testes, hypotonia and feeding difficulties. Cytogenetics revealed only 45 chromosomes due to the fusion of the Y short arm and 15 long arm(q13qter). Q and C banding as well as alphoid Y and 15 FISH were negative. Additional FISH targeting SRY was positive while loss of the paternal SNRP confirmed Prader-Willi syndrome. An apparent neocentromere with loss of centromeric associated proteins, but presence of a kinetichore was confirmed. Subtelomeric FISH studies were also ordered, but only served to confirm Yq loss. No alphoid repeats could be detected in either marker. These cases represent two novel sites for neocentromeres, increasing the spectrum for this new class of marker.

A Comparison of Publicly Accessible Y Chromosome Databases for Ancestral and Population Studies. *U.A. Perego, J. Ekins, N.M. Myres, K. Ritchie, R. Hughes, N. Angerhofer, S.R. Woodward* Sorenson Molecular Genealogy Foundation, Salt Lake City, UT.

Y-chromosome haplotyping has been heavily utilized in academic settings for ancestral and population studies in recent years. As molecular technologies have become more affordable and publicly available, a number of online searchable genetic databases have arisen to serve the private individual. Among the largest and most comprehensive Y-chromosome databases utilized by the public for personal ancestral research are the Y Chromosome Haplotype Reference Database (www.YHRD.org), the Sorenson Molecular Genealogy Foundation Y Chromosome Database (www.SMGF.org), and the Family Tree DNA Ysearch Database (www.YSEARCH.org), each containing thousands of haplotypes correlated to genealogical, historical and geographic data. This study provides a comparison of the unique array of applications available to the end user, often at no cost, from each database. All have the common goal of making powerful genetic tools available to the public, in order to promote discovery of recent and ancient paternal connections of the human family that are significant to the individual.

Genetic Profiling of Lung Cancer. *V. Venkatraj[1], T. Bhari[1], G. Zhou[2], E.T. Castiglioni[1], J.C. Huber[2], P.W. Dunne[1], K.C. Donnelly[2]* 1) Dept VIBS, Texas A&M Univ, College Station, TX; 2) SRPH,Texas A&M Univ, College Station, TX.

Lung cancer is the leading cause of cancer mortality worldwide.DNA adducts formed as a consequence of exposure to tobacco smoke may be involved in carcinogenesis, and their quantification is used as a dosimeter to evaluate DNA repair and risk of lung cancer.In an effort to uncover the relationship between genetic changes and DNA repair we did a pilot study on primary lung tumors using two approaches. To determine the genomic copy changes in primary lung cancer evolution we employed array Comparative Genomic Hybridization (aCGH) technique (Spectral Chip TM 2600, Spectral Genomics,USA) on 10 lung primary tumors and normal tissue from adjoining areas. Second, to quantify DNA adducts we used nuclease-P1 enhanced 32P DNA post-labeling on these same samples. Our results indicated the average number of genetic aberrations were higher in smokers with lung cancer (20/tumor) compared to nonsmokers (13/tumor) with lung cancer. In addition, our data points to recurrent changes in several chromosomal regains; DNA gain of 1p13-21, 1p31-p36, 1q21-25, 8q12-24(60%) of the samples, followed by DNA gain of 1q42-43, 12q12-q24 (50%).DNA loss was observed less frequently and included 10q (40%) and 3p, 4q, 6q, 12p and 12q (30%). Some of the genes relevant to lung cancer tumoriginesis mapping to these loci include N-ras, GSTM1, L-Myc,EGFR-1,C-Myc,MDM2, Bcl-2, BAX, GSTT1,FHIT, PTEN, RARB,p16,RB and p27/Kip1. The Diagonal Radioactive Zone (DRZ) in the adjacent lung tissues from current smokers was higher than those from former smokers. Moreover, the number of DNA adducts was about 6 fold less in tumor tissue as when compared to adjoining normal tissue. These results support the conclusions that lung tumor cells in smokers have a higher frequency of chromosomal aberrations compared to lung tumor cells in nonsmokers, indicating an enhanced genomic instability. Furthermore our data points to the importance of analyzing the apparently normal adjoining tissue for genetic changes as they may reveal chromosomal changes that are relevant to early transformation events during lung cancer evolution and provide accurate quantification of DNA adducts compared to tumor samples.

Detection and characterization of insertion-deletion polymorphisms in normal human populations. *D.A. Wheeler[1,2], S.I. Yakub[1,2], Y. Ding[2], D.M. Muzny[1,2], R.A. Gibbs[1,2]* 1) Molecular and Human Genetics, Baylor Col Medicine, Houston, TX; 2) Human Genome Sequencing Center.

Insertion/deletion polymorphisms (indels) occur much less frequently than single nucleotide polymorphisms but are more likely to exhibit severe functional consequences when located in coding or regulatory sequences. The Human Gene Mutation Database catalogues over 17,000 insertions and deletions associated with 3,500 phenotypes in humans including the well known CCR5-del32 polymorphism that, as a homozygote, confers resistance to infection by R5-HIV-I infection. Inspite of this extraordinary compendium demonstrating the influence of indels on human health, relatively little effort has gone into cataloguing natural variation due to indels in human populations. We have systematically extracted data reflecting genetic diversity on a wide range of scales within each species sequenced in the Human Genome Sequencing Center. Three million whole genome shotgun reads were generated from a library of pooled genomic DNA from 8 individuals of African American origin. They were compared to the reference human genome (build 35) using BLAST and the output was examined for any read with 2 matches to the genome. Through analysis of these matches we have discovered more than 5,000 indels between 10 bases to over 1 million bases, a sampling of which have been validated by PCR. Scores of indels are involved in functional gene alterations, including single amino acid deletion, frame shift mutations and deletion of entire exons and genes. We are currently exploring the population frequencies of these indels in European, Chinese and African populations.

Gene Conversion in Palindromic Regions of the Y Chromosome. *A. Turner, U. Perego, N. Myres, R. Hughes, J. Ekins, K. Ritchie, I. Masannat, N. Angerhofer, S. Woodward* Sorenson Molecular Genealogy Foundation, Salt Lake City, UT.

Several microsatellite markers on the Y chromosome are located in the palindromic regions of the Y chromosome. The SMGF database, with over 15000 records, includes data for the multi-copy markers DYS385 a/b, DYS459 a/b, DYS464 a/b/c/d/, and YCAII a/b. These markers typically have multiple alleles in an individual. However, gene conversion may result in a single allele for one or more of those markers (homozygosity) and violate the single-step mutation model for microsatellites. We will present the distribution of alleles, and the correlation of the homozygous state in one marker with other markers, providing data on the frequency and length of gene conversion events.

KDR gene polymorphism is associated with coronary artery lesions in Kawasaki disease. *I.S. Park[1,2], E.J. Seo[2,3], J.K. Lee[2], K.J. Kim[2], J.J. Kim[2], S.J. Hong[1], Y.H. Kim[1,2], J.G. Ko[1,2]* 1) Department of Pediatrics, University of Ulsan College of Medicine and Asan M, Seoul, Korea; 2) Genome Research Center for Birth defects and Genetic disorders, Asan Medical Center, Seoul, Korea; 3) Department of Laboratory Medicine, University of Ulsan College of Medicine and Asan M, Seoul, Korea.

Kawasaki disease (KD) is an acute febrile vasculitis of young children and is complicated by coronary artery lesions (CAL). Although an infectious agent is suspected as the cause of KD, genetic factors might influence on susceptibility to KD and the risk of the developing CAL. Forty-one common polymorphisms of 17 genes (ACE, AGTR1, CCL2, CCR5, CD14, IL1A, IL1B, IL4, IL6, IL10, KDR, MBL2, MMP3, NPPB/BNP, SERPINE1, TNF, VEGF) were genotyped in 97 Korean KD patients including 49 patients with CAL and 100 healthy controls. Allele and genotype frequencies were compared between groups using Chi square and haplotypes were estimated using the PL-EM algorithm. All genotypes were in Hardy-Weinberg equilibrium, but allele and genotype frequencies of those polymorphisms did not differ between KD patients and controls. Interestingly, we found a significant association for the 1719A/T (rs1870377) polymorphism of the KDR gene with CAL within the KD patients. The frequency of T allele was significantly lower in KD patients with CAL than in those without CAL (P=0.03, OR=0.50; 95% CI 0.28-0.91). Haplotype analysis for -319A/T (rs6824124), 1192A/G (rs2305948) and 1719A/T (rs1870377) of the KDR gene showed that TGA haplotype differed significantly between two groups. KDR gene encodes kinase insert domain receptor which is the receptor of VEGF. In previous reports, VEGF and VEGF receptor were upregulated in blood vessels in acute KD. Our findings suggest that KDR gene polymorphism may be responsible for the development of CAL in KD patients.

Autosomal dominant hidradenitis suppurativa is not linked to 1p21.1-1q25.3, in two large multigenerational Indian families. *U. Radhakrishna[1], T.Y. Mehta[2], J.V. Solanki[3], U.C. Patel[3], U. Ratnamala[1], S.K. Nath[4]* 1) Green Cross Blood Bank & Genetics Research centre, Ahmedabad India; 2) Samarpan Medical & Research Organization, Modasa, India; 3) Department of Animal Genetics & Breeding, Veterinary College, Gujarat Agriculture University, Anand, India; 4) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, USA.

Hidradenitis suppurativa (HS) (HS: OMIM 142690) is an aggravating chronic inflammatory skin condition characterized by swollen, painful, inflamed lesions in the axillae, groin, and other parts of the body that contain apocrine glands. It affects more females than males with an incidence ranging from 0.1/100 to 4/100. The risk of developing nonmelanoma skin cancer including buccal cancer and primary liver cancer is very high among patients with HS (Arch Dermatol 2001 137:730-4). We have studied two large Indian hidradenitis suppurativa families with autosomal dominant mode of inheritance and full penetrance. There are 84 individuals in these pedigrees including 25 affected. The age of onset is 25-35 years. All affected had typical characters of HS and some of the clinical findings included folliculitis, GI polyps, cutaneous scars, epidermoid carcinoma and polymorph function defects and hirsuitism in few affected females. Recently, a locus for autosomal dominant form of HS was (J Invest Dermatol. 2006 126:1302-6) reported on chromosome 1p21.1-1q25.3 in a large four generation Chinese pedigree, subsequently we genotyped two of our families using several polymorphic microsatellite markers closely linked to HS1 locus. Analyzing 45 individuals, all twenty markers yielded significant negative (<-2.0) at = 0. Thus the HS1 locus can be excluded as the candidate locus responsible for HS in our Indian families. We suggest that genetic heterogeneity is present in the pathogenesis of HS and that the reported HS1 locus may be ethnic specific. We are planning to perform genome-wide linkage analysis in this family to identify the responsible locus.

Molecular Investigation SCA in 28 patients suspected to SCA in Iran. *S. Saber, M. Rostami, M.M. Banoei, S.H. Nafisi, M. Houshmand* medical genetics, NIGEB, Tehran, Iran.

More than 20 types of SCA have been described.These types are given numbers(1-22,excluding the number 9). All types of SCA are characterized by a progressive incoordination of walking.They are often associated with poor coordination of hand movments,eye movments,and speech.With some exceptions,the onset of symptoms usually occurs after the age of 18.SCA is slowly progressive M.R.I and C.T of affected persons often show shrinkage or atrophy of cerebellum. Most common of SCA is SCA3(21%),SCA2 and SCA6(15%) The genetic change that causes SCA types 1,2,3,6,7,12 and 17 is called a CAG repeat expantion. We checked these types of SCA in our lab with PCR analysis across the CAG region of the SCA1, SCA2, SCA3, SCA6, and SCA7 genes to determine allele sizes. We checked 28 patients refer to our lab for detection of these types of SCA by molecular technique.13 patients were normal repeat size for these types of SCA and 6 patients were expanded repeat size(2 patients SCA3,2 patients SCA6 and 2 patients SCA2).9 patients have intermediate repeat size.After detection of normal repeat, we checked other hereditary ataxia.Then,we proved AT for 2 patients by molecular technique.

Type	Chromosome	Normal repeat size	Expanded repeat size
SCA 1	6p23	6-36	39-83
SCA 2	12p24	15-31	34-220
SCA 3	14q24.3-q32	12-40	55-86
SCA 6	19	4-18	21-33
SCA 7	3p12-p21.1	4-19	37-300

.

Polymorphisms in the PTPN22 region are associated with psoriasis of early onset. *Rh.Ll. Smith[1], R.B. Warren[2], S. Eyre[1], H.S. Young[2], C.E.M. Griffiths[2], J. Worthington[1]* 1) ARC-EU, University of Manchester, Manchester, United Kingdom; 2) The Dermatology Centre, Hope Hospital, University of Manchester, Manchester.

T-cell recruitment and activation at the site of new psoriasis lesions are considered to be of primary importance in the pathogenesis of the disease. A functional polymorphism (R620W) in the haematopoietic-specific protein tyrosine phosphatase (PTPN22) gene, a negative regulator of T-cell activity, is associated with a number of autoimmune diseases including rheumatoid arthritis and Type I diabetes but not psoriasis. The purpose of this study was to investigate further the role of the PTPN22 gene region in susceptibility to chronic plaque psoriasis of onset on or before age 40yr (Type I psoriasis). Using Sequenom MassArray technology we genotyped 13 single nucleotide polymorphisms (SNPs), including R620W, in the PTPN22 region in 647 unrelated Type I psoriasis patients and 566 population based controls. Two SNPs demonstrated significant association with Type I psoriasis: - SNP rs1217414, which resides in intron 2 of PTPN22, conferred risk by carriage of two copies of the minor allele with OR = 2.39 (95% CI 1.43 - 4.11, p=0.0005); and - SNP rs3789604, located downstream of the gene- under a dominant model for the major allele (OR = 1.43; 95% CI 1.13-1.80, p = 0.0017). The rs2476601 (R620W) SNP showed no evidence of association with Type I psoriasis (p=0.67) susceptibility, thereby replicating existing literature. This study suggests that association does exist between Type I psoriasis and 2 SNPs in the region of the PTPN22 gene. SNP rs1217414 has not been identified previously as associated with antibody-associated autoimmune diseases and its exact function is unknown. SNP rs3789604, located in a predicted transcription factor binding site, has been associated with rheumatoid arthritis but only when independent of R620W. Further investigation and replication is required in other psoriasis cohorts as well as other autoimmune diseases un-associated with the R620W polymorphism.

Analysis methods for whole-genome, whole-population association and application to Metabolic Syndrome in the island of Kosrae, Micronesia. *I. Pe'er[1,2], J.K. Lowe[1,2,3], J. Salit[3], S. Purcell[2,4], M.L. Blundell[3], P.E. Bonnen[3], R.P. Lifton[5], J.L. Breslow[3], J.M. Friedmann[3,6], M. Stoffel[3], M.J. Daly[1,2,4], D.M. Altshuler[1,2,4]* 1) Broad Inst, MIT & Harvard, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) The Rockefeller University, New York, NY; 4) Harvard Medical School, Boston, MA; 5) Yale University, New Haven, CT; 6) Howard Hughes Medical Institute.

With the current ability to genotype most human variants, the approaching challenge for genetic association is, at the limit, analysis of whole genome data collected from the entire population. The magnitude of such data, the broad range of analyzable heritable traits, and the freedom from sample ascertainment issues make them very compelling. The complications arise from the collection being less controlled than traditional study design: * Sampled families have noin uniform structure, and are interconnected in a complex manner. * Hidden and known stratification may be present. * Phenotypes may be collected in different, less consistent batches. We develop methods for tackling these issues by computing between-family and within family components of association signal, and controlling remaining stratification issues empirically, thereby achieving both utilization of the available information, as well as avoidance of tainted association scores. We apply these methods to the island population of Kosrae, Micronesia, where 100k SNPs provide ample coverage of the genetic variation, and wwhere essentially the entire adult population (N>3000) have been thus genotyped and phenotyped for a collection of traits related to Metabolic Syndrome.

Sex-specific Linkage to Total Serum Immunoglobulin E in Families of Children with Asthma in Costa Rica. *BA. Raby[1,2,3], ME. Soto-Quiros[4], L. Avila[4], SL. Lake[1,3], C. Liang[1], E. Fournier[4], M. Spesny[4], JS. Sylvia[1], R. Lazarus[1,3], A. Verner[5], TJ. Hudson[5], BJ. Klanderman[1], NB. Freimer[6], EK. Silverman[1,3], ST. Weiss[1,3], JC. Celedon[1,2,3]* 1) Channing Laboratory, Brigham & Women's Hosp, Boston, MA; 2) Division of Pulmonary and Critical Care Medicine, Beth Israel Deaconess Medical Center; 3) Harvard Medical School, Boston MA; 4) Division of Pediatric Pulmonology, Hospital Nacional de Niños, San José, Costa Rica; 5) University and Genome Québec Innovation Centre, Montreal, QC; 6) Department of Psychiatry, ULCA, Los Angeles, CA.

Total serum immunoglobulin E (IgE) is a critical intermediate phenotype of asthma and allergic diseases. Although it has long been recognized that total serum IgE levels exhibit sexual dimorphism in humans (males consistently demonstrating higher total serum IgE levels than females), the basis for this difference is unknown. To identify genetic determinants of total serum IgE, a genome-wide scan of 380 short tandem repeat markers was performed in 655 members of 8 extended pedigrees of children with asthma in the Central Valley of Costa Rica. Genome-wide linkage analysis of log-transformed total serum IgE levels was performed by variance component models implemented in SOLAR. Because of prior evidence and sexual dimorphism of IgE in participating families, the analysis was repeated after stratification by sex. Only one genomic region (chromosome 7p15) showed modest evidence of linkage to IgE (LOD=1.60 at 23 cM) among all subjects. After stratification by sex, the evidence for linkage of specific genomic regions to IgE differed greatly between males and females: there was significant evidence for linkage of a novel locus on chromosome 20p12 to IgE (LOD = 3.63 at 36 cM) in males and suggestive evidence of linkage to IgE for three loci (chromosomes 3q21 [LOD = 1.93 at 146cM] and 7p21 [LOD = 2.27 at 12cM] in females, and chromosome 17q12 [LOD = 1.98 at 34cM] in males). These data are the first to provide a possible genetic basis for differences in total serum IgE between sexes. In addition, this genome-wide linkage analysis of total serum IgE is the largest ever conducted in a Hispanic population.

Mutation spectrum in X-linked retinitis pigmentosa in the Danish population. *H. Prokisch[1, 2], M.B. Hartig[1], R. Hellinger[1], T. Meitinger[1, 2], T. Rosenberg[3]* 1) GSF-Research Center, Inst of Human Genetics, Neuherberg, Germany; 2) Technical University Munich, Inst of Human Genetics, Munich, Germany; 3) Gordon Norrie Centre for Genetic Eye Disease, Hallerup, Denmark.

Retinitis pigmentosa is found with an overall prevalence of 1:4000 in the Danish and other populations (Boughman JA et al 1980; Haim et al 1993). The X-linked pattern of inheritance (xlRP) is observed in approximately 10 to 15% of RP cases 2, 3 . In the first or second decade of live affected males develop night blindness and restriction of visual fields, finally disease may lead to complete blindness. Although 5 loci have been proposed in xlRP, more than 90% of cases are caused by mutations in the RPGR and RP2 genes (Meindl et al 1996, Schwahn et al. 1998). Numerous 3` splice variants of RPGR have been described in different tissues. One transcript expressed in the retina includes exon 1 to 14 and the 3`terminal ORF15 (Vervoort et al. 2000). All mutations, which are identified so far, affect this transcript. As 50 to 80% of RPGR mutations were found in ORF15 (size ~ 1,7 kb) versus 20 to 35% of mutations in the exons 1 to 14 (size ~ 1,8kb), ORF 15 was claimed a mutational hotspot (Vervoort et al 2000, Bader et al 2003, Breuer et al 2002, Sharon et al 2003). Here we provide the molecular characterization of the 23 uncharacterized X-linked RP families and give an overview of the 30 known families in Denmark.

Lung cysts and Spontaneous Pneumothrorax: Clinical and Genetic Associations among 198 cases of Birt-Hogg-Dubé Syndrome. *J.R. Toro, S. Pautler, L. Stewart, G. Glenn, O. Toure, M. Wei, P. Choyke, B. Zbar, S. Steinberg, D. Nguyen, M. Linehan* National Cancer Institute, NIH, Bethesda, MD.

Birt-Hogg- Dubé syndrome (BHDS) (OMIM #135150) is an autosomal dominantly inherited genodermatosis that predisposes to fibrofolliculomas, kidney cancer, lung pneumatocysts and spontaneous pneumothorax. To date no study has investigated in detail the pulmonary manifestations of BHDS. In this study, we conducted the largest investigation to date of the pulmonary features, genotype-pulmonary correlation and risk factors for pneumothorax in 198 patients with BHDS. Using direct sequencing we screened patients for mutations in the BHD. BHD mutations were in all coding exons (4-14) except 4 and 8. Exon 11 had the largest number of individuals and families with BHD mutations. Screening using computerized tomography of the chest revealed pulmonary cysts in 89% (177/198) of BHDS patients. Twenty-four percent (48/198) of patients with BHDS had a history of one or more pneumothoraces. We examined the relationship of pneumothorax with categorical parameters (gender, smoking history, kidney tumors and lung cysts) and continuous parameters (the total number of cysts, total number of intraparenchymal cysts, total number of subpleural cysts, number of lobes with cysts, total lung cysts volume, largest cyst diameter and volume). The only categorical parameter that was significantly associated with pneumothorax was the presence of lung cysts ($P=0.006$). Total lung cyst volume, largest cyst diameter and volume, and every parameter related to the number of lung cysts were significantly associated ($P<0.0001$) with pneumothorax. A logistic regression analysis showed that only total number of cysts in the right parenchymal lower lobe and the total number of cysts located in the pleura in the right middle lobe were needed to classify a patient as to whether he or she is likely to have a pneumothorax or not. Kaplan-Meier analysis showed that the probability of a BHDS patient of not having the first pneumothorax by age 30 is 94%, and 75% by age 50. Our study shows a significant association between the lungs cysts (number and location) and pneumothrorax.

Genomic literacy and public attitudes toward the medical applications of genome research: a nationwide opinion survey concerning genome research in Japan. *Z. Yamagata[1], K. Muto[2], I. Ishiyama[1], A. Nagai[1], A. Tamakoshi[3], K. Mimura[4]* 1) Department of Health Sciences, University of Yamanashi, Chuo, Yamanashi, Japan; 2) Faculty of Medicine, Shinshu University, Matsumoto, Nagano, Japan; 3) National Center for Geriatrics and Gerontology, Obu City, Japan; 4) Ochanomizu University, Tokyo, Japan.

Objectives: Due to recent marked advances in genome science, studies on its medical applications have been performed. However, such medical applications have ethical, legal, and social implications (ELSI). In Japan, although there have been few large-scale surveys of public attitudes toward genome science, their attitudes toward its medical applications are unclear. Therefore, the purpose of this study was to clarify the public attitudes toward the medical applications of genome research, i.e., the relationship between genomic literacy and decision making regarding genetic medicine Participants and Methods: In 2005, an anonymous mail questionnaire survey was conducted among 4000 males and females aged 20-69 years. In the questionnaire, the attitude was classified into affective (image), cognitive (belief), and behavioral (decision making) components, and questions corresponding to each component were used. We evaluated genomic literacy based on a 3-dimensional measurement: (i) the degree of understanding of genome science terms and other science terms as terms (term understanding), (ii) the degree of understanding of genome science terms and other science terms in the given context (context understanding), and (iii) the perception of values/risks (value/risk perception). Result and Discussions: The response rate was 54.3%; 2171 participants (991 men and 1180 women) were analyzed. The participants generally had a positive attitude toward the medical applications of genome research. Participants who had a positive image, positive belief, and high level of genomic literacy made positive decisions, while those who had marked negative beliefs and a low level of genomic literacy made negative decisions. It is suggested that a deficit model of public understanding of genomic research may be generally accepted in Japan.

Global gene expression analysis links glutamatergic and GABAergic neurotransmission alterations to suicide and depression. *A. Sequeira[1], T. Kemplan[1], F. Mamdani[1], J. ffrench-Mullen[2], G. Turecki[1]* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Gene Logic Inc., Gaithersburg, MD, US.

Suicide is a complex disorder with a clear genetic predisposition and often associated with psychiatric disorders. Several lines of evidence have established that molecular alterations in many different areas of the brain may be implicated in the physiopathology of suicide and depression, but typically those studies have focused on one or a few genes at a time. Microarray analysis allows the parallel monitoring of expression at the mRNA level of thousands of genes. We performed a gene expression study on total mRNA isolated from 17 cortical (Brodman areas (BA) 4, 6, 8-9, 10, 11, 20, 21, 38, 44, 45, 46, 47) and subcortical (BA24, BA29, amygdala, hippocampus, Nucleus Accumbens) brain regions from 28 suicide cases (18 with and 10 without major depression) and 13 matched controls using the Affymetrix HG-U133AB chip set. We observed the highest number of suicide specific alterations in prefrontal cortical areas in agreement with previous observations implicating this region in suicide and depression. Global ontological profiling revealed an overrepresentation in the prefrontal cortex of genes implicated in the adenosine triphosphate (ATP) metabolic pathway. Synaptic neurotransmission and G-protein coupled signaling was on the other hand globally overrepresented and lead us to the observation that Glutamatergic and GABAergic related genes were globally altered. In conclusion, this constitutes the first overview of global molecular changes in the brain of suicide victims and suggests an alteration of the ATP metabolic pathway in the prefrontal cortex and global changes in the expression of genes implicated in GABAergic and Glutamatergic neurotransmission in suicide and depression.

Fine Mapping of the *CHRNA7* Candidate Gene for Association Studies with Schizophrenia. *S.H. Stephens, S. Leonard* Psychiatry, University of Colorado Health Sciences Center, Aurora, CO.

Schizophrenia has been linked to the 15q14 locus in multiple independent studies and across ethnicities. The 15q14 linkage region was independently linked to a P50 sensory processing deficit found in most schizophrenics. The 7 nicotinic acetylcholine receptor subunit gene, *CHRNA7*, maps to this region and was selected as the best candidate gene for the P50 gating deficit based on both human and animal studies. Smoking is particularly prevalent in schizophrenics and is hypothesized to be a form of self-medication for these patients. Binding studies with 7 receptor agonists found 50% fewer receptors in the post-mortem brains of persons with schizophrenia, than those without the illness. Low levels of the 7 receptor may have downstream consequences for multiple neurotransmitter systems resulting in changes in expression normally triggered by these neurotransmitters. As smoking appears to alter gene expression in all individuals, it may actually help to normalize gene expression in schizophrenics. *CHRNA7* is now considered one of few important candidate genes for schizophrenia. Mutation screening of the *CHRNA7* coding region and intron/exon splice junctions revealed multiple synonymous variants and rare non-synonmous variants that were not associated with schizophrenia or the P50 deficit; however, this screening also revealed a large number of functional mutations in the upstream regulatory region of *CHRNA7*, particularly, the core promoter. My hypothesis is that genetic variance at the *CHRNA7* gene is associated with risk for schizophrenia and accounts for linkage to this region. To test this hypothesis I will expand on the mutation screening by fine mapping the *CHRNA7* gene using a combination of SNP and microsatellite markers to capture all genetic variance in this region. I will also use known polymorphic markers in the upstream regulatory region of the *CHRNA7* gene for single SNP association studies as well as multi-locus models for association. Results of this study will reveal whether variance in the *CHRNA7* candidate gene and/or its upstream regulatory region accounts for the linkage to schizophrenia.

Lysosomal N-acetyltransferase deficient in mucopolysaccharidosis type IIIC is encoded by the TMEM76 gene on human chromosome 8. *A. Pshezhetsky[1], V. Seyrantepe[1], S. Durand[1], N.M. Roslin[2], A. Verner[3], C.E. Beesley[4], I. Maire[5], B. Poorthuis[6], J. van de Kamp[7], O. van Diggelen[8], T.J. Hudson[2,3], T.M. Fujiwara[2], K. Morgan[2]* 1) Ste-Justine Hospital, Montreal University, Canada; 2) McGill University Health Centre, Montréal, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montréal, Canada; 4) UCL Institute of Child Health, London, United Kingdom; 5) Hôpital Debrousse, Lyon, France; 6) Leiden University Medical Center, Leiden, the Netherlands; 7) Clinical Genetics Center, Utrecht, the Netherlands; 8) Erasmus University, Rotterdam, the Netherlands.

Mucopolysaccharidosis type IIIC (MPS IIIC) is an inherited recessive disorder caused by lysosomal storage of heparan sulphate. The biochemical defect in MPS IIIC is a deficiency of an enzyme required to N-acetylate the terminal glucosamine residues of heparan sulfate. Since its acetyl-CoA substrate would be rapidly degraded in the lysosome, N-acetyltransferase employs unique mechanism acting both as an enzyme and a channel and catalysing the transmembrane acetylation of heparan sulfate without transporting acetyl-CoA into the lysosome. Using linkage analysis in MPS IIIC families and a biochemical purification of lysosomal N-acetyltransferase, we identified that the enzyme is encoded by the transmembrane protein 76 (TMEM76) gene in the centromeric region of chromosome 8. The gene contains mutations in MPS IIIC patients incompatible with the normal function of the predicted protein. Functional expression of TMEM76 demonstrates that it has N-acetyltransferase enzymatic activity and lysosomal localization. Since the TMEM76 protein does not show a structural similarity to any known pro- or eukaryotic N-acetyltransferases, we think that it belongs to a new structural class of proteins capable of carrying out the transport of the activated acetyl residues across the cell membrane. Moreover, our results may define the function for a conserved family of bacterial proteins COG4299 that share homology with N-acetyltransferase-TMEM76. Our work sets the stage for DNA-based diagnosis of MPS IIIC and genotype-phenotype correlation studies and marks the end of the gene discovery phase for lysosomal storage diseases.

Identification of a novel chromosome region 13q21.3-q22.3 for susceptibility genes in familial chronic lymphocytic leukemia. *O. Toure[1], D. Ng[1], M. Wei[1, 2], D. Arthur[3], G. Marti[4], L. Fontaine[5], J.F. Fraumeni[6], L.R. Goldin[1], N. Caporaso[1], J. Toro[1]* 1) Division of Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 2) Program of Division of Cancer Epidemiology and Genetics, SAIC-Frederick, Inc., Frederick, MD 21702; 3) Laboratory of Pathology, Center for Cancer Research, National Cancer Institute, NIH, DHHS, Bethesda, MD 20892; 4) Flow and Image Cytometry Laboratory, Cellular Therapy and Tissues Branch, Division of Gene and Cell Therapy, Food and Drug Administration/Center for Biologics Evaluation and Research, Bethesda, MD 20892; 5) Westat Inc., Rockville, MD, 20852; 6) Office of the Director, Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, DHHS, Rockville, MD 20892.

Chronic lymphocytic leukemia (CLL) is the most prevalent form of leukemia in adults in western countries. A genome scan of CLL-prone families in 2003 found a lod score of one in band 13q22.1. To investigate this finding, we selected six CLL families consisting of 65 individuals (CLL affected n=19, unaffected n=46) for fine mapping of a 23 megabase region in 13q14.2-q22.3. The median age at diagnosis was 52 years (range 38-76). Interphase FISH revealed 13q14 deletion in 11 of 13 CLL patients. An unaffected sibling in family 2 [2-1006], who shared the at-risk haplotype, also had 13q14 deletion by FISH. Four CLL families shared a 3.8 Mb minimal region in 13q21.31-q22.3. Using direct sequencing analysis we screened 12 genes and one predicted gene for mutations. Eighty-one percent (69/85) of the polymorphisms identified did not result in a predicted amino acid change. A deep intronic polymorphism (IVS10-68_-71delGTAA) was detected in PIBF1 that co-segregated with affected and unaffected members who shared a haplotype in 13q21.31-q22.3 in one family. We did not detect nonsense or frameshift mutations in the coding region of these 13 genes. In conclusion, we identified a novel candidate region that may predispose to familial CLL.

Fabry disease in women and daughters: the key role of family history in the diagnosis, the dilemmas of treatment and prenatal diagnosis. *A. Raas-Rothschild[1], B. Mitchnick[2], A.J.J.T. Rein[3], M. Zeigler[1], G. Bach[1], R. Backenroth[4]* 1) Department of Human Genetics, Hadassah Hebrew University Medical Center, Jerusalem, Israel; 2) Day Care Hospital; 3) Division of Pediatric Cardiology; 4) Department of Nephrology.

Since 1976, nine women and 4 girls with Fabry disease have been diagnosed in the Hadassah medical center because of a positive family history. Age at diagnosis varied from birth to 60 years. Symptoms and signs were variable: onset was between age 12 and 55, and ranged from proteinuria which lead to a kidney biopsy at age 12; painful acroparesthesias which lead to psychologic treatment of a 15 year old girl; retinal vessel occlusion, hypertension and end stage renal insufficiency at age 40, and cardiomyopathy at ages 55 and 60. The family history of Fabry disease was key to the diagnosis in these women and their daughters: all were diagnosed only after a male relative. Treatment at our medical center has been started in 3 women (ages 31, 33, and 54) and two (ages 34 and 60) are in the process of starting. Mean duration of therapy is 29 + 18 (SD) months. There have been no apparent treatment related side effects, nor worsening of kidney and cardiac function; Proteinuria regressed, and there was a subjective improvement in symptomatology. Angiokeratomata appear not to have regressed. Two among three additional women (ages 29-32) have acroparesthesias during intercurrent illnesses and no other objective organic signs of Fabry disease. Among the four young girls (ages 2-7), one has been recently diagnosed as affected with attention deficit disorder, while the others are asymptomatic. We would like to present and discuss the following questions regarding female Fabry patients: When should be treatment started? What is the optimal dose of therapy? What is the best way to evaluate the efficacy of the treatment? In addition, we would like to raise some issues in prenatal diagnosis of Fabry disease.

Signature of Group II introns ORF in chick embryos? *M.A. Sabry[1], A. Jones[2], G.K. Dhoot[3]* 1) Al-Jawhara Center For Molecular Medicine, Genetics and Inherited Disorders, College of Medicine, Arabian Gulf University, Manama, Bahrain; 2) Functional Genomics and Proteomics Laboratories, School of Biosciences, University of Birmingham, UK; 3) Department of Basic Veterinary Sciences, The Royal Veterinary College, University of London, UK.

Group II introns represent a unique class of RNAs, abundant in organellar (mitochondrial and chloroblast) genomes of lower eukaryotes and higher plants. Organellar group II introns contain an ORF which encodes three proteins: a reverse transcriptase, a maturase, and an endo-nuclease, all functioning in splicing. Group II introns have not been identified in higher eukaryotes or in nuclear genomes. We followed a proteomics approach (electrophoresis/mass spectrometry) to investigate trypsin-digested protein extracts from chick embryos to identify proteins with potential significance during embryonic development. On Mascot/BLAST analysis, we identified two maturase-like, non-overlapping peptide fragments in chick embryos at stages 12 (16 somites) and 29 (6 days).Verifying these findings could shed some light onto the potential existence/expression of group II introns ORF in higher eukaryotes and provide insight into possible functional roles in these species, e.g. during development.

An excess of G over C in mutagenesis: evidence from human genetic diseases in support of methylation-insulation hypothesis for conserved amino acid evolution. *L. Xiao[1], Y.F. Yin[2], J. Zhang[1], H.L. Gao[2], K. Li[2]* 1) SNP Institute, Nanhua University, China; 2) Human Genetics, City of Hope National Medical Center, Duarte, California, CA91010, USA.

At the epigenetic point of view, the human genome contains five sequence specific nucleotides of A, C, G, T and 5-methyl C. The 5-methyl C is at about 0.25% of the sequence in adult genome and is expected to play a role in the formation of the leading type of C/T or G/A polymorphism in mammalian genomes. Recently, we recognized an excess of G>A over C>T substitutions in hemophilia B patients. Further analysis demonstrated biased point mutations between sense and antisense strands when unique changes in factor IX were counted. Data of 11 genes (based on their large number (>100) of missense mutations) retrieved from HGMD were analyzed for their point mutation spectra. Similar to factor IX, all genes selected in this study have a biased G>A over C>T unique mutations (Fig 1). The excess of G base over C base was valid when an expanded comparison between G>H (C/G/T) and C>D (A/G/T) was evaluated. Interestingly, all possible amino acid changes by substitution involving the G or C nucleotides show different consequences to protein function: a relatively tolerable or deleterious according to Blossom 62 scoring. These data prompted a hypothesis that C nucleotide is highly mutable because of the presence of 5-methyl C and neutral or tolerable C to T substitutions have been nearly saturated/exhausted during evolution. This hypothesis has two implications: First, the conserved amino acids of C, Er, G, and W have evolved by excluding C nucleotides from the first two bases in their genetic triplets and employing GDN or GDN instead; and secondly, mutations from substitutions of conserved amino acids or those with nonsynonymous cytidine are thus subjected to more severe clinical phenotypic consequences.

Pleiotropic effects of polymorphisms in MICB on human herpes virus seroposivity and schizophrenia risk. *B.H. Shirts[1], J.J. Kim[2], S. Reich[1], F.B. Dickerson[3], R.H. Yolken[3], B. Devlin[1], V.L.. Nimgaonkar[1]* 1) Dept Psychiatry & Human Gen, Univ Pittsburgh, Pittsburgh, PA; 2) Psychiatry Dept, Catholic U of Korea, Seoul, Korea; 3) Stanley Center for Developmental Neurovirology, Baltimore, MD.

We report the identification of associations of MICB SNPs with cytomegalovirus (CMV) and herpes simplex virus 1 (HSV1) seropositivity in the process of mapping for schizophrenia risk genes. Several studies have implicated exposure to herpes viruses as a risk factor for schizophrenia. We previously found associations at anonymous polymorphisms on chromosome 6q21 with schizophrenia among patients seropositive for CMV and HSV1, suggesting that such viruses confer risk in conjunction with specific host genetic variation. To localize the association further, we conducted a multi-staged study among individuals of Caucasian ancestry. We analyzed 21 SNPs spanning an 100kb genomic region in a sample of 236 schizophrenia patients and 240 unscreened controls. Based on suggestive associations we selected five SNPs at MICB to assay among two independent samples which had been serotyped for CMV and HSV1: a case-control sample recruited in Baltimore (n=272 cases, 108 controls), and a case-parent trio sample recruited in Pittsburgh (n=221). Among Baltimore control individuals there were significant associations with serum status for infectious agents: rs1051788 with HSV1 seropositivity ($p = 0.03$, OR= 2.4) and rs2523651 with CMV seropositivity ($p = 0.003$, OR = 3.8). The former association was also detectable among the parents of cases recruited in Pittsburgh ($p = 0.04$, OR = 1.4). Neither association was noted among the schizophrenia cases. With respect to schizophrenia risk, significant transmission distortion was noted at rs1051788 among the case-parent trios ($p=0.014$) regardless of antibody status. In the Baltimore cases sample we a found similar overrepresentation at rs1051788 ($p = 0.101$, OR= 1.4). Associations with schizophrenia at rs1051788 may be due to interactions between MICB alleles and HSV1 status. Our analyses suggest complex associations with schizophrenia and certain herpes viruses at the MICB gene. Further replicate studies are warranted, as are functional studies of these polymorphisms.

Juvenile Pagets disease: The second reported, oldest patient is homozygous for *TNFRSF11B* Balkan mutation (966_969delTGACinsCTT) which elevates circulating immunoreactive osteoprotegerin levels. *M.P. Whyte[1,2], P.N. Singhellakis[3], M.B. Petersen[4], S. Mumm[1,2]* 1) Ctr Metab Bone Dis & Mol Res, Shriners Hosp, St. Louis, MO; 2) Div Bone & Min Dis, Wash Univ Sch Med, St. Louis, MO; 3) Dept Endo, St. Savvas Hosp, Univ Athens, Athens, Greece; 4) Dept Genet, Inst Child Health, Aghia Sophia Children's Hosp, Athens, Greece.

Juvenile Pagets disease (JPD) is a rare, autosomal recessive osteopathy featuring accelerated bone turnover causing skeletal pain, fracture, deformity, and early-onset deafness. Most JPD patients lack osteoprotegerin (OPG) inhibition of osteoclastogenesis due to loss-of-function mutation of TNFRSF11B, the gene encoding OPG. The genetic defect is homozygous in most patients. Circulating immunoreactive OPG levels in JPD have been reported only for the Navajo mutation (selective, complete deletion of TNFRSF11B) where OPG concentrations are, as anticipated, undetectable. We update a 60-year-old Greek patient who is the second reported, oldest JPD patient. Over 4 years, serum immunoreactive OPG levels have been quantified by ELISA assay. Mutation analysis of TNFRSF11B was performed by PCR and sequencing of leukocyte DNA from the patient, his mother and sister. Since age 32 years, he has received bone antiresorptive therapy; initially synthetic human calcitonin, and then bisphosphonates of increasing potency. Despite recent normalization of biochemical markers of bone remodeling, he mentions relentless loss of sight and hearing. Mutation analysis revealed homozygosity for the same mutation, an insertion/deletion in TNFRSF11B (966_969delTGACinsCTT), recently reported for an unrelated Greek boy and Croatian man with JPD. Serum immunoreactive OPG levels and soluble RANKL concentrations were persistently elevated, consistent with a mutation that precludes biosynthesis of the carboxyterminus of OPG, including a cysteine necessary for dimerization. Hence, the circulating, mutated OPG is detectable by immunoassay, but dysfunctional in controlling osteoclastogenesis. Among JPD patients, assay of immunoreactive OPG may result in a range of levels, making laboratory diagnosis uncertain by such testing, and instead dependent on TNFRSF11B gene analysis.

The first case of inherited sub-microscopic terminal duplication 12q in non-affected mother and affected child.

M. Velinov[1], N. Zellers[1], E.C. Jenkins[1], K. Wisniewski[2] 1) Dept Human Genetics, New York State Institute for Basic Research, Staten Island, NY; 2) Dept Developmental Neurobiology, New Your State Institute for Basic Research , Staten Island, NY.

Case presentation: The patient was born to a 34-year-old mother who had one spontaneous abortion at 6-7 weeks gestation and no other pregnancies. This pregnancy was complicated by fetal hypotonia. Amniocentesis was done because of abnormal MSAFP. The chromosomal analysis was normal. The child was born at 34 weeks gestation by normal delivery. The birth weight was 5 lbs 5 oz. The newborn period was complicated by poor feeding. The child's development was delayed since birth. On exam the patient had mild dysmorphic appearance with epicanthal folds and wide nasal bridge. No other abnormalities were noted. Cytogenetic findings: Sub-telomere analysis showed an extra signal of the 12q sub-telomere probe (Vysis) on the short arm of chromosome 13 resulting in a duplication of a very small terminal portion of 12q with no other significant chromosomal abnormalities. The same abnormality was found in the patients mother, who apparently had normal development and was in good health. Discussion: To our knowledge this is the first reported case of sub-microscopic terminal duplication of 12q, where no abnormalities were initially seen on routine chromosome analysis. Interestingly, this abnormality was inherited from a parent with apparently normal development. The smallest previously reported terminal 12q duplication resulted in a mild mental retardation and no dysmorphic features (Am J Med Genet, 2004, 128A:305). A likely explanation of our findings is that this chromosomal abnormality has variable clinical presentation and may lead to mild developmental delay in some individuals, or normal development/subtle and not easily noticeable developmental abnormalities in others. Similar variability in the clinical presentation of other chromosomal abnormalities has been previously described. Another possible explanation such as UPD 12 in the affected patient is considered unlikely since UPD 12 has been previously reported in association with a normal phenotype. This work is supported in part by the NYS OMRDD.

A Study on the correlation between ER-alpha gene polymorphism and Osteoporosis in Iranian women. *F. Pouresmaeili[1], A. Roohi[1], M.J. Tehrani[2], E. Azargashb[3], J. Ghasemi[2], T. Khalili[1], Sh. Samangooee[4], B. Kazemi[5], M. Akhoondi[6], Romatology Department of Loghman Hospital* 1) Genetics & Biochemistry Dept., Shahid Beheshti University of Medical Sciences, tehran, Iran; 2) Genetics Department of Avesina Research Center, Tehran 19835-177, Iran; 3) Health Dept. , Shahid Beheshti University of Medical Sciences, tehran, Iran; 4) Romatology Clinic, Taleghani hospital, Shahid Beheshti University of Medical Sciences, tehran, Iran; 5) Cell& Molecular Biology research center, Shahid Beheshti University of Medical Sciences, tehran, Iran; 6) Avesina Research Center, Tehran 19835-177, Iran.

Osteoporosis is a common skeletal disease characterized by low bone mass and micro architectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fracture. Genetic factors play an important role in regulating bone mass density (BMD). While in few isolate conditions, osteoporosis can be inherited in a simple Mendelian pattern, due to single gene mutations, in the majority of cases has to be considered a multifactorial polygenic disease. The disease initiation, progression and severity in every given individual are influenced by interaction of several environmental factors with several genes. Genetically, early diagnosis of osteoporosis is important, particularly, before appearance of disease symptoms. We investigated the correlation between osteoporosis and allelic variation (polymorphism) of Estrogen receptor alpha gene in 250 individuals aged 40-60 years old . DNA was extracted from peripheral blood samples taken from all individuals under study. Analysis of PCR products and comparison of patients and controls RFLPs using restriction end nucleases PVUII and XbaI revealed that there are 3 different PVUII (PP, Pp, pp) and XbaI (XX, Xx, xx) genotypes among both groups under the study. Chai-2, Fisher test, and comparison between frequency distribution of normal-patient did not show any significant correlation between the disease appearance and observed genotypes. Therefore, we conclude that intron I polymorphism of ER-alpha has no precise effect osteoporosis and bone tissue differences in Iranian women, exclusively.

Selective reconstitution of liver cholesterol biosynthesis promotes lung maturation but does not prevent neonatal lethality in Dhcr7 null mice. *H. Yu[1], G.S. Tint[2], J. Chen[1], Y. Cai[1], G. Xu[2], S.B. Patel[1]* 1) Medicine, Medical College of Winsconsin, Milwaukee, WI 53226; 2) VA Medical Center, East Orange, NJ 07018 & UMDNJ-New Jersey Medical School, Newark, NJ. 07103-2714.

Targeted disruption of the murine 3?-hydroxysterol-?7 reductase gene (Dhcr7), an animal model of Smith-Lemli-Opitz syndrome, leads to greatly reduced cholesterol synthesis and neonatal death because of markedly impaired lung development. We recently reported partial rescue of this neonatal lethality in Dhcr7 null mice by the transgenic restoration of human DHCR7 expression in brain. To gain further insight into the role of non-brain tissue cholesterol deficiency in the pathophysiology, we tested whether the lethal phenotype could be abrogated by selective transgenic complementation with DHCR7 in the liver. We generated mice that carried a liver-specific human DHCR7 transgene whose expression was driven by the human apolipoprotein E (ApoE) promoter and its associated liver-specific enhancer. These mice were then crossed with Dhcr7+/- mutants to generate Dhcr7-/- mice bearing a human DHCR7 transgene. Robust hepatic transgene expression resulted in the significant improvement of cholesterol homeostasis in liver, lung and plasma with cholesterol concentrations increased to 80~90 % of normal levels. Significantly, the cholesterol deficiency in brain was not altered. Although late gestational lung sacculation was greatly improved, there was no parallel increase in postnatal survival in the transgenic mice. Thus, the reconstitution of Dhcr7 function selectively in liver induced a significant improvement of cholesterol homeostasis in non-brain tissues, but failed to rescue the neonatal lethality of Dhcr7 null mice. These results provide further evidence that impaired CNS development very likely plays a major role in the pathogenesis and early death of Dhcr7-/- mice.

A Balanced Accuracy Metric for Epistasis Modeling in Imbalanced Datasets using Multifactor Dimensionality Reduction. *D.R. Velez[1], B.C. White[2], A.A. Motsinger[1], W.S. Bush[1], M.D. Ritchie[1], S.M. Williams[1], J.H. Moore[2]* 1) Vanderbilt University, Nashville, TN; 2) Computational Genetics Laboratory, Dartmouth Medical School, Lebanon, NH.

Multifactor dimensionality reduction (MDR) was developed as a computational method for detecting, characterizing, and interpreting statistical patterns of epistasis. The overall goal of MDR is to change the representation space of the data using constructive induction to make interactions easier to detect using machine learning methods and statistical classifiers such as logistic regression. It is well-known that machine learning methods such as MDR may not provide robust models when the class variable (e.g. case-control status) is imbalanced or unequal and accuracy is used as the fitness measure. This is because most methods learn patterns that are relevant primarily for the larger of the two classes. The goal of this study was to evaluate three different strategies for improving the power of MDR to detect epistasis in imbalanced datasets. The first method evaluated was oversampling that samples with replacement the smaller class until the data are balanced. The second method evaluated was undersampling that randomly removes subjects from the larger class until the data are balanced. The third method evaluated used balanced accuracy [(sensitivity+specificity)/2] as the fitness metric. These three methods were compared using using simulated epistatic interactions of varying heritability (0.01, 0.025, 0.05, 0.1, 0.2, 0.3, 0.4) and minor allele frequency (0.2, 0.4) that were embedded in 100 replicate datasets of varying sample sizes (200, 400, 800, 1600). Each dataset with a given sample size was generated with different ratios of cases to controls (1:1, 1:2, 1:4). We found that the balanced accuracy metric significantly outperformed both oversampling and undersampling and fully recovered the power observed using accuracy in the balanced datasets. The new balanced accuracy metric has been included in the open-source and freely-available MDR software package for application to imbalanced case-control datasets. (Supported by NIH R01s AI59694 and LM009012, PI-Moore).

A De Novo SCN5A Mutation (W1191X) Its Relation with Brugada Syndrome. *D.J. Shin[1], E.M. Kim[2], Y.S. Bae[1], J.H. Han[1], Y.S. Jang[1,3], B.Y. Joung[3], M.H. Lee[3], S.S. Kim[3], H. Huang[4], M. Chahine[4], S.J.K. Yoon[2]* 1) Cardiovascular Genome Center, Yonsei Univ Colledge of Medicine, Seoul 120-749, Republic of Korea; 2) Research Institute of Molecular Genetics, The Catholic University of Korea, Seoul 137-701, Republic of Korea; 3) Department of Cardiology, Yonsei Cardiovascular Center, Seoul 120-749, Republic of Korea; 4) Laval Hospital Research Centre and Department of Medicine, Laval University, Quebec, Quebec, Canada.

Brugada syndrome (BS) is an inherited cardiac disorder associated with a high risk of sudden cardiac death and is caused by mutations in the SCN5A gene encoding the cardiac sodium channel alpha-subunit (Nav1.5). The aim of this study was to identify the genetic cause of familial BS and characterize its electrophysiological property of a novel SCN5A mutation (W1191X). Four families and one patient with BS were screened for mutations of the SCN5A gene by PCR and direct sequencing. Wild-type (WT) and mutant Nav1.5 channels were expressed in tsA201 cells, and the sodium currents were analyzed using the whole-cell patch-clamp technique. A novel mutation, W1191X, was identified in a family with BS. Expression of WT or mutant channel (Nav1.5/W1191X) cotransfected with the beta 1-subunit in tsA201 cells resulted in a loss of function of Nav1.5 channels. While voltage-clamp recordings of the WT channel showed a distinct acceleration of Nav1.5 activation and fast inactivation kinetics, the Nav1.5/W1191X mutant failed to generate any currents. Co-expression of both WT and mutant channels resulted in a 50% reduction in sodium current. Our results revealed that the W1191X mutation is associated with BS that resulted in the loss of function of the cardiac sodium channel.

Morbid obesity is associated with multiple obesity genes: PPARG, UCP2, GNB3, and ESR1. *W.H. Pan[1, 2], H.H. Chen[2], C.S.J. Fann[1], W.J. Lee[3]* 1) Institute of Biomedical Sciences, Academia Sinica, Taiwan; 2) Department of Biochemical Science and Technology, Institute of Microbiology and Biochemistry, College of Life Science, National Taiwan University, Taiwan; 3) Min-Sheng Hospital, Taiwan.

The prevalence of obesity is increasing rapidly worldwide. It is urgent to uncover genes which interact with environmental factors and contribute to the development of obesity in order to overcome the problem. Previous studies showed heterogeneous findings on potential obesity loci, using varied obesity phenotypes across multiple populations. Yet there are relatively few systematic studies in Chinese to screen for obesity genes. Our attempt is the first of its kinds in Han Chinese to search for major obesity genes, using morbid obesity as the phenotype(BMI>=40), which is rare (around 0.064%)in Taiwan. We applied a two-staged association study design with a total of 315 unrelated cases and 315 controls. All subjects participated in our study voluntarily. Signed informed consents were obtained. The inclusion criteria of the case were:(1)age in the range of 20-59(2)BMI>=40, (3)ancestral origin of Han Chinese from either side of parents. Each case was matched with a control (BMI<=24) by gender, age, educational level and residential location. In 1st stage of the study, a total of 94 cases and 94 matched controls were genotyped for 133 tag SNPs http://www.hapmap.org) or previously identified SNPs on 33 candidate genes. Eighteen genes have been linked or associated with obesity in at least 5 positive studies. The SNPs of another 15 genes have been significantly associated with obesity in Asians. A total of 17 SNPs on 11 genes showed potential associations with morbid obesity in the 1st stage. Subsequently, more subjects (221 cases and 221 matched controls) were genotyped for these 17 SNPs. With data from all cases and controls, we found 5 SNPs (in PPARG, UCP2, GNB3, and ESR1) were significantly associated with morbid obesity. Three SNPs increase risk of morbid obesity in recessive manner and the other 2 dominant.Our data suggest that morbid obesity may be resulted from joint effects of multiple obesity genes.

Improved Beta-thalassemia genotyping by means of reverse-hybridization teststrips tailored to population-specific mutations. *H. Puehringer[1], H. Najmabadi[2], W. Krugluger[3], H.-Y. Law[4], V. Viprakasit[5], C. Oberkanins[1]* 1) ViennaLab, Labordiagnostika, Vienna, Austria; 2) Genetics Research Center, Social Welfare and Rehabilitation Sciences University, Tehran, Iran; 3) Dept. Clinical Chemistry, Municipal Hospital Rudolfstiftung, Vienna, Austria; 4) Genetics Service, KK Women's and Children's Hospital, Singapore; 5) Dept. Paediatrics, Mahidol University, Bangkok, Thailand.

Beta-thalassemia is among the most common inherited diseases throughout Southeast Asia, India, the Middle East, parts of Africa and the Mediterranean area. Mutations in the beta-globin gene are leading to structural abnormalities (e.g. Hb S, Hb E, Hb C), reduced synthesis or complete absence of the beta-globin chains and consequently to deleterious effects of haemoglobin imbalances. In each population at risk beta-thalassemia results from a limited number of common mutations and a larger, more variable number of rare mutations. We have improved an existing reverse-hybridization assay (Beta-Globin StripAssay), originally designed for Mediterranean countries, to make it applicable for a wider range of ethnic groups. Three separate test strips, specific for the most prevalent mutations in Southeast Asia, the Middle East plus India and the Mediterranean region, have been designed. Each test strip comprises 22 mutations and represents an average allele coverage of 91.4 %, 91.7 % and 95 %, respectively. Comprehensive genotyping of beta-thalassemia is performed by a single multiplex DNA amplification reaction and subsequent hybridization to the adequate test strip. The entire procedure from blood sampling to the identification of mutations requires less than 6 hours, and hybridization/detection may be carried out manually or essentially automated using existing instrumentation (e.g. TECAN profiBlot). The test is simple and convenient, and requires very small amounts of samples, which is of particular importance for prenatal diagnosis. The broad range of beta-thalassemia mutations covered by the StripAssay should make it a globally useful diagnostic tool.

Possible role of Infection in the etiology of Endometriosis. *K. Vijayalakshmi[1], M. Sireesha[2], P. Shivani[3], Y.R. Ahuja[1], H. Qurratulain[2,3]* 1) Dept of Genetics, Vasavi Hospital, Lakdi-ka-pul, Hyderabad -500 004, Andhra Pradesh, India; 2) Dept of Genetics, Bhagwan Mahavir Medical Research Centre, AC Guards, Hyderabad-500 004, Andhra Pradesh, India; 3) Dept of Genetics & Molecular Medicine, Kamineni Hospital, LB Nagar, Hyderabad- 500 068, Andhra Pradesh, India.

Endometriosis is a common, chronic, benign, gynecological disorder associated with pelvic pain and infertility. Its main characteristic is the presence of endometrial tissue outside the uterus. Even though it is not life-threatening, it is associated with considerable morbidity and suffering. The prevalence of pelvic endometriosis ranges between 6% and 10% women during their reproductive years. Endometriosis is one of the most common gynaecological disorders, but its aetiology and pathogenesis remain obscure. Hormonal, genetic and environmental factors are considered to play a role in its etiology. The aim of the present study was to identify novel genes with differential display Reverse Transcriptase Polymerase chain reaction (DD-RT-PCR) between eutopic and ectopic endometrium. Eutopic and ectopic tissue from 3 patients was collected for RNA isolation and cDNA was prepared using reverse transcriptase. Differential display RT PCR was carried out twice using two sets of 7 different arbitrary primers. Ectopic endometriotic tissue of one case showed a unique band of 350bp after DD-RT-PCR using the second set. The band was cut out, eluted, re-amplified with individual primers and automatically sequenced. The sequence when subjected to BLAST search revealed 100% homology of 157 bp with Shigella dysenteriae species. The identification of Shigella bacteria in the present study suggests that infection may play an important role in the etio-pathogenesis of endometriosis. This has not been reported in the world literature as yet. It could be postulated that the infection like Shigella may be the trigger that sets into action, the immunological changes in the pelvic peritoneum resulting in the phenotype of endometriosis. Further work in this area is required to establish the role of infection in the etiology of endometriosis.

The attitude of Chinese females on prenatal screening of fragile X syndrome. *Y-Z. Zhang[1], N. Zhong[1,2]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) New York State Institute for Basic Research.

Fragile X syndrome (FRX) is the most common cause of inherited mental retardation. The prevalence of FRX is estimated at 1 in 4000 males and 1 in 8000 females. Our earlier study has determined that the frequency of FRX in China is similar to that in western countries. We found that FRX accounts for 2.8-3.2% of Chinese mental retardations. A recent national survey conducted in China determined that there are about 13 millions of mental retardation among the children of 0-6 years old, which may give a figure that there exist, at least currently, about 500,000 fragile X families in China. Because there is no causative treatment presently and the major effort for preventing this disease is prenatal diagnosis, we have performed a preliminary study on the prenatal attitude among 72 Chinese women who have never heard about FRX before participating. The 72 participants were grouped into: married with child(ren) (6/72), married with no child (40/72), and unmarried single (26/72). A one-hour short course of education was provided to these females for introducing the basic knowledge about FRX, which includes clinical features of the FRX, genetic defect of FRX, current status of diagnosing and treatment of FRX, and prenatal diagnosis of FRX, etc. After the short course, a survey with 15 questions about the FRX and prenatal attitude was conducted. About 80% of the 15 questions were correctly answered among three groups, suggesting that a short course of education provided to non-knowledgeable population may increase the awareness on FRX. Seventy-one percent (51/72) women preferred to have prenatal screening for FRX, even without a family history. Ninety-six percent (69/72) of women chose to terminate pregnancy if a positive FRX was found in the fetus. The strong attitude of prenatal screening of FRX in the Chinese women indicated the acceptance of applying prenatal screening for severe birth defect, for which there is no effective treatment or prevention available.

Redefining the null hypothesis for Hardy Weinberg equilibrium. *K. Ryckman[1,2], L. Jiang[1], J. Haines[1], S. Williams[1,2]* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Medicine, Vanderbilt University Medical Center, Nashville, TN.

Purpose: Current approaches for testing deviations from Hardy-Weinberg equilibrium (HWE) in case-control studies usually test the null hypothesis of genotype frequencies in cases against the case allele frequency and the same in controls. Using this method violates the assumption of a random mating population as it assumes that cases mate randomly with cases and controls with controls. We have therefore compared the typical way of HWE testing to what we propose is a more accurate and informative method. Methods: Our method uses an estimate of the population allele frequency that is a combination of both case and control allele frequencies, p_T, to test for deviations from HWE. The proportion of case and control allele frequencies used in the calculation of p_T is based on the prevalence of the disease in the population. A chi-square test is then used to detect deviations from HWE. This method was applied to simulated case-control data, as well as a study examining age-related macular degeneration (AMD). Results: Under dominant, recessive and additive models our method of calculating HWE is more sensitive to detecting deviations than the commonly used method of testing for HWE. Our simulations show that under most genetic models using p_T to calculate HWE can be just as powerful for detecting disease associated SNPs as standard allelic and genotypic chi-square association tests. The AMD data shows two SNPs (rs2019724 and rs6428379) that were previously significantly associated with AMD, demonstrate a similarly strong deviation from HWE in cases when using p_T (P0.001 for both SNPs). However, these SNPs did not deviate significantly (rs2019724 P=0.8046, rs6428379 P=0.8820) in the cases when using the traditional method of testing for HWE. Conclusions: These observations suggest that using p_T rather than case or control allele frequencies alone is a better technique for assessing deviations from HWE. In addition, this method can be a powerful tool for identifying potential disease pre-disposing genes.

Evidence for interacting susceptibility genes on chromosome 1p and 4q as well as on 2q and 6q in 108 families with bipolar affective disorder. *J. Schumacher[1], R. Abou Jamra[1], R. Fürst[2], R. Kaneva[3], A. Flaquer[2], TG. Schulze[4], G. Orozco Diaz[5], V. Milanova[6], S. Cichon[7], P. Propping[1], M. Rietschel[4], TF. Wienker[2], MM. Nöthen[7]* 1) Institute of Human Genetics, University of Bonn, Germany; 2) Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Germany; 3) Laboratory of Molecular Pathology, Medical University, Sofia, Bulgaria; 4) Central Institute of Mental Health, Division Genetic Epidemiology in Psychiatry, Mannheim, Germany; 5) Civil Hospital Carlos Haya, Málaga, Spain; 6) Department of Psychiatry, Medical University, Sofia, Bulgaria; 7) Department of Genomics, Life & Brain Center, University of Bonn, Germany.

Linkage evidence between bipolar affective disorder (BPAD) and loci on chromosomes 1p, 2q, 4q, and 6q was observed in four European samples consisting of 108 families with German, Spanish, Bulgarian, and Roma descent. Here we report on a systematic interaction analysis using all 4 regions under a broad and narrow disease definition. In each region, non-parametric linkage analysis was performed after conditioning on linkage evidence to the other three regions. On chromosome 2q we observed a NPL-Score of 5.93 (increase of the initial NPL finding) under a broad disease definition when conditioning on linkage signals to chromosome 6q. Vice versa, we found a NPL-Score of 5.08 on 6q when conditioned on the initial linkage data to chromosome 2q. On chromosome 1p, a NPL-Score of 3.12 was observed using a narrow disease definition and conditioned on linkage findings to chromosome 4q, and a NPL-Score of 2.41 on chromosome 4q was found when conditioned on linkage signals to chromosome 1q. Our results point to an interaction between chromosomal loci on 1p and 4q, and between 2p and 6q. Susceptibility genes located in these regions may have interfering regulative effects or interact together within the same biological pathway.

Epigenetics of the retinoic acid paradox. *S. Rossetti, M.Q. Ren, G. Bistulfi, N. Sacchi* Cancer Genetics, Roswell Park Cancer Institute , Buffalo, NY.

Vitamin A through its bioactive derivative retinoic acid (RA) normally inhibits human cells' growth. In contrast, RA, can promote the growth of human cancer cells. Specifically, RA was shown to induce cancer cell growth both in vitro and in vivo. The molecular basis of the RA-paradox is obscure. Normally, RA inhibits cell growth by modulating the transcription of cellular genes carrying regulatory regions characterized by distinct sequence motifs, either the RA-responsive elements or the GC -boxes. RA- mediated transcriptional regulation involves dynamic epigenetic changes at the chromatin associated with these cellular genes. We found that an impaired integration of RA signal through the RA receptor alpha (RARA) triggers a domino repressive epigenetic effect in human cells, which leads to concerted transcriptional silencing of RA-responsive tumor suppressor genes. Unexpectedly, in conjunction with an aberrant epigenotype, cells become susceptible of being growth promoted by RA. Apparently, the epigenotype plays a major role in determining the biological cell response to RA.

A prospective study of two major age-related macular degeneration susceptibility alleles and interactions with modifiable risk factors. *D.A. Schaumberg[1,3], S.E. Hankinson[2,5], Q. Guo[2,4], E. Rimm[2,5,6], D.J. Hunter[2,4,5,6]* 1) Div Preventive Med, Brigham & Women's Hosp, Harvard Medical School; 2) Channing Lab, Brigham & Women's Hosp, Harvard Medical School; 3) Schepens Eye Research Inst, Dept Ophthalmology, Harvard Medical School; 4) Program in Molecular & Genetic Epidemiology, Harvard Sch Public Health; 5) Dept Epidemiology, Harvard Sch Public Health; 6) Dept Nutrition, Harvard Sch Public Health, Boston, MA.

Purpose: Common variants in complement factor H (CFH) and LOC387715 are associated with age-related macular degeneration (AMD) in prevalent case-control studies. We aimed to delineate the magnitude of susceptibility to AMD due to these variants and their interactions with modifiable risk factors in two prospective cohorts. **Methods**: Cases who developed AMD (N=457) were compared with 1071 age- and sex-matched controls in a prospective nested case-control study of participants in the Nurses Health Study and the Health Professionals Follow-up Study. We determined the incidence rate ratios (IRR) and 95% confidence intervals (CI) for AMD associated with the genotype at each locus and examined interactions between the genes and with modifiable risk factors for AMD. **Results**: Cohort participants with one and two copies of the Y402H variant of CFH were 1.98 (CI= 1.64 to 2.40) and 3.92 (CI=2.69 to 5.76) times more likely to develop AMD; whereas the IRR (CI) for one and two copies of LOC387715 A69S were 2.38 (1.92 to 2.96) and 5.66 (3.69 to 8.76), respectively. The estimated fraction of AMD cases in the population attributable to these two variants was 63% (58% to 68%). Subjects homozygous for both risk alleles had a 50-fold increased risk of AMD (CI=11 to 237) compared to those with no risk alleles, and there was evidence that cigarette smoking and obesity multiplied the risks associated with these variants. **Conclusion**: With these data, AMD emerges as a paradigmatic example of a common disease caused by a complex interaction of an underlying genetic predisposition conferred by common variants, and exposure to modifiable risk factors. These observations highlight the need for continued attention to risk modification strategies to reduce the public health impact of AMD.

Sex-specific heritability and linkage of 1,373 traits in French-Canadian population. *O. Seda[1], J. Tremblay[1], D. Gaudet[2], P. Brunelle[1], A. Gurau[1], E. Merlo[3], L. Pilote[4], T. Kotchen[5], A.W. Cowley[5], P. Hamet[1]* 1) Research Ctre, CHUM Research Ctre, Montreal, QC, Canada; 2) Complexe Hospitalier de la Sagamie, Chicoutimi, QC; 3) École Polytechnique de Montreal, Montreal, QC; 4) The Montreal General Hospital, Montreal, QC; 5) Medical College of Wisconsin, Milwaukee, WI.

Sex is one of the influential factors affecting the genetic architecture of most complex traits, yet details of its effects received only limited attention so far. We assessed the sex-specific heritability and linkage of 1,373 direct and derived anthropometric, metabolic, hemodynamic and humoral phenotypes in 120 French-Canadian families (n = 810 subjects) from the Saguenay-Lac-St-Jean (SLSJ) region of Quebec, Canada. Multipoint linkage analysis was performed with a variance components approach implemented in SOLAR, version 2.1.1., in three settings: all, males and females. The genetic information was represented by 437 microsatellite markers uniformly distributed throughout the whole genome. To asses the significance of the sex-specific linkage LOD score difference, we computed an empirical p-value based on 10,000 permutations for each locus with a LOD difference between sexes >2. Using linear regression, we found 45.7% phenotypes to be age- and sex-independent, 16.0% phenotypes to be age-dependent only, 19.2% phenotypes to be sex-dependent only, and 19.2% phenotypes to be both age- and sex-dependent at $p < 3.65 \times 10^{-5}$. We have identified over 25 loci showing highly significant linkage x sex interaction. Furthermore, comparative genomic analysis of sex-specific QTLs revealed several loci significantly linked to similar or even identical phenotypes in both humans and rodent models. We identified female-specific linkage of diastolic blood pressure to the chromosome 2 locus (173 cM LODall = 1.5, LODmen = 0.01, LODwomen = 2.37) syntenic to the rat chromosome 3 region with a peak female-specific linkage of mean arterial pressure in hypertriglyceridemic rats. We propose that multiple geoethnic human cohorts of men and women as well as comparative genomics using non-human models of relevant pathophysiological states are necessary to gain insight into sex-driven aspects of genetic architecture of complex traits.

Multiple Sclerosis North American Pregnancy Programme (MS-NAPP). *A. Sadovnick, E. Dwosh, C. Guimond*
Department of Medical Genetics, Univ. British Columbia, Vancouver, BC, Canada.

Multiple sclerosis (MS) is one of the most common neurological disorders, other than trauma, affecting young adults, especially during the period of their lives when reproduction is an option. Females are affected approximately twice as often as males. Until the advent of laboratory tests for MS, in particular magnetic resonance imaging (MRI), it was not uncommon for the lag time (time from the onset to diagnosis of MS) to be years or even decades. Thus, in many situations, women had pregnancies after the onset of MS but without knowing that they had the disease. The disadvantage (or possibly an advantage) stemmed from the fact that informed decisions about childbearing did not have to be made. Reproductive issues for males with MS were either never or very rarely addressed. The objectives if MS-NAPP are to: 1. Develop an interactive website for use by health care professions in the reproductive counseling of males and females with MS. Topics include recurrence risks, interaction of pregnancy and MS with respect to disease course and pregnancy management and outcome, long-term effects on the developing child (e.g. immunological), and psychosocial issues. 2. Through the use of questionnaires, to determine the reproductive patterns currently followed by MS patients since the clinical use of disease modifying therapies (DMTs) such as interferons. 3. Develop a prospective, pregnancy register to determine the safety of the DMTs and symptom-specific therapies such as prednisone and hence identify needs for wash-out as well as safety for reintroduction of therapy during gestation and breastfeeding, identify any long-term impacts on children born to MS parents (e.g. problems with the immune system, child development in general. etc.). The long-term goal is to develop the first ever evidence-based protocol for reproduction and MS. Data from items 1 and 2 will be presented as the ASHG 2006 meeeeting. Funding for MS-NAPP is through Berlex Canada, Teva Neuroscience, and the Edward Bronfman Family Foundation. Intellectual and technical support has been provided by the National MS Society, the MS Society of Canada, and the Consortium of MS Clinics.

Global Impact of a Web-based Birth Defects Information System. *W. Wertelecki* Dept Med Genetics, Univ South Alabama, Mobile, AL.

IBIS, an International Birth Defects (BD) Information System, is a web-based resource that evolved from systems developed for Ukraine and Alabama (http://www.ibis-birthdefects.org). BD information on most websites provide information of varied quality, and limited in scope. IBIS was designed to facilitate access to a broad spectrum of BD information, selected for its quality and inclusive of non-English materials. The majority of information in Ukraine had to be developed by Ukrainian IBIS partners. IBIS is organized along information channels, mainly about specific disorders, topics concerned with child development and support sources. A companion website (Pandora Word Box, www.consultsos.com/pandora/intro.htm) was developed to complement IBIS with humanistic vistas, inclusive of bioethics.

Visitors to IBIS quickly expanded from Ukraine and Alabama to include a large array across the globe. In the past three years, IBIS has welcomed ~1.26 million visitors and Pandora ~1 million. Ukrainian visitors to IBIS rank ninth, and those from neighboring Poland and Russia rank twenty-second and twenty-fifth. Mostly English-speaking countries outrank Ukraine in this regard. Visitors to the Pandora web site offer a frame of reference because it was not promoted in Ukraine, as was IBIS. Visitors to Pandora from Poland and Russia rank thirteenth and thirty-eighth while Ukraine ranks forty-ninth. We conclude that IBIS is a major BD information resource in Ukraine. Although English is a medical "lingua franca", BD information in native languages is needed by patients and their families. In our view, a Spanish IBIS version, is demonstrably needed.

Association of ENPP1 Variants with Quantitative Measure of Glucose Homeostasis and Adiposity: The IRAS Family Study. *N. Palmer[1], A. Lehtinen[1], J. Campbell[1], J. Norris[2], M. Bryer-Ash[3], S. Haffner[4], C. Langefeld[1], D. Bowden[1]* 1) Wake Forest University, Winston-Salem, NC; 2) University of Colorado, Denver, CO; 3) University of California, Los Angeles, CA; 4) University of Texas, San Antonio, TX.

Ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) is a candidate for type 2 diabetes (T2DM). It is widely expressed in insulin-sensitive tissues and has elevated activity in T2DM. ENPP1 interacts with the insulin receptor to impair insulin signaling. Six SNPs, with prior evidence of association, were genotyped in 1102 Hispanic and African Americans in the IRAS Family Study. SNPs were tested for association with quantitative measures of glucose homeostasis (insulin sensitivity; S_i, acute insulin response, fasting insulin and fasting glucose) and adiposity (body mass index; BMI, waist circumference and waist to hip ratio, visceral and subcutaneous adipose tissue) using variance component analysis in SOLAR. In Hispanic Americans, ENPP1 was contained in two LD blocks. Two SNPs within the block spanning the coding region were associated with S_i ($P<0.007$) while flanking SNPs trended toward association. The SNP most strongly associated with S_i ($P<0.007$) was a coding mutation (K121Q). This SNP has been shown to be associated with quantitative measures of insulin resistance (fasting insulin, fasting glucose, and S_i). Increasing evidence suggests that the same mutation is also associated with obesity phenotypes; however, our data do not support these findings in Hispanic Americans. In African Americans there was a single LD block which contained all six SNPs. There was no association with measures of glucose homeostasis; however, there was modest evidence for association with BMI and waist ($P<0.04$). In conclusion, ENPP1 SNPs are significantly associated with S_i, in a well-characterized Hispanic cohort which is consistent with the biological effect of this gene in vivo. This study is unique because we assess a mechanism of contribution of this gene to diabetes via quantitative measures of glucose homeostasis. Based on our findings, further studies are warranted to determine the validity of ethnic specific associations.

Origin of complex human mutations. *J. Zhang, L.D. Liu, Y.F. Yin, H.L. Gao, L. Xiao, K. Li* SNP Institute, Nanhua Univ, Hengyang, China 42100.

Indels are a unique type of infrequent mutations, and about 20% of which are del2_ins1 microindels. Upon examination of the preferential del2_ins1 microindels microindels reported in the HGMD, Lac I gene in Big Blue mice, and the IRAC p53 human somatic databases, we revealed that: i). ratios of del2_ins1 over del1_ins2 are between 2-5, similar to the ratio of deletion over insertion; and ii). del2_ins1 microindels indels have 30-40% CG>TA in the inserted bases, inherited the characteristic figureprint of single base substitution. These pieces of evidence are consistent with the simple speculation that the preferential del2_ins1 microindel may derive from the two leading types of mutations: single base substitution and deletion. Interestingly, an opposite supporting clue was identified by analyzing the del1_ins2 microindel. As expected, 8 of 14 such microindels in HGMD may attribute to the single nucleotide run (tab 1). Thus, the first two leading types of simple mutations of single base substitution and single base deletion, as well as the third leading mutation type of single base insertion play important roles in the genesis of complex mutations.

.

A 1-2-3 principle as the standard for distinguish of rare single nucleotide polymorphism from causal mutation.
Y.F. Yin, L.D. Liu, C.L. Zhou, K. Li, H.L. Gao SNP Institute, Nanhua University, Hengyang, China 42100.

Correct identification of the real causal mutation is required for prenatal screening. Using hemophilia B as a model, we suggested a 1-2-3 principle for distinguishing rare polymorphisms from mutations. Multiple genetic changes are classified into three subgroups. A 1-2-3 principle has been applied to the analyses of 30 patients carrying multiple nucleotide changes in factor IX. Nucleotide changes are annotated as the causal mutation when they fall into the subgroup I: nonsense mutation, frameshift deletion or insertion. For mutations in subgroup II (mutant alone reported in literature, or a highly conserved amino acid substitution), both criteria are required or one criterion plus another criterion from subgroup III are required to annotate a mutation. However, at least three criteria are needed to separate causal mutations from polymorphisms when the multiple nucleotide changes all fall into the subgroup III. Subgroup III includes: not a CG to TA transition / mutant aa not used by other species / physiochemical different aa / residing in important domains. Of the 30 hemophilia B patients with multiple mutations two (potentially three) have double causative mutations. Twenty-seven polymorphisms have been identified, which are consistent with the rare polymorphism database (www.kcl.ac.uk/ip/petergreen/haemBdatabase.html) except we identified two novel rare polymorphisms. As the incidence of hemophilia B is about 1/40,000, a real double mutation is estimated in every forty-thousand patients. Results obtained based on the 1-2-3 principle stand true statistically and the 1-2-3 principle may have applications in the analyses of other genetics diseases with low incidence. The two novel rare genetic variants are to be confirmed by DNA pool.

Molecular characterization of lactase gene regulation in African populations. *A. Ranciaro[1,2], F.A. Reed[1], J. Hirbo[1], K. Powell[1], M. Osman[3], S. Omar[4], M. Ibrahim[3], S.A. Tishkoff[1]* 1) biology, university of university, college park, MD; 2) Dept. of Biol., Univ. of Ferrara, Ferrara, Italy;; 3) Dept. of Molecular Biology, Inst. of Endemic Diseases, Univ. of Khartoum, Khartoum, Sudan; 4) KEMRI, CBRD, Nairobi, Kenya.

In most human populations, the ability to digest lactose, the sugar present in milk, declines rapidly after weaning because of decreasing levels of the enzyme lactase (lactase-phlorine hydrolase, LPH) in the small intestine. However, there are individuals who maintain the ability to digest milk and other dairy products into adulthood due to a genetic adaptation. The highest frequencies of LP are in N. European and certain African and Arabian pastoralist populations and lowest frequencies are in Native Americans, Pacific islanders, Sub-Saharan Africans(with the exception of East African pastoralists) and Southeast Asians. This pattern suggests that selection has played a major role in determining the frequencies of LP in different human populations since the development of pastoralism ~9,000 years ago. In order to identify genetic mutations associated with LP, we collected phenotype data from 470 individuals from Tanzania, Kenya, and the Sudan. We resequenced 2 kb of the promoter region of the gene coding for LPH (LCT), as well as introns 9 (1.7 kb) and 13 (3.3 kb) of the MCM6 gene, which had previously been identified as regions with SNPs associated with LP in Europeans, in 150 African individuals at the extremes of the phenotype distribution. Two novels SNPs were identified that showed a significant phenotypic association with the LP trait, one common in Tanzanian and Kenyan pastoralist populations, and the other common in the Beja population from the Sudan. Resequencing of these regions in a panel of great apes indicated that the alleles associated with LP are derived. We then screened a larger panel of African populations, as well as Middle Eastern populations, to determine the geographic distribution of these alleles. We have characterized patterns of nucleotide diversity and genetic signatures of natural selection in these regions in order to reconstruct the evolutionary history of LCT regulatory regions.

Association of warfarin dose with genes involved in its action and metabolism. *M. Wadelius[1], L.Y. Chen[2], N. Eriksson[3], S. Bumpstead[2], J. Ghori[2], C. Wadelius[4], D.R. Bentley[2], R. McGinnis[2], P. Deloukas[2]* 1) Dept Medical Sciences, Clinical Pharmacology, University Hospital, Uppsala, Sweden; 2) The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, UK; 3) UCR - Uppsala Clinical Research Center, Uppsala Science Park, Uppsala, Sweden; 4) Department of Genetics and Pathology, Medical Genetics, Rudbeck Laboratory, Uppsala, Sweden.

Warfarin is a commonly prescribed anticoagulant that is difficult to use because of the twenty-fold variation in dose required to achieve a therapeutic effect. Of all used drugs, warfarin probably has the highest risk of severe side-effects in the form of bleeding. We genotyped 201 Swedish warfarin-prescribed patients for polymorphisms in 29 genes involved in the action and biotransformation of warfarin, and tested them for association with warfarin dose requirement. Genotyping was performed with the Homogeneous Mass Extend assay (Sequenom). In our study, single polymorphisms in or flanking eleven genes and haplotypes of twelve genes were associated with dose ($p<0.05$). VKORC1, CYP2C9, CYP2C18, CYP2C19 were significant after experiment-wise correction for multiple testing ($p<0.000175$), while PROC and APOE were significant after within-gene correction. We found that the association of CYP2C18 and CYP2C19 was fully explained by linkage disequilibrium with CYP2C9*2 and/or *3. A multiple regression model with VKORC1, CYP2C9, PROC and the non-genetic predictors age, bodyweight, drug interactions, and indication for treatment jointly accounted for 62% of the warfarin dose variance. Weaker associations observed for other genes could explain up to ~10% additional dose variance, but require testing and validation in an independent and larger data set. We are therefore genotyping 1500 additional Swedish warfarin-prescribed patients for tagSNPs and functional SNPs in the 29 genes. Translation of warfarin pharmacogenetics into guidelines for prescription will be likely to have a major impact on the safety and efficacy of warfarin.

No effect of 'autoimmunity' genes on the clinical outcome of Multiple Sclerosis. *S.V. Ramagopalan[1,2], G.C. DeLuca[1,2], B.M. Herrera[1,2], M.R. Lincoln[1,2], S. Orton[1,2], M.W. Chao[1,2], A.D. Sadovnick[3], G.C. Ebers[1,2]* 1) Department of Clinical Neurology, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) Faculty of Medicine, Division of Neurology, University of British Columbia, Vancouver, Canada.

There can be few diseases with as much variation in outcome as multiple sclerosis (MS). There is substantial support for a significant inherited component in MS; evidence also suggests that genetic factors may affect the phenotypic expression of the disease. In sibling pairs with MS the rate of acquisition of disability is similar and significant concordance for disease course exists. Further supporting a role for disease modifying genes in MS, monozygotic twins concordant for MS have a more similar disease course than dizygotic twins (unpublished data). Despite the many unique clinical and serological features associated with specific autoimmune diseases, there have been numerous reports that suggest that different autoimmune diseases share susceptibility loci. If this is true, one or more of the known autoimmune genes (major histocompatibility complex class II transactivator (MHC2TA), cytotoxic T-lymphocyte-associated protein 4 (CTLA4), protein tyrosine phosphatase, non-receptor type 22 (PTPN22) and caspase recruitment domain family, member 15 (CARD15)) may affect the clinical outcome of the putative autoimmune disease MS. We therefore investigated the effect of MHC2TA, CTLA4, PTPN22 and CARD15 on MS disease severity. We genotyped a dense panel of single nucleotide polymorphisms (SNPs) using the MassEXTEND protocol (Sequenom Inc., San Diego, CA). Examination of SNPs for each gene and their corresponding haplotypes did not show any association with outcome of the disease.

Detection of interactions: are we using correct approach? *L. Padyukov[1], H. Källberg[2], L. Klareskog[1], L. Alfredsson[2]*
1) Rheumatology Unit, Department of Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Department of Environmental Medicine, Karoliska Institutet, Stockholm, Sweden.

Current analysis of gene-gene and gene-environment interactions in complex diseases is based on the assumption that each pair of risk factors is independent and deviation from independence for the patient group but not for the control group could be interpreted as an interaction. However, this analysis does not directly compare influence of risks between cases and controls. We propose that an examination of the disease odds for each specific combination of risk factors in comparison with a reference odds in which both risk factors are absent, provides a more accurate basis for studying interaction and that interaction between two factors should be defined as a deviation from additivity of absolute effects. In this case, quantification of the amount of interaction can be made by means of the attributable proportion due to interaction. Using a large Swedish population-based material for investigation of RA (816 cases with anti-CCP positive RA and 793 controls) we have investigated interaction between two well-established genetic risk factors of RA: shared epitope (SE) alleles of MHC2-DRB1 gene and A allele of PTPN22 gene. The Chi-square test for the entire RA patient group did not show significant association. However, using cases and controls without SE alleles and A allele of PTPN22 as a reference group demonstrates high odds for individuals with SE without A PTPN22 alleles (5.1 95%CI 3.7-6.8), and with both variations (10.1 95%CI 7.0-14.8), while no difference in group with A PTPN22 allele without SE alleles was found (1.2 95%CI 0.7-2.0). Attributable proportion due to interaction confirms the significant deviation from additivity of effect in double positive group (0.5 95%CI 0.3-0.7) hence clearly demonstrating genetic on susceptibility to RA. Since so dramatically different conclusions could be drawn from different types of statistical analyses, one has to be aware of the methodology used to reveal genetic interactions. We here present a way to detect these interactions with better sensitivity, which also provides a simple way for biological interpretation of the data.

The complex PRKCA genome region on 17q shows association to Multiple Sclerosis in independent populations.

J. Saarela[1], S.P. Kallio[1], D. Chen[2], V. Leppa[1], A. Montpetit[3], M.R. Lincoln[4], A. Palotie[5,6], H. Harbo[7], A. Oturai[8], J. Hillert[9], G.C. Ebers[4], T.J. Hudson[3], L. Peltonen[1,5,6] 1) Natl Public Health Inst, Helsinki, Finland; 2) David Geffen School of Medicine at UCLA, Los Angeles, US; 3) McGill University and Genome Quebec Innovation Centre, Montreal, Canada; 4) University of Oxford, Oxford, UK; 5) The Broad Institute of MIT and Harvard, Cambridge, US; 6) University of Helsinki, Helsinki, Finland; 7) Rikshospitalet University Hospital, Oslo, Norway; 8) Copenhagen University Hospital, Copenhagen, Denmark; 9) Karolinska University Hospital, Stockholm, Sweden.

Complex diseases such as multiple sclerosis (MS) likely result from problems in networks of interactions between several genes and environmental factors. HLA-DRB1*15 is the only consistent locus observed in most populations, but numerous genome screens also provide evidence for a MS locus on 17q. Association screen of the critical linkage region on 17q24 in Finnish MS families identified several SNPs within the PRKCA gene region. This association was also replicated in Canadian MS pedigrees. Two allelic variants of PRKCA were found to be over-represented in Finnish or Canadian MS cases (odds ratios: 1.34 and 1.64). An analysis of 200 MS trio families from Sweden, Denmark and Norway suggested a role for the Finnish risk haplotype in MS susceptibility also in other Scandinavian populations. Transcript levels of PRKCA correlated with the copy number of the risk alleles in 20 Finnish and 11 CEPH individuals of European origin in an initial expression analysis. A recent sequencing effort of chromosome 17 revealed this chromosome to be highly enriched with segmental duplications, which may predispose to copy-number or other structural variations. We have previously shown that the critical MS region is flanked by duplicated sequences. Detailed analysis of these duplicons identified a set of retrotransposable sequence elements, which are clustered in 12 duplicated sequence domains within the 17q. An ongoing analysis suggests variation in the copy-number of these retrotransposable elements, which may co-segregate with the PRKCA risk haplotype.

Prenatal diagnosis of Smith-Lemli-Opitz syndrome (SLOS): Identification of a novel, *de novo* mutation of the *DHCR7* gene. *J.S. Waye[1,2], B. Eng[2], M.A. Potter[1,2], M.J.M. Nowaczyk[1,2,3], D. McFadden[4], S. Langlois[5]* 1) Dept Pathology & Molecular Med, McMaster Univ, Hamilton, ON, Canada; 2) Genetic Services, Hamilton Health Sciences, Hamilton, ON, Canada; 3) Dept Pediatrics, McMaster Univ, Hamilton, ON, Canada; 4) Dept Pathology, Children's & Women's Health Care Ctr, Vancouver, BC, Canada; 5) Dept Medical Genetics, Univ of British Columbia, Vancouver, BC, Canada.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive disorder of cholesterol biosynthesis resulting from deficient 7-dehydrocholesterol reductase. We report a prenatal SLOS case in a 35-year-old G2P1 woman with a positive MSS for Down syndrome (estriol, AFP). Cytogenetic analysis of cultured amniocytes indicated a normal 46, XX karyotype, and detailed ultrasound examination revealed severe IUGR and multiple congenital anomalies. The pregnancy was terminated and autopsy examination showed a female fetus with a cardiac defect, renal hypoplasia, hypoplastic and unilobar lungs, dysgenesis of the corpus collosum, equinovarus deformity of the feet, bilateral 2-3 toe syndactyly, and uterus didelphys with septate vagina. Elevated 7-dehydrocholesterol levels in the fetal blood and amniotic fluid confirmed the diagnosis of SLOS. Nucleotide sequence analysis of the *DHCR7* coding sequences revealed two mutations. The fetus was heterozygous for the common splice acceptor mutation of IVS8 (c.964-1G>C), and heterozygous for a silent mutation at codon 137 (p.Ala137Ala, c.411A>G). The latter mutation alters the conserved, penultimate nucleotide of exon 5 and may adversely affect splicing. The mother was heterozygous for the c.964-1G>C mutation, but neither parent carried the novel c.411A>G mutation. Paternity was confirmed using a panel of 15 STR markers. We propose that the c.411A>G mutation occurred *de novo* during spermatogenesis, or that the father is a germline mosaic. Prenatal testing was conducted for the subsequent pregnancy, and the fetus was shown to be heterozygous for the maternal c.964-1G>C mutation and negative for the c.411A>G mutation. Haplotyping confirmed that the fetus inherited a different paternal chromosome than the previous, affected fetus.

Variant of transcription factor 7-like 2 gene and the risk of type 2 diabetes mellitus in large cohorts of U.S. women and men. *C. Zhang[1], L. Qi[1], DJ. Hunter[1, 2, 3], JB. Meigs[4], JE. Manson[2, 3, 5], RM. Van Dam[1], FB. Hu[1, 2, 3]* 1) Nutrition, Harvard Sch Public Health, Boston, MA; 2) Channing Laboratory, Department of Medicine, Brigham and Womens Hospital and Harvard Medical School, Boston, MA; 3) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 4) General Internal Medicine and Clinical Epidemiology Units, General Medicine Division, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts; 5) Division of Preventive Medicine, Department of Medicine, Brigham and Womens Hospital and Harvard Medical School, Boston, Massachusetts.

Emerging evidence indicates that variation in the transcription factor 7-like 2 gene (TCF7L2) may play a role in the pathogenesis of type 2 diabetes mellitus (T2DM). In a prospective, nested case-control study (total n=3,520) within the Nurses' Health Study (687 type 2 diabetes cases and 1051 controls) and the Health Professionals Follow-up Study (886 cases and 896 controls), we examined the association of a common variant of the TCF7L2 gene (rs12255372 (T/G)) with T2DM risk among Caucasians. Frequencies of the T allele were significantly higher among cases than controls; each copy of the T allele was associated with a 1.32 (P=0.0002) and 1.53-fold (P<0.0001) increased T2DM risk in women and men, respectively. The odds ratios (95% CI) associated with homozygous carriers of the T allele were 1.86 (1.30, 2.67) and 2.15 (1.48, 3.13) in women and men, respectively. Population attributable risks for diabetes associated with the T allele were 14.8% and 22.3% for women and men, respectively. In a meta-analysis of 3347 cases and 3947 controls, each copy of the T allele was associated with a 1.48-fold increased risk (P<10-16). Our findings confirm that the TCF7L2 gene represents an important locus for predicting inherited susceptibility to T2DM.

Semen analysis of patients with TGCT; correlation with Y chromosome gr/gr deletion. *E. Rapley[1], J. Coffey[1], R. Linger[1], D. Dudakia[1], J. Pugh[1], K. Lindsay[2], M. Stratton[1], R. Huddart[3], E. Rapley[1]* 1) Testicular Cancer Genetics Team, Section Cancer Genetics, Institute of Cancer Research,UK; 2) Andrology Unit, Hamersmith Hospital NHS Trust, UK; 3) Section of Academic Radiotherapy, Institute of Cancer Research, UK.

The gr/gr deletion of the Y chromosome is associated with a 2 fold increased risk of testicular germ cell tumour (TGCT). The deletion is also associated with infertility, itself a risk factor for TGCT. We report the provisional findings of a study examining the relationship between the 'gr/gr' deletion, TGCT and fertility. Research participants were divided into 5 groups; gp1, TGCT case with a family history of disease; gp2, TGCT case without a family history of disease; gp3 & gp4, unaffected relatives of gp1 & gp2, respectively; and gp5, healthy male controls. To date 209 research participants have provided semen samples, 204 of which have been examined for gr/gr deletions. 'gr/gr' deletions were identified in 5 patients, 1 in gp1, 3 in gp2 & 1 in gp4 (son of TGCT patient in gp2). No gr/gr deletions were detected in male controls. Semen analysis (according to WHO 1999) of the gr/gr deletion cases revealed a full range of fertility parameters. Two patients (gps 1&4) had normal semen analysis, 2 patients (gp2) were oligospermic (< 20 million per ml) and one patient (gp2) was azoospermic. The three patients with abnormal semen analysis, had fathered children. Control male patients had a higher frequency of normal semen analyses (80.4%) than TGCT patients (40.6%;gp1 & 41.0%;gp2); some part of this difference may be treatment related. 'gr/gr' deletion was more common in TGCT patients (3.3% vs 0% in controls), as previously reported, but numbers are too small for conclusive p values. The provisional data suggests that TGCT patients have reduced fertility, as measured by the difference in frequency of normal semen parameters between TGCT cases and controls. While 'gr/gr' deletion is associated with an increase risk of TGCT, there was no correlation between fertility status and the presence of 'gr/gr' deletion in this series and despite abnormal semen analysis, several individuals had fathered children.

Genome-wide *In Silico* Prediction of USF1 Binding Sites and Target Genes. *T. Wang, J.J. Connelly, S.G. Gregory, E.R. Hauser* Center for Human Genetics, Duke University Medical Center, Durham, NC.

Transcription factors (TFs) play an important role in transcriptional regulation by interacting with transcription factor binding sites (TFBSs) to control gene expression in temporal, cell type, or environmental specific ways. Upstream stimulatory factor 1 (USF1) is a key regulator of the stress and immune responses, the cell cycle and cell proliferation. Several publications, and our own unpublished data, have identified single nucleotide polymorphisms (SNPs) in USF1, and several other TFs, which are significantly associated with coronary artery disease (CAD) (Pajukanta *et al*., 2004; Komulainen *et al*., 2006). We therefore hypothesize that identifying the target genes of TFs, such as USF1, will improve our understanding of genetic effects in CAD risk. Experimental approaches to *de novo* localization of TFBS include ChIP-chip microarrays (Rada-Iglesias *et al*., 2005). This method, though successful, is time-consuming when being applied on a genome-wide scale. Thus it would be advantageous to develop an *in silico* computational method to independently predict TF binding sites. Using USF1 as our model, our goals were to develop, evaluate and optimize methods for USF1 binding site prediction, and make genome-wide predictions of potential TFBSs and target genes. We have developed a flexible and efficient core binding site search method to identify all potential TFBSs for USF1, and also gathered several important features of each potential TFBS. Utilizing all features, we developed several prediction methods based on statistical classification models. We used published USF1 ChIP-chip results from ENCODE regions to evaluate and optimize our prediction models. The final prediction model was able to achieve optimal sensitivity, specificity and discovery rate. Then we applied this method to make genome-wide predictions. The results of this study will help identify and prioritize CAD candidate genes, prioritize SNPs within and around candidate genes and allow targeted evaluation of gene-gene interactions.

Extended mutation search in patients with L1 syndrome -update of the L1 mutation database-. *Y.J. Vos[1], K.K. Bos[1], E. Verlind[1], A. Vrieling-Kooistra[1], A.M. ten Berge[1], B.E. Hiemstra[1], I. Stolte-Dijkstra[1], W.S. Kerstjens-Frederikse[1], N.B.B. Knops[2], R.M.W. Hofstra[1]* 1) Department of Genetics, University Medical Center, Groningen, Netherlands; 2) Wilhelmina Children's Hospital, Utrecht, Netherlands.

L1 syndrome comprises four neurological syndromes that all have been found associated with mutations in the *L1CAM* gene. They include HSAS (X-linked Hydrocephalus with Stenosis of the Aqueduct of Sylvius), MASA (Mental retardation, Aphasia, Spastic paraplegia and Adducted thumbs), SPG1 (X-linked complicated hereditary spastic paraplegia type 1) and X-linked ACC (Agenesis of Corpus Callosum). L1 syndrome is an X-linked recessive disorder with an incidence of one in every 30,000 males. In our laboratory an efficient screening method has been developed and the DNA of more than 250 patients has been analysed, resulting in the identification of 48 different mutations in 50 patients. Among the newly identified mutations was one deletion of the entire gene in a patient with X-linked Hydrocephalus and Nephrogenic Diabetes Insipidus. The deletion includes besides the *L1CAM* gene also the *AVPR2* gene.

All new mutations are added to the L1CAM database which can be found at our website. It includes almost 200 different pathogenic mutations, scattered over the entire gene. The database was taken over from Prof dr. G. van Camp (University of Antwerpen). It can be found at the L1CAM web page at the website of the University of Groningen: http://www.rug.nl/umcg/faculteit/disciplinegroepen/medischegenetica/hereditarydiseases/ l1cam/index.

In only 20% of our patients a mutation was found. So we extended the mutation analysis of the coding region of the *L1CAM* gene with a screen of the most important regulatory sequences namely the promoter region, the Homeodomain and Paired Domain binding site (HPD site) and the Neuron Restrictive Silencer Element region (NRSE region). Screening of 140 patients did not result in additionally mutations.

Neurotrophins, their receptors and EGR1: peculiarities of expression in human lung cancer and normal lung tissue. *E.L. Voloshenyuk, L.V. Dergunova, N.M. Raevskaya, S.A. Limborska* Institute of Molecular Genetics RAS, Moscow, Russian Federation.

Neurotrophins (NTs) are a family of related polypeptide growth factors, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), NT3, NT4/5, and NT6. These molecules bind two types of cell surface receptors characterized by different binding affinities and including a low affinity glycoprotein receptor p75 and high-affinity receptors recognized by a tyrosine-specific protein kinase (Trk) activity. NTs play a role in the modulation of certain human malignancies, including those of neurogenic and ectodermal origin. They are also involved in stimulation of clonal growth on human lung cancer cells in vitro via NT receptors. mRNA expression of NGF, BDNF, NT3, their related high- (TrkA, TrkB, TrkC) and low-affinity (p75) receptors, and also NGF-induced gene EGR1 was studied by RT-PCR in 30 double surgical specimens (histologically diagnosed human lung cancer and appropriate adjacent tissue) and in 10 specimens of normal lung tissue. Tumor specimens set included 25 squamous cell lung cancer samples and 5 adenocarcinoma samples. The expression of GAPDH mRNA was used as the internal control. In normal tissues we have observed differential expression pattern of all NTs examined. Varying levels of NGF expression was demonstrated in double specimens. Interestingly, half of the double specimens studied have shown no difference in NGF expression between cancer and adjacent tissue. In the majority of the double specimens we have detected low levels of NT3 and BDNF expression for both cancer and adjacent to tissue. No expression of TrkA, TrkB, p75 was found in double specimens and normal tissues. However, we have observed differential expression patterns of TrkC in normal tissues. TrkC expression was not detected in the majority of the double specimens, whereas in 32% cases we have detected high levels of TrkC expression in adjacent tissue compared with cancer. High levels of EGR1 expression was detected in normal tissues. In the majority of double specimens (74%) no EGR1 expression was revealed in cancer tissue compared to its high expression level in adjacent tissue.

hMSH2 Mutation Identified in a Family with Muir-Torre Syndrome: Genetic Counseling Perspective. *Z. Wang*[1, 2], *M. Flynn*[1, 2], *M.A. Whalen*[1, 2], *J.M. Milunsky*[1, 2, 3] 1) Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Department of Pediatrics, Boston University School of Medicine, Boston, MA; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Muir-Torre syndrome (MTS) is an autosomal dominant disorder characterized by sebaceous adenomas and carcinomas, and multiple keratoacanthomas in conjunction with tumors typical of hereditary non-polyposis colorectal cancer (HNPCC) spectrum. hMSH2 and hMLH1 mutations have been described in families with MTS, with hMSH2 mutations predominating. We identified a well-described splicing mutation in intron 5 of the hMSH2 gene (c.942+3 AT) in a 56-year-old male (proband), who was diagnosed with sebaceous carcinoma at age 49 and colon adenocarcinoma at age 52. One of his brothers was diagnosed with colon adenocarcinoma at age 54, and another brother died at age 15 from a glioblastoma. The probands mother was diagnosed with breast cancer in her 50s. She also has a history of sebaceous tumors and colon polyps. His maternal aunt (age 72) has uterine cancer. His maternal grandmother was diagnosed with breast cancer in her late 70s. After a mutation was identified in the proband, subsequent genetic counseling and testing identified the familial hMSH2 mutation in one of the probands daughters, his brother, and two of his brothers children. The individuals with the familial mutation have been started on surveillance protocols, including colonoscopy, EGD/upper GI series, and dermatology evaluations. As glioblastoma is a cancer that has been reported to be associated with hMSH2 mutations, we discussed the benefits and ethical considerations of molecular testing for the minor children in this family. Due to the early brain tumor in the family along with the availability of screening options, this family has decided to proceed with molecular testing in the minors. Early recognition of MTS will allow more optimal anticipatory guidance for those mutation positive family members and free those mutation negative family members from years of costly and unpleasant screening protocols.

Polymorphisms in methotrexate efflux transporters are associated with methotrexate effects in psoriasis. *R.B. Warren[1,3], R. Smith[1], E. Campalani[2], C.H. Smith[2], J.N.W.N. Barker[2], C.E.M. Griffiths[3], J. Worthington[1]* 1) ARC-EU, University Of Manchester, Manchester, United Kingdom; 2) St Johns Institute of Dermatology, St Thomas Hospital, London, United Kingdom; 3) The Dermatology Centre, University of Manchester, Hope Hospital, Manchester, United Kingdom.

Methotrexate remains a first-line systemic therapy for severe psoriasis but unpredictable efficacy and toxicity limits its use. Previous pharmacogenetic studies have focused on isolated single nucleotide polymorphisms (SNPs), within the folate and purine pathways. Efflux of methotrexate from cells has the potential to reduce efficacy, therefore we hypothesised that SNPs in the ATP-binding cassette (ABC) family of efflux transporters, ABCC1 and ABCG2, are associated with clinical response to methotrexate. DNA was collected from 374 psoriasis patients defined as either responder or non-responder to methotrexate therapy. Haplotype tagging SNPs (r2 >0.8) for ABCC1 (n=42) and ABCG2 (n=12) with a minor allele frequency of >5% were selected from the HAPMAP phase II data, giving 73.3% and 74.1% gene coverage respectively. Genotyping was undertaken using the MassArray spectrometry (Sequenom). SNP rs17731538 (ABCG2) was significantly (p=0.02) associated with response to methotrexate and development of any adverse event (p=0.01); carriage of the major allele confers an OR = 1.84 (95%CI 0.98 -3.4, p=0.02) and 1.2 (95%CI 0.7-2.1, p=0.2) respectively. This SNP had a strong (p=0.0005) association with development of significant gastrointestinal adverse events. SNP rs2238476 (ABCC1) was significantly (p=0.02) associated with response to methotrexate and development of an adverse event (p=0.01); carriage of the major allele confers an OR =2 (95%CI 0.79-4.9,p=0.07) and 2.16 (95%CI 0.9-5.3 p=0.03) respectively. Two further SNPs rs246240 (ABCC1) and rs3784862 (ABCC1) were also associated with the development of an adverse event, p= 0.01 and p=0.005; conferring an OR 1.6 (95%CI 0.97-2.8, p=0.03) and 1.8 (95%CI 1.1-3.2, p=0.01) respectively. These data indicate that SNPs in the efflux transporters may prove important when identifying psoriasis patients suitable for methotrexate therapy and this should be validated in a prospective trial.

Novel acetylcholine receptor duplication mutations in three Iranian families with congenital myasthenic syndrome. *P. Soltanzadeh[1, 4], P. Richard[1], J. Müller[2], K. Kahrizi[3], A. Ghorbani[4], A. Abicht[2], Y. Shafeghati[3], H. Najmabadi[3], J.A. Urtizberea[5], A. Soltanzadeh[4], H. Lochmüller[2], D. Hantaï[1]* 1) INSERM U582/Institute of Myology & Functional Unit of Cardiogenetics & Myogenetics, Pitié-Salpêtrière Hospital, Pierre & Marie Curie University, Paris, France; 2) Molecular Myology Lab, Friedrich-Baur-Institute, Department of Neurology, Ludwig-Maximilians-University, Munich, Germany; 3) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 4) Department of Neurology, Tehran University of Medical Sciences, Tehran, Iran; 5) AP-HP, Hôpital Marin, Hendaye, France.

Most congenital myasthenic syndrome (CMS) mutations affect the subunit gene of the acetylcholine receptor (*CHRNE*). Only one *CHRNE* mutation has already been documented in Iranian CMS patients. In three Muslim Iranian families, two from the northeastern province of Semnan and the third from the western province of Hamadan, CMS presented with early-onset ptosis and a slowly progressive generalized weakness. In the first family, without known consanguinity, one of the two affected siblings was analyzed. In the second family which had consanguinity, there was only one affected girl. In the third family from the western province of Hamadan, consanguineous marriage led to two affected siblings. *CHRNE* screening was performed by sequencing of the entire coding sequence and the promoter region. A homozygous frameshift mutation 98_101dupTCAA in exon 2 was found in the first two families. This duplication is predicted to introduce a shift in the reading frame leading to a null allele. A homozygous duplication of 14 nucleotides [GGCTCCGCAGCTCT] at position 444 of the *CHRNE* cDNA including the end of intron 5 and the first nucleotides of exon 6 was identified in the third family. This duplication probably generates a new splice acceptor site in mRNA. This study shows that *CHRNE* mutations exist in Persian population and *CHRNE* screening has to be considered in Iranian patients with a myasthenic phenotype. The possibility of a founder mutation in Semnan province has to be investigated by haplotyping analysis.

The GenDisCAN project (Gene Discovery for Complex traits in Asian population of Northeast) - study design and interim results -. *J. Sung[1,6], J-S. Seo[2,6], H-R. Kim[3], J-I. Kim[4], S-I. Cho[5], H-S. Park[2], M. Lee[6,7]* 1) Dept Preventive Medicine, Kangwon Natl Univ Sch Medicine, Chuncheon, Kangwon, Korea; 2) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine; 3) Department of Biochemistry and Molecular Biology, Ewha Womens University Medical College; 4) Department of Biochemistry and Molecular Biology, Hallym University Medical College; 5) Department of Biostatistics and Epidemiology Seoul National University School of Public Health; 6) ILCHUN Molecular Medicine Institute, Medical Research Center, Seoul National University; 7) Macrogen Inc.

The GenDisCAN (Gene Discovery for Complex traits in Asians of Northeast), started in 2002, is one of few non-Caucasian studies, which are devoted to the genetics of complex diseases. The study successfully included 1,518 individuals from 196 families, in three isolated rural provinces of Mongolia, and now recruiting 2,500 individuals this year. One huge family consists of 700 relatives. Measurements of detailed anthrometrics were taken in addition to basic clinical tests and questionnaires. A biorepository was constructed to store sera, plasma, and DNA extracts. We finished genotyping 400 microsatellite markers. A make-up genotyping is undergoing for mistyped markers (>1% genotype errors) and markers with low information contents (heterozygosity < 0.6). Identity by descent (IBD) matrix are being calculated. Heritabilities were estimated and genome-wide linkage analyses were tried (using 196 persons). Heritabilities were estimated to be 0.55 (height) 0.40 (weight), 0.49 (BMI), 0.44 (intraocular pressure, right), 0.42 (intraocular pressure, left), 0.40 (bone density, radius), 0.33 (bone density, heel). Some preliminary QTL analyses (by SOLAR) showed novel loci for LDL cholesterol (LOD score 2.6 on 3q), bone density of radius (LOD 2.7 on 7q), and forehead width (LOD 3.6 on 8q). Our study was designed and ethically permitted to incorporate technical progresses and is open to collaborations to hurdle the complexities of complex human diseases. Keywords: gene discovery study, population isolate, Quantitative Trait Loci (QTL), complex diseases/traits, Mongolian, large extended family.

Preimplantation genetic diagnosis (PGD) for Chronic Granulomatous Disease (CGD, gp91-phox) coupled to HLA matching and with subsequent successful pregnancy. *C. Pangalos[1], C. Konialis[1], G. Kokkali[2], A. Biricik[3], F. Fiorentino[3], C. Pantos[2]* 1) Dept. of Molecular Genetics and Preimplantation Diagnosis, Diagnostic Genetic Center, Athens, Greece; 2) Center for Human Reproduction, Genesis Maternity Hospital, Athens, Greece; 3) Genoma Molecular Genetics Laboratory, Rome, Italy.

Preimplantation genetic diagnosis (PGD) with HLA matching has only recently been recognized as an invaluable approach for couples wishing to produce a healthy offspring, which in turn will act as donor of cord blood hemopoietic stem cells for transplantation into seriously affected siblings. Due to the severe limitations of the whole procedure, only a very small number of cases have resulted in successful transplantation and therapy of the affected sibling, albeit demonstrating the usefulness of the approach. The present case involved a Greek couple with a 3-year old affected male child, harboring the R73X C>T mutation in the CYBB/gp91-phox gene and a phenotype characterized by recurrent infections. A flexible, indirect HLA typing protocol, based on single-cell multiplex PCR analysis of polymorphic STR markers within the human HLA complex, was optimized for the simultaneous amplification of the informative STR markers together with the gene region containing the mutation and the sexing marker amelogenin. Detection of the mutation was performed by minisequencing. Following an adapted IVF protocol, a total of 37 embryos were biopsied on day 3, resulting in an equal number of blastomeres. A successful result for all STR markers and for the mutation detection was obtained for 36 (out of the 37) samples and 6 embryos were found to be unaffected and HLA-matched. 2 of these embryos were transferred and a singleton pregnancy was achieved. The results of the PGD were confirmed following standard prenatal diagnosis from a CVS sample. Birth is expected within the next few weeks, at which time cord blood haemopoietic stem cells from the newborn will be obtained for transplantation into the affected sibling, demonstrating the valuable application of this rather complex approach in similar cases of X-linked chronic granulomatous disease.

Obesity, reduced fertility, and disrupted cicadian rhythm in mice with a targeted mutation in the Prader-Willi syndrome gene *MAGEL2*. *R. Wevrick[1], S.V. Koslov[2], J.M. Bischof[1], A.A. Tennese[1], J. W. Bogenpohl[3], R. van Gelder[4], E.D. Herzog[3], C.L. Stewart[2]* 1) Dept Med. Genetics, Univ Alberta, Edmonton, AB, Canada; 2) Lab. of Cancer and Dev. Biol., NCI, Frederick, MD; 3) Dept of Biology, Wash. Univ, St. Louis, MO; 4) Dept of Ophthalmology and Visual Sciences, Wash. Univ School of Med, St. Louis, MO.

Prader-Willi syndrome is a complex disorder resulting from the inactivation of paternally expressed, imprinted genes on chromosome 15q11-q13. Findings include neonatal failure to thrive, developmental delay, sleep apneas, pain insensitivity, excessive daytime sleepiness, neuroendocrine abnormalities, hypogonadotrophic hypogonadism, and insatiable appetite leading to morbid obesity, indicative of hypothalamic dysfunction affecting sleep, circadian rhythm, appetite, and fertility. We are examining the effects of loss of PWS genes individually, and have generated mice with targeted mutations of the PWS imprinted candidate genes*necdin* and *Magel2*. We now show that *Magel2*-null mice recapitulate fundamental aspects of hypothalamic deficiency in PWS. MAGEL2 shares a MAGE protein homology domain with necdin and may, like necdin, promote neuronal migration and differentiation during development.*Magel2* is highly expressed the hypothalamus and in a circadian manner in the suprachiasmatic nucleus. *Magel2*-null mice have reduced total activity and a less coherent circadian rhythm than control littermates, although they do entrain to a light:dark cycle with a normal period, suggesting a defect in circadian output from the suprachiasmatic nucleus. *Magel2*-null mice weigh less at weaning, have increased weight gain after weaning that is exacerbated by a moderately high-fat diet, and have reduced fertility compared to control. These results strongly implicate loss of *MAGEL2* in the hypothalamic deficiency that profoundly affects appetite, sleep, and reproduction in people with PWS. Previous studies in gene-targeted mice have shown that loss of necdin causes defects in neonatal respiration, sympathetic nervous system function, and pain sensitivity. We propose that the combined loss of necdin and MAGEL2 plays a major role in the complex phenotype of PWS.

Genes of the extracellular matrix contribute to the development of intracranial aneurysms. *Y.M. Ruigrok[1,2], G.J.E. Rinkel[2], R. van 't Slot[1], M. Wolfs[1], S. Tang[1], C. Wijmenga[1]* 1) Complex Genetics Section, Department of Biomedical Genetics, University Medical Center Utrecht; 2) Department of Neurology, University Medical Center Utrecht.

Intracranial aneurysms probably develop due to the interaction of several genes and environmental factors. Previously, we hypothesized that a disruption of the extracellular matrix (ECM) of the arterial wall is a likely factor in the pathogenesis of intracranial aneurysms. We analyzed 44 potential candidate genes involved in the maintenance of the integrity of the ECM in 382 Dutch Caucasian patients with intracranial aneurysms and 609 Dutch Caucasian controls for 384 tag single nucleotide polymorphisms (SNPs) using the GoldenGate assay on an Illumina BeadStation 500 GX. We identified SNPs that were associated with intracranial aneurysms ($p<0.01$) in six of these 44 genes: serpine1 (PAI1, p=0.0008), transforming growth factor, beta induced (TGFBI, p=0.0026), perlecan (HSPG2, p=0.0044), fibronectin (FN1, p=0.0069), fibrillin 2 (FBN2, p=0.0077) and collagen 4A1 (COL4A1, p=0.0087). In a second independent cohort of 310 Dutch Caucasian intracranial aneurysm patients and 336 Dutch Caucasian controls, the association for the HSPG2 gene (combined odds ratio (OR) 1.33, 95% confidence interval (CI) 1.13-1.57, p=6x10-4) was replicated. The population attributable risk (PAR) for this SNP is 19%. Combining the two cohorts still showed association for the PAI1 (combined OR 1.27, 95% CI 1.07-1.50, p=0.004, PAR 6%), FBN2 (combined OR 1.37, 95% CI 1.07-1.75, p=0.01, PAR 3%) and COL4A1 (combined OR 1.22, 95% CI 1.05-1.42, p=0.007, PAR 7%) genes. Our findings indicate that variation in genes involved in the maintenance of the integrity of the ECM of the arterial wall plays a role in susceptibility to intracranial aneurysms. These findings further support our hypothesis that diminished maintenance of the ECM of the arterial wall is important in the development of intracranial aneurysms.

An atypical presentation of systemic epidermal nevus syndrome in childhood. *N. Shur[1], R.W. Marion[1, 2], J. Samavich[1], J. Schaffer[3], A. Roe[2]* 1) Department of Pediatrics, Division of Genetics, Montefiore Medical Center, Bronx, NY; 2) Department of Obstetrics, Division of Genetics, Albert Einstein College of Medicine, Bronx, NY; 3) Department of Dermatology, New York University, Manhattan, NY.

Background: Epidermal nevus syndromes (ENS) are rare neurocutaneous disorders characterized by extensive nevi on the skin, and variable neurological, ocular, and skeletal abnormalities. ENs are postulated to arise from post-zygotic mutations and reflect cutaneous mosaicism. Mosaicism in extracutaneous tissue causes systemic disruptions termed organ nevi. The diagnosis of ENS depends on the presence of characteristic nevi distributed along the Blaschko lines. We describe an atypical presentation of systemic ENS with lesions not evident at birth and did not appear to follow lines of Blaschko. Case report: We evaluated a 3 1/2-year-old African-American boy with global developmental delay. The full-term product of an unremarkable pregnancy and delivery, the only initial perinatal abnormality was a mild eczematous-appearing rash. At 2 y.o dark, velvety, papillomatous lesions appeared and, over the next year, became increasingly extensive, involving his entire trunk and crossing the midline. On exam, he had microcephaly, a sloping forehead and high hairline, brachydactyly of his fingers, and prominent hypertonicity. Initial genetic testing for high resolution chromosomes, FISH for subtelomeric probes, and Fragile X was negative. Further testing ruled out neurocutaneous syndromes. including SjÖgren-Larsson syndrome, and infantile Gaucher disease. Repeat dermatological evaluation and biopsy led to the diagnosis of ENS. Discussion: In most cases, the diagnosis of ENS is straightforward with nevi typically appearing at birth and following lines of Blaschko. However, our patient demonstrates that occasionally, EN may be so extensive that the linear bands become confluent. In addition, profound neurological problems may become evident prior to the skin involvement. Our case highlights the importance of considering an atypical presentation of ENS in patients with variable neurocutaneous manifestations.

A rapid and flexible multiplexed SNP based procedure to screen for DNA variation in the mitochondrial genome.

W. Tang[1], J. Petros[2,3,4,5,], K.-H. Huang[1], M. Wilson[1], M. Benton[2], M. Bouzyk[1] 1) Center for Medical Genomics, Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Urology, Emory University, Atlanta, GA; 3) Department of Pathology, Emory University, Atlanta, GA; 4) Winship Cancer Institute, Emory University, Atlanta, GA; 5) The Atlanta VA Medical Center, Atlanta, GA.

Mutations in the mitochondrial genome have been increasingly associated with several cancers and individuals with certain mitochondrial polymorphisms have increased susceptibility to mitochondrial diseases such as Parkinsons disease and Lebers hereditary optic neuropathy. Rapid, efficient, low cost and large scale identification of variations in the mitochondrial genome that better predict likelihood of disease would be extremely valuable. This is particularly important for prostate and renal cancers where screening tools for early detection do not exist or are crude.

We have developed a single nucleotide polymorphism (SNP) genotyping technology to assay for known mitochondrial variations in a high throughput, multiplexed and flexible manner. Utilizing the Beckman SNPStream single base extension genotyping technology we have taken a novel approach which provides the ability to specifically, sensitively and at low cost assay variations in the mitochondrial genome. We are initially screening nearly 300 prostate or renal cancer patients. Developing this capability to generate panels of mitochondrial genetic markers associated with prostate and renal cancer in particular will provide a powerful technique to supply accurate information crucial for determining susceptibility to mitochondrial disease, treatment options including early interventions and patient outcomes.

Abnormal Magnesium Balance in *Trpm6* and *Trpm7* mutant mice. *R.Y. Walder[1], L.V. Ryazanova[4], B. Yang[2], M.P. Andrews[1, 6], X. Cao[2], M.V. Dorovkov[4], L. Rondon[5], A. Mazur[5], J.B. Stokes[3], V.C. Sheffield[1, 6], A.G. Ryazanov[4]* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Dept Obstetrics and Gynecology, Univ Iowa, Iowa City, IA; 3) Dept Internal Medicine, Univ Iowa, Iowa City, IA; 4) UMDNJ-Robert Wood Johnson Medical School, Dept Pharmacology, Piscataway, NJ; 5) Centre de Recherche en Nutrition Humaine d'Auvergne, INRA, Theix, St. Genes Champanelle, France; 6) Howard Hughes Medical Institute, Iowa City, IA.

Recent evidence suggests that the channel kinases, TRPM6 and TRPM7, play a key role in the regulation of magnesium homeostasis in vertebrates. Mutations in *TRPM6* cause familial hypomagnesemia with secondary hypocalcemia (HSH) (MIM 602014). TRPM7 is a ubiquitously expressed Mg permeable ion channel and TRPM7-deficient cells fail to grow in the absence of supplemental Mg. There is evidence that TRPM6 and TRPM7 combine to form heteromeric channels and regulate Mg transport into the cell. We have constructed mice with a targeted deletion of the *Trpm6* gene and two lines of *Trpm7* mutant mice, one with a complete elimination of *Trpm7* and one in which the kinase catalytic domain was deleted, leaving the channel portion intact (kinase). Some of the homozygous *Trpm6*$^{(-/-)}$ mice die *in utero*, but some are born with a reduced survival rate. Some *Trpm6*$^{(-/-)}$ mice survive to adulthood and are fertile. Homozygous mice from both lines of *Trpm7* mutant mice are embryonic lethal: mice completely lacking *Trpm7* die at day 6.5, while *Trpm7* kinase mice die at day 7.5. Heterozygous *Trpm6* and *Trpm7* kinase mice showed abnormalities of Mg handling. On a normal diet, the *Trpm6*$^{(+/-)}$ animals excreted much less Mg in their urine and on a low Mg diet had lower plasma Mg levels. *Trpm7* kinase$^{(+/-)}$ mice on a normal diet had lower plasma Mg and lower urinary Mg excretion than controls. On a low Mg diet, the *Trpm7* kinase$^{(+/-)}$ mice developed signs of neuromuscular irritability and abnormal motility and some developed seizures characteristic of a severe hypomagnesemic state. The *Trpm7* kinase$^{(+/-)}$ mice had more severe hypomagnesemia than the *Trpm6*$^{(+/-)}$ mice. Our data indicate that Trpm6 and Trpm7 are involved in Mg homeostasis.

A t(4;11)(p12;q23) in a therapy-related acute myeloid leukemia. *S.N.J. Sait[1], M.A. Claydon[1], M. Barcos[2], M.R. Baer[3]* 1) Clinical Cytogenetics Laboratory, Roswell Park Cancer Institute, Buffalo, NY; 2) Department of Pathology, Roswell Park Cancer Institute, Buffalo, NY; 3) Department of Medicine, Roswell Park Cancer Insitute, Buffalo, NY.

We describe a t(4;11)(p12;q23) in a patient with therapy-related acute myeloid leukemia (t-AML) as the third reported case of t(4;11)(p12;q23) in patients with secondary leukemias. The patient is a 56-year-old female who was diagnosed in 1998 with a small lymphocytic lymphoma and treated with fludarabine and rituximab, following which she had persistent cytopenias. In 1999, she was diagnosed with multifocal invasive ductal carcinoma of the left breast, which was treated with mastectomy without adjuvant chemotherapy due to cytopenias, and in 2004 biopsy of a left chest wall mass revealed a poorly differentiated adenocarcinoma, which was treated with radiation therapy, again without chemotherapy. Bone marrow histology and karyotype were normal in 2004, but in 2005 the patient was diagnosed with acute myeloid leukemia (FAB M1), therapy-related. The karyotype at that time was 54,XX,+1,der(1;7)(q10;p10),+3,t(4;11)(p12;q23),+der(4)t(4;11)(p12;q23),+6,+6,+8,+8,+8,+19,del(20)(q11q13),+22 in all 20 cells analyzed. Fluorescence in situ hybridization (FISH) using the MLL probe (Abbott Molecular) showed rearrangement of the MLL locus and confirmed the t(4;11)(p12;q23). The t(4;11)(p12;q23) has been reported previously in two patients-one with conversion of childhood acute lymphocytic leukemia (ALL) with a t(12;21) to juvenile myelomonocytic leukemia with t(4;11) (Manor et al, 2003; Cancer Genet Cytogenet) and the other with therapy-related ALL following breast adenocarcinoma (Hayette et al, 2005; Cancer Res). Hayette et al identified the AF4p12 gene at 4p12, a human homologue of the furry gene of Drosophila, as the fusion partner of the MLL gene in their patient. It is not known whether the same gene is involved in our patient.

Genome-wide admixture mapping for coronary artery calcification identifies atherosclerosis locus on chromosome 6 in African-Americans. *Q. Zhang[1], C.E. Lewis[2], L.E. Wagenknecht[3], R.H. Myers[4], J.S. Pankow[5], S.C. Hunt[6], K.E. North[7], J.E. Hixson[8], I. Borecki[1], M.A. Province[1]* 1) Washington University School of Medicine, St Louis, MO; 2) University of Alabama, Birmingham, AL; 3) Wake Forest University School of Medicine, Winston-Salem, NC; 4) Boston University School of Medicine, Boston, MA; 5) University of Minnesota, Minneapolis, MN; 6) University of Utah School of Medicine, Salt Lake City, UT; 7) University of North Carolina, Chapel Hill, NC; 8) University of Texas School of Public Health, Houston, TX.

To identify the genetic loci contributing to coronary artery calcification (CAC), an important measure of subclinical coronary atherosclerosis, we conducted a genome-wide scan with 374 microsatellite markers by applying admixture mapping to 618 African American participants in the NHLBI Family Heart Study (FHS). 868 Caucasian participants in FHS and 157 Africans genotyped by the Marshfield Medical Genetics Center were used as two reference founding populations of African Americans. A Bayesian method and Markov Chain Monte Carlo (MCMC) algorithm were used to estimate Caucasian and African ancestries among African Americans. A permutation test for regression of CAC score on marker specific African ancestry found 4 markers, D10S189 at 10p14 (P=0.0012), D20S159 at 20q13 (P=0.0075), D12S1294 at 12q14 (P=0.0082) and D6S1053 at 6q11 (P=0.0098), significant at the 0.01 level. D10S189 and D6S1053 were further confirmed at the 0.05 significance level by regression of CAC on allelic copy number. Two independent linkage scans in the FHS Caucasian families and in the Framingham Offspring Study have also identified significant linkage signals at one of these locations (D6S1053 @ 80cM) with LODs=2.2 and 3.3(ODonnell et al., 2006), respectively. Four other published studies show suggestive linkages (LODs between 1.0-2.2) to this same region for various measures of CHD and/or atherosclerosis. This region seems to harbor a highly promising, replicated QTL for atherosclerosis.

A molecular defect causing impaired ganglioside synthesis in a familial form of multiple sclerosis. *E. Vitale[1,4], C. Yildirim - Toruner[1], G. Mahon[2], S. Husain[1], G. Toruner[1], M. Schwalb[1], S. Cook[3]* 1) Microbiology & Mol Genetics, UMDNJ New Jersey Medical School, Newark, NJ; 2) NJMS-UH Cancer Center UMDNJ, Newark, NJ, USA; 3) Department of Neuroscience UMDNJ-New Jersey Medical School, Newark NJ, USA,; 4) CNR Institute of Cybernetics, Naples, Italy.

Rapid communication between neurons requires energy and the insulation of axons by discontinuous segment of myelin. Voltage-gated Na+ channels produce nerve impulses and are concentrated at the nodes Ranvier. The nerve impulse rapidly jumps from node to node by a process called saltatory conduction. MS is an inflammatory demyelinating disease of the central nervous system that destroys myelin, oligodendrocytes, axons and neurons. As a result the saltatory conduction is interrupted. We previously demonstrated a linkage between the MS and markers on 12p12 conditional on the presence of HLA DR15 DQ6 alleles in a pedigree of Pennsylvania Dutch extraction. We have evidence of an existing disruption of the ganglioside pathway that could lead to a defective distribution of GD3G on PBLs cell membranes thus representing a foundation of the disease in this unique pedigree. Sequencing of the GD3 Synthase gene localized in the 12p12 locus shows a novel G29A genetic variant at +29 in the 5' splice donor site of intron 4/5. Contingency table analysis on the family showed that all MS affected individuals have both the DR15 DQ6 allele and the G29A variant whereas the unaffected individuals have either one or neither of these markers ($p = 0.00011$). Molecular analyses revealed that in the MS patients in this family there is a premature degradation of GD3S mRNA and that the transcript is about 150 times lower when compared to the normal sample. We also analyzed the cell surface expression of GD3S and GD3 Gangliosides by Flow Cytometric Analyses on controls in the general population. Our results show that GD3S is mainly expressed by the B cell subpopulation of the immune system while GD3G it is ubiquitously expressed in PBLs . The observation of differences in protein and/or ganglioside profile and distribution in the patients supports the hypothesis that the genotype HLA DR15 DQ6 and G29A of GD3S are the major components in the disease.

Reading disability: is the 6p22 locus DCDC2, KIAA0319 or both? Using integromic techniques to resolve the conflict. *G.P. Page[1], A. Patki[1], K. Zhang[1], T. Mehta[1], V. Srinivasasainagendra[1], H. Main[2], J.R. Gruen[2]* 1) Department of Biostatistics Univ Alabama Birmingham, AL; 2) Department of Pediatrics, Yale University New Haven, CT.

Last year at this meeting we reported that polymorphisms and a deletion in and near the DCDC2 gene were associated with multiple reading traits. KIAA0319, a gene near DCDC2 has also been reported to be associated with reading disability. Since then several published studies have reported positive and negative replication of both associations. To further complicate matters is the complexity of the reading disability phenotypes, each study uses multiple different measures of reading disability, making thus it is difficult to assess agreement between studies. To make matter worse, most published studies have some evidence of association to markers in multiple genes in this region. We are using integromic approaches to understand reading disability in this genomic region. For association studies we typed over 200 markers and constructed haplotypes in the region. While single marker association still maximizes to DCDC2, we have found uncommon haplotypes that span the region from at least DCDC2 to THEM2 that are associated with some of the reading disability phenotypes. Using multidimensionality reduction approaches we have found also found evidence for interactions between SNPs in and around DCDC2 and KIAA0319 for reading disability traits. To assist in assigning functions to DCDC2 and KIAA0319 we have also built a co-expression engine containing data from over 2300 human expression arrays. We find that genes co-expressed with DCDC2 are highly enriched for transcriptional activator, nucleic acid binding, synaptic transmission, ubiquitin activity, and sensory perception, and zinc ion binding while and the majority are in the nucleus while KIAA0319 is enriched for microtubule motor activity, GTP binding, calcium, and calmodulin binding genes which are mostly in the membrane. These two lines of evidence suggest that the region on 6p22 may contain interacting genes that contribute to different aspects of reading, and do so through different pathways or different steps on the same pathway.

Evidence Based Information: Lessons learned from Fragile X and Duchenne/Becker Muscular Dystrophy. *M. Weaver[1], K. Reed[2], C. Greene[1], M. Blitzer[1], P. Furlong[3], K. Clapp[4], S. Terry[5]* 1) Univ. of Maryland, Baltimore, MD; 2) NCHPEG, Lutherville, MD; 3) Parent Project Muscular Dystrophy, Middletown, OH; 4) FRAXA Research Foundation, Newburyport, MA; 5) Genetic Alliance, Washington, DC.

Current focus on evidence-based medicine creates challenges for families and health professionals dealing with diagnosis and management of single-gene disorders. Although evidence basis for rare conditions is growing, significant uncertainty often remains about natural history and management options. The quality of information available is highly variable, and families and health professionals must assess and synthesize information from many sources to make informed decisions. The Access to Credible Genetics Resources Network is a collaborative effort led by the Genetic Alliance and funded by the CDC. One goal of this project is to enable access to accurate and scientifically valid information on single gene disorders for families and health professionals.

A critical step to accomplish this goal is describing evidence-based information. By analyzing methods used by other organizations to assess information quality, this project created a draft metric. The purpose of the metric is to assess quality of information in educational materials. Examples of criteria included in the metric are: currency and accuracy of information, and source of expertise. We will use the metric to inform the construction of a module designed to help families independently evaluate the quality of information. Further, we will develop an outline of content topics that families and experts believe are important to include in educational materials for the purpose of informed decision making. The development of both of these tools will be an iterative process to engage both families and health professionals. The recommendations on content and the quality metric will provide a comprehensive standard to assess existing materials and to guide the creation of new materials. The goal of presentation of the draft metric at ASHG is to invite critique by the professional community. After incorporation of comments from this meeting, a revised draft will be formally disseminated for further comment.

Evaluation and introduction of new techniques in the genetic testing service by EuroGentest. *N. van der Stoep*[1, 2], *G. Matthijs*[2], *M. Macek*[2], *E. Bakker*[1, 2] 1) Clinical Genetics, LUMC, Leiden, Netherlands; 2) EuroGentest, http://www.eurogentest.org/.

At present, the field of genetics is witnessing a fast expansion of new technologies that could have a strong potential for application in genetic testing. Unfortunately, implementation of these novel technologies is often hampered by the lack of complete evaluation of their technical performance in a diagnostic setting. EuroGenTest(EGT)is a European Network of Excellence aiming at harmonizing genetic testing services throughout Europe. One key objective is to bridge the gap observed in the chain of new technology transfer from research into implementation and ultimate accreditation in genetic diagnostics. EGT Unit 5 is specifically involved with the coordination and guidance of activities required for complete technical evaluation, validation and subsequent implementation of emerging technologies into diagnostic application. Recently several interesting new techniques were recruited by a EGT directed call for new techniques and introduced at the first EGT Unit 5 open meeting on 'New Technologies in Genome Diagnostics' at the European Society of Human Genetics Conference (ESHG) conference in Amsterdam (see our webpage for more details. As a follow up two of these new approaches in genetic testing are currently under evaluation in the EGT-setting in collaboration with their manufacturers and inventors. In this respect we are setting up a new test for BRCA1 mutation scanning using high-resolution melting curve analysis (hrMCA), a method to scan DNA fragments for the presence of mutations/variants, in collaboration with Idaho Technologies. In addition, we are evaluating Pyrophosphorolysis Activated Polymerization (PAP), a very sensitive detection method for the presence of low frequency mutations in the presence of excess wt allele, in collaboration with the City of Hope National Medical Center and Beckman Research Institute and ServiceXS. PAP technology will be primarily evaluated as a non-invasive prenatal diagnostic tool for the detection of paternal sequences in the presence of excess the maternal allele on fetal DNA isolated from serum of pregnant women.

Effects of *INSIG2* gene and substance dependence on body mass index. *B.Z. Yang[1], H.R. Kranzler[2], R. Weiss[3], K. Brady[4], L. Farrer[5], J. Gelernter[1]* 1) Dept Psychiatry, Yale Univ Sch Medicine, New Haven, CT. & VA CT, West Haven, CT; 2) Univ CT Health Center, Farmington, CT; 3) Dept Psychiatry, Harvard Med School, Boston, MA; 4) Med Univ South Carolina, Dept Psychiatry, Charleston, SC; 5) Boston Univ School Med, Boston, MA.

We investigated the effects of *INSIG2* gene and substance dependence (SD), including dependence on alcohol, cocaine, marijuana, opiates, and tobacco (AD, CD, MjD, OD, TD), on body mass index (BMI). We genotyped a single nucleotide polymorphism (rs7566605, designated as SNP-*INSIG2*) in insulin induced gene 2, a susceptibility gene variant for obesity, in a linkage sample collected for mapping genes increasing risk of CD and OD. The linkage sample contains 1485 subjects from 319 and 313 African American and European American pedigrees, respectively; 47.7% are male, and the average age is 39. 37.8% have BMI >30 (i.e., are considered obese), 43.2% AD, 81.8% CD, 26.7% MjD, 43.9% OD, and 65.1% TD. The family-based association test (FBAT) for the binary trait of obesity for the recessive genetic model of SNP-*INSIG2* showed borderline significance (p=0.057); alternatively, the FBAT for the quantitative trait of BMI after controlling for the effects of age and sex was not significant (p=0.093), but had only 5% power because of low number of informative families used in FBAT. We then sought to use all of the available data by implementing the generalized linear model via generalized estimating equations (GEE) for incorporating the familial correlation structure, which accounts for genetic and environmental heterogeneity across families. The results, after controlling for sex (p=0.0008) and age (p=0.007), showed significantly greater BMI for AD (p=0.014), CD (p=0.010), and MjD (p<0.0001), and a decreased BMI for OD (p=0.033). There was no genetic effect from SNP-*INSIG2* although homozygous CC individuals showed a trend for increased BMI, consistent with a prior report. TD was not included in the model due to colinearity with the other SD diagnoses. We conclude that the effect of SD on BMI is far greater than that of the genetic variant from SNP-*INSIG2*, which carries low relative risk in the general population.

European mitochondrial haplogroups exhibit differential risk of developing presbycusis. *S. Ramon[1], A.C. Braganza[1], F.M. Mapes[2], S.T. Frisina[2], R.D. Frisina[2], D.R. Frisina[2], D.A. Eddins[2], D.L. Newman[1]* 1) Biological Sciences, Rochester Institute of Technology, Rochester, NY; 2) International Center for Speech & Hearing Research, Rochester, NY.

The genetic basis of human presbycusis (age-related hearing loss) is unknown. This common disorder is characterized by difficulty understanding conversation, particularly in noisy backgrounds. Audiograms of presbycusics show sloping hearing loss, with greatest deficiencies at the highest frequencies, and over time an individuals hearing loss progresses into the lower frequencies that are more important for understanding speech. We investigated the hypothesis that the mitochondrial (mt) genome plays a role in presbycusis. Subjects of European ancestry, all over age 58, were tested using both classical and advanced audiometric measures and then genotyped to determine mt haplogroups. We found that subjects belonging to haplogroup H (N=93) had better hearing than other Europeans (N=80), with the greatest differences observed in the right ear at 3 kHz (p=0.017) and 10-14 kHz (p=0.016). The difference at 3 kHz correlates with the common noise notch location, and thus may indicate a difference in susceptibility to noise damage. Distortion product otoacoustic emissions also indicated better hair cell health in haplogroup H subjects, at higher frequencies and in the right ear (average DPOAE for 4-6 kHz, p= 0.010). These results support the hypothesis that a mitochondrial factor influences susceptibility to the development of presbycusis. We are currently investigating the mt genome for causative mutations linked to the haplogroups.

Mutations in LRRK2 other than G2019S are rare in familial Parkinson disease. *N. Pankratz[1], M.W. Pauciulo[2], V.E. Elsaesser[2], D.K. Marek[2], C. Halter[1], A. Rudolph[3], C.W. Shults[4], T. Foroud[1], The Parkinson Study Group - PROGENI Investigators* 1) Indiana University School of Medicine, Indianapolis, IN; 2) Cincinnati Childrens Hospital Medical Center, University of Cincinnati College of Medicine, Cincinnati, OH; 3) University of Rochester, Rochester, NY; 4) University of California, San Diego, San Diego, CA; VA San Diego Healthcare System, San Diego, CA.

Mutations in the LRRK2 gene cause some forms of autosomal dominant Parkinson disease (PD) and have been found in 5% of familial cases and 1% of sporadic cases. We screened 956 primarily Caucasian individuals from 430 multiplex PD pedigrees for 12 previously reported, pathogenic LRRK2 mutations: R793M, L1114L, I1371V, R1441C, R1441G, R1441H, Y1699C, M1869T, I2012T, I2020T, G2385R, and IVS31 +3G>A. Previous screening identified the LRRK2 G2019S mutation in 5% of our families. Only one of the 12 newly screened mutations, R1441C, was detected in a single family in our patient cohort. Two brothers were concordant for the mutation and had an average age of onset of 53 years. The mother did not harbor the mutation, and no other family members were reported to be affected; however the father died at the age of 61. These results indicate that while the G2019S mutation remains the most common mutation identified in familial PD patients, other mutations in LRRK2 are infrequent. This will make it difficult to gather adequate penetrance data for these rarer mutations. Coupled with the presence of nonpathogenic coding variants, this will make it difficult to provide proper genetic counseling to individuals undergoing genetic testing. Until these ambiguities have been resolved, it is recommended that presymptomatic testing be delayed until more is learned about the frequency, penetrance and risk assessment of LRRK2 mutations.

The L10P polymorphism of TGF-1 shows no association with prostate cancer in a US Caucasian study population. *B. Yaspan, J. Breyer, B. Elmore, K. Bradley, K. McReynolds, J.R. Smith* Departments of Medicine and Cancer Biology, Vanderbilt University Medical Center, Nashville, TN.

Transforming growth factor (TGF-) is a tumor suppressor and a potent inhibitor of cellular proliferation. However the pathway has a dual role, as excess TGF- signaling is implicated in cancer progression. TGF- has been shown to regulate proliferation and apoptosis of prostate epithelial and stromal cells. Significantly elevated levels of TGF- expression in prostate cancer cell lines have also been observed. A well-studied polymorphism in codon 10, a T to C transition, results in a proline to leucine substitution in the hydrophobic core of the signal peptide of TGF- isoform 1 (TGF-1). Presence of the T allele has been shown to be significantly associated with increased risk of prostate cancer and of benign prostate hyperplasia in a Japanese study population. We tested the hypothesis that the presence of the T allele confers risk for prostate cancer in a Caucasian study population from Vanderbilt University. We observed no significant association of the TGF-1 L10P polymorphism with risk of prostate cancer in a study population of 597 cases, and 513 screened controls without a personal or family history of prostate cancer.

Common genetic variation in ATM does not determine susceptibility to non-Hodgkin lymphoma. *P. Sipahimalani[1], J. Spinelli[2], A. MacArthur[2], A. Lai[2], J. Connors[3], R. Gascoyne[4], R. Gallagher[2], A. Brooks-Wilson[1]* 1) Genome Sciences Centre; 2) Cancer Control Research Department; 3) Medical Oncology; 4) Pathology, British Columbia Cancer Agency, Vancouver, Canada.

The ataxia telangiectasia mutated (ATM) gene is critical for the detection and repair of DNA double-stranded breaks (dsb). Mutations in ATM cause the autosomal recessive syndrome ataxia telangiectasia, a feature of which is a high risk of lymphoma. We undertook a population-based study of 798 NHL cases and 793 controls to assess the role of genetic variation in ATM on the risk of non-Hodgkin lymphoma (NHL). Many of the subtypes encompassed by the term NHL have in common the occurrence of specific somatic translocations. We hypothesize that variants that affect ATM function could reduce dsb repair capacity, contributing to the occurrence of translocations and subsequent lymphomas.

Genetic variation in the promoter and all exons of ATM was determined by bi-directional sequencing of the germline DNA of 86 NHL patients. Sequencing revealed 79 variants, 18 of which correspond to amino acid differences. Six rare variants (0.5-1.1%) were predicted to be deleterious to protein function. Eleven variants had a minor allele frequency of 5%; these made up 10 haplotypes that could be specified by seven tagSNPs. Linkage disequilibrium across the ATM gene is high but incomplete. Six tagSNPs and the 6 putatively deleterious rare variants converted successfully to Taqman assays and were genotyped in the case/control set. Direct and haplotype-based indirect association tests were performed. Subtype specific and ethnicity specific analyses were performed when sample numbers permitted.

The results of these association tests indicated that common variants of ATM do not significantly contribute to the overall risk of NHL in the general population. The effect of multiple rare deleterious ATM variants at the population level was more difficult to assess, and may require the use of new technologies to permit extensive sequencing of hundreds or even thousands of NHL cases and controls.

Functional genetic variants of both cysteinyl leukotriene 1 and 2 receptors are independently associated with atopic asthma in the population isolated on Tristan da Cunha. *M.D. Thompson[1], J. Takasaki[2], V. Capra[3], W.M. Burnham[4], D.E. Cole[1], K.A. Siminovitch[5]* 1) Lab Medicine, Banting Inst, Univ Toronto, Toronto, ON, Canada; 2) Drug Discovery Research, Astellas Pharma Inc. Tsukuba, Ibaraki 305-8585, Japan; 3) Laboratory of Molecular Pharmacology, Section of Eicosanoid Pharmacology, Department of Pharmacological Sciences, University of Milan; 4) Department of Pharmacology, University of Toronto, Toronto, Ontario; 5) Departments Medical Genetics and Microbiology, University of Toronto, the Samuel Lunenfeld Research Institute, Mount Sinai Hospital.

The contribution to asthma of variability in the genes encoding the cysteinyl leukotriene (CysLT) system was quantitated in the population resident on the island of Tristan da Cunha. Environmental risk factors such as allergies and smoking history were controlled. Genetic variation in the cysteinyl leukotriene 1 and 2 receptors has been associated with atopic and/or asthmatic disease in some populations and with variable response to the cysteinyl leukotriene family of inflammatory mediators (LTC4, LTD4 and LTE4) that regulate human airway contraction. In particular, we report the association of CysLT1 G300S and the CysLT2 M201V variants with atopic asthma in the Tristan da Cunha. In vitro studies of these variants using a calcium flux assay suggest that discrete portions of the genes encoding the CysLT1 and CysLT2 transmembrane domains may be critical to maintaining the conformation necessary for leukotriene agonist and antagonist second messenger coupling. While the M201V variant is partially inactivating, the G300S variant is partially activating. Both variants are highly associated with atopic asthma in the study population. We augue that together these variants may give rise to atopic athma and may result in a significant alteration in drug efficacy.

Neonatal hypertrophic cardiomyopathy (HCM) due to mitochondrial SCO2 deficiency: An enzyme histochemical and targeted mutation approach to the diagnosis of a novel mutation. *H. Vogel[1,3], L.J. Wong[2], E.J. Prijoles[3], A.M. Dubin[3], G.M. Enns[3]* 1) Department of Pathology, Stanford University, Palo Alto, CA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Pediatrics, Stanford University, Palo Alto, CA.

In order to demonstrate the utility of enzyme histochemistry and targeted mutational analysis in the evaluation of mitochondrial (mt) disease, we present a neonate who developed HCM. She was the first child born to consanguineous parents of Indian ethnicity. Intrauterine growth retardation and decreased fetal movement were noted the week before delivery. At birth she required resuscitation and was hypotonic with lactic acidosis (9.0 to 21.0 mmol/L). Initial echocardiography was normal, but she developed a concentric non-compacted HCM and died at 30 days. MtDNA analysis for common mutations and testing for congenital disorders of glycosylation were normal. Electron transport chain (ETC) analysis on skin fibroblasts was normal. Muscle biopsy performed on DOL 29 revealed a neuropathic pattern suggestive of spinal muscular atrophy (SMA) and enzyme histochemistry revealed marked diffuse cytochrome oxidase (COX) deficiency. Interestingly, with additional incubation from 1 to 8 hours, COX activity was detectable. ETC analysis could not be done because of insufficient muscle. DNA analysis of nuclear encoded COX assembly genes SURF1, SCO1, SCO2 and COX10 identified a novel homozygous missense alteration (c.577G>A; p.G193S) in the SCO2 gene. The parents were heterozygous carriers of p.G193S. The amino acid glycine at position 193 in the SCO2 protein is highly conserved from yeast to human and not found in 100 normal control chromosomes. Since HCM is a hallmark of SCO2 deficiency, our results support the pathogenicity of p.G193S. The deficiency likely represents defective catalytic properties of COX rather than a truncated protein as has been linked to SCO2 deficiency with SMA. This case illustrates the importance of multiple modalities in identifying mt disease, including enzyme histochemistry and targeted gene sequencing. By identifying an etiology of HCM, appropriate genetic counseling may be provided to the family.

Whole genome association studies for ADHD using samples from the Quebec founder population. *B. Paquin, J. Raelson, P. van Eerdewegh, R. Little, R. Paulussen, V. Bruat, M. Lapalme, J. Hooper, A. Belouchi, T. Keith* Genizon Biosciences, St Laurent, PQ, Canada.

We previously performed whole genome association studies (WGAS) for six complex diseases including Crohns disease. Recently, we completed genotyping 469 parent-parent-child trios with the child of each trio being affected with attention deficit and hyperactivity disorder (ADHD). The phenotype was determined following a series of interviews and tests performed both with the affected child and one of the parents, according to the DSM-IV criteria. The 469 trios were collected from the Quebec Founder Population (QFP). A total of 317,503 SNPs were genotyped in house using the Infinium assay from Illumina, generating 447 million genotypes. An additional 60,000 SNPs consisting of tag SNPs and markers spaced according to variation in LD, determined specifically from the QFP, will also be genotyped. Utilizing parental non-transmitted chromosomes as controls, haplotype case-control association analyses were carried out using a proprietary software LDSTATS calculating exact P values based on permutation. Seven regions with -log10 p values 5 have been identified. These regions range in size from 33 to 207 kb, with an average size of 125 kb. These regions contain up to 4 genes, including 5 regions with single-gene resolution. Some of the identified genes consist of ion channels or receptors that represent strong candidate genes. We are currently in the process of evaluating the genome-wide significance of the signals using a permutation-based approach. The data is also being analyzed using a proprietary TDT algorithm applied to haplotypes and genome-wide conditional analyses using the risk and protective haplotypes from the strongest signals are being conducted. The confirmed associated genes will then be analyzed in silico for the construction of GeneMaps which will reveal the underlying genetic etiology of the disease. The results of each of these analyses will be presented. In addition to our ADHD study we are also conducting gene discovery programs in more than 20 common diseases.

Mining Affymetrix 10K SNP data from the Autism Genome Project for copy number variation. *S.W. Scherer for the Autism Genome Project* Dept Genetics & Genomic Biol, Hospital for Sick Children, Toronto, ON, Canada.

Autism is a neurodevelopmental disorder characterized by impairments in social interaction, communication, and a preference for repetitive activities. The major susceptibility genes are not known but twin studies suggest autism is mainly a genetic condition of complex etiology. Previously we have observed that chromosomal abnormalities detectable by karyotyping are more prevalent in autistic patients compared to controls. We have proposed that sub-microscopic copy number variation (CNV) may also be associated with autism. In addition to providing evidence for potential disease-associated loci, copy number information can also be used to reduce genetic heterogeneity in linkage and association studies. Further to these points, we have mined Affymetrix Mapping 10K 2.0 SNP data from the Autism Genome Project (AGP) linkage analysis study for copy number variation. Upon removal of failed and noisy experiments, 5823 10K scans from 1329 families were available for copy number analysis using DNA-Chip Analyzer (dChip) software. Samples were analyzed blindly in plate by plate batches. After normalization of scan intensities and model based expression, copy number was inferred using a Hidden Markov Model built into dChip. Despite the relatively low resolution of the Affymetrix Mapping 10K 2.0 SNP Array, we detected imbalances in greater than 10% of individuals for a total of 1317 putative CNVs (median size of 1.2 Mb). The majority (~85%) of variants were gains, likely owing to a greater tolerance in the genome for large gains versus large deletions. There were 384 regions (917 CNVs) exhibiting partial or full genomic overlap between more than one individual. Multiple occurrences within a family or overlap with Mendelian errors were interpreted as additional evidence for a particular CNV to be a real event. Of the 1317 putative CNVs, 87 were familial and 50 overlapped with obvious Mendelian errors from 1168 families used in the final linkage analysis. Families with large CNVs that are not seen in controls (e.g. 15q duplications) can be flagged for removal from linkage analysis to help stratify results and guide positional cloning studies.

Comparison of results for whole genome association studies of schizophrenia using pooled DNA samples and individually genotyped samples. *J. Raelson[1], P. Croteau[1], V. Perepetchai[1], P. Van Eerdewegh[2], R. Allard[1], H. Fournier[1], N. Laplante[1], M. Lapalme[1], Q. Nguyen-Huu[1], N. Paquin[1], B. Paquin[1], J. Segal[2], J-M. Vidal[1], T. Keith[2], A. Belouchi[1]* 1) Genetics Dept, Genizon Biosciences, St Laurent, QC, Canada; 2) Genizon Biosciences, Waltham, MA, USA.

Whole genome association studies for schizophrenia were performed using both pooled DNA and individually genotyped samples from the Quebec French Canadian founder population. The pooling study used 469 patients and 469 controls divided into 9 case and 9 control pools. Each pool contained between 51 and 52 individuals. Each pool was genotyped for approximately 200,000 SNPs by Perlegen Sciences Inc. Differences in mean allele frequencies between case and control pools were determined and exact P values for single marker association and for Fisher combined P values for multi-marker windows were determined using all permutations of pool status. The maximum possible significance was - log P = 4.687 which occured when no permutation gave a larger allele frequency difference than that observed. All markers or multi-marker windows with an exact - log P value greater than 3.5 were individually genotyped and retested using permutation of individual case/control status. Thirty-eight percent of peaks remained at - Log P > 3.5. The entire genome-wide scan was repeated using individual genotyping for 510 patients and 1235 controls. Individuals used in the pooling study form a subset of the individually genotyped sample. Each individual was genotyped for a panel of approximately 370,000 SNPs using the Illumina Infinium II platform. All significantly associated regions are currently being further fine mapped. Here we examine similarities and differences between the pooling and individual genotyped results. These studies are part of our program for gene discovery in multiple complex diseases including Crohn's, psoriasis, asthma, ADHD and Alzheimer's.

Characterization of Two Female Patients with Pelizaeus-Merzbacher disease. *R. Tenconi[1], L. Salviati[1], E. Trevisson[1], A. Friso[1], M. Clementi[1], O. Zuffardi[2], A.M. Laverda[3]* 1) Dept Pediatrics, Clinical Genetics, Univ. of Padova, Italy; 2) Biologia Generale e Genetica Medica, Univ. of Pavia, Italy; 3) Dept Pediatrics, Univ. of Padova, Italy.

Pelizaeus-Merzbacher disease (PMD) is a disorder of the central nervous system characterized by severe hypomyelination and neurological involvement with nystagmus, spasticity, ataxia,and developmental delay.It is an X-linked recessive disorder caused by mutation in the PLP1 gene. Both point mutations, deletions and duplications of the entire PLP1 gene have been described.A PMD-like disease,inherited as an autosomal recessive trait,is caused by mutations in the GJA12 gene. A 5 year-old Pakistani girl was diagnosed with nystagmus since age 3 months.MRI at 1 year of age showed diffuse hypomyelination, confirmed by a second MRI at 4 years.Neurologic examination revealed nystagmus, truncal hypotonia, lower limb spasticity, and dysarthric speech.EMG and nerve conduction studies were normal. Standard karyotype and analysis of the PLP1 gene were normal.Sequencing of the GJA12 gene showed a homozygous 34 bp deletion within the coding region of the gene. Both parents were heterozygous for the mutation. A 4 year-old Italian girl was diagnosed prenatally with a duplication of chromosome Xq.Mild dysmorphic features were noted at birth. She developed nystagmus, and marked psychomotor retardation, with ataxia, hyopotonia and spasticity. MRI at 4 years showed cerebral atrophy and marked hypomyelination. She had signs of peripheral neuropathy at EMG. FISH analysis revealed that the duplicated segment contained the PLP1 gene. High resolution CGH-array mapped the duplication to cromosome Xq22-Xq28. Female carriers of Xq duplications are usually asymptomatic,however a number of patients are reported with a severe clinical picture.It is thought that some of the genes within the duplicated region escape X inactivation in tissues.We believe that our patient is functionally disomic for part of Xq, including the PLP1 gene.In fact she displayed clinical and radiological features of PMD associated with other abnormalities probably related to the effect of other dosage-sensitive genes in the duplicated region.

Binding prediction and probe design for non-continuous probes used for molecular haplotying, genotyping and multiplex-genotyping. *G. Pont-Kingdon[1], R. L. Margraf[1], A. Phansalkar[1], A. Millson[1], K. Damjanovich[1], E. Lyon[1,2]* 1) ARUP Institute for Clinical & Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) Department of Pathology, University of Utah Health Sciences Center, Salt Lake City, Utah.

Many approaches for genotyping mutations use sequence specific probes. Usually the probes are complementary to a continuous stretch of DNA that contains the variant(s). We have previously demonstrated that probes can span template sequences and analyze distant loci, causing the template to bulge. We have used probes that span several loci (loci-spanning probes) that create template bulges of up to 55 nucleotides for molecular haplotyping and for multiplex-genotyping. Selected sequence variation(s) can be masked by using probes with 1-3 base deletions to simplify melting interpretation of other mutations under the probe. Thermodynamic stability (Tm-melting temperature) of a probe hybridized to the template varies with the presence or absence of mismatches and is determined by monitoring fluorescence as a function of temperature. Prediction of probe stability allows efficient design of molecular assays. Many software programs are able to predict the Tms of continuous probes but do not allow for formation of bulges in either the template or the probe. We have been evaluating the VisualOMP folding software for the stability prediction of loci-spanning and masking-deletion probes. Comparison of experimental and predicted Tms was performed with several systems: haplotyping of 3 SNPs of the beta 2 adrenergic receptor gene, and multiplex genotyping of 3 loci of the beta globin gene using loci-spanning probes, and unambiguous genotyping of mutations in the RET protooncogene and the fibroblast growth factor-3 gene in presence of other sequence variations using masking-deletion probes. Data show that predictions can be efficiently used for the design of non-continuous probes for molecular assays.

A QTL influencing blood pressure maps to the region of the essential hypertension susceptibility locus 3 (HYT3) on chromosome 2p in Alaskan Eskimos: the Genetics of Coronary Artery Disease in Alaska Natives (GOCADAN) study. *S. Rutherford[1], S.L. Laston[1], R.B. Devereux[2], H.E. Resnick[3], J.G. Umans[3], S.O.E. Ebbesson[3], R.R. Fabsitz[4], B.V. Howard[3], J.W. MacCluer[1], A.G. Comuzzie[1], S.A. Cole[1]* 1) Southwest Foundation for Biomedical Research, San Antonio, TX; 2) Weill Medical College of Cornell University, New York, NY; 3) MedStar Research Institute, Washington, DC; 4) National Heart, Lung and Blood Institute, Rockville, MD.

Hypertension is a leading cause of death and morbidity in our society because it leads to myocardial infarction, stroke, renal failure and death due to cardiovascular disease (CVD). Despite much effort, limited progress has been made in identifying specific genes responsible for the well-documented heritability of hypertension. We performed a genome-wide scan using markers distributed at approximately 10cM density to identify loci contributing to blood pressure in the Genetics of Coronary Artery Disease in Alaska Natives (GOCADAN) study. Blood pressures were measured in 674 adult Eskimos from families living in coastal villages in the Norton Sound region. In multipoint linkage analysis using 386 microsatellite markers, evidence for linkage was observed with mean arterial blood pressure (LOD = 3.0; P= 0.0001) and less strongly with systolic (LOD = 2.6; P = 0.0003) and diastolic (LOD = 2.4; P = 0.0004) blood pressures in the region of chromosome 2p24.3-p22.1. Peak evidence for linkage occurred at 28.5Mb for mean arterial blood pressure with a 1-LOD score support interval spanning 19 Mb. Our signal on chromosome 2p replicates the findings of 13 previous linkage studies in 9 different populations that also report modest evidence for linkage to blood pressures and/or hypertension in this region. The populations in which this has been observed include Sardinians, Japanese, Chinese, Nigerians, Mexican Americans, African Americans and Caucasians. Because of this, a susceptibility locus for hypertension (hypertension susceptibility locus 3: HYT3) has been mapped to this same region, suggesting that one or more of the 164 genes positioned within our 1-LOD score support interval also influences variation in systolic and diastolic blood pressures in Alaskan Eskimos.

Complete X-linkage map in the domestic cat (*Felis catus*). *A. Schmidt-Küntzel[1,2], E. Eizirik[3], A.A. Schäffer[4], S.S. Hannah[5], B. Neelam[6], V. David[7], S.J. O'Brien[7], M. Menotti-Raymond[7]* 1) Laboratory of Genomic Diversity, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD; 2) Genetics Department, George Washington University, Washington, DC; 3) Centro de Biologia Genomica e Molecular PUCRS, Porto Alegre, RS, Brasil; 4) NLM/NCBI/CBB, National Institutes of Health, Bethesda, MD; 5) Nestlé Purina PetCare Company, Saint Louis, MO; 6) ABCC, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD; 7) Laboratory of Genomic Diversity, NCI-Frederick, Frederick, MD.

A genetic recombination map of the X-chromosome was generated in the domestic cat as a tool for the discovery of X-linked loci. Primers amplifying over thirty microsatellite markers were designed from the sequences of the cat 2x whole genome sequence (WGS) database. The microsatellites were chosen in order to obtain complete coverage of the domestic cat X chromosome. Their location was determined based on sequence alignment with the dog genome assembly. It has been previously demonstrated that the marker order on the X chromosome is completely conserved between the dog and the cat. The marker density is one or more microsatellites every 10 megabases (Mb) and includes the pseudoautosomal region 1 (PAR1). This map provides one of the first integrations of PAR1 in a linkage map for a mammalian species. Recombination frequencies were determined between markers in a multi-generational pedigree of 256 outbred cats. The recombination frequencies show extreme variation across the X chromosome in the studied pedigree, ranging from an absence of recombination events in a region estimated to be greater than 20 Mb, to recombination frequencies of 26% in a region estimated to be less than 3 Mb. Although various factors have been proposed to account for variation in recombination frequency (i.e. GC content, gene density), the phenomena is not well understood. The map is currently being used in the analysis of X-linked phenotypes in the cat. Funded by NCI Contract NO1-CO-12400.

Combined effect of several common SNPs on plasma level of HDL-cholesterol. *S. Sunyaev[1], V. Spirin[1], S. Schmidt[2], J. Cohen[3]* 1) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Max-Planck-Institut für Entwicklungsbiologie Spemannstr. 35 / I D-72076 Tübingen Federal Republic of Germany; 3) University of Texas Southwestern Medical Center, Dallas, TX.

Complex phenotypes are expected to be caused by multiple genetic and environmental factors. Identifying genetic variation underlying complex phenotypes is complicated because many allelic variants may act in concert and because frequent variants may have individually small effects. Plasma level of HDL-Cholesterol is an ideal model for studies of the relationship between genetic and phenotypic variation because genes involved in HDL metabolism are very well characterized biochemically. The impact of multiple rare alleles in genes involved in the reverse cholesterol transport pathway on HDL-C was shown previously. Here, we report the analysis of higher frequency variants in both coding and non-coding regions of genes involved in the HDL metabolism and their effect on plasma level of HDL-C. We used statistical approach based on stepwise regression to relate genetic variation in candidate genes to variation in HDL-C levels in a large panel of individuals. We incorporated a simultaneous analysis of the multiple allelic variants in several candidate genes. First, we used an ANCOVA model which included only race and gender as a seed model. Next, SNPs were subsequently added to the model based on the significance of the increase in the model likelihood as estimated by permutation test. The analysis involved 839 common SNPs from 7 candidate genes from RCT pathway genotyped in the Dallas Heart Study population. The population included 3552 males and females of African-American, European-American and Hispanic origin. An independent population was used for the final validation of the model. The final model consists of four SNPs from three genes. Epistatic interactions were not found to be significant, so our model is purely additive, and can be easily understood in terms of number of HDL-lowering alleles per individual. The model was developed using a half of the dataset and tested using the second half. The model was finally validated on a completely independent panel of ~700 individuals.

No association with risk of prostate cancer for *LDOC1* and *SPANX-C* candidate genes within the HPC-X locus in a US Caucasian study population. *J.R. Smith, B. Elmore, J. Breyer, K. Bradley, K. McReynolds, B. Yaspan*
Departments of Medicine and Cancer Biology, Vanderbilt University Medical Center, Nashville, TN.

We and others have previously undertaken linkage analysis in hereditary prostate cancer (HPC), typically in families with three or more cases, yielding significant loci difficult to confirm across study populations. Described HPC loci include Xq27-28 (HPC-X). Recent haplotype analysis of a Finnish founder population within the HPC-X locus has implicated *LDOC1* and *SPANX-C* as candidate prostate cancer genes, with a 150 kb region from markers D3S2390 to bG82i1.0 containing the critical region. *LDOC1* encodes a protein containing a leucine zipper-like motif and has been shown to be downregulated in some cancers. *SPANX-C* encodes a member of the sperm protein associated with the nucleus family, expressed solely in the testis and cancerous tissue. We sought to investigate *LDOC1* and *SPANX-C* as potential candidate genes in a study population of 597 US Caucasian prostate cancer cases and 513 controls ascertained at Vanderbilt University. We screened for common polymorphisms, and selected and genotyped 19 haplotype tagging SNPs (htSNPs) within and flanking *SPANX-C* and 1 htSNP within *LDOC1*. Analyses showed no evidence of prostate cancer risk in the study population.

Radial ray and skeletal anomalies, but not aneuploidy, are associated with RECQL4 mutations in Rothmund-Thomson syndrome. *L.L. Wang, C.A. Kozinetz, R. Naeem, M. Folsom, R. Krishnamurthy, S.E. Plon* Dept Pediatrics, Baylor Col Medicine, Houston, TX.

Background: Patients with Rothmund-Thomson syndrome (RTS) have poikiloderma, skeletal anomalies, small stature, and osteosarcoma (OS). We previously showed that patients with RECQL4 mutations (Type II) are at higher risk of developing OS compared to those without mutations (Type I). Some patients with RAPADILINO and Baller-Gerold syndromes also have RECQL4 mutations and skeletal defects. These data suggest that cancer predisposition and skeletal defects in RTS may be specific to RECQL4 mutations. Therefore, we assessed the association between RECQL4 mutations and presence of skeletal defects and chromosomal instability in RTS. Methods: 24 RTS subjects enrolled in an IRB-approved study underwent physical examination and skeletal survey at our center. Blood and skin samples were sent for karyotype and FISH analyses of chromosomes 7 and 8. Genomic DNA was analyzed for RECQL4 mutations. Genotype-phenotype analysis was performed by Fishers exact test. An additional 54 subjects enrolled in a second study were evaluated for association between RECQL4 mutation status and radial ray defect or OS by chi-square analysis. Results: Cytogenetic analysis revealed abnormalities in 50 percent of subjects. There was no significant correlation between RECQL4 mutation status and cytogenetic abnormalities ($p=0.16$). Clinical and imaging evaluations revealed bone defects in 67%. Genotype-phenotype analysis demonstrated significant association between presence of RECQL4 mutation and skeletal abnormalities ($p=0.0007$). In addition, of RTS subjects ($n=78$) from both studies, 43 (55%) had RECQL4 mutations, 14 had OS, and 16 had radial ray anomalies. Genotype/phenotype analysis demonstrated significant correlation between RECQL4 mutation status and presence of OS ($p=0.0017$) and radial ray defect ($p<0.0001$). Conclusion: These data suggest a strong correlation between RECQL4 mutations and skeletal defects and OS in RTS. In contrast, RECQL4 mutation status did not correlate with cytogenetic defects. Future studies will focus on characterizing the role of RECQL4 in bone development and transformation.

A Novel Method for Integrating SNP and Microarray Data with an Application to Chronic Fatigue Syndrome. *A. Presson[1], E. Sobel[3], J. Papp[3], A. Lusis[3], S. Horvath[2,3]* 1) Dept Statistics; 2) Dept Biostatistics; 3) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

Because complex diseases involve many small-effect genes, it is easier to identify them when aided by both genetic marker and expression data. We present a novel systems biology approach that integrates SNP, microarray, and trait data to identify complex disease genes. This method relies on a weighted gene co-expression network which is constructed from Pearson correlations in mRNA levels. Using methods from network analysis, we define gene connectivity and gene modules, i.e. groups of highly interconnected genes. We use gene ontology software to characterize the biological pathway(s) composing these modules. Relating the modules to clinical data narrows the disease gene search to the most relevant module. We then correlate selected SNPs with the module to identify the SNPs that have the most influence on our module. We show that the gene co-expression model is robust to data preprocessing, and we identify several associative genes according to the following selection criteria. (1) We attempt to choose genes that belong to a disease related pathway by requiring membership to the module that is related to the clinical trait. (2) To select for genes most likely to play an essential role in the pathway, we require them to have high gene network connectivity. (3) To identify genes that are possibly under genetic control and are therefore potentially causal for the trait, we require that they have significant association with the influential SNPs. (4) Finally, we check that these genes have some direct correlation with the trait. As an illustration, we apply our methods to a real data set collected by the CDC for studying chronic fatigue syndrome (CFS) and report results from simulation studies.

Evidence that PAM is a candidate gene for autism. *S.L. Santangelo[1, 2], S. Haddad[2], T.M. Santos[2], J. Fagerness[2], I. Moilanen[3,5], M.L. Mattila[3,5], K. Jussila[3,5], S. Kuusikko[3,5], H. Ebeling[3,5], J. Ignatius[4,5], L.H. Yamaki[2], P. Moorjani[2], D.L. Pauls[1,2], V. Ramesh[1,2]* 1) Harvard Medical School, Boston, MA, USA; 2) Psychiatric & Neurodevelopmental Genetics Unit, Center for Human Genetic Research, Mass General Hosp, Boston, MA, USA; 3) University of Oulu, Department of Child Psychiatry, Oulu, Finland; 4) University of Oulu, Laboratory of Genetics, Oulu, Finland; 5) University Hospital of Oulu, Oulu, Finland.

The well known co-occurrence of autism spectrum disorders (ASD) and Tuberous Sclerosis Complex (TSC) may yield clues to the etiology of autism. We recently identified *Pam* (a Protein Associated with the Myc oncogene) as an interactor of the tuberin-hamartin protein complex in mammalian CNS. Tuberin and hamartin function together to inhibit mammalian target of rapamycin (mTOR) signaling and cause TSC. The multiple functional domains of *Pam*, its highest expression in the CNS, and the role of *Pam* homologs in synapse development make it a strong functional candidate gene for autism. The gene for *Pam* (a.k.a. MYCBP2) maps to chromosome 13q22, spans ~ 280kb, and contains 84 exons. In a sample of 156 ASD parent-offspring trios, we genotyped 70 htSNPs (MAF > 5%, $r^2 > 0.8$), 58 of which remained after excluding those with errors. Genotype success rate was > 90%. All affecteds were diagnosed via the Autism Diagnostic Interview and/or Autism Diagnostic Observation Schedule.

Using Haploview, (http://www.broad.mit.edu/mpg/haploview/), we identified a nominally significant (p=0.006) 5-SNP haplotype in block 1. We then used the sliding window approach in *whap* (http://pngu.mgh.harvard.edu/~purcell/whap/) to examine all non-overlapping 5-SNP haplotype blocks, which yielded a primary omnibus permutation test p-value of 0.02 for the first block. Individual analyses of the first 5 SNPs returned a global permutation p-value of 0.02 (corrected for multiple testing) and revealed the significance of the fourth SNP (likelihood ratio test = 8.09, primary omnibus permutation p-value = 0.007, on 10,000 permutations). We are currently carrying out a replication study in several hundred families from the AGRE repository.

Genetic mutations on acid -glucosidase gene of Brazilian Pompe patients according to the Pompe Registry. *A.A.P. Santa Rosa[1], S.K.N. Marie[2], J.C. Llerena[3], C.R. Berditchevsky[4], H. Pimentel[5], C.D. Marrone[6]* 1) Ministério da Saúde, Hospital Geral de Bonsucesso, Rio de Janeiro, Brazil; 2) Depto. Neurologia, Universidade de São Paulo, Brazil; 3) Ctro. Genética Médica, IFF/FIOCRUZ, Brazil; 4) Hospital dos Servidores do Estado, Rio de Janeiro, Brazil; 5) APAE Salvador, Brazil; 6) Hospital São Lucas, PUCRS, Brazil.

INTRODUCTION: Pompe disease or glycogen storage disease type II (OMIM#232300) is a progressive, autosomal recessive and often fatal muscle disorder caused by deficiency of lysosomal acid -glucosidase. As a rare and highly heterogeneous condition, knowledge of its natural history requires a broad effort of many physicians having affected patients under their care and willing to share their data with one another, which is why the International Pompe Registry has been developed. Since Brazil is an important contributor (the fifth in number of patients), knowledge of mutations affecting Brazilian Pompe population and increase our understanding about this rare disease.

METHODS: As Pompe Registry is strictly observational and participation is voluntary, physician enrollment and patient authorization are mandatory for entering data. below.

RESULTS: from September, 2004 to March, 2006 The total amount of Pompe patients is 150 and Brazil accounts for 15 (10%), being 7 (47%) infantile-onset and 8 (53%) late-onset. It is after Netherlands with 29 patients (19%), Germany and Italy with 27 each (18%), and USA with 18 (12%). Regarding genetic data however, 12 out of 15 (80%) Brazilian patients have undergone genetic analysis compared to 31 out of 135 (23%) non-Brazilians. The common IVS1-13G>T was found in 6 Brazilian late-onset patients. The other detected mutations are IVS17-18del, 1905C>A, 1655T>C, 1905C>A, 377G>A, and IVS7-2AG>GG, present in infantile-onset ones.

CONCLUSION: Despite accounting for only 10% of world Pompe population, Brazil is playing a pivotal role in writing the natural history of Pompe disease as Brazilian contribution to Pompe Registry is increasing our knowledge of the genetic basis of this condition.

Potential of a Sequential Replication Filter to Detect Disease Associated SNPs. *M.D. Ritchie, A.A. Motsinger, X. Liang, S.M. Dudek, J.L. Haines* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Whole genome association (WGA) using dense SNP sets is rapidly becoming the norm rather than the exception for studies of common, complex disease. The current challenge is not in the generation of these data, but in the analysis and interpretation of the results. The most common analysis of WGA case/control data is a chi-square test of association. One major criticism of such an approach is the large number of expected false positive results. We propose a solution that allows for identifying associated SNPs while minimizing the number of false positive results: the sequential replication filter. The SEquential Replication Filter (SERF) is based on the premise that a result that replicates in one or more independent datasets is more believable than a result that is generated in only one dataset. SERF merges the goals of cross-validation and sequential multiple decision procedures by allowing the number and size of the replication datasets to be determined dynamically from the overall dataset. Each replication begins with a randomly selected subset of the data and samples are added until the analysis reaches significance or the samples are exhausted. This allows the SNPs to be filtered based on the strength of the association signal. Intuitively, SNPs with strong associations will replicate more often than those with weaker associations. To test this approach, we simulated 1000 datasets with 500 cases and 500 controls and ten different single gene models with an odds ratio between 1.6 and 2.5. We applied SERF to chi-square tests of association, although it can be applied to any number of analytical methods. SERF replicates the functional SNP three or more times for all models simulated ($p<0.05$ based on permutation testing). More importantly, SNPs with nominal significance in the overall dataset (false positives) replicate less than two times for all simulations. Thus using a replication criterion can reduce the overall false positive rate below the nominal false positive rate of 5% (for an alpha of 0.05). Thus, SERF reduces the number of SNPs that must be examined in additional association, biological, or functional experiments.

Analysis of 144 of patients with schizophrenia reveals a variant at a highly conserved amino acid in the Disrupted in schizophrenia 1(DISC1) gene. *W. Song, J. Feng, S. Sommer* Dept Molecular Genetics, Beckman Research Inst, Duarte, CA.

Schizophrenia may be the most catastrophic of all psychological disorders. In a large Scottish pedigree, a balanced translocation t(1;11)(q42.1;q14.3) segregates with major mental illness, including schizophrenia and bipolar disorder. The translocation is predicted to result in the loss of the C-terminal region of the protein product of DISC1. In addition, a four nucleotide C-terminal deletion was reported in another Scottish family. To explore the frequency of DISC1 mutation in patients of schizophrenia, a total of 1,081 kilobases in cases and 601 kilobases in controls of genomic sequence of the DISC1 gene were scanned with DOVAM-S (Detection of Virtually All Mutations-SSCP), a method that detects virtually all mutations. Four missense variants were found in cases and controls without a significant excess in cases. An additional two missense variants were found only in cases. One of the missense variants occurs at a highly conserved amino acid, hinting that the sequence change will be of functional significance. This missense variant was found in one patient with schizophrenia, and not in 455 control samples. The presence at most one good candidate for a schizophrenia mutation in 144 patients suggests that DISC1 mutations are uncommon in schizophrenia. A larger case-control analysis may be warranted to better define the frequency of mutation in patients with schizophrenia.

Large Scale Association Study Genotype Data at the National Center for Biotechnology Information. *S.T. Sherry, M. Feolo, L. Phan, M. Mailman, M. Ward, A. Vinokurov, M. Kholodov, D. Hoffman, R. Dunivin, A. Kitts, A. Graef, J. Ostell* National Center for Biotechnologg Information, National Library of Medicine, National Institutes of Health, Bethesda, MD.

NCBIs database of genetic variation, dbSNP, currently contains over 12 million non-redundant sequence variations (single nucleotide polymorphisms, insertion/deletions, and short tandem repeats) and over 1 billion individual genotypes from HapMap and other large-scale genotyping activities. In addition, NIH has established a new genome-wide association study database at NCBI to assemble and redistribute comprehensive data sets from large scale association studies. These resources offer researchers rich datasets for researching problems in population structure, haplotype analysis, genetic epidemiology, and case-control or family based association studies. The database serves the community in dual roles; both as an author-driven archive and curated resource for whole genome annotation. Whole genome association data and metadata are integrated with other existing records such as genotype probe array configurations, genotype-specific intensity data, patterns of linkage disequilibrium, genes, OMIM, and the references curated by OMIM, RefSeq staff, and others. The expanding scale and complexity of dbSNP content will be discussed in terms of new features, tools for use, and mechanisms for Authorized Access.

Quantitative Detection of EGFR 18-bp deletion by proofreading genotyping real time PCR. *C.L. Zhou, L. Xiao, L.D. Liu, Y.F. Yin, L.L. Chen, K. Li* SNP Institute, Nanhua University, Hengyang, Hunan, China.

Except for single nucleotide substitutions, small deletions are leading mutation type. According to our recently recognized pattern of small insertion/deletion, small in-frame deletions are biomedical important in causing gain of function of the mutated gene, such as the cases of EGFR in lung cancer and PDGFR (KIT) in gastrointestinal stromal tumors. Detection of somatic mutation has been a technical challenge in molecular diagnostics. We have developed a proofreading genotyping mediated on/off molecular switch (Trends Biotechnol. 2005, 23:92-6) that is advantageous over conventional mutation detection methods using Taq DNA polymerase. This study used the 18 nucleotide in-frame deletion of EGFR gene as a target in method development. With a 3 phosphorothioated mutation specific primer of tcccgtcgctatcaaggaatcg and its downstream pairing primer, proofreading DNA polymerase Pfu only yielded specific product in correct size from mutated template at the annealing temperature of 50 to 60 C but no amplified product observed with wild type DNA template. A serial dilutions of mutated EGFR template in plasmid showed that the sensitivity of detecting the specific EGFR mutant is nearly to single molecule. As controls, false positives from wild template were obtained when mutation specific primer was not phosphorothioate modified or amplified by Taq polymerase. Interestingly, the false positive products by Taq polymerase was annealing temperature dependent: lower temperature amplified relatively longer products and higher annealing temperature yielded relatively shorter products. This 18 nucleotide specific mutation assay was further used in real time PCR platform to quantitatively determine the EGFR mutant. The combination of proofreading genotyping mediated on/off molecular switch and real time PCR technology has immediate application in molecular diagnostics with its reliability, sensitivity, and time and financial cost-effective. Similar assay targeting the 15 nucleotide in-frame deletion of EGFR is in testing. *This project is supported by Hunan Education Ministry #04A048 and Chinese Ministry of Education 2005, No3 #205106.

Statistical Considerations in the Analyses of Pharmacogenomic Studies. *S.L. Senneke[1], C.M. Bromley[1], D. Goldstaub[2], S. Close Kirkwood[3]* 1) BioStat Solutions, Inc., Mount Airy, MD 21771; 2) TEVA Pharmaceutical Industries Ltd., Kiryat Nordau, Netanya, Israel; 3) Eli Lilly and Company, Indianapolis, Indiana 46285.

Pharmacogenomic studies are different from traditional genetic studies in that the primary phenotype of interest is drug response, compounded by a disease background. Traditional approaches used to analyze genetic effects are not always directly applicable for pharmacogenomic studies. Multiple factors influence the statistical and clinical interpretation of pharmacogenomic studies. Careful specification of the variables both influenced by the genetic effects and confounding the interpretation is critical. One of the most important is the definition of response. How response is defined is dependent on the disease and drug under investigation In psychiatric disease the definition of response is often determined by a measurement instrument or scale that has not been linked to the underlying biological mechanism. Further complicating this is the fact that the definition of response varies with the scale. The characteristics of these measures such as the distribution of the data should inform the statistical methodology chosen. For example, typical statistical methods assume the data be normally distributed; however, if data are non-normal, methods such as repeated measures and the standard ANOVA may not apply. The increasingly widespread use of large marker data sets, such as genome wide SNP association studies, makes statistical methodology for multiple comparison adjustments, missing data handling including imputation, LD structure and haplotypes and validation (within study, across studies), critical to the success of the projects. Further confounding this is the quality of the genotype data, LD structure and imputation of missing observations. The methodology, results and interpretation need to be clearly conveyed to statisticians and non-statisticians alike. In analyses of pharmacogenomic studies, although several statistical methodologies may be applied, it is important to choose the method that makes the most sense with respect to the drug being investigated and relates to the hypothesis in question.

Polymorphisms in the SEC8L1 (EXOC4) gene encoding a component of the exocyst complex influence BMI, leptin, and insulin levels in the NHLBI Family Heart Study. *J.B. Wilk[1], J.M. Laramie[1], S. Williamson[1], C. Leiendecker-Foster[2], J.H. Eckfeldt[2], I.B. Borecki[3], M.A. Province[3], R.H. Myers[1]* 1) Department of Neurology, Boston University School of Medicine, Boston, MA; 2) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 3) Division of Statistical Genomics, Washington University School of Medicine, St. Louis, MO.

Linkage to body mass index (BMI) was identified on chromosome 7q in the NHLBI Family Heart Study. Fine-mapping of the region with SNPs was performed in a subset of 730 people from 171 families exhibiting linkage. SEC8L1 is an 800kb gene residing within 660kb of the microsatellite with the peak evidence for linkage. The SEC8L1 protein translocates to the plasma membrane as a component of the exocyst complex (Exo70) where it is thought to influence the docking of GLUT4, an insulin-responsive transporter protein in adipocytes. BMI, glucose, insulin and plasma leptin measurements were studied. All traits were defined separately by sex adjusting for age and study center locations in MA, MN, NC, and UT. Thirty SNPs in the SEC8L1 gene were evaluated using family based association tests (FBAT) and generalized estimating equations (GEE). The best FBAT result was found for insulin (p=0.005), whereas GEE results were strongest for glucose (p=0.004) and BMI traits (p=0.009). Haplotype studies in FBAT identified a 3-SNP haplotype predicting BMI (p=0.002) and 5 and 7-SNP haplotypes predicting insulin levels (p=0.001). In a subset of 237 obese/overweight participants, a dichotomous outcome variable was defined based on the gender specific median of plasma leptin measurements (12.9 ng/mL for men; 36.7 ng/mL for women). This cutoff on leptin levels splits the sample into two groups with a mean BMI difference of 5 units (mean BMI 37 vs. 32 in men and 40 vs. 35 in women). Insulin levels were also different between the two groups. SNPs in SEC8L1 produced odds ratios of 3.2 (p-value=0.004) for a 16% frequent recessive genotype predicting high leptin/high BMI in the obese/overweight subset. These results suggest that polymorphisms in SEC8L1 may influence risk for obesity.

Case-control association testing with related individuals: A more powerful quasi-likelihood score test. *T. Thornton[1], MS. McPeek[2]* 1) Department of Statistics, University of California, Berkeley, Berkeley, CA; 2) Department of Statistics, University of Chicago, Chicago, IL.

Case-control studies have been extremely valuable in evaluating associations between candidate genes and complex diseases. Traditional case-control studies use unrelated subjects and compare allele or genotype frequencies of the cases and the controls at genetic markers. When affected related individuals are used in association studies, the power to detect an association is increased since affecteds with affected relatives have a higher expected frequency of the alleles that increase susceptibility for a genetic trait than do affected individuals that do not have affected relatives. When related individuals are used in a study, the correlations among the relatives must be taken into account to ensure validity of the test, and consideration of these correlations can also improve power. To test for allelic association with a binary trait, we propose a new test, the MQLS test, that is an extension of the quasi-likelihood score test of Bourgain et al. (2003) and which takes advantage of the fact that affected individuals that have affected relatives are more likely to have the predisposing variants than individuals that do not have affected relatives. One of the motivations for using the MQLS test is that for any arbitrary set of outbred individuals, the MQLS statistic has maximal non-centrality parameter in a general class of linear statistics, for all 2 allele disease models, as the effect size tends to zero. Simulations are performed to compare the type I error and power of the new test with those of competitors. We apply the allelic methods to analyze data on an alcoholism related phenotype in a sample of moderate-size outbred Caucasian pedigrees from GAW 14 data provided by the Collaborative Study on the Genetics of Alcoholism (U10AA008401). This research was supported by National Institutes of Health grant HG001645.

DISCOVERY OF HIGHER-ORDER FUNCTIONAL DOMAINS WITHIN THE HUMAN GENOME. *R. Thurman[1], W.S. Noble[2], J.A. Stamatoyannopoulos[2]* 1) Medical Genetics, University of Washington, Seattle, WA; 2) Genome Sciences, University of Washington, Seattle, WA.

It has long been thought that the human and other large genomes are organized into higher-order (i.e., greater than gene-sized) functional domains. Under the NHGRI ENCODE Project, a number of functional experimental data types including both activating and repressive histone modifications, RNA output, and DNA replication timing have been measured in a nearly continuous fashion across 1% of the human genome. We hypothesized that these data, viewed collectively, could reveal coherent higher-order features that may in turn illuminate the underlying functional architecture of the genome. To address this, we developed a novel approach combining wavelet analysis and hidden Markov models for unbiased discovery of 'domain-level' behavior in high-resolution functional genomic data. We find that higher-order patterns in histone modifications, transcription, and DNA replication timing are generally concordant and can be used to define discrete active and inactive functional domains ranging from 15-500kb in size. Active and inactive domains differ markedly from one another with respect to annotated genomic features including gene content, CpG islands, the spectrum of repetitive elements, the frequency of polymorphisms, and the density of known human disease-causing mutations. One striking feature of this domain map is the degree to which different genomic territories highlighted by integrating multiple functional data types reflects an organization that cannot be readily predicted from the distribution of non-coding evolutionary conservation. Our results collectively provide powerful new insights into the functional organization of the human genome.

Beyond the TDT: Application of new analytical methods to high density SNP data reveals association, inherited deletions, and regions of IBD on Chromosome 17 in autistic trios. *J. Stone[1], B. Merriman[1], Z. Chen[1], R.M. Cantor-Chiu[1], D.H. Geschwind[1,2], S.F. Nelson[1]* 1) Dept Human Gen, Gonda, #5554, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Neurology, Univ California, Los Angeles, Los Angeles, CA.

Recently, male-specific linkage to chromosome 17 has been established (Stone et al., 2004; Cantor et al., 2005) in a large sample of ASPs with autism. To follow-up on these linkage findings, 2053 SNPs were genotyped in 219 trios to test for association of autism to these common variants within the region. Standard application of the TDT to the families contributing to the male-specific linkage peak originally highlighted 43 genes (112 SNPs, P0.05) for further study. To go beyond this, and leverage the strong sex-specific linkage, we established case and control groups consisting of affected male children from the most linked families (male-only) and parents from the least linked (female containing) families, respectively. Requiring further significance in this subdivision highlighted 11 genes, most notably MYO1D and ACCN1. These data were also analyzed for inherited deletions. Three different deletions were discovered and confirmed in three different families. Consequently, genes within these regions become prime candidate genes for contributing to autism susceptibility, including KCNJ12, MYO1D and four function-unknown genes. Affected children of unknown relationship to each other were further scanned for extended regions inherited IBD from a hypothetical unknown ancestor from whom they have inherited a susceptibility allele. Ancestral IBD sharing of long contiguous stretches of 14cM and 17cM were identified overlapping the KCNJ12 gene. Another region of apparent IBD was identified spanning 11cM, and smaller subcomponents of this very long inferred haplotype were enriched in autistic individuals relative to a control population, further highlighting the MYO1D locus. These additional observations provide supporting evidence that MYO1D and KCNJ12 may have both common and rare autism susceptibility alleles.

Premature Graying of hair: study of two large families with autosomal dominant inheritance. *P.Y. Hasmukhlal*
Nuclear Medicine Department, Dubai Hospital, Dubai, United Arab Emirates.

One of the most recognizable early signs of aging is gradual development of gray hair. It is caused by the gradual decrease of pigmentation that occurs when melanin ceases to be produced in the hair root, and new hairs grow in without pigment. The change naturally occurs as people age, usually turning hair from its natural color to gray, then to white. Usually, majority of persons have some gray hair through their 40 years of age. Premature Graying of hair (MIM 139100) or whiteness of the hair is called as a condition that if grey hairs appear as early as the teens and twenties for some, even in childhood. There are families with autosomal dominant (J. Hered. 20: 31-32, 1929) premature whitening of hair and association between known disorders, such as Book syndrome, Waardenburg syndrome; Lison syndrome and pernicious anemia have been reported. Conditions such as tobacco smoking may cause premature graying (BMJ ; 313:1616, 1996). We have studied two large autosomal dominant families of Asian origin with premature graying of hair. The pedigrees consist of 115 individuals with 20 affected males and 25 affected females. The age of onset ranged from 8-14 years and the degree of graying was variable ranged from 20-50% and in some it was over 50% at 25 years of their age? Male to male transmission was seen in both the families and skipping of a generation was observed in one pedigree. Eyebrows of all affected were normal and no other anomalies were present in these pedigrees. The present study indicates a monogenic mode of inheritance with complete expression. Systematic genome-wide linkage analyses, using larger families that show autosomal dominant may reveal chromosomal loci for the phenotype. E-mail: yogen4@yahoo.com.

Respecting patient confidentiality and professional disclosure while avoiding potential patient harm. *J.S. Wilbur, J.L. Kent, J.S. Gass, E.K. Brown, R.D. Legare* Cancer Risk Assessment and Prevention Program, Program in Womens Oncology, Women & Infants Hospital, Brown Medical School, Providence, RI.

One benefit of genetic testing in BRCA gene positive families is the ability to greatly reduce cancer risk in non-carriers. We present a case of a woman who requested that her BRCA test result, if negative, not be disclosed to her breast surgeon in apprehension that she would not be able to continue annual breast MRI screening. This case presents a challenging ethical and medical dilemma in regards to the attempt to avoid potential patient harm while remaining cognizant of professional disclosure and patient confidentiality. The proband is a 48 year old woman who was referred to our high risk clinic for predictive BRCA gene testing as her sister was found positive for the BRCA2 deleterious gene mutation, 4075delGT. The patient was apprehensive about disclosing a negative BRCA test to her surgeon as she would no longer be considered a candidate for breast MRI screening and her insurance could deny coverage for this procedure. According to the ASHG consensus statement, in order to override patient confidentiality, the harm from failing to disclose should outweigh the harm from disclosure, thus, one could argue that the patient may actually suffer more from disclosure if denied MRI because a cancer may be detected at a later stage, or the patient may suffer from heightened anxiety. However, because the surgeon felt bound to adhere to contemporary guidelines for breast cancer screening, she would not recommend MRI if a negative BRCA2 test resulted. Therefore, the patient chose not to proceed with BRCA testing through our institution. This case brings to light the issues of patient confidentiality and professional disclosure, as well as the need to assess the effectiveness of screening breast MRI for average risk women. However, only with technologic advancement will breast MRI costs decrease and therefore become a more realistic option for screening but until that time, and with the increasing uptake of cancer genetic testing, healthcare practitioners should be aware of the heightened potential for ethically and medically challenging cases within a high risk clinic setting.

Discrepancy of karyotype and phenotype in monochorionic twins. *J. Pappas[1], K. Daley[1], A. Roman[2]* 1) Human Gnetics Program, New York Univ, Sch Medicine, New York, NY; 2) Department of Obstetrics nad Gynecology, New York Univ, Sch Medicine, New York, NY.

We present two sets of unrelated monochorionic diamniotic female twins with phenotypic and karyotypic discrepancy. The first set of twins were product of in vitro fertilization. Two embryos were transferred and implanted and one spontaneously aborted. This suggested that the twins were monozygotic. Amniocentesis was performed and twin A had normal chromosomes 46,XX. Twin B was not sampled because of the high probability of monozygosity. Midtrimester prenatal sonography did not reveal fetal abnormalities. At 15 months twin B had generalized hypotonia, strabismus, downslanting eyes, elongated face, narrow high arched palate, submucosal cleft, posteriorly rotated ears with a history of bilateral myringotomies, prominent grooves of the philtrum, thick eyebrows and pectus excavatum. Twin A was developmentally normal and was not dysmorphic. Peripheral blood chromosome studies from twin B revealed mosaicism of a small ring chromosome 47,XX,+r[8]/46,XX[12]. Spectral karyotyping (SKY) and centromeric FISH probe studies revealed that the supernumerary ring chromosome originated from chromosome 1. Parental karyotypes were normal. More than 100 cells from twin A were reviewed utilizing the amniotic fluid cytogenetic slides and there was no evidence of mosaicism. The second set of twins presented prenatally with discrepant karyotypes in CVS and amniocentesis. The karyotype for twin B was 47,XX+13 with consistent midtrimester ultrasonographic abnormalities. Twin A had 46,XX chromosomes and normal midtrimester ultrasonographic phenotype. Zygosity studies utilizing DNA markers revealed that the twins were monozygotic. The pregnancy was terminated and pathology confirmed the prenatal findings. A few cases of monochorionic twins with discrepant karyotypes were reported in the medical literature (P. F. Colm et al, 2004, A. Nieuwint et al, 1999). Our cases demonstrate that monochorionic/monozygotic twins can have karyotypic and phenotypic discrepancies even when prenatal sonography is unremarkable. This report supports a recommendation for sampling both monochorionic twins for prenatal testing.

Two new novel point mutations localized upstream and downstream of the HMG box region of the SRY gene in three Indian 46,XY females with sex reversal and gonadal tumour formation. *M. Shahid, V.S. Dhillion, M. Raish, A. Ahmad, N.J. Khan, Rahimunnisha, S. A. Husain* Department of Biosciences, Jamia Millia Islamia,, New Delhi, New Delhi, India.

The Y chromosome-specific gene SRY is one of the key genes involved in human sex determination. The SRY gene encodes a testis-specific transcription factor that plays a key role in sexual differentiation and development in males and is located on the distal region of the short arm of the Y chromosome. Mutations in SRY gene result in XY sex reversal and pure gonadal dysgenesis. SRY expression initiates a network of gene activity that transforms the undifferentiated gonad, genital ridge into testis. Mutations in the SRY gene have been considered to account for only 10-15% of 46,XY gonadal dysgenesis cases, whereas the majority of the remaining cases may have mutation(s) in the SRY regulatory elements or other genes involved in the sex differentiation pathway. Patients both with gonadal dysgenesis and Y-chromosome presence are at high risk of developing gonadoblastoma. Using PCR, single strand conformational polymorphism (SSCP) and automated DNA sequencing, we analysed the mutations in the SRY gene in three 46,XY sex reversal patients. Two patients demonstrated nucleotide substitution (A G) within the open reading frame just outside and upstream of the conserved DNA-binding motif called the high-mobility group (HMG) box, replacing glutamine at codon 57 with arginine. Altered SSCP patterns were also observed in these patients. Histological examination of gonads in patient 1 revealed the formation of gonadoblastoma. Patient 3 demonstrated A T substitution which replaces serine at codon 143 with cysteine, just outside but downstream of the HMG box. Results suggest the involvement of SRY gene in sex reversal which further supports the relationship between SRY alterations, gonadal dysgenesis and/or primary infertility.

The rare nonsynonymous SCN5A-S1103Y variant in Caucasians is due to recent African Admixture as revealed by 100k SNP genotyping. *A. Pfeufer[1,2], M. Akyol[1,2], M. Sinner[1,2], S. Jalilzadeh[1,2], A. Rauch[3], A. Reis[3], T. Illig[4], H.E. Wichmann[4], M. Hinterseer[5], S. Kääb[5], T. Meitinger[1,2]* 1) Institute of Human Genetics, TU Munich and GSF Research Center, Munich, Bavaria; 2) Institute of Human Genetics, GSF National Research Center, D-85764 Neuherberg; 3) Institute of Human Genetics, University of Erlangen, D-91054 Erlangen; 4) Institute of Epidemiology, GSF National Research Center, D-85764 Neuherberg; 5) Department of Medicine I, Klinikum Grosshadern, University of Munich, D-81366 Munich.

The SCN5A-S1103Y variant is an established and confirmed risk factor conferring an odds ratio up to 8.5 for cardiac ventricular arrhythmias and sudden cardiac death (Splawski et al, Science, 2002, Burke et al., Circulation, 2005, Plant et al., J. Clin. Invest. 2006). In Africans it is a common nonsynonymous SNP (MAF=8%), but it is rarely observed in Caucasians (Chen et al, J. Med. Genet. 2002). In a Bavarian family appearing of entirely Caucasian descent and affected with long QT Syndrome we have detected this variant in heterozygote state as the only causal nonsynonymous variation upon diagnostic ion channel resequencing. To resolve the question, whether in the family the variant was (a) of ancient African descent, (b) due to recent African admixture or (c) a de novo mutation, we analyzed the genetic segment it resided on. Dense SNP genotyping in admixed individuals allows to infer the ethnicity of chromosomal regions if allele frequencies are known in the original populations. Ethnicity inference for any given locus can be carried out by applying the product rule to a sliding window of neighboring SNPs or via modeling ancestry by hidden Markov Chain Monte Carlo Methods (Tang et al. Am. J. Hum. Genet, 2006). By 100k SNP genotyping of the Bavarian family, we demonstate that the S1103 variant is due to recent African admixture (b) and could rule out possibilities (a) and (c). This application demonstrates that inferring ethnicity of chromosomal regions by high density SNP genotyping is a powerful approach with prospects also to admixture mapping of disease loci and population stratification correction of genomewide association mapping of complex disease loci.

Japanese public attitudes toward blood donation for genomic research. *K. Muto[1, 2], I. Ishiyama[3], A. Nagai[3], A. Tamakoshi[4], M. Kokado[5], K. Mimura[6], Z. Yamagata[3]* 1) Department of Health Sciences, Shinshu University, Japan; 2) Institute of Medical Science, University of Tokyo, Japan; 3) Department of Health Sciences, Interdisciplinary Graduate School of Medicine and Enginering, University of Yamanashi, Japan; 4) Department of Clinical Research Management, National Hospital for Geriatric Medicine, Japan; 5) Center for Life Science and Society, Japan; 6) School of Interdisciplinary Gender Studies, Ochanomizu University, Japan.

Objectives: While large-scale and long-term human genomic studies were launched in Japan, its not clear public attitudes toward blood donations for research. The purpose of our study is to examine the validity of the deficit model (Ziman 1991) on genome sciences in Japan on the ground that the willingness of blood donation for genome research would be one of the indicators of public understanding of genome science. Participants and methods: We used a dataset compiled from a postal questionnaire survey in 2005, which was mailed to 4,000 Japanese adults who were sampled randomly from the whole population. Results: A total of 2,171 completed the questionnaire (991 men and 1,180 women; 18-60 years old). The response rate was 54.3%. 69.6% of all respondents agree to promote healthcare research. On the other hand, those who expressed willingness blood donations are much fewer (39.1%). Educational backgrounds on genetics slightly affect their willingness to donate. By estimating the multi-nominal logit model, it's indicated if all respondents had obtained the full scientific literacy score, the want to donate group would increase up to 78%(from current 39.1%). This group would require scientists to disclose analyzed data of themselves (85%) and safe environment for donation (72.4%) in return for donation. Discussions: These data shows that the deficit model has still some power to explain in case of Japanese citizens. However, genomic research doesn't always return direct benefit to each participant though some may donate without any scientific interests. We need further discussions and research to analyze what determines the attitudes toward blood donation.

Introduction and overview: Local versus federal regulations regarding genetic studies in humans. *M.L. Marazita*
Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA.

Session Descriptions:
For many human genetics researchers, the current regulatory climate is a source of increasing concern, depending on the specific policies of their local Institutional Review Boards (IRB). In this session, speakers and panelists will address several aspects of this complex topic, such as: Is genetic research inherently different from other research on human beings? What about genetic research on children? How does federal policy become implemented at the local IRB, with specific reference to genetic risk and benefit estimates? Are there consent issues specific to large-scale genomic studies with open-access databases? Do regulatory bodies have a more constricted view of risk than research participants, and is this appropriate? A final question and answer session will explore avenues by which human geneticists can work more effectively with their regulatory counterparts to enable genetic research on human subjects, while protecting them from exploitation or unnecessary risk.

Consent issues for large-scale studies where data access is increasingly open. *F.S. Collins* NHGRI/NIH, Bethesda, MD.

Session Descriptions:

Pharmacogenetics: Current progress and future prospects. *D.B. Goldstein* Institute for Genome Sciences and Policy, Duke University, Durham, NC.

Session Descriptions:
Pharmacogenetics, the study of the genetic basis for differences in drug response, promises the tailoring of therapeutic regimes to specific patients genomic profiles, an advance widely anticipated to revolutionize both drug evaluation and clinical practice. While the advantages of using genetic information to increase drug efficiency and safety are clear, many important questions remain about the ways in which genetic variation relevant to drug response will be characterized, how such characterizations will direct the stratification of clinical trial participants in an effort to expedite drug development, and whether these choices will promote or impede the broad availability of desired therapeutic interventions. This session will examine the complex nexus of basic science, translational advance, and clinical application relevant to these challenging questions with the aim of identifying the specific social and ethical implications of current practice in this rapidly developing area.

The role of pharmacogenomics in drug development: Economic and regulatory considerations. *A.M. Issa* Univ of Houston and The Methodist Hospital, Houston, TX.

Session Descriptions:

Going beyond nature versus nurture: Advances and challenges in studying genetic and environmental factors together in association studies. *M.J. Khoury* Centers for Disease Control and Prevention, Atlanta, GA.

Session Descriptions:
Many birth defects appear to be complex, resulting from a combination of risk factors. Even for cases where defects are largely determined by exposures, the genetic background of the infant, mother or both may confer increased susceptibility to environmental effects. Therefore, examining exposures without considering genetic background might obscure the causative role of an exposure. Likewise, studying genetic factors alone might not show associations. Thus, genetic and environmental factors must be considered simultaneously. This session will present techniques, advances and challenges in the identification of gene-environment interactions contributing to birth defects. The session will review the study of gene-environment interactions, discussing accomplishments and limitations using traditional epidemiological study designs and how future studies and alternative designs may address these issues. Specific examples of birth defects studies combining environmental and genetic factors will be presented, as well as methods for identifying novel gene-environment interactions involved in birth defects using animal models.

Maternal smoking, genetic variation of Glutathione S-Transferases, and risk for orofacial clefts. *E.J. Lammer*
Children's Hospital Research Institute, Oakland, CA.

Session Descriptions:

Population genetics in common diseases. *K. Stefansson* Decode Genetics, Reykjavik, Iceland.

Session Descriptions:
Special populations had discrete founders whose descendants experienced genetic isolation as the result of geography, religion, or cultural practice. In turn, these populations accumulated prevalent founder mutations for Mendelian conditions with extended intervals of linkage disequilibrium (LD). The LD has been used for identifying founder mutations for diseases and coalescence times for these mutations. Once identified, these founder mutations have been used for studies of prevalence and penetrance and, in turn, for the creation of genetic programs for prevention or early identification of disease. Among the special populations that have been studied are Icelandics, Sardinians, Amish and Mennonites, and Jews. Over the last 5 to 10 years, several common diseases have been extensively studied in these relatively isolated populations. This approach has come of age and has yielded several genes for common diseases such as schizophrenia, stroke, hyperlipidemia, nephrolithiasis, and myocardial infarction.

The Sardinian genetic park of Ogliastra: An ideal isolated population for complex traits. *M. Pirastu* National Research Council of Italy and Shardna Lifesciences, Località Piscinamanna, 09010 Pula (CA), Italy.

Session Descriptions:
Special populations had discrete founders whose descendants experienced genetic isolation as the result of geography, religion, or cultural practice. Among the special populations that have been studied are Icelandics, Sardinians, Amish and Mennonites, and Jews. Over the last 5 to 10 years, several common diseases have been extensively studied in these relatively isolated populations. This approach has come of age and has yielded several genes for common diseases such as schizophrenia, stroke, hyperlipidemia, nephrolithiasis, and myocardial infarction.

The 4000-year genetic history of Jewish populations. *H. Ostrer* Human Genetics Program, NYU School of Medicine, New York, NY.

Session Descriptions:
Special populations had discrete founders whose descendants experienced genetic isolation as the result of geography, religion, or cultural practice. In turn, these populations accumulated prevalent founder mutations for Mendelian conditions with extended intervals of linkage disequilibrium (LD). The LD has been used for identifying founder mutations for diseases and coalescence times for these mutations. Once identified, these founder mutations have been used for studies of prevalence and penetrance and, in turn, for the creation of genetic programs for prevention or early identification of disease. Among the special populations that have been studied are Icelandics, Sardinians, Amish and Mennonites, and Jews. Over the last 5 to 10 years, several common diseases have been extensively studied in these relatively isolated populations. This approach has come of age and has yielded several genes for common diseases such as schizophrenia, stroke, hyperlipidemia, nephrolithiasis, and myocardial infarction.

The ENCODE project: functional annotation of one percent of the human genome. *A. Reymond* Center for Integrative Genomics, Lausanne, Switzerland.

Session Descriptions:
One of the biggest problems in the post-genome era is the interpretation of the nature of variation, nucleotide or large scale, in the human genome. Although we have some idea of how to interpret variation within coding sequences, the majority of functional DNA is non-coding and variation within noncoding sequences is difficult to interpret. In addition, many aspects of coding variation are still unknown (e.g., positive selection). In this session the speakers will present their research efforts in interpreting the function and phenotypic impact of such variation in both coding and noncoding regions and how this relates to the identification of disease variants. These efforts will have a high impact on the understanding of phenotype-genotype associations and the pathophysiology of genetic disorders.

Functional and regulatory variation in the ENCODE regions. *E.T. Dermitzakis* Population & Comparative Genomics, Wellcome Trust Genome Campus, Hinxton Cambridge, United Kingdom.

Session Descriptions:
One of the biggest problems in the post-genome era is the interpretation of the nature of variation, nucleotide or large scale, in the human genome. Although we have some idea of how to interpret variation within coding sequences, the majority of functional DNA is non-coding and variation within noncoding sequences is difficult to interpret. In addition, many aspects of coding variation are still unknown (e.g., positive selection). In this session the speakers will present their research efforts in interpreting the function and phenotypic impact of such variation in both coding and noncoding regions and how this relates to the identification of disease variants. These efforts will have a high impact on the understanding of phenotype-genotype associations and the pathophysiology of genetic disorders.

Inference of functional variation in coding and noncoding DNA. *A.G. Clark* Dept. of Molecular Biology & Genetics, Cornell University, Ithaca, NY.

Session Descriptions:
One of the biggest problems in the post-genome era is the interpretation of the nature of variation, nucleotide or large scale, in the human genome. Although we have some idea of how to interpret variation within coding sequences, the majority of functional DNA is non-coding and variation within noncoding sequences is difficult to interpret. In addition, many aspects of coding variation are still unknown (e.g., positive selection). In this session the speakers will present their research efforts in interpreting the function and phenotypic impact of such variation in both coding and noncoding regions and how this relates to the identification of disease variants. These efforts will have a high impact on the understanding of phenotype-genotype associations and the pathophysiology of genetic disorders.

Structural variation and disease in the human genome. *E. Eichler* Genome Sci, HSB K336B, University of Washington, Seattle, WA.

Session Descriptions:
One of the biggest problems in the post-genome era is the interpretation of the nature of variation, nucleotide or large scale, in the human genome. Although we have some idea of how to interpret variation within coding sequences, the majority of functional DNA is non-coding and variation within noncoding sequences is difficult to interpret. In this session the speakers will present their research efforts in interpreting the function and phenotypic impact of such variation in both coding and noncoding regions and how this relates to the identification of disease variants. These efforts will have a high impact on the understanding of phenotype-genotype associations and the pathophysiology of genetic disorders.

What can genetics say (or not say) about complex traits? *D. Goldstein* Duke University, 2006 Durham, NC.

Session Descriptions:
Behavioral genetics raises a number of issues due to the complexity of human behavior. Understanding what genetic tools can say about such complex and socially-charged traits as intelligence, sexuality, or aggression is an important consideration. Researchers may see the scientific value in and validity of such studies. How these findings are interpreted and used by the public and societal institutions, however, are other important considerations. This session will identify some of the most significant ethical, legal, social, and policy issues raised by anticipated research on behavioral genetics. The role of geneticists in incorporating consideration of these issues into the conduct of research will be discussed. What is the responsibility of researchers who study the genetics of behavior to deal with the potential positive and negative consequences of their work? How, if at all, should ethical, legal, social, and policy considerations affect study design, data analysis, and reporting results?

How should ethical, legal, and social considerations affect study design, analysis, and reporting? *L. Baker*
University of Southern California, Los Angeles, CA.

Session Descriptions:
Behavioral genetics raises a number of issues due to the complexity of human behavior. Understanding what genetic tools can say about such complex and socially-charged traits as intelligence, sexuality, or aggression is an important consideration. Researchers may see the scientific value in and validity of such studies. How, if at all, should ethical, legal, social, and policy considerations affect study design, data analysis, and reporting results?

Direct-to-consumer DNA Testing: The way to the future. *H. Coleman* Chairman and CEO, Genelex Corporation, Seattle, Washington.

Session Descriptions:
Some genetic testing companies are beginning to sell tests directly to consumers, eliminating the need to go to a doctors office. Test results usually are made available online, in the privacy of ones own home. Will at home genetic tests provide useful genetic information in a private, nonthreatening way? Or will these tests pose real risks to health and take advantage of people desperately seeking answers? Panelists will share their diverse perspectives and explore the commercial, legal, medical and ethical issues raised by direct-to-consumer (DTC) marketing of genetic tests. In addition, the panel and audience will consider what position, if any, the ASHG should take regarding DTC genetic testing.

At-home fetal gender DNA testing: Caveat emptor. *D. Bianchi* Professor of Pediatrics, Obstetrics, and Gynecology; Tufts New England Medical Center, Boston, MA.

Session Descriptions:
Some genetic testing companies are beginning to sell tests directly to consumers, eliminating the need to go to a doctors office. Test results usually are made available online, in the privacy of ones own home. Will at home genetic tests provide useful genetic information in a private, nonthreatening way? Or will these tests pose real risks to health and take advantage of people desperately seeking answers? Panelists will share their diverse perspectives and explore the commercial, legal, medical and ethical issues raised by direct-to-consumer (DTC) marketing of genetic tests. In addition, the panel and audience will consider what position, if any, the ASHG should take regarding DTC genetic testing.

Regulatory landscape for DTC genetic testing. *G. Javitt* Genetics and Public Policy Center, Johns Hopkins University, Washington, DC.

Session Descriptions:
Some genetic testing companies are beginning to sell tests directly to consumers, eliminating the need to go to a doctors office. Test results usually are made available online, in the privacy of ones own home. Will at home genetic tests provide useful genetic information in a private, nonthreatening way? Or will these tests pose real risks to health and take advantage of people desperately seeking answers? In addition, the panel and audience will consider what position, if any, the ASHG should take regarding DTC genetic testing.

Evidence-based medicine in rare genetic conditions. *R.D. Steiner* Pediatrics, OHSU, Portland, OR.

Session Descriptions:
The practice of evidence-based medicine continues to be a challenge in the field of medical genetics. In this session, the speakers will introduce the topic of evidence-based medicine in general, and will also discuss whether or not it currently applies to both rare, pediatric disorders as well as common, chronic diseases of adulthood that have a genetic component. The evaluation of genetic tests and their entry into the clinical arena will also be discussed. Approaches for the systematic collection of evidence to guide the treatment and management of genetic conditions will be presented, including the development of national and international collaborative genetics research networks for testing and evaluating new genetic tests, treatments, and management recommendations for genetic diseases.

Evidence-based medicine in common disease genetics. *M.T. Scheuner* Rand Corporation, Health Unit, Santa Monica, CA.

Session Descriptions:
The practice of evidence-based medicine continues to be a challenge in the field of medical genetics. In this session, the speakers will introduce the topic of evidence-based medicine in general, and will also discuss whether or not it currently applies to both rare, pediatric disorders as well as common, chronic diseases of adulthood that have a genetic component. The evaluation of genetic tests and their entry into the clinical arena will also be discussed. Approaches for the systematic collection of evidence to guide the treatment and management of genetic conditions will be presented, including the development of national and international collaborative genetics research networks for testing and evaluating new genetic tests, treatments, and management recommendations for genetic diseases.

Evidence-based evaluation of genetic tests. *W. Burke* Univ Washington Sch Med, Seattle, WA.

Session Descriptions:
The practice of evidence-based medicine continues to be a challenge in the field of medical genetics. In this session, the speakers will introduce the topic of evidence-based medicine in general, and will also discuss whether or not it currently applies to both rare, pediatric disorders as well as common, chronic diseases of adulthood that have a genetic component. Approaches for the systematic collection of evidence to guide the treatment and management of genetic conditions will be presented, including the development of national and international collaborative genetics research networks for testing and evaluating new genetic tests, treatments, and management recommendations for genetic diseases.

Efforts for collecting the missing evidence base in medical genetics. *M.S. Watson* ACMG, Bethesda, MD.

Session Descriptions:
The practice of evidence-based medicine continues to be a challenge in the field of medical genetics. In this session, the speakers will introduce the topic of evidence-based medicine in general, and will also discuss whether or not it currently applies to both rare, pediatric disorders as well as common, chronic diseases of adulthood that have a genetic component. The evaluation of genetic tests and their entry into the clinical arena will also be discussed. Approaches for the systematic collection of evidence to guide the treatment and management of genetic conditions will be presented, including the development of national and international collaborative genetics research networks for testing and evaluating new genetic tests, treatments, and management recommendations for genetic diseases.

Whole genome association studies: The why and how. *A. Chakravarti* McKusick-Nathans Inst Gen Med, Baltimore, MD.

Session Descriptions:
Identifying genetic factors that influence health, disease, and response to treatment is essential to reduce the burden of disease. With the sequencing of the human genome, more efficient genotyping and sequencing technologies, and the International Haplotype Map project, we now have powerful research tools for identifying genetic variants that contribute to common diseases. Researchers can now employ whole genome association studies to uncover regions of the genome and even specific genes contributing to disease susceptibility. We have an historic opportunity to understand key aspects of the complex contributions of genetic variation to health, with major consequences for prevention, diagnosis, and treatment. This session will draw upon recent large, coordinated whole genome association studies to consider the scientific opportunities presented by such studies and the challenges they face, how to mine and analyze the data from such projects, and the opportunities they offer for devising new diagnostics and therapeutics.

Whole genome association studies: Mining and analyzing data. *D. Altshuler* Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA.

Session Descriptions:
Identifying genetic factors that influence health, disease, and response to treatment is essential to reduce the burden of disease. With the sequencing of the human genome, more efficient genotyping and sequencing technologies, and the International Haplotype Map project, we now have powerful research tools for identifying genetic variants that contribute to common diseases. The Type 1 Diabetes Genetics Consortium: Linkage, fine mapping of the human MHC and beyond. *S.S. Rich*
Public Health Services, Wake Forest Univ Sch of Medicine, Winston-Salem, NC.

Session Descriptions:
This session will cover the current progress being made in understanding the genetic basis of type 1 diabetes. Four presentations will provide updates on genomewide linkage studies, including an in-depth examination of the MHC, in humans (Type 1 Diabetes Genetics Consortium); results from the first major genomewide association study of type 1 diabetes in humans (Wellcome Trust Case Control Consortium); progress in resolving the genetic basis of type 1 diabetes in mouse; and the search for genes that influence risk of micro- and macrovascular complications of type 1 diabetes. Studies in type 1 diabetes genetics may serve as a model for other complex human diseases, including the coordination of international efforts to collect, characterize, and analyze samples. The use of human (linkage and association) and model system approaches and resources for performing these genetic studies may provide insights for addressing the genetic basis of other "classically complex human traits."

Whole genome association approaches to the genetic basis of type 1 diabetes: the Wellcome Trust Case Control Consortium. *J. Todd* Medical Genetics, Wellcome Trust/JDRF Diabetes Inflammation Laboratory, CB2 2XY Cambridge, United Kingdom.

Session Descriptions:
This session will cover the current progress being made in understanding the genetic basis of type 1 diabetes. Four presentations will provide updates on genomewide linkage studies, including an in-depth examination of the MHC, in humans (Type 1 Diabetes Genetics Consortium); results from the first major genomewide association study of type 1 diabetes in humans (Wellcome Trust Case Control Consortium); progress in resolving the genetic basis of type 1 diabetes in mouse; and the search for genes that influence risk of micro- and macrovascular complications of type 1 diabetes. Studies in type 1 diabetes genetics may serve as a model for other complex human diseases, including the coordination of international efforts to collect, characterize, and analyze samples. The use of human (linkage and association) and model system approaches and resources for performing these genetic studies may provide insights for addressing the genetic basis of other "classically complex human traits."

Identification and modulation of molecular genetic mechanisms leading to type 1 diabetes in the NOD mouse. *L. Wicker* Medical Genetics, Addenbrooke Hospital, Cambridge, United Kingdom.

Session Descriptions:
This session will cover the current progress being made in understanding the genetic basis of type 1 diabetes. Four presentations will provide updates on genomewide linkage studies, including an in-depth examination of the MHC, in humans (Type 1 Diabetes Genetics Consortium); results from the first major genomewide association study of type 1 diabetes in humans (Wellcome Trust Case Control Consortium); progress in resolving the genetic basis of type 1 diabetes in mouse; and the search for genes that influence risk of micro- and macrovascular complications of type 1 diabetes. Introduction. *N. Blau* Department of Pediatrics, University of Zurich, 8032 Zurich, ZH, Switzerland.

Session Descriptions:
Phenylketonuria (PKU) is a disease of temperate-zone human populations and certain mutations are surprisingly prevalent. How might one explain these features? PKU is the flagship for treatable human genetic disease. Restriction of phenylalanine intake prevents brain damage but disagreement persists on how long the diet should be continued. Adolescents and young adults tend not to comply with dietary treatment and 2/3 of pregnant women (in the USA) do not follow the diet before becoming pregnant. New approaches to treatment are of interest: 1. use of the r- AAV2/8 vector to correct hyperphenylalaninemia in a murine model; 2. treatment of murine PKU with recombinant phenylalanine ammonia lyase; 3. use of tetrahydrobiopterin (6R- BH4) to treat a relatively high proportion of patients with PAH-mutant hyperphenylalaninemia who benefit from the cofactor acting either as a chaperone-like molecule or by overcoming adverse binding kinetics.

Advances in treatment of PKU: an overview. *C.R. Scriver* Montreal Children's Hospital Research Institute, McGill University, Montreal Quebec H3H 1P3, Canada.

Session Descriptions:
Phenylketonuria (PKU) is a disease of temperate-zone human populations and certain mutations are surprisingly prevalent. How might one explain these features? Large-scale mutation discovery in ion channels. *R.A. Gibbs* Department of Molecular and Human Genetics, Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Session Descriptions:

The triumph of the Human Genome Project requires little embellishment. The availability of the entire euchromatic genomic sequence serves as a routine starting point for a huge multidisciplinary investigator base and has accelerated our understanding of human genome content, organization and evolution. Yet, the greatest fruits of having such an initial blueprint are still to come, as we unravel how genomic changes lead to a plethora of human diseases and to our inter-individual phenotypic diversity. Continued advances in DNA sequencing methodologies and their further cost reductions will significantly increase clinical access to such technology and exponentially increase the availability of medical sequence- based datasets. These resources will undeniably further our understanding of the genetic bases of human disease susceptibility but will also present significant computational challenges to properly interpret their biological relevance.

Genetic architecture of plasma lipoprotein levels. *M. Meyerson* Department of Pathology, Dana-Farber Cancer Institute, Dept of Medical Oncology, Boston, MA.

Session Descriptions:
The triumph of the Human Genome Project requires little embellishment. Animal models of developmental diaphragmatic defects: Gateway to candidate gene discovery in humans. *K.G. Ackerman* Genetics, Brigham and Women's Genetics, Boston, MA.

Session Descriptions:

Congenital diaphragmatic hernia (CDH) is an extremely common birth defect affecting ~1/2500 births and is estimated to constitute up to eight percent of all congenital malformations. The condition remains associated with a high mortality and considerable morbidity among long-term survivors. The etiology is currently unknown in most cases, but new developments from human and model organism investigations indicate a major role for genetic causation of CDH. Four talks will highlight the following: 1) diaphragm and lung embryology; basis of pulmonary hypoplasia; genetic and teratogenic model organisms; 2) prevalence of common cytogenetic abnormalities including microdeletions detected by array based CGH; suggested testing guidelines for both isolated CDH and CDH with anomalies; 3) Fryns syndrome; single gene disorders associated with CDH; differential diagnoses; 4) mutations associated with human CDH; candidate gene sequence analysis and explanation for major pathways currently being sequenced; multiplex families with CDH and linkage analysis.

Fryns syndrome and single gene disorders associated with CDH. *A.M. Slavotinek* Department of Pediatrics, U585P, Univ California, San Francisco, San Francisco, CA.

Session Descriptions:
Congenital diaphragmatic hernia (CDH) is an extremely common birth defect affecting ~1/2500 births and is estimated to constitute up to eight percent of all congenital malformations. The condition remains associated with a high mortality and considerable morbidity among long-term survivors. The etiology is currently unknown in most cases, but new developments from human and model organism investigations indicate a major role for genetic causation of CDH. Four talks will highlight the following: 1) diaphragm and lung embryology; basis of pulmonary hypoplasia; genetic and teratogenic model organisms; 2) prevalence of common cytogenetic abnormalities including microdeletions detected by array based CGH; suggested testing guidelines for both isolated CDH and CDH with anomalies; 3) Fryns syndrome; single gene disorders associated with CDH; differential diagnoses; 4) mutations associated with human CDH; candidate gene sequence analysis and explanation for major pathways currently being sequenced; multiplex families with CDH and linkage analysis.

Findings from cytogenetics and array-based comparative genomic hybridization: Methods to identify loci associated with CDH. *K. Klein* Department of clinical Genetics, Erasmus MC, Rotterdam, The Netherlands.

Session Descriptions:
Congenital diaphragmatic hernia (CDH) is an extremely common birth defect affecting ~1/2500 births and is estimated to constitute up to eight percent of all congenital malformations. The condition remains associated with a high mortality and considerable morbidity among long-term survivors. Dynamic mutations and RNA-mediated disease. *M. Swanson* Molec Gen & Microbiology, Univ Florida Col Medicine, Gainesville, FL.

Session Descriptions:
The most widely accepted view on mechanisms leading to neuronal cell death in neurodegenerative disease is that the main culprits are proteins abnormally modified as the result of mutations, aberrant processing or post-translational modifications. However, over the past few years, new evidence has emerged for the involvement of RNA-mediated mechanisms in a number of degenerative pathologies of the central nervous system. The main objective of this session is to review the most recent advances on the groundbreaking concept of RNA neurotoxicity, and to provide a thought-provoking forum from which working models with a wide implication for human diseases will emerge. This session will particularly focus on DM1, DM2, SCA8, and FXTAS, in which the toxicity of noncoding RNAs has been demonstrated in different animal and cell models.

Insights into molecular pathogenesis through comparative studies of DM1, DM2 and SCA8. *L. Ranum* Institute of Human Genetics, University of Minnesota, Minneapolis, MN.

Session Descriptions:
The most widely accepted view on mechanisms leading to neuronal cell death in neurodegenerative disease is that the main culprits are proteins abnormally modified as the result of mutations, aberrant processing or post-translational modifications. However, over the past few years, new evidence has emerged for the involvement of RNA-mediated mechanisms in a number of degenerative pathologies of the central nervous system. The main objective of this session is to review the most recent advances on the groundbreaking concept of RNA neurotoxicity, and to provide a thought-provoking forum from which working models with a wide implication for human diseases will emerge. This session will particularly focus on DM1, DM2, SCA8, and FXTAS, in which the toxicity of noncoding RNAs has been demonstrated in different animal and cell models.

Molecular pathogenesis of FXTAS. *P.J. Hagerman* Biochemistry & Molecular Medicine, University of California Sch Med, Davis, Davis, CA.

Session Descriptions:
The most widely accepted view on mechanisms leading to neuronal cell death in neurodegenerative disease is that the main culprits are proteins abnormally modified as the result of mutations, aberrant processing or post-translational modifications. However, over the past few years, new evidence has emerged for the involvement of RNA-mediated mechanisms in a number of degenerative pathologies of the central nervous system. The main objective of this session is to review the most recent advances on the groundbreaking concept of RNA neurotoxicity, and to provide a thought-provoking forum from which working models with a wide implication for human diseases will emerge. This session will particularly focus on DM1, DM2, SCA8, and FXTAS, in which the toxicity of noncoding RNAs has been demonstrated in different animal and cell models.

From fruit fly to bedside: translating lessons from a Drosophila model of FXTAS. *P. Jin* Human Genetics, Emory University SOM, Atlanta, GA.

Session Descriptions:
The most widely accepted view on mechanisms leading to neuronal cell death in neurodegenerative disease is that the main culprits are proteins abnormally modified as the result of mutations, aberrant processing or post-translational modifications. However, over the past few years, new evidence has emerged for the involvement of RNA-mediated mechanisms in a number of degenerative pathologies of the central nervous system. The main objective of this session is to review the most recent advances on the groundbreaking concept of RNA neurotoxicity, and to provide a thought-provoking forum from which working models with a wide implication for human diseases will emerge. Introduction to DNA damage response genes and their role in preventing human cancer. *M. Meyn* Dept Genetics, Hospital for Sick Children, Toronto, Ontario.

Session Descriptions:
The DNA damage response (DDR) protects us against the harmful effects of DNA and chromosomal breakage. The impact of loss of these defenses extends beyond the rare situations in which loss or altered function of the ataxia telangiectasia gene, ATM and its downstream targets in the DDR (e.g., BRCA, FANC genes) cause familial cancer syndromes and in some cases, chromosomal breakage syndromes. This session will review the DDR pathways and the chromosomal instability syndromes, the impact of DDR gene mutations and polymorphisms on cancer susceptibility in carriers, mouse models for various genes in the DDR and their value in understanding the DDR pathways and cancer susceptibility, interindividual variation in DNA repair capacity and cancer susceptibility, recent research findings on the cellular response to DNA breaks, and pertinent clinical and genetic counseling issues. Genome instability and cancer susceptibility is an important emerging area of cancer genetics and public health genetics.

Mouse models of genome instability syndromes. *L. Niedernhofer* University of Pittsburgh Cancer Institute, Hillman Cancer Center, 2.6, Pittsburgh, PA.

Session Descriptions:
The DNA damage response (DDR) protects us against the harmful effects of DNA and chromosomal breakage. The impact of loss of these defenses extends beyond the rare situations in which loss or altered function of the ataxia telangiectasia gene, ATM and its downstream targets in the DDR (e.g., BRCA, FANC genes) cause familial cancer syndromes and in some cases, chromosomal breakage syndromes. This session will review the DDR pathways and the chromosomal instability syndromes, the impact of DDR gene mutations and polymorphisms on cancer susceptibility in carriers, mouse models for various genes in the DDR and their value in understanding the DDR pathways and cancer susceptibility, interindividual variation in DNA repair capacity and cancer susceptibility, recent research findings on the cellular response to DNA breaks, and pertinent clinical and genetic counseling issues. Genome instability and cancer susceptibility is an important emerging area of cancer genetics and public health genetics.

The role of DNA repair capacity in genetic susceptibility to cancer. *X. Wu* Dept of Epidemiology, UT MD Anderson Cancer Center, Houston, TX.

Session Descriptions:

The DNA damage response (DDR) protects us against the harmful effects of DNA and chromosomal breakage. The impact of loss of these defenses extends beyond the rare situations in which loss or altered function of the ataxia telangiectasia gene, ATM and its downstream targets in the DDR (e.g., BRCA, FANC genes) cause familial cancer syndromes and in some cases, chromosomal breakage syndromes. This session will review the DDR pathways and the chromosomal instability syndromes, the impact of DDR gene mutations and polymorphisms on cancer susceptibility in carriers, mouse models for various genes in the DDR and their value in understanding the DDR pathways and cancer susceptibility, interindividual variation in DNA repair capacity and cancer susceptibility, recent research findings on the cellular response to DNA breaks, and pertinent clinical and genetic counseling issues. Genome instability and cancer susceptibility is an important emerging area of cancer genetics and public health genetics.

Visualizing the DNA damage response (DDR): How DDR and telomeric proteins protect against genetic damage.
M. Meyn Dept. Genetics, Hospital for Sick Children, Toronto, Ontario, Canada.

Session Descriptions:
The DNA damage response (DDR) protects us against the harmful effects of DNA and chromosomal breakage. The impact of loss of these defenses extends beyond the rare situations in which loss or altered function of the ataxia telangiectasia gene, ATM and its downstream targets in the DDR (e.g., BRCA, FANC genes) cause familial cancer syndromes and in some cases, chromosomal breakage syndromes. Genome instability and cancer susceptibility is an important emerging area of cancer genetics and public health genetics.

Human meiotic aneuploidy: Where weve been, where were going. *T. Hassold* School of Molecular Bioscience, Washington State University, Pullman, WA.

Session Descriptions:
In the human genetics community, we frequently take a narrow view of aneuploidy, thinking of it as due to meiotic nondisjunction and leading to either miscarriage or birth defects. Clearly, this is an important component of aneuploidy and, as part of this session, we will update recent studies of nondisjunction in humans and mammalian models. However, a variety of studies suggest that we need to expand our thinking of both the causes and consequences of aneuploidy. Accordingly, we will discuss emerging evidence that aneuploidy is an important driver for cancer and will also focus on aneuploid cells in neurons, providing data that we are all mosaics for chromosome abnormalities and that aneuploidy may be necessary for functioning neurons. Finally, we will summarize recent data indicating that exposure to endrocrine disruptors affects meiotic synapsis, recombination and chromosome segregation in mice, suggesting that the environment is an important contributor to aneuploidy.

Aneuploidy and cancer. *D. Cleveland* Neuroscience & Molecular Medicine, University of California at San Diego, La Jolla, CA.

Session Descriptions:
In the human genetics community, we frequently take a narrow view of aneuploidy, thinking of it as due to meiotic nondisjunction and leading to either miscarriage or birth defects. Clearly, this is an important component of aneuploidy and, as part of this session, we will update recent studies of nondisjunction in humans and mammalian models. However, a variety of studies suggest that we need to expand our thinking of both the causes and consequences of aneuploidy. Accordingly, we will discuss emerging evidence that aneuploidy is an important driver for cancer and will also focus on aneuploid cells in neurons, providing data that we are all mosaics for chromosome abnormalities and that aneuploidy may be necessary for functioning neurons. Finally, we will summarize recent data indicating that exposure to endrocrine disruptors affects meiotic synapsis, recombination and chromosome segregation in mice, suggesting that the environment is an important contributor to aneuploidy.

Naturally occurring aneuploidy in the brain. *J. Chun* Department of Molecular Biology, The Scripps Research Institute, La Jolla, CA.

Session Descriptions:
In the human genetics community, we frequently take a narrow view of aneuploidy, thinking of it as due to meiotic nondisjunction and leading to either miscarriage or birth defects. Clearly, this is an important component of aneuploidy and, as part of this session, we will update recent studies of nondisjunction in humans and mammalian models. However, a variety of studies suggest that we need to expand our thinking of both the causes and consequences of aneuploidy. Accordingly, we will discuss emerging evidence that aneuploidy is an important driver for cancer and will also focus on aneuploid cells in neurons, providing data that we are all mosaics for chromosome abnormalities and that aneuploidy may be necessary for functioning neurons. Finally, we will summarize recent data indicating that exposure to endrocrine disruptors affects meiotic synapsis, recombination and chromosome segregation in mice, suggesting that the environment is an important contributor to aneuploidy.

Aneuploidy and the environment: are we making things worse? *P. Hunt* School of Molecular Bioscience, Washington State University, Pullman, WA.

Session Descriptions:

In the human genetics community, we frequently take a narrow view of aneuploidy, thinking of it as due to meiotic nondisjunction and leading to either miscarriage or birth defects. Clearly, this is an important component of aneuploidy and, as part of this session, we will update recent studies of nondisjunction in humans and mammalian models. Cancer as a model for understanding complex trait epigenetics. *A.P. Feinberg* Molecular Biology/Genetics, Johns Hopkins Univ School of Medicine, Baltimore, MD.

Session Descriptions:
While it is well established that DNA variation contributes to complex disease, epigenetic variations, i.e., nonsequence changes associated with DNA and heritable during somatic cell division, are emerging as an additional source of diversity contributing to disease risk. In addition to cancer, in which the role of epigenetics is well established, epigenetic variation is associated with aging and environmental perturbation including diet, and it may both mediate and promote genetic alterations in somatic cells. The purpose of this session is to provide an introduction to this new frontier, focusing on examples of cancer as a model of the epigenetics of complex traits, strategies for high throughput epigenome analysis, the challenges of the resulting large quantitative data sets and their incorporation into disease risk modeling, and the epigenome as a target for environmental perturbation and aging.

Incorporating epigenetic hypotheses into genetic epidemiology. *M. Fallin* Dept of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Session Descriptions:
While it is well established that DNA variation contributes to complex disease, epigenetic variations, i.e., nonsequence changes associated with DNA and heritable during somatic cell division, are emerging as an additional source of diversity contributing to disease risk. In addition to cancer, in which the role of epigenetics is well established, epigenetic variation is associated with aging and environmental perturbation including diet, and it may both mediate and promote genetic alterations in somatic cells. The purpose of this session is to provide an introduction to this new frontier, focusing on examples of cancer as a model of the epigenetics of complex traits, strategies for high throughput epigenome analysis, the challenges of the resulting large quantitative data sets and their incorporation into disease risk modeling, and the epigenome as a target for environmental perturbation and aging.

Advances in epigenome technology and implications for the study of aging. *M. Esteller* Cancer Epigenetics Branch, Spanish National Cancer Center, 28029 Madrid, Spain.

Session Descriptions:
While it is well established that DNA variation contributes to complex disease, epigenetic variations, i.e., nonsequence changes associated with DNA and heritable during somatic cell division, are emerging as an additional source of diversity contributing to disease risk. In addition to cancer, in which the role of epigenetics is well established, epigenetic variation is associated with aging and environmental perturbation including diet, and it may both mediate and promote genetic alterations in somatic cells. Parathyroid tumor genetics. *A.J. Arnold* Murray-Heilig Chair in Molecular Medicine, University of Connecticut Health Center, Farmington, CT.

Session Descriptions:

New genetic and molecular information clarifies thyroid and parathyroid tumors, chromaffin tumors, multiple endocrine neoplasia types 1 and 2, and Carney Complex. There are important implications in counseling, in normal signal transduction pathways, and in tumorigenesis. An endocrine neoplasia syndrome can express striking metabolic features from hormone excess. Traditionally, these features have defined carriers and have given tools to monitor tumor burden. Other morbid features are from benign and malignant neoplasia of endocrine and sometimes non-endocrine tissues. Focus on the phenotypes from hormone excess in these syndromes has sped discoveries about genetics and tumorigenesis. Not only does mutation testing in the germline benefit rare families, but mutation testing in somatic tissues benefits management of cases with similar common variety tumors. Some of the disturbed molecular pathways are already promising for interventions against neoplasia in vitro, and some are already under exploration in clinical trials.

Genomic medicine practice: Lessons learned from pheochromocytoma. *C. Eng* Chairman and Director, Genomic Medicine Institute, Cleveland Clinic Lerner Research Institute, Cleveland, OH.

Session Descriptions:
New genetic and molecular information clarifies thyroid and parathyroid tumors, chromaffin tumors, multiple endocrine neoplasia types 1 and 2, and Carney Complex. There are important implications in counseling, in normal signal transduction pathways, and in tumorigenesis. An endocrine neoplasia syndrome can express striking metabolic features from hormone excess. Traditionally, these features have defined carriers and have given tools to monitor tumor burden. Other morbid features are from benign and malignant neoplasia of endocrine and sometimes non-endocrine tissues. Focus on the phenotypes from hormone excess in these syndromes has sped discoveries about genetics and tumorigenesis. Not only does mutation testing in the germline benefit rare families, but mutation testing in somatic tissues benefits management of cases with similar common variety tumors. Some of the disturbed molecular pathways are already promising for interventions against neoplasia in vitro, and some are already under exploration in clinical trials.

MEN1 Gene function and molecular diagnosis. *A.E. Bale* Yale University, School of Medicine, New Haven, CT.

Session Descriptions:
New genetic and molecular information clarifies thyroid and parathyroid tumors, chromaffin tumors, multiple endocrine neoplasia types 1 and 2, and Carney Complex. There are important implications in counseling, in normal signal transduction pathways, and in tumorigenesis. An endocrine neoplasia syndrome can express striking metabolic features from hormone excess. Traditionally, these features have defined carriers and have given tools to monitor tumor burden. Other morbid features are from benign and malignant neoplasia of endocrine and sometimes non-endocrine tissues. Molecular principles of human telomerase function and dysfunction in disease. *K. Collins* Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA.

Session Descriptions:

In order to distinguish a normal telomere from a double strand break, a minimum number of telomere repeats must cap each chromosome end. The length of each repeat array will reflect a unique history of addition and losses. Telomere losses are known to occur sporadically as well as with every replication cycle. Losses of telomeric DNA are countered by the telomerase enzyme containing telomerase RNA (encoded by the TERC gene) and a reverse transcriptase protein (encoded by TERT gene) as minimal components. Telomerase activity is limiting in most somatic (stem) cells and the average length of telomere repeats in most somatic cells shows a highly significant decline with age. In this session basic aspects of telomere and telomerase biology will be reviewed together with recent observations indicating that haplo-insufficiency for either the TERC or TERT gene can give rise to disease including autosomal dominant dyskeratosis congenita (DKC) and aplastic anemia.

Dyskeratosis congenita: a disease of defective telomere maintenance. *I. Dokal* Department of Haematology, Imperial College London, London, UK.

Session Descriptions:

In order to distinguish a normal telomere from a double strand break, a minimum number of telomere repeats must cap each chromosome end. The length of each repeat array will reflect a unique history of addition and losses. Telomere losses are known to occur sporadically as well as with every replication cycle. Losses of telomeric DNA are countered by the telomerase enzyme containing telomerase RNA (encoded by the TERC gene) and a reverse transcriptase protein (encoded by TERT gene) as minimal components. Telomerase activity is limiting in most somatic (stem) cells and the average length of telomere repeats in most somatic cells shows a highly significant decline with age. In this session basic aspects of telomere and telomerase biology will be reviewed together with recent observations indicating that haplo-insufficiency for either the TERC or TERT gene can give rise to disease including autosomal dominant dyskeratosis congenita (DKC) and aplastic anemia.

Mechanisms of telomere loss. *P.M. Lansdorp* Terry Fox Laboratory, BC Cancer Agency, Vancouver, BC, Canada.

Session Descriptions:

In order to distinguish a normal telomere from a double strand break, a minimum number of telomere repeats must cap each chromosome end. The length of each repeat array will reflect a unique history of addition and losses. Telomere losses are known to occur sporadically as well as with every replication cycle. Losses of telomeric DNA are countered by the telomerase enzyme containing telomerase RNA (encoded by the TERC gene) and a reverse transcriptase protein (encoded by TERT gene) as minimal components. Telomerase activity is limiting in most somatic (stem) cells and the average length of telomere repeats in most somatic cells shows a highly significant decline with age. In this session basic aspects of telomere and telomerase biology will be reviewed together with recent observations indicating that haplo-insufficiency for either the TERC or TERT gene can give rise to disease including autosomal dominant dyskeratosis congenita (DKC) and aplastic anemia.

Pathophysiology and treatment of bone marrow failure resulting from mutations in telomerase genes. *N. Young*
NHLBI, National Institutes of Health, Bethesda, MD.

Session Descriptions:
In order to distinguish a normal telomere from a double strand break, a minimum number of telomere repeats must cap each chromosome end. The length of each repeat array will reflect a unique history of addition and losses. Telomere losses are known to occur sporadically as well as with every replication cycle. Losses of telomeric DNA are countered by the telomerase enzyme containing telomerase RNA (encoded by the TERC gene) and a reverse transcriptase protein (encoded by TERT gene) as minimal components. Pharmacogenetics: Lessons learned and the "Blockbuster" model. *D. Goldstein* Institute for Genome Sciences & Policy (IGSP), Duke University, CIEMAS DUMC Box 3382, Durham, NC.

Session Descriptions:
Traditional models of drug discovery, particularly the "blockbuster" model, are widely believed to be in crisis. For some diseases, few new medicines are in the pipeline and there are persistent safety concerns. The genetic personalization of treatment may help, but the current research base allows few firm conclusions. Recent developments suggest that this situation may be changing. In the wake of advances from large-scale genomic initiatives, the capacity for the pharmacogenetic prediction of treatment response and adverse side-effects may be improving due to a new generation of studies. Indeed, the genetics of drug response/adverse drug reactions may be more tractable phenotypes than the genetics of disease predisposition. The purpose of this invited session is to describe these developments. We provide examples of where genotype-clinical phenotype correlations are compelling and appear to be ready for clinical translation (warfarin and gefitinib) and examples that have not worked out as consistently along with the regulatory perspective of the United States FDA.

A comprehensive pharmacogenetic analysis of antipsychotic use in the CATIE schizophrenia trial. *P.F. Sullivan*
Genetics, UNC-Chapel Hill, CB#7264, Chapel Hill, NC.

Session Descriptions:
Traditional models of drug discovery, particularly the "blockbuster" model, are widely believed to be in crisis. For some diseases, few new medicines are in the pipeline and there are persistent safety concerns. The genetic personalization of treatment may help, but the current research base allows few firm conclusions. Recent developments suggest that this situation may be changing. In the wake of advances from large-scale genomic initiatives, the capacity for the pharmacogenetic prediction of treatment response and adverse side-effects may be improving due to a new generation of studies. We provide examples of where genotype-clinical phenotype correlations are compelling and appear to be ready for clinical translation (warfarin and gefitinib) and examples that have not worked out as consistently along with the regulatory perspective of the United States FDA.

Traffic jams: a compendium of human diseases that affect intracellular transport processes. *M. Huizing* NHGRI, NIH, Bethesda, Maryland.

Session Descriptions:
Genetic mutations that result in human disease provide insights into the complex mechanisms of protein routing within the cell. In this session, distinct cellular compartments, their protein routing, and the associated genetic disorders will be addressed. Topics include protein folding and quality control in the endoplasmic reticulum, protein glycosylation and sorting in the Golgi complex, and endosomal and caveolar protein trafficking to and from distinct organelles and the plasma membrane. Each speaker will address groups of human genetic disorders associated with each compartment and the insights that specific disorders provide into the underlying cellular mechanisms. These cellular insights are ultimately essential for a rational approach to therapies.

Disorders of protein routing through the Golgi complex. *H.H. Freeze* Glycobiology and Carbohydrate Chemistry Program, Burnham Institute for Medical Research, La Jolla, CA.

Session Descriptions:
Genetic mutations that result in human disease provide insights into the complex mechanisms of protein routing within the cell. In this session, distinct cellular compartments, their protein routing, and the associated genetic disorders will be addressed. Topics include protein folding and quality control in the endoplasmic reticulum, protein glycosylation and sorting in the Golgi complex, and endosomal and caveolar protein trafficking to and from distinct organelles and the plasma membrane. Each speaker will address groups of human genetic disorders associated with each compartment and the insights that specific disorders provide into the underlying cellular mechanisms. These cellular insights are ultimately essential for a rational approach to therapies.

RAB GTPases and endocytic trafficking in health and disease. *A. Wandinger-Ness* Deptartment of Pathology, Univ of New Mexico Health Sciences Center, Albuquerque, NM.

Session Descriptions:
Genetic mutations that result in human disease provide insights into the complex mechanisms of protein routing within the cell. In this session, distinct cellular compartments, their protein routing, and the associated genetic disorders will be addressed. Topics include protein folding and quality control in the endoplasmic reticulum, protein glycosylation and sorting in the Golgi complex, and endosomal and caveolar protein trafficking to and from distinct organelles and the plasma membrane. Each speaker will address groups of human genetic disorders associated with each compartment and the insights that specific disorders provide into the underlying cellular mechanisms. These cellular insights are ultimately essential for a rational approach to therapies.

Caveolins, caveolae and lipid rafts in cellular transport: From cell biology to medicine. *M.P. Lisanti* Departments of Medicine and Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY.

Session Descriptions:
Genetic mutations that result in human disease provide insights into the complex mechanisms of protein routing within the cell. In this session, distinct cellular compartments, their protein routing, and the associated genetic disorders will be addressed. Topics include protein folding and quality control in the endoplasmic reticulum, protein glycosylation and sorting in the Golgi complex, and endosomal and caveolar protein trafficking to and from distinct organelles and the plasma membrane. Each speaker will address groups of human genetic disorders associated with each compartment and the insights that specific disorders provide into the underlying cellular mechanisms. These cellular insights are ultimately essential for a rational approach to therapies.

Heritability in prematurity: New insights into the genetics of preterm birth. *K. Ward* Dept of OB/GYN and Women's Health, Kapi'olani Hospital, Honolulu, Hawaii.

Session Descriptions:

Preterm birth is the number one obstetrical problem today, exacting a huge toll upon individuals, families, and society. In addition to being the leading cause of neonatal mortality, prematurity contributes to lifelong morbidity for many children. The incremental rise in preterm birth in the United States continued in 2004, reaching 12.5% (almost 500,000 births), the highest rate ever reported. But, despite the lifelong impact of prematurity on health, there are few effective strategies to predict preterm birth and fewer clinical interventions to prevent preterm birth. Prematurity is increasingly appreciated to result from the interaction of environmental influences on varying genetic backgrounds, and thus it can be approached as a common complex disorder, using the tools of genetic epidemiology and applied genomic research. This session will outline applied genomic research approaches to preterm birth and propose broad implications for clinical care and public health.

Genetics to genomics: A framework for approaching preterm birth as a common complex disorder. *S. Dolan*
OB/GYN & Reproductive Genetics, March of Dimes & Albert Einstein College of Medicine, White Plains, NY.

Session Descriptions:
Preterm birth is the number one obstetrical problem today, exacting a huge toll upon individuals, families, and society. In addition to being the leading cause of neonatal mortality, prematurity contributes to lifelong morbidity for many children. The incremental rise in preterm birth in the United States continued in 2004, reaching 12.5% (almost 500,000 births), the highest rate ever reported. But, despite the lifelong impact of prematurity on health, there are few effective strategies to predict preterm birth and fewer clinical interventions to prevent preterm birth. Prematurity is increasingly appreciated to result from the interaction of environmental influences on varying genetic backgrounds, and thus it can be approached as a common complex disorder, using the tools of genetic epidemiology and applied genomic research. This session will outline applied genomic research approaches to preterm birth and propose broad implications for clinical care and public health.

Meta-analysis and knowledge integration: Implications for research on complex disease. *J.P. Ioannidis*
Department of Hygiene and Epidemiology, University of Ioannina School of Medicine, Ioannina, Greece, Greece.

Session Descriptions:
Preterm birth is the number one obstetrical problem today, exacting a huge toll upon individuals, families, and society. In addition to being the leading cause of neonatal mortality, prematurity contributes to lifelong morbidity for many children. The incremental rise in preterm birth in the United States continued in 2004, reaching 12.5% (almost 500,000 births), the highest rate ever reported. But, despite the lifelong impact of prematurity on health, there are few effective strategies to predict preterm birth and fewer clinical interventions to prevent preterm birth. Prematurity is increasingly appreciated to result from the interaction of environmental influences on varying genetic backgrounds, and thus it can be approached as a common complex disorder, using the tools of genetic epidemiology and applied genomic research. This session will outline applied genomic research approaches to preterm birth and propose broad implications for clinical care and public health.

Implications of applied genomic research for public health: What will it take to bring down the rate of preterm birth? *M. Khoury* Coordinating Center for Health Promotion, CDC Office of Genomics & Disease Prevention, Atlanta, GA.

Session Descriptions:

Preterm birth is the number one obstetrical problem today, exacting a huge toll upon individuals, families, and society. In addition to being the leading cause of neonatal mortality, prematurity contributes to lifelong morbidity for many children. The incremental rise in preterm birth in the United States continued in 2004, reaching 12.5% (almost 500,000 births), the highest rate ever reported. Prematurity is increasingly appreciated to result from the interaction of environmental influences on varying genetic backgrounds, and thus it can be approached as a common complex disorder, using the tools of genetic epidemiology and applied genomic research. This session will outline applied genomic research approaches to preterm birth and propose broad implications for clinical care and public health.

Malaria pressure on the human genome: A paradigm for genomic epidemiology of common disease. *D. Kwiatkowski* Oxford University, Wellcome Trust Centre for Human Genetics, Oxford, UK.

Session Descriptions:
Human genetic variation affects the severity of infectious disease progression for many pathogens. Individual polymorphisms, and epistatic interactions between them, substantially influence the host response to infection. Immune-response genes and non-immune genes are involved, but the innate immune response is emerging as a system in which these effects are most pronounced. Quantitative immune variation, arising from promoter mutations or from Copy-Number Polymorphisms (CNPs), influences the host response to pathogens, especially the early stages of infection, and has recently been demonstrated in the defensin and cytokine systems. Advances in genome analysis now enable these phenomena to be quantified, and candidate-gene approaches are completed by techniques that can detect patterns of disease-resistance polymorphism in whole-genome SNP datasets. This session will present examples of recent work that has utilized these approaches to detect many new loci affecting resistance to pathogens such as malaria, tuberculosis, and viral diseases such as HIV and hepatitis.

Natural selection on genes influencing susceptibility to infectious disease. *M.J. Bamshad* Dept Pediatrics, University of Washington, Seattle, WA.

Session Descriptions:

Human genetic variation affects the severity of infectious disease progression for many pathogens. Individual polymorphisms, and epistatic interactions between them, substantially influence the host response to infection. Immune-response genes and non-immune genes are involved, but the innate immune response is emerging as a system in which these effects are most pronounced. Introduction. *W. Robinson* Department of Medical Genetics, University of British Columbia, 950 W. 28th Ave, Rm 3086, Vancouver, BC V5Z 4H4, Canada.

Session Descriptions:
While it is well-established that structural and numerical chromosome abnormalities arise frequently during meiosis and early embryo development, abnormalities in chromatin structure (i.e., epigenetic alterations) may also be important in human disorders, ranging from classical imprinting syndromes to intrauterine growth restriction, obesity and diabetes. But what do we really know about how epigenetic programming can be altered in gametogenesis and early placental and embryo development? And how can we test for such abnormalities in clinical samples? This workshop is meant to "set the stage" in terms of our knowledge of normal and abnormal epigenetic programming in mammalian development and lead to a discussion of the possible medical implications of epigenetic change. The emphasis of this session will be on the types of epigenetic alterations that may occur in early development and factors influencing epigenetic change.

Epigenetic marking during gametogenesis. *L. Lefbvre* Medical Genetics, University of British Columbia, UBC Vancouver V6T 1Z3, BC, Canada.

Session Descriptions:
While it is well-established that structural and numerical chromosome abnormalities arise frequently during meiosis and early embryo development, abnormalities in chromatin structure (i.e., epigenetic alterations) may also be important in human disorders, ranging from classical imprinting syndromes to intrauterine growth restriction, obesity and diabetes. Introduction. *E. Mardis* Lawrence Berkeley National Laboratory, Berkeley, CA.

Session Descriptions:
The triumph of the Human Genome Project requires little embellishment. The availability of the entire euchromatic genomic sequence serves as a routine starting point for a huge multidisciplinary investigator base and has accelerated our understanding of human genome content, organization and evolution. Yet, the greatest fruits of having such an initial blueprint are still to come, as we unravel how genomic changes lead to a plethora of human diseases and to our inter-individual phenotypic diversity. Continued advances in DNA sequencing methodologies and their further cost reductions will significantly increase clinical access to such technology and exponentially increase the availability of medical sequence- based datasets. These resources will undeniably further our understanding of the genetic bases of human disease susceptibility but will also present significant computational challenges to properly interpret their biological relevance.

Introduction. *S. J. Marx* NIDDK, NIH, Bethesda, MD.

Session Descriptions:
New genetic and molecular information clarifies thyroid and parathyroid tumors, chromaffin tumors, multiple endocrine neoplasia types 1 and 2, and Carney Complex. There are important implications in counseling, in normal signal transduction pathways, and in tumorigenesis. An endocrine neoplasia syndrome can express striking metabolic features from hormone excess. Traditionally, these features have defined carriers and have given tools to monitor tumor burden. Other morbid features are from benign and malignant neoplasia of endocrine and sometimes non-endocrine tissues. Focus on the phenotypes from hormone excess in these syndromes has sped discoveries about genetics and tumorigenesis. Not only does mutation testing in the germline benefit rare families, but mutation testing in somatic tissues benefits management of cases with similar common variety tumors. Some of the disturbed molecular pathways are already promising for interventions against neoplasia in vitro, and some are already under exploration in clinical trials.

Introduction. *C. A. Moore* Centers for Disease Control and Prevention, Atlanta, GA.

Session Descriptions:
Preterm birth is the number one obstetrical problem today, exacting a huge toll upon individuals, families, and society. In addition to being the leading cause of neonatal mortality, prematurity contributes to lifelong morbidity for many children. The incremental rise in preterm birth in the United States continued in 2004, reaching 12.5% (almost 500,000 births), the highest rate ever reported. Discussion.

Session Descriptions:
While it is well established that DNA variation contributes to complex disease, epigenetic variations, i.e., nonsequence changes associated with DNA and heritable during somatic cell division, are emerging as an additional source of diversity contributing to disease risk. In addition to cancer, in which the role of epigenetics is well established, epigenetic variation is associated with aging and environmental perturbation including diet, and it may both mediate and promote genetic alterations in somatic cells. The purpose of this session is to provide an introduction to this new frontier, focusing on examples of cancer as a model of the epigenetics of complex traits, strategies for high throughput epigenome analysis, the challenges of the resulting large quantitative data sets and their incorporation into disease risk modeling, and the epigenome as a target for environmental perturbation and aging.

Introduction. *A. Feinberg* Johns Hopkins University School of Medicine, Baltimore, MD.

Introduction. *P. F. Sullivan* University of North Carolina, Chapel Hill.

Session Descriptions:
Traditional models of drug discovery, particularly the "blockbuster" model, are widely believed to be in crisis. For some diseases, few new medicines are in the pipeline and there are persistent safety concerns. The genetic personalization of treatment may help, but the current research base allows few firm conclusions. Recent developments suggest that this situation may be changing. In the wake of advances from large-scale genomic initiatives, the capacity for the pharmacogenetic prediction of treatment response and adverse side-effects may be improving due to a new generation of studies. Indeed, the genetics of drug response/adverse drug reactions may be more tractable phenotypes than the genetics of disease predisposition. The purpose of this invited session is to describe these developments. We provide examples of where genotype-clinical phenotype correlations are compelling and appear to be ready for clinical translation (warfarin and gefitinib) and examples that have not worked out as consistently along with the regulatory perspective of the United States FDA.

Questions and answers.

Discussion.

Session Descriptions:
Pharmacogenetics, the study of the genetic basis for differences in drug response, promises the tailoring of therapeutic regimes to specific patients genomic profiles, an advance widely anticipated to revolutionize both drug evaluation and clinical practice. While the advantages of using genetic information to increase drug efficiency and safety are clear, many important questions remain about the ways in which genetic variation relevant to drug response will be characterized, how such characterizations will direct the stratification of clinical trial participants in an effort to expedite drug development, and whether these choices will promote or impede the broad availability of desired therapeutic interventions. This session will examine the complex nexus of basic science, translational advance, and clinical application relevant to these challenging questions with the aim of identifying the specific social and ethical implications of current practice in this rapidly developing area.

Introduction. *W. Burke* University of Washington, Seattle.

Introduction. *J. M. Friedman* University of British Columbia, Children's and Women's Hospital, Vancouver, British Columbia, Canada.

Session Descriptions:
Many birth defects appear to be complex, resulting from a combination of risk factors. Even for cases where defects are largely determined by exposures, the genetic background of the infant, mother or both may confer increased susceptibility to environmental effects. Therefore, examining exposures without considering genetic background might obscure the causative role of an exposure. Likewise, studying genetic factors alone might not show associations. Thus, genetic and environmental factors must be considered simultaneously. This session will present techniques, advances and challenges in the identification of gene-environment interactions contributing to birth defects. The session will review the study of gene-environment interactions, discussing accomplishments and limitations using traditional epidemiological study designs and how future studies and alternative designs may address these issues. Specific examples of birth defects studies combining environmental and genetic factors will be presented, as well as methods for identifying novel gene-environment interactions involved in birth defects using animal models.

Introduction. *J. Gulcher* deCode Genetics, Reykjavik, Iceland.

Session Descriptions:
Special populations had discrete founders whose descendants experienced genetic isolation as the result of geography, religion, or cultural practice. In turn, these populations accumulated prevalent founder mutations for Mendelian conditions with extended intervals of linkage disequilibrium (LD). The LD has been used for identifying founder mutations for diseases and coalescence times for these mutations. Once identified, these founder mutations have been used for studies of prevalence and penetrance and, in turn, for the creation of genetic programs for prevention or early identification of disease. Among the special populations that have been studied are Icelandics, Sardinians, Amish and Mennonites, and Jews. Over the last 5 to 10 years, several common diseases have been extensively studied in these relatively isolated populations. This approach has come of age and has yielded several genes for common diseases such as schizophrenia, stroke, hyperlipidemia, nephrolithiasis, and myocardial infarction.

Introduction. *K. Hudson* Genetics & Public Policy Center, Johns Hopkins University, Washington DC.

Session Descriptions:
Some genetic testing companies are beginning to sell tests directly to consumers, eliminating the need to go to a doctors office. Test results usually are made available online, in the privacy of ones own home. Will at home genetic tests provide useful genetic information in a private, nonthreatening way? Or will these tests pose real risks to health and take advantage of people desperately seeking answers? Panelists will share their diverse perspectives and explore the commercial, legal, medical and ethical issues raised by direct-to-consumer (DTC) marketing of genetic tests. In addition, the panel and audience will consider what position, if any, the ASHG should take regarding DTC genetic testing.

Panel discussion and questions and answers.

Introduction. *M. Feldman* Stanford University, Stanford, CA.

Session Descriptions:
Behavioral genetics raises a number of issues due to the complexity of human behavior. Understanding what genetic tools can say about such complex and socially-charged traits as intelligence, sexuality, or aggression is an important consideration. Researchers may see the scientific value in and validity of such studies. How these findings are interpreted and used by the public and societal institutions, however, are other important considerations. This session will identify some of the most significant ethical, legal, social, and policy issues raised by anticipated research on behavioral genetics. The role of geneticists in incorporating consideration of these issues into the conduct of research will be discussed. What is the responsibility of researchers who study the genetics of behavior to deal with the potential positive and negative consequences of their work? How, if at all, should ethical, legal, social, and policy considerations affect study design, data analysis, and reporting results?

Discussion.

Questions and answers.

Session Descriptions:
The practice of evidence-based medicine continues to be a challenge in the field of medical genetics. In this session, the speakers will introduce the topic of evidence-based medicine in general, and will also discuss whether or not it currently applies to both rare, pediatric disorders as well as common, chronic diseases of adulthood that have a genetic component. The evaluation of genetic tests and their entry into the clinical arena will also be discussed. Approaches for the systematic collection of evidence to guide the treatment and management of genetic conditions will be presented, including the development of national and international collaborative genetics research networks for testing and evaluating new genetic tests, treatments, and management recommendations for genetic diseases.

Introduction. *M. Boehnke* Univ of Michigan, Dept of Biostatistics, Ann Arbor MI.

Session Descriptions:
This session will cover the current progress being made in understanding the genetic basis of type 1 diabetes. Four presentations will provide updates on genomewide linkage studies, including an in-depth examination of the MHC, in humans (Type 1 Diabetes Genetics Consortium); results from the first major genomewide association study of type 1 diabetes in humans (Wellcome Trust Case Control Consortium); progress in resolving the genetic basis of type 1 diabetes in mouse; and the search for genes that influence risk of micro- and macrovascular complications of type 1 diabetes. Studies in type 1 diabetes genetics may serve as a model for other complex human diseases, including the coordination of international efforts to collect, characterize, and analyze samples. The use of human (linkage and association) and model system approaches and resources for performing these genetic studies may provide insights for addressing the genetic basis of other "classically complex human traits."

Panel discussion and questions.

Session Descriptions:
For many human genetics researchers, the current regulatory climate is a source of increasing concern, depending on the specific policies of their local Institutional Review Boards (IRB). In this session, speakers and panelists will address several aspects of this complex topic, such as: Is genetic research inherently different from other research on human beings? What about genetic research on children? How does federal policy become implemented at the local IRB, with specific reference to genetic risk and benefit estimates? Are there consent issues specific to large-scale genomic studies with open-access databases? Do regulatory bodies have a more constricted view of risk than research participants, and is this appropriate? A final question and answer session will explore avenues by which human geneticists can work more effectively with their regulatory counterparts to enable genetic research on human subjects, while protecting them from exploitation or unnecessary risk.

Introduction. *F. S. Collins* National Human Genome Research Institute, National Institutes, of Heath, Bethesda, MD.

Session Descriptions:
Identifying genetic factors that influence health, disease, and response to treatment is essential to reduce the burden of disease. With the sequencing of the human genome, more efficient genotyping and sequencing technologies, and the International Haplotype Map project, we now have powerful research tools for identifying genetic variants that contribute to common diseases. Researchers can now employ whole genome association studies to uncover regions of the genome and even specific genes contributing to disease susceptibility. We have an historic opportunity to understand key aspects of the complex contributions of genetic variation to health, with major consequences for prevention, diagnosis, and treatment. This session will draw upon recent large, coordinated whole genome association studies to consider the scientific opportunities presented by such studies and the challenges they face, how to mine and analyze the data from such projects, and the opportunities they offer for devising new diagnostics and therapeutics.

Questions and answers.

Our Society and the Scientist-Citizen. *S. T. Warren* Emory University School of Medicine, Atlanta, GA.

Session Descriptions:

Stephen T. Warren
ASHG President
Emory University School of Medicine, Atlanta, GA

As investigators and practitioners of our wonderful field of human genetics, it is easy to become so engrossed in our daily work that we occasionally risk losing sight of all the external influences that affect our professional lives. Social, governmental, and educational policies are evolving, and the dynamics are often driven by the most influential but not necessarily the most well informed. Governmental actions can affect how we practice our craft, indeed they can legislatively ban aspects of our work, and limit the scope of our efforts. Often the actions taken mirror social opinions that influence what should or should not be taught in our schools. As human geneticists I believe we have a special responsibility to be aware of and participate in the dialog surrounding these issues.

As a prominent biomedical society we must be more active to educate and influence our legislative bodies at the federal and state levels. Toward this end, at the spring ASHG Board of Directors meeting in Washington DC, we set aside a day to meet with members of Congress and their staff regarding genetic nondiscrimination legislation and NIH funding. I encourage you all to get involved in these advocacy efforts. Meet with your representative, either at their home office or when you visit the DC area. Invite your elected officials to your laboratory to see first hand that NIH funding goes well beyond Bethesda (a common misconception on the hill is that the NIH appropriation is for the Bethesda campus). When you receive an email from ASHG (or any other professional societies) regarding an upcoming congressional vote, please be sure to make your opinion known to your representative or senator.

In addition to active participation in science policy, education is the other cornerstone to enhanced biomedical research. The Society is expanding its efforts in public education. Consider participating by joining the ASHG mentor network; become a human genetics advocate and invest in the future of our field. People fear the unknown, and I believe some of the mistrust of genetics research by the public is due a lack of understanding and journalistic sensationalism. If you read a newspaper article that does not give a balanced view of what we do, write a letter to the editor. We do good work that benefits society and we must continually make that point clear.

Finally, not all efforts should be external to the ASHG. We need more involvement in our Society by its members. Participation is essential to the growth, vibrancy and success of the organization. Play a role in the direction that ASHG takes and let your voice be heard regarding how our Society can better serve members. For example, seek nomination to one of the ASHG committees. This year we set up a postdoctoral fellow committee to develop meeting content specifically for those in training and to let the board know the ideas and concerns of that demography of our membership. Similarly, we are developing a program to involve our early career members, for example, assistant professors and those in comparable positions, to learn more about the Society and how to play an active role in it as well as to provide networking opportunities. Please attend this years business meeting to hear updates on the exciting activities of ASHG. Only through engagement of the membership can we really be a strong and positive force influencing the many aspects of the future of human genetics.

Reponses of Cells and Organisms to Altered Telomere Maintenance. *E. H. Blackburn* University of California, San Francisco.

Session Descriptions:
A gold medal and a $250,000 prize will be presented to Dr. Elizabeth H. Blackburn, Morris Herzstein Professor of Biology and Physiology in the Department of Biochemistry and Biophysics at the University of California, San Francisco. This prize is awarded annually to a leading scientist or group of scientists working in genetics, in recognition of groundbreaking contributions and fundamental insights in the field of genetics research. These may include original discoveries in genomic organization, function, regulation variation, and transmission. The Peter Gruber Prize recognizes her achievements in research and science advocacy.

By discovering the unique structure and mechanism of replication of telomeres, the ends of chromosomes, Dr. Blackburn demonstrated that these genetic elements play a fundamental role in normal development, and in carcinogenesis.

She has characterized telomerase, the enzyme responsible for making telomeres, in normally aging cells, in cancer cells, and in stem cells, enabling the development of new drugs based on these biological roles.

Her accuracy and honesty in debates on therapeutic cloning and stem cell research have raised public awareness of the importance of this work, and she is a model for the role of the scientist as citizen.

The Peter Gruber Foundation gives international prizes in genetics, neuroscience, justice, womens rights, and cosmology. Its goal is to recognize, honor, and encourage individuals who have transformed their field, and by shining a spotlight on them, to encourage others to follow in their footsteps.

Past winners are:

Robert H. Waterston
Mary-Claire King
H. Robert Horvitz
Rudolf Jaenisch
David Botstein
Eric Knudsen
Seymour Benzer

Elizabeth Blackburn was selected to win the 2006 Prize by a distinguished advisory panel that included:

David Botstein
Uta Francke
Robert H. Waterston
Mary-Claire King
H. Robert Horvitz
Rudolf Jaenisch

For further information about the Peter Gruber Foundations prizes, please visit http://www.petergruberfoundation.org

Reponses of Cells and Organisms to Altered Telomere Maintenance
Telomeres are the structures that protect and stabilize the ends of chromosomes, ensuring genomic stability. Telomeres consist of simple DNA sequences, which bind protein factors and make a cap. Without telomeric DNA and its special way of replicating, chromosome ends dwindle away, eventually causing cells to stop dividing, a process called cellular senescence. The enzyme telomerase replenishes the DNA at telomeres, partly counteracting the progressive shortening of telomeres throughout the human life span. Although telomerase activity is normally kept in check in adult human

cells, throughout life a certain level of telomerase is still required for replenishment of tissues, such as the immune system. Recent findings have highlighted the importance of telomerase and telomere length maintenance. For example, low telomerase in white blood cells in young to middle aged humans was found to be associated with six of the known major risk factors for cardiovascular disease.

In contrast to many normal cells in human adults, late-stage cancer cells characteristically have very high telomerase levels. A major known function of telomerase in cancer is to replenish telomeric DNA and maintain cell immortality. However, knocking down the high telomerase in cancer cells also inhibited their growth surprisingly rapidly, even without telomere shortening. Rapid and distinct cellular and transcriptional responses were elicited by reducing the level of telomerase RNA component. The distinctive alterations in the gene-expression profiles were predicted to be associated with diminished cancer progression. These and other recent results indicate that telomerase likely plays roles in other aspects of cancer known to be central to cancer progression.

Having It All. *D. Warburton* Columbia University, New York, NY.

Session Descriptions:
This award, which includes $10,000 and an engraved medal, is presented for substantial scientific contributions to human and medical genetics carried out over a lifetime of scientific inquiry.

Introduced by:
Professor Patricia A. Jacobs
Co-director of Research
Wessex Regional Genetics Laboratory
Salisbury District Hospital
Salisbury, Wiltshire, United Kingdom

Recipient:
Dorothy Warburton
Professor of Clinical Genetics and Development
Columbia University, New York, NY

Having It All

Having it all is a phrase usually applied to the attempt, implicitly by a woman, to combine career and family life without short-changing either. While happily the traditional meaning is valid in my case, the phrase also describes my life in human genetics in several other ways. First, cytogenetics has allowed me to combine two seemingly disparate passions: a love of playing with numbers and a fascination with new laboratory techniques. Thus my work has involved epidemiological and population studies of spontaneous abortions, chromosome abnormalities and ovarian aging. It has also involved the development and application of cytogenetic techniques, starting with autoradioagraphy, chromosome banding, in situ hybridization and somatic cell hybridization, and moving into the molecular era of FISH, CGH and genomic microarray analysis. Secondly, I have derived great personal satisfaction from being able to combine both clinical and research activities during almost forty years of directing a clinical cytogenetics lab in an academic setting. Cytogenetic analysis has revealed a vast array of chromosome aberrations associated with congenital malformations and/or mental retardation, and defined many new syndromes. Studying these aberrations has also impacted on our basic knowledge of chromosome structure and function, epigenetics and cancer. I have seen human genetics change from a discipline where patients contemplating pregnancy could be counseled only about Mendelian or empirical risks to one that now offers prenatal diagnosis for a large number of conditions and treatment for a few.

Lastly, having it all can also be used as a metaphor for the human genome project, which I have seen come to fruition since attending the first human gene mapping conference in 1973. The new tools available have revealed that small-scale copy number variation is widespread in the genome, and may be associated with pathology or phenotypic variation. Cytogenetics has entered an exciting era of ultra high-resolution chromosome analysis via microarray, which is likely to have as big an impact on human genetics as conventional cytogenetics did in the past. At the same time, it is still true that complete trisomy, no matter how diagnosed, remains the most common cause of mortality and morbidity among human conceptions. The molecular and evolutionary explanation of why our species is so prone to meiotic error, and the extraordinary phenomenon of its association with maternal aging, remain among the most significant and intriguing unsolved problems in biology. We do not really have it all: there is much to come.

Reflections on the Value of "Sticking with" Marfan Syndrome. *H. C. Dietz* Howard Hugh Medical Institute, Johns Hopkins University School of Medicine, Baltimore, Maryland.

Session Descriptions:
The Curt Stern Award is granted yearly to a scientist or scientists for major scientific achievement in human genetics that has occurred in the last 10 years. The work could be a single discovery or a series of contributions on a similar or related topic. The Award honors the memory of Curt Stern (1902-1981) as an outstanding pioneer in human genetics and ASHG president in 1956. An engraved crystal award and $2500 will be presented to the awardee at the annual meeting.

Presenter: Victor A. McKusick, University Professor of Medical Genetics
The Johns Hopkins University School of Medicine, Baltimore, MD

Recipient: Harry C. Dietz
Victor McKusick Professor of Medicine and Genetics; Investigator, Howard Hughes Medical Institute; Professor of Pediatrics, Institute of Genetic Medicine
The Johns Hopkins University School of Medicine, Baltimore, Maryland

Reflections on the Value of Sticking with Marfan Syndrome
I am commonly asked why I stick with Marfan research given that the work after gene discovery is often more difficult and tedious than simply moving on to the next gene and disease. A growing trend in medical genetics is to emphasize common and complex traits, perhaps at the expense of dwindling excitement and resources devoted to relatively rare Mendelian disorders. Here, my thoughts are flavored by my lifes experiences as a clinician who also happens to do research. If I had been asked 10 years ago about the prospects of developing a productive medical therapy for a systemic disorder of connective tissue such as Marfan syndrome, I would have placed the chances just slightly ahead of curing a chromosomal disorder. My continuing dedication to Marfan syndrome was more a reflection of obligation to my patients, as opposed to perceived opportunity. At that time we thought that the pathogenesis of Marfan syndrome simply reflected loss of physical integrity of the tissues due to a deficiency of the structural protein fibrillin-1. It was a clinical encounter (including unbiased and astute questioning by a patient) that first challenged this paradigm. Why should weakness of the tissues lead to overgrowth of the bones? Why, for that matter, should it lead to the craniofacial features of Marfan syndrome, valve thickening, or low muscle mass and tone? We turned to mouse models of Marfan syndrome to address these issues, and learned that fibrillin-1 normally regulates the activation of and signaling by the TGFbeta family of cytokines. Furthermore, antagonism of TGFbeta using either neutralizing antibodies or the FDA-approved drug losartan could prevent the multisystem manifestation of Marfan syndrome including lung emphysema, aortic aneurysm and failed muscle regeneration in the mouse model. Having established this foundation for Marfan syndrome, we learned that excess TGFbeta signaling contributes to overlapping disease phenotypes including other forms of syndromic aortic aneurysm and emphysema and failed muscle regeneration in the mdx mouse model of Duchenne muscular dystrophy. A clinical trial of losartan for Marfan syndrome will begin soon, and this strategy has proven equally powerful in ameliorating muscle disease in mdx mice. Sticking with Marfan syndrome (or, more generally, rare Mendelian disorders) remains an obligation based upon the contributions (through personal commitment) such patients have made to the maturation of genetic technologies and human genetics as a discipline. This and other examples also underscore the privilege and opportunity that continues to be granted by these individually rare but collectively indispensable partners in research.

Genetic differences between humans and great apes: finding a bundle of needles in the haystack. *A, Varki*
University of California, San Diego.

Session Descriptions:
Despite remarkable conservation of many DNA sequences throughout evolution, cataclysmic alterations in the genes of certain pathways signal the generation of a new species. Dr. Ajit Varki illustrates this phenomenon by detailing profound differences in the glycosylation systems of apes and human. Those differences are primarily manifest by changes in the metabolic handling of sialic acid, the terminal, charged carbohydrate on N-linked and O-linked oligosaccharides that provide untold diversity to proteins and lipids alike. Nobelist Peter Agre follows with an exposition of aquaporin water channels responsible for the movement of water across membranes. The elegant discovery of these elemental systems provides new understanding of trans-cellular water fluxes and serves as a basis for therapeutic interventions. Finally, Dr. Alain Fischer explains the genetics of immune deficiency and the current state of the art regarding the application of gene therapy, complete with a rationale for the pitfalls and promise of this treatment modality in severe combined immune deficiency.

Aquaporin water channels: from atomic structure to clinical medicine. *P. Agre* The Johns Hopkins University School of Medicine, Baltimore, MD.

Before submission. *C. C. Morton The American Journal of Human Genetics.*

Session Descriptions:
Publishing experimental results is a goal of most researchers, but the process is often filled with frustration and disappointment. For many authors, organizing and discussing data in a clear and concise fashion is a cumbersome task. Additionally, it is difficult to know which journal is the most appropriate for a manuscript. At the journal office, editors often receive papers that lack a few fundamental pieces that would have allowed an extra level of consideration. Also, peer-review is an essential part of the publication system, but it is only as effective as the comments that are generated and the response of the authors to the reviews. At this session, the editors from three prominent genetics journals will offer some guidelines to follow during the publication and review process. Following the speakers' presentations, there will be a 20-minute question and answer session with a panel of editors from a variety of journals.

At the Journal. *R. A. King* University of Minnesota, Minneapolis.

Deep ancestry: inside the Genographic Project. *S. Wells* National Geographic Society, Washington, DC.

Session Descriptions:
The Genographic Project, directed by Explorer-in-Residence, Dr. Spencer Wells, is a five-year effort to map humanitys genetic journey through the ages. Research labs across the globe have scientists visiting remote regions in a comprehensive effort to map migration and assess the worlds remaining indigenous and ethnic population isolates. An overview of the genetic findings will help explain the diversity and source of variation in human populations.

In an effort to bring context to the variation we represent, Rick Guidotti, an energetic and talented photographer, will share his passion and vision of the importance of celebrating human differences.

This symposium will engage the audience and enlighten the scientific perspective of our daily laboratory and patient activities.

The spirit of difference. *R. Guidotti* Positive Exposure, New York, NY.

Forebrain neural stem cells: from basic biology to brain repair. *S. Weiss* University of Calgary, Alberta, Canada.

Session Descriptions:
The pluripotent nature of stem cells offers promise for regeneration of a variety of cell types and tissues. That promise, in turn, provides hope for victims of numerous diseases previously considered incurable. For this symposium, Dr. Weiss begins with a description of the isolation and characterization of forebrain neural stem cells and their potential use in repairing the injured brain. Dr. Daley then provides a discussion of his methodology for preparing customized stem cells, with productive results. Dr. Orkin provides details on how stem cells are controlled at the molecular level. Finally, Dr. Grompe expounds on the surprising ability of the liver to repopulate via hepatic stem cells. Each expert employs a model system to demonstrate the dynamic underpinnings of tissue homeostasis, i.e., the action of stem cells. Each presentation addresses the feasibility of using stem cells for the renewal of impaired organs and tissues, whether damaged by genetic, environmental, or traumatic causes. Stem cell therapy stands at our doorstep, about to enter the future of medicine.

Customized stem cells. *G. Daley* Children's Hospital, Boston, MA.

Opening Remarks. *D. Scholes* National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland; Science Policy Fellow, Washington, DC.

Session Descriptions:
This program is a special session for graduate students and post-doctoral fellows organized by the newly formed Ad Hoc Postdoctoral Committee. ASHG trainees interested in an event designed to broaden their knowledge about rewarding careers ranging from laboratory research to patent law should attend. Members of the biotechnology, patent law, clinical diagnostic, academic research, policy and journalism communities will describe what it takes for PhD recipients to be successful in different scientific careers. Finally, a network session will be open to all participants to discuss these careers and a variety of others including education, public health, and science writing. The event is limited to 250 attendees.

Keynote Address: Challenges for Young Scientists. *B. Lindstaedt* University of California, San Francisco.

Session Descriptions:
This program is a special session for graduate students and post-doctoral fellows organized by the newly formed Ad Hoc Postdoctoral Committee. ASHG trainees interested in an event designed to broaden their knowledge about rewarding careers ranging from laboratory research to patent law should attend. Leadership Award Presentation. *M. M. Kaback* Department of Pediatrics and Reproductive Medicine, University of California, San Diego.

Session Descriptions:
This award is presented to an individual whose professional achievements have fostered and enriched the development of various human genetics disciplines. Potential recipients should exemplify the enduring leadership and vision required to ensure that the field of human genetics will flourish and successfully assimilate into the broader context of science, medicine, and health. They also may have made major contributions to awareness or understanding of human genetics by policy makers or by the general public. A plaque and $2500 will be presented to the awardee at the annual meeting.

Presenter:
Michael M. Kaback, Professor
Department of Pediatrics and Reproductive Medicine,
University of California, San Diego

Recipient:
David L. Rimoin, Professor of Pediatrics, Medicine and Human Genetics
University of California, Los Angeles, School of Medicine/Cedars-Sinai Hospital, Los Angeles, CA

The Societys newest award will be presented for the first time to Dr. David Rimoin, Professor of Pediatrics, Medicine and Human Genetics, David Geffen School of Medicine at UCLA and Steven Spielberg Chair and Director of the Medical Genetics Institute, Cedars-Sinai Medical Center. In addition to his many well-recognized research and educational achievements, particularly in the area of skeletal dysplasias, he served as the founding president of the American Board of Medical Genetics (ABMG), which established the educational standards for certification of medical geneticists and the accreditation of training programs throughout the nation. He was also the founding president of the American College of Medical Genetics (ACMG) and then president of its Foundation, whose primary goal is to foster education in medical genetics to the practitioner, as well as the public. He was responsible for establishing the American College of Medical Genetics annual meetings in conjunction with the March of Dimes to provide an educational forum for clinical geneticists and other individuals providing genetic services.

ASHG Membership/Business Meeting. *S. T. Warren* Emory University School of Medicine, Atlanta, GA.

Session Descriptions:
Reports highlighting current Society business are presented to inform the members and anyone else attending the meeting. The minutes of the previous meeting are presented for approval. Committee chairpersons report on their activities for the year and discuss plans for the upcoming year. Retiring board members are thanked for their years of service.

The meeting offers an opportunity for members to discuss items of new business. All members are encouraged to attend.

Trainee Award Presentations. *D. Valle* The Johns Hopkins University, Institute of Genetic Medicine, Howard Hughes Medical Institute, Baltimore, MD.

Session Descriptions:
The Society will present $500 to each awardee for outstanding research presented by a trainee in each of the following areas: predoctoral clinical, postdoctoral clinical, predoctoral basic, postdoctoral basic, predoctoral translational, and postdoctoral translational. Finalists have been selected from nominees who submitted abstracts in the competition. Their names are listed in the section of this book entitled Trainee Awards Program..

C. W. Cotterman Award Presentation. *C. C. Morton* The American Journal of Human Genetics, Brigham & Women's Hospital, Boston, Massachusetts.

Session Descriptions:
Monetary awards of $500 each and commemorative plaques will be presented to the first authors of the best papers published in *The American Journal of Human Genetics* during the previous year on which the first author is either a pre- or postdoctoral trainee and an ASHG member. Each September, the editorial board of the Journal selects the articles that best represent outstanding contributions to the field of genetics. Two awards are presented annually.

Presenter:
Cynthia C. Morton, editor
The American Journal of Human Genetics
Brigham & Women's Hospital, Boston, Massachusetts.

Excellence in Human Genetics Education Award Presentation. *R. Pagon* University of Washington, Seattle.

Session Descriptions:
Nominees for this award have made a contribution that is recognized nationally or internationally as being of exceptional quality and great importance to human genetics education. An award of $2500 and a plaque will be presented to the awardee at the annual meeting.

Introduced by: Robert Nussbaum
Chief of the Division of Medical Genetics and Holly Smith Professor of Medicine, Department of Medicine
University of California, San Francisco.

Recipient:
Roberta Bonnie Pagon
Professor of Pediatrics
University of Washington, Seattle

This award is being presented to Dr. Pagon for her tireless work in the development of the GeneTests database that includes GeneReviews. These resources are indispensable educational tools for geneticists and counselors wishing to learn abut the practical aspects of caring for patients with genetic diseases. The information is freely available on the web and is playing a major role in the education of our genetic fellows, counseling students and clinicians.
